Dentists and health care providers systematically screen patients for oral cancer. Oral assessment has become a part of the routine dental examination. People should visit a dentist at least twice a year for professional dental hygiene and oral cancer screening, which includes inspecting and palpating the mouth for lesions.

Prevention strategies for oral cancer include minimizing sun and tanning-bed exposure, tobacco cessation, and decreasing alcohol intake. Most dentists use digital technology instead of x-rays when performing the annual or biannual dental examination because excessive, prolonged radiation from x-rays has been associated with head and neck cancer (Oral Cancer Foundation [OCF], 2017). Teach adults to follow the guidelines in [Chart 53-1](#) to maintain oral health.

### ❖ Pathophysiology

More than 90% of oral cancers are *squamous cell carcinomas* that begin on the surface of the epithelium. Over a period of many years, premalignant (or dysplastic) changes begin. Cells begin to vary in size and shape. Alterations in the thickness of the lining of the epithelium develop, resulting

in atrophy. These tumors usually grow slowly, and the lesions may be large before the onset of symptoms unless ulceration is present. *Mucosal erythroplasia is the earliest sign of oral carcinoma. Oral lesions that appear as red, raised, eroded areas are suspicious for cancer. A lesion that does not heal within 2 weeks or a lump or thickening in the cheek is a symptom that warrants further assessment (OCF, 2017).*

Squamous cell cancer can be found on the lips, tongue, buccal mucosa, and oropharynx. The major risk factors in its development are increasing age, tobacco use, and alcohol use. Most oral cancers occur in people older than 40 years. Tobacco use in any form (e.g., smoking or chewing tobacco) can increase the risk for cancer. A person who frequently consumes alcohol and uses tobacco in any form is at the highest risk

## Genetic/Genomic Considerations

### Patient-Centered Care QSEN

Genetic variations in patients with oral cancer have been found, especially the mutation of the *TP53* gene (McCance et al., 2014). The *TP53* gene is nicknamed the “guardian of the genome” because tumor protein *p53* is essential for cell division regulation and prevention of tumor formation (National Institutes of Health, 2017). Because mutations in this gene are linked to various cancers, always ask about a personal and family history of *any* type of cancer when assessing the patient with oral cavity problems.

An increased rate of squamous cell cancer is found in people with occupations such as textile workers, plumbers, and coal and metal workers, mainly as a result of prolonged exposure to polycyclic aromatic hydrocarbons (PAHs). People with **periodontal** (gum) **disease** in which mandibular (jaw) bone loss has occurred are especially at risk for cancer of the mouth. Additional factors, such as sun exposure, poor NUTRITION habits, poor oral hygiene, and infection with the human papilloma virus (HPV16) may also contribute to oral cancer (OCF, 2017).

Research indicates a correlation between specific strains of the human papilloma virus (HPV) and oral cancer. Oral cancer associated with HPV appears in the tonsillar area or along the base of the tongue in younger people. Because HPV-positive oral cancers account for a large number of oral cancer diagnoses, routine oral assessment is essential. Oral cavity inspection combined with neck palpation is recommended yearly to aid in early detection (OCF, 2017).

*Basal cell carcinoma* of the mouth occurs primarily on the lips. The lesion is asymptomatic and resembles a raised scab. With time, it evolves into a characteristic ulcer with a raised, pearly border. Basal cell carcinomas do not metastasize (spread) but can aggressively involve the skin of the face. The major risk factor for this type of cancer is excessive sunlight exposure.

Basal cell carcinoma occurs as a result of the failure of basal cells to mature into keratinocytes. It is the second most common type of oral cancer, but it is much less common than squamous cell carcinoma.

*Kaposi's sarcoma* is a malignant lesion in blood vessels, appearing as a raised, purple nodule or plaque, which is usually painless. In the mouth, the hard palate is the most common site of Kaposi's sarcoma, but it can be found also on the gums, tongue, or tonsils. It is most often associated with AIDS. (See [Chapter 19](#) for a complete discussion of Kaposi's sarcoma.)

As a group, oral cancers account for about 3% of all cancers in men and 2% of all cancers in women in the United States. Over 45,000 new cases are diagnosed each year, and over 8000 deaths occur (OCF, 2017). Most cancers occur in middle-age and older people, although in recent years, younger adults have been affected, probably as a result of sun exposure and HPV.

## NCLEX Examination Challenge 53-2

### Health Promotion and Maintenance

The nurse is caring for four clients. Which is at the **highest** risk for development of oral cancer?

- A. 32-year-old client with ankle fracture
- B. 41-year-old with human papilloma virus (HPV) infection

C. 60-year-old who quit smoking 20 years ago

D. 83-year-old who lives in a warm climate during the winter

### ❖ **Interprofessional Collaborative Care**

Care of the patient with oral cancer takes place in a variety of settings ranging from the hospital to the community, depending on the degree of treatment needed. The interprofessional team that treats and cares for a patient with oral cancer may include the health care provider, dentist, surgeon, oncologist, nurse, speech therapist, dietician, social worker, and spiritual leader of the patient's choosing.

### ◆ **Assessment: Noticing**

Begin by assessing the patient's routine oral hygiene regimen and use of dentures or oral appliances, which might add to discomfort or mechanically irritate the mucosa. Ask about oral bleeding, which might indicate an ulcerative lesion or periodontal (gum) disease. Determine the patient's past and current appetite and NUTRITION state, including difficulty chewing or swallowing. A continuing trend of weight loss may be related to metastasis, heavy alcohol intake, difficulty eating or chewing, or an underlying health problem (Chart 53-3).

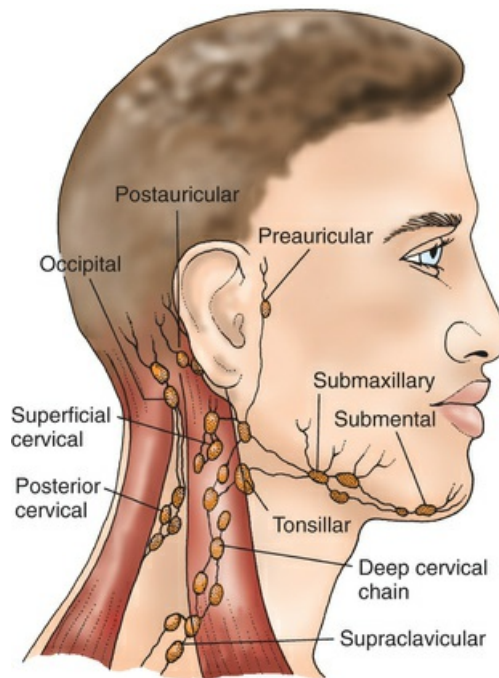

### ▶ **Chart 53-3**

## **Key Features**

### **Oral Cancer**

- Bleeding from the mouth
- Poor appetite
- Difficulty chewing
- Difficulty swallowing
- Poor nutrition status and weight loss
- Thick or absent saliva
- Painless oral lesion that is red, raised, or eroded
- Thickening or lump in cheek

An examination of the oral cavity requires adequate lighting. Thoroughly inspect the oral cavity for any lesions, evidence of alterations in COMFORT, or restriction of movement. Gently using a tongue blade and penlight, examine all areas of the mouth. Carefully note any change in speech caused by tongue movement. Notice any change in voice or swallowing and assess for thick or absent saliva. After inspection, the advanced practice nurse, specialty nurse, or other health care provider uses bimanual palpation of any visible nodules to determine size and fixation. The cervical lymph nodes are also palpated (Fig. 53-2).

**FIG. 53-2** The lymph nodes of the cervical region.

The functioning and appearance of the mouth are strongly linked with body image and quality of life. Therefore it is important to assess the impact of oral lesions on the patient's self-concept. Assess for any educational, cultural, and/or spiritual needs that might affect health teaching or treatment. Evaluate the patient's support system and past coping mechanisms.

*OralCDx is a diagnostic procedure usually performed by a dentist during a routine dental examination.* The procedure involves brushing of a lesion and is helpful in determining whether the lesion is precancerous (OralCDx, 2017). However, biopsy is the definitive method for diagnosis of oral cancer. The health care provider obtains a needle-biopsy specimen of the abnormal tissue to assess for malignant or premalignant changes. Incisional biopsies may also be performed. An intraoral biopsy can be done under local anesthesia. In very small lesions, an excisional biopsy can permit complete tumor removal. MRI is useful in detecting perineural involvement and evaluating thickness in cancers of the tongue. Both CT and MRI can be used to determine spread to the liver or lungs if further staging of the disease is warranted.

#### ◆Interventions

Both the presence of tumors of the oral cavity and the effects of their treatment threaten the integrity of the oral mucosa and the patient's airway. Oral cavity lesions can be treated by surgical excision, nonsurgical treatments such as radiation or chemotherapy, or a combination of treatments (referred to as *multimodal therapy*). Chemotherapy is currently not used independently in the treatment of oral cancers but is used in addition to other modes of treatment to sensitize malignant cells to radiation, shrink a malignancy before surgery, or decrease the potential for malignancy (OCF, 2017). Multimodal therapy is the most costly treatment option, yet it is more frequently used (OCF, 2017). *If the patient has extensive tumor involvement and copious, tenacious (thick and "stringy") secretions, maintaining an open airway is your priority for care to promote GAS EXCHANGE.* Other nursing interventions focus on restoring and maintaining oral health.

#### Nonsurgical Management.

Implement interventions to *manage the patient's airway* by increasing air exchange, removing secretions, and preventing aspiration as needed. Assess for dyspnea resulting from the tumor obstruction or from excessive secretions. Assess the quality, rate, and depth of respirations. Auscultate the lungs for adventitious sounds, such as wheezes caused by aspiration. Listen for stridor caused by partial airway obstruction. Promote deep breathing to help produce an effective cough to mobilize the patient's secretions.

To promote GAS EXCHANGE, place the patient in a semi-Fowler's or high-Fowler's position. If the

patient is able to swallow and gag reflexes are intact, it is beneficial to encourage fluids to liquefy secretions for easier removal. Chest physiotherapy also increases air exchange and promotes effective coughing. If available, collaborate with the respiratory therapist about performing this procedure. If needed, use oral suction equipment with a dental tip or a tonsil tip (Yankauer catheter) to remove secretions that obstruct the airway. Teach the patient and family to use the catheters as needed.

If edema occurs with oral cavity lesions, the patient may receive steroids to reduce inflammation. Antibiotics may be prescribed if infection is present because it can increase inflammation and edema. A cool mist supplied by a face tent may help with oxygen transport and control of edema.

## Nursing Safety Priority QSEN

### Action Alert

Aspiration Precautions prevent or reduce the risk factors for aspiration. Assess the patient's level of consciousness (LOC), gag reflex, and ability to swallow. To prevent aspiration, place the patient sitting upright at 90 degrees (high-Fowler's position). As a precaution, keep suction equipment nearby. For patients at high risk, assess the gag reflex before giving any fluids. Remind UAP to feed patients at risk for aspiration in small amounts. Teach visitors to speak with you before offering any type of food or drink to the patient. Provide thickened liquids as an aid to prevent aspiration. Referral to the speech/language pathologist can be beneficial for patients who are experiencing aspiration with swallowing. A swallow study may be needed to fully assess the risk for aspiration.

It is important to work with the patient to *establish an oral hygiene routine*. Perform oral hygiene every 2 hours for ulcerated lesions or infection or in the immediate postoperative period. Modifications might be needed because of oral discomfort, bleeding, or edema. Oral care with a soft-bristled toothbrush is preferred. If the platelet count falls below 40,000/mm<sup>3</sup>, switch the patient to an ultrasoft “chemobrush.” The use of “Toothettes” or a disposable foam brush is discouraged because these products may not adequately control bacteremia-promoting plaque and may further dry the oral mucosa. Lubricant can be applied to moisten the lips and oral mucosa as needed.

Teach patients and their families that the patient should avoid using commercial mouthwashes and lemon-glycerin swabs. Commercial mouthwashes contain alcohol, and lemon-glycerin swabs are acidic. These substances can cause a burning sensation and contribute to dry oral mucous membranes. Encourage frequent rinsing of the mouth with sodium bicarbonate solution or warm saline (see also [Chart 53-2](#)). Follow hospital or health care provider protocol if available.

*Radiation therapy* for oral cancers can be given by external beam or interstitial implantation to reduce the size of the tumor before surgery. *External-beam* radiation passes through the skin or mucous membrane to the tumor site. Typically, treatments are given as five daily treatments per week, with a 2-day break each week, over a 6- to 9-week period. Each treatment lasts only about 10 to 15 minutes, with more time being dedicated to undertaking special precautions to minimize the dose of radiation to the brain or spinal cord ([OCF, 2017](#)).

Another option is the implantation of radioactive substances (*interstitial radiation therapy* or *brachytherapy*) to either boost the dosage or deliver a radiation dose close to the tumor bed. This form of implant therapy can be curative in early-stage lesions in the floor of the mouth or anterior tongue. It may also add a boost of radiation to a tumor that received external-beam radiation.

With the exception of radioactive seeds, which have a low level of emission, patients receiving interstitial radiation are usually hospitalized for the duration of treatment. *Place patients on radiation transmission precautions while the materials are active or in place*. Patients need to be placed in a private room with lead-lined walls or movable panels. When permitted, visitors may stay only 30 minutes or less each day and must sit or stand away from the patient in designated areas. Pregnant women and children younger than 18 years should not be permitted to visit. A tracheostomy may be required with interstitial implants because of edema and increased oral secretions. (See [Chapter 22](#) for general nursing care of patients undergoing radiation therapy.)

Teach the patient undergoing *chemotherapy* and family members about the side effects of these agents, which vary with each drug. Give antiemetics as prescribed and provide other comfort measures as needed. (See [Chapter 22](#) for general care of patients receiving chemotherapy.)

## Nursing Safety Priority QSEN

### Drug Alert

Patients who are undergoing radiation and/or chemotherapy treatment may experience a decreased ability to tolerate prescribed and over-the-counter medications as a result of being immunocompromised. Teach patients about expected side effects and remind them to not take any medication (including over-the-counter medications, herbs, or vitamin supplements) without first discussing them with their health care provider.

One of the most recent advances in the use of drugs for oral cancer is targeted therapy. Hormone-like substances known as *growth factors (GFs)* occur in the body's cells. Oral tumor cells, along with other types of cancers, grow quickly because they have more GF receptors than does normal healthy tissue. One of these GFs is called *epidermal growth factor (EGF)*, which has been associated with oral cancers. Newer drugs that can target and block EGF receptors (EGF-R) are being tested, and more than a dozen have been approved, including cetuximab (Erbix), erlotinib (Tarceva), and panitumumab (Vectibix). ([Chapter 22](#) describes targeted molecular therapy.)

## NCLEX Examination Challenge 53-3

### Health Promotion and Maintenance

The nurse is caring for a client who is concerned about developing oral tumors. Which client statement requires **immediate** nursing intervention?

- A. "I used to chew tobacco but quit 5 years ago."
- B. "I use sunscreen to cover my face and body when I'm at the beach."
- C. "I don't have dental insurance, so I can't get dental check-ups."
- D. "I only drink alcohol on special occasions like my birthday and anniversary."

### Surgical Management.

The health care provider can often remove small, noninvasive lesions of the oral cavity in an ambulatory surgical center with local anesthesia. The surgical opening is usually small enough to be closed by sutures. These smaller lesions may also be responsive to carbon dioxide laser therapy or **cryotherapy** (extreme cold application), as well as photodynamic therapy. These procedures can be performed as an ambulatory care procedure in a surgical center but may require general anesthesia.

Small oral cancers are equally responsive to radiation or photodynamic therapy and to surgery. More invasive lesions (stages III and IV) require more extensive surgical excision and result in a greater loss of function and disfigurement. Not all lesions can be excised by the peroral approach (through the mouth). The goal of surgical resection is removal of the tumor with a surgical margin that is free of cancer cells.

### Preoperative Care.

Before excision of a lesion in the oral cavity, assess and document the patient's level of understanding of the disease process, the rationale for the surgery, and the planned intervention. Problems associated with cancer therapy can be reduced or optimally managed by collaborating with the patient and family regarding preparation and instruction. Reinforce information as needed. Include family members or other caregivers in the health teaching unless culturally or spiritually inappropriate.

For small, local excisions, postoperative restrictions include a liquid diet for a day and then advancing as tolerated. There are no activity limitations, and postoperative analgesics are prescribed. Research shows that preoperative oral health reduces postoperative inflammation and complications, so teach patients how to perform proper oral care before procedures take place (see the [Evidence-Based Practice box](#)).

### Preoperative Oral Care Contributes to Better Postsurgical Outcomes (Safety)

Shigeishi H., et al. (2016). Preoperative oral health care reduces postoperative inflammation and complications in oral cancer patients. *Experimental and Therapeutic Medicine*, 12, 1922-1928.

This study reviewed the records of 70 patients with oral cancer who were treated at one institution between 2008 and 2014, focusing on body temperature, white blood cell count, and C-reactive protein (CRP) levels between those who received preoperative oral care versus those who did not. Those who received professional teeth cleaning and were instructed in self-care had lower incidences of inflammation and postoperative complications.

#### Level of Evidence: 2

This research was designed as a retrospective review.

#### Commentary: Implications for Practice and Research

Patients who received oral care in the form of professional teeth cleaning or scaling at least 3 days before surgery and who received oral care at least once daily following surgery experienced a significantly lower CRP on days 3 to 5 after surgery. Although body temperature and white blood cell counts were not statistically different between those who received oral care before surgery versus those who did not, the data suggest that preoperative oral care contributes to lesser postoperative inflammation in patients who have invasive surgery for oral cancer. Nurses must teach patients to seek professional oral care before surgery, to perform ongoing oral care after surgery while hospitalized, and about home oral care before discharge, all of which contribute to better patient outcomes.

Instructions for the patient undergoing large surgical resections may include but are not limited to these expectations after surgery:

- Placement of a temporary tracheostomy, oxygen therapy, and suctioning
- Temporary loss of speech because of the tracheostomy
- Frequent monitoring of postoperative vital signs
- NPO status until intraoral suture lines are healed
- Need to have IV lines in place for drug delivery and hydration
- Postoperative drug therapy and activity (out of bed on the day of surgery or first postoperative day)
- Possibility of surgical drains

Because communication is interrupted, assess the patient's ability to read, write, and draw pictures to communicate. In coordination with the patient, select the method of communication to use after surgery with staff and family members (e.g., Magic Slate, handheld mobile device, computer, picture board, or pad and pencil). Preprinted flashcards may be used to communicate the patient's needs, such as "I'm tired," "I'm in pain," or "I'm hungry." Urge the patient to practice the chosen method before surgery to reduce frustration after surgery.

#### Operative Procedures.

Three factors influence the extent of surgery performed for oral cancers: the size and location of the tumor, tumor invasion into the bone, and whether there has been metastasis (cancer spread) to neck lymph nodes. Small, noninvasive tumors can be removed perorally (through the mouth). Otherwise an external approach may be used. The most extensive oral operations are composite resections, which combine partial or total **glossectomy** (tongue removal) and partial **mandibulectomy** (jaw removal). In the **commando** (co-mandible) **procedure** (**COM**combined neck dissection, **MAND**ibulectomy, and **O**ropharyngeal resection), the surgeon removes a segment of the mandible with the oral lesion and performs a radical neck dissection (see [Chapter 29](#)).

Metastasis to cervical lymph nodes usually indicates a poor prognosis for patients with cancer of the oral cavity. In those with cervical node metastasis, a neck dissection may also be performed. A radical neck dissection usually involves the removal of all cervical lymph nodes on the affected side, along with cranial nerve XI (the accessory nerve), the internal jugular vein, and the

sternocleidomastoid (front neck) muscle. Modified and selective neck dissections may be performed in patients with minimal lymph node involvement.

### Postoperative Care.

The patient may have a temporary or permanent tracheostomy, requiring intensive nursing care to promote airway clearance. In addition, care must be taken to protect the surgical incision site from mechanical damage and infection (see [Chapter 29](#)). Nursing interventions to relieve discomfort and promote NUTRITION are also important. Older adults are a special risk for surgery and need to be monitored very carefully ([Chart 53-4](#)).

#### **Chart 53-4**

### Focused Assessment

#### The Postoperative Older Adult With Oral Cancer

- Assess the mouth and surrounding tissues for candidiasis, mucositis, and pain; assess for loss of appetite and taste.
- Monitor the patient's weight.
- Monitor nutrition and fluid intake.
- Assess for difficulty in eating or speech.
- Assess pain status and measures used to control pain.
- Monitor the patient's response to medications.
- Identify psychosocial problems, such as depression, anxiety, and fear.
- Assess the patient's overall physiologic condition and how this may affect pharmacologic therapy.

### **Nursing Safety Priority** QSEN

#### Action Alert

*After extensive excision or resection for oral cancer, the most important nursing intervention is maintaining the patient's airway to promote GAS EXCHANGE! On awakening from anesthesia, the patient may not recall, or realize, that a tracheostomy tube is in place and may initially panic because of the inability to speak. Remind the patient why he or she cannot speak and provide reassurance that the vocal cords are intact (unless a total laryngectomy has been performed, in which case the loss of voice is permanent).*

Ensure that the predetermined method of communication is available for the patient, family members, and staff. When the patient has an adequate airway and can effectively clear secretions by coughing, the tracheostomy tube may be removed. When the tube is removed, an airtight dressing is placed over the site, and the tracheostomy incision heals without the need for sutures.

Patients who have undergone extensive resection may have slurred speech or difficulty in speaking as a result of nerve damage or tongue removal. Collaborate with the speech-language pathologist if speech is altered.

*Protect the incision site to avoid infection.* Provide gentle mouth care for cleaning away thick secretions and stimulating the flow of saliva. The delivery of oral care depends on the nature and extent of the surgical procedure. Give oral care at least every 4 hours in the early postoperative phase. The presence of unusual odors from the mouth can indicate infection; therefore continual assessment of the oral cavity is very important. In the early postoperative phase, take care to avoid disruption of the suture line during oral hygiene.

Elevate the head of the bed to assist in decreasing edema by gravity. If skin grafting was done,

inspect the donor site (generally on the anterior thigh) every 8 hours for bleeding or signs of infection. (See [Chapter 29](#) for specific nursing care of the patient with a radical neck dissection.)

To provide optimal pain relief in the postoperative period, rely on subjective and objective data to assess the need for analgesics and their effectiveness. The desired outcome of drug therapy during this period is to promote COMFORT while allowing the patient to function at an optimal level. Those who have undergone surgery for oral cancer describe their pain as throbbing or pounding. IV morphine is usually the initial pain medication given with acetaminophen or ibuprofen to decrease inflammation. Percocet (oxycodone plus acetaminophen) may be used for systemic relief of moderate pain after the IV morphine is discontinued.

Patients who have undergone extensive resections of the oral cavity remain on NPO status for several days. This time allows healing in the oral cavity before food comes in contact with the incision. Nasogastric feeding or total parenteral NUTRITION may be needed until oral nutrition can begin (see [Chapter 60](#)).

## Nursing Safety Priority QSEN

### Action Alert

*When oral fluid intake is started, assess for and document signs of difficulty swallowing, aspiration, or leakage of saliva or fluids from the suture line. Monitor daily weights and hydration. NUTRITION supplementation may improve the patient's quality of life. Patients who have weight loss or who are having difficulty maintaining hydration may be candidates for the placement of a gastrostomy tube. Coordinate NUTRITION care with the dietitian.*

Encourage the patient to perform swallowing exercises. Collaborate with the speech-language pathologist to assist with swallowing techniques. Thickened fluids may be needed to prevent aspiration. A swallowing impairment may be temporary or permanent.

### Care Coordination and Transition Management

Continuing care for the patient with an oral tumor depends on the severity of the tumor, its collaborative care, and available support systems. Most patients are maintained at home during follow-up care. Ongoing NUTRITION management remains a vital part of the treatment plan. In addition, the patient and family may benefit from a community-based support group for cancer patients.

#### Home Care Management.

If radiation therapy is part of the patient's treatment plan, home care considerations include health teaching and management strategies. Complications from radiation to the head or neck can be acute or delayed. Acute effects include treatment-related mucositis, stomatitis, and alterations in taste. Long-term effects such as **xerostomia** (excessive mouth dryness) and dental decay require ongoing oral care, the use of saliva substitutes, and follow-up dental visits. Although ongoing dental care is important, the possible adverse effects that radiation has on bone make elective oral surgical procedures, such as tooth extraction, impossible in the area of the radiation. Fatigue is a common side effect of radiation and chemotherapy.

The patient whose tracheostomy tube has been removed is often placed on a soft diet by mouth before discharge. However, occasionally patients are discharged from the hospital while still requiring tracheostomy suction, oral suction, and nasogastric feedings. Suction equipment, NUTRITION supplies, and nursing care can be provided by home care companies. (See [Chapter 60](#) for home care preparation for the patient receiving home parenteral nutrition and [Chapter 28](#) for home care preparation for the patient with a tracheostomy.)

#### Self-Management Education.

Before hospital discharge, teach the patient and family about drug therapy, NUTRITION therapies, any treatments (e.g., tracheostomy care, suture line care, dressing changes), and early symptoms of infection ([Chart 53-5](#)). Alterations in taste and dysphagia make maintaining adequate nutrition a challenge for the oral cancer patient. Alterations in taste occur when the taste buds are included in

the radiation treatment field. Taste sensation may begin to return several weeks after the completion of treatment. Some types of chemotherapy can also affect the patient's taste. Sometimes the loss of taste is permanent.

### **Chart 53-5**

## **Patient and Family Education: Preparing for Self-Management**

### **Care of the Patient With Oral Cancer at Home**

- Follow the treatment plan for cancer therapies.
- Remember that taste sensation may be decreased; add nonspicy seasonings to food to better enjoy it.
- Use a thickening agent for liquids if dysphagia is present.
- Eat soft foods if stomatitis occurs.
- Inspect the mouth every day for changes, such as redness or lesions.
- Continue meticulous oral hygiene at home using a chemobrush and frequent rinsing; clean brush after every use.
- Use saliva substitute as prescribed.
- Avoid sun or tanning-bed exposure if radiation is part of therapy.
- Clean with a gentle, nondeodorant soap, such as Ivory.

Changes in taste include dislike of meat, such as beef or pork, and metallic tastes in the mouth. Teach patients to add seasonings to foods, to use gravies or sauces to make foods more palatable, and to use high-protein foods such as cheeses, milk, eggs, puddings, and legumes in place of meat. Instruct patients with dysphagia in swallowing exercises. Recommend thickened liquids because thin liquids, such as water, are difficult to control during swallowing. Collaborate with the dietitian to teach the family how to assess the NUTRITION intake of the patient who is just beginning to eat. Liquid dietary supplements are usually recommended at this time. If bleeding or stomatitis is present, recommend soft foods to prevent further injury to the mucous membranes.

Teach the patient or family members to inspect the oral cavity daily for areas of redness, which can indicate the onset of stomatitis. Meticulous oral hygiene should be continued at home, especially with adjuvant chemotherapy or radiation. Reinforce the oral hygiene routine, emphasizing the need for frequent mouth rinsing to reduce the number of microorganisms and to maintain adequate hydration. The patient should use a chemobrush (an extra-soft type of toothbrush), rinse the chemobrush with hydrogen peroxide and water or with a diluted bleach solution after each use, and change chemobrushes weekly. The brush may also be cleaned in a dishwasher.

Saliva production is greatly reduced as a consequence of radiation. The resulting xerostomia (dry mouth) causes the inability to eat dry foods and may be permanent. Teach the patient regarding the use of saliva substitutes.

Skin reactions are also a common side effect of radiation. Instruct the patient to avoid sun exposure, to avoid perfumed lotions and powders, and to cleanse the face and neck area with a gentle nondeodorant soap. Teach individuals to use an electric razor for shaving and to avoid alcohol-based aftershave lotions to prevent further skin irritation.

### **NCLEX Examination Challenge 53-4**

## Physiological Integrity

A client completing radiation treatment has developed dysphagia and stomatitis. What teaching will the nurse provide? **Select all that apply.**

- A. Brush teeth twice daily with chemobrush.
- B. Thin liquids will make it easier to swallow.
- C. Limit alcohol consumption to three drinks per day.
- D. Rinse mouth with mild saline and water mix before and after eating.
- E. Refrain from using liquid dietary supplements because these will irritate mucous membranes.
- F. Plan to eat soft foods such as cheese, well-cooked legumes, peanut butter, and pudding.

### Health Care Resources.

Patients who have undergone composite resection often require community services because they have both physical and psychosocial needs. Depression related to a change in body image is common. Excision of part of the jaw can leave a facial defect that may be difficult to hide. Assess for depression and other behavioral responses such as anxiety, fear, anger, shame, and/or loneliness. A social worker or other health care professional may be needed for patient and family counseling. Those who have undergone a total glossectomy may be able to speak with special training and the use of an intraoral prosthesis created by a maxillofacial prosthodontist. The prosthesis is similar to dentures.

Collaborate with the case manager to provide assistance in obtaining special equipment or NUTRITION resources needed by the patient at home. The case manager assesses the patient's financial needs and makes referrals to government, community, and religious organizations as needed. Refer the patient to the American Cancer Society (ACS) ([www.cancer.org](http://www.cancer.org)), the Oral Cancer Foundation ([www.oralcancerfoundation.org](http://www.oralcancerfoundation.org)), and/or the Canadian Cancer Society ([www.cancer.ca/en/region-selector-page/](http://www.cancer.ca/en/region-selector-page/)) for local support groups and resources, including additional information. The ACS often provides dressing supplies and transportation to and from follow-up visits or medical treatments.

## Clinical Judgment Challenge 53-1

### Safety; Patient-Centered Care **QSEN**

A 55-year-old patient is beginning outpatient radiation therapy for a small mass near the submaxillary lymph node. She has transportation and sees a local dentist yearly. You are preparing to teach the patient methods of self-care management.

1. What are your teaching priorities for her before the radiation treatment?
2. For what complications is this patient most at risk?
3. What would you teach the patient that would be most helpful to minimize radiation side effects?
4. Considering that this is a female patient, what psychosocial or sociocultural concerns would you anticipate that she may experience after beginning radiation therapy?
5. What follow-up care will you recommend for this patient?

# Disorders of the Salivary Glands

## Acute Sialadenitis

### ❖ Pathophysiology

**Acute sialadenitis**, the inflammation of a salivary gland, can be caused by infectious agents, irradiation, or immunologic disorders. Salivary gland inflammation can have a bacterial or viral cause, such as infection with cytomegalovirus (CMV). The most common bacterial organisms are *Staphylococcus aureus*, *Staphylococcus pyogenes*, *Streptococcus pneumoniae*, and *Escherichia coli*. This disorder most commonly affects the parotid or submandibular gland in adults.

A decrease in the production of saliva (as in dehydrated or debilitated patients or in those who are on NPO status after surgery for an extended time) can lead to acute sialadenitis. The bacteria or viruses enter the gland through the ductal opening in the mouth. Systemic drugs, such as phenothiazines and the tetracyclines, can also trigger an episode of acute sialadenitis. Untreated infections of the salivary glands can evolve into abscesses, which can rupture and spread infection into the tissues of the neck and the mediastinum.

Patients who receive radiation for the treatment of cancers of the head and neck or thyroid may develop decreased salivary flow, predisposing them to acute or persistent sialadenitis. The effect of radiation on the salivary glands is rapid and dose related. Immunologic disorders such as HIV infection can cause enlargement of the parotid gland that results from secondary infection. Sjögren's syndrome, an autoimmune disorder, is characterized by chronic salivary gland enlargement and inflammation that cause a very dry mouth (see [Chapter 20](#)).

### ❖ Interprofessional Collaborative Care

The primary individuals who will care for the patient with acute sialadenitis include the health care provider, nurse, and radiological specialist. During the initial interview, assess for any predisposing factors for sialadenitis, such as ionizing radiation to the head or neck area. Collect a thorough drug history and ask about systemic illnesses, such as HIV infection.

Dehydration can be assessed by examining the oral membrane for dryness and the skin for turgor. Other assessment findings include pain and swelling of the face over the affected gland. Assess facial function because the branches of cranial nerve VII (the facial nerve) lie close to the salivary glands. Fever and general malaise also occur, and purulent drainage can often be massaged from the affected duct in the oral cavity.

Collaborative care includes the administration of IV fluids and measures such as these to treat the underlying cause and increase the flow of saliva:

- Hydration
- Application of warm compresses
- Massage of the gland
- Use of a saliva substitute
- Use of **sialagogues** (substances that stimulate the flow of saliva)

Sialagogues include lemon slices and citrus- and other fruit-flavored candy. Massage is accomplished by milking the edematous gland with the fingertips toward the ductal opening. Elevation of the head of the bed promotes gravity drainage of the edematous gland.

Acute sialadenitis is best prevented by adherence to routine oral hygiene. This practice prevents infection from ascending to the salivary glands from the mouth.

## Post-Irradiation Sialadenitis

The salivary glands are sensitive to ionizing radiation, such as from radiation therapy or radioactive iodine treatment of thyroid cancers. Exposure of the glands to radiation produces a type of sialadenitis known as **xerostomia** (very dry mouth caused by a severe reduction in the flow of saliva) within 24 hours. Radiation to the salivary glands can also cause alterations in COMFORT and edema, which generally abate after several days.

Xerostomia may be temporary or permanent, depending on the dose of radiation and the percentage of total salivary gland tissue irradiated. Little can be done to relieve the patient's dry

mouth during the course of radiation therapy. Frequent sips of water and frequent mouth care, especially before meals, are the most effective interventions. After the course of radiation therapy has been completed, saliva substitutes may provide moisture for 2 to 4 hours at a time. Over-the-counter solutions are available; or methylcellulose (Cologel), glycerin, and saline may be mixed to form a solution.

## Salivary Gland Tumors

Of all oral tumors, those of the salivary glands are relatively rare. Initially malignant tumors present as slow-growing, painless masses. Involvement of the facial nerve results in facial weakness or paralysis (partial or total) on the affected side.

Collect information about any prior radiation exposure, because radiation to the head and neck areas is associated with the occurrence of salivary gland tumors. Salivary gland tumors present as localized, firm masses. Submandibular and minor salivary gland tumors may be tender or painful. Tumor invasion of the hypoglossal nerve causes impaired movement of the tongue, and a loss of sensation can follow. *Pay particular attention to assessment of the facial nerve because of its proximity to the salivary glands.* Assess the patient's ability to:

- Wrinkle the brow
- Raise the eyebrows
- Squeeze and hold the eyes shut while you gently pull upward on the eyebrows and cheeks beneath the orbit to check for symmetry
- Wrinkle the nose
- Pucker the lips
- Puff out the cheeks
- Grimace or smile

Be aware of any asymmetry when the patient performs these motions. The treatment of choice for both benign and malignant tumors of the salivary glands is surgical excision. However, radiation therapy is often used for salivary gland cancers that are large, have recurred, show evidence of residual disease after excision, or are highly malignant.

## NCLEX Examination Challenge 53-5

### Physiological Integrity

Which facial assessment finding in a client with a salivary gland tumor prompts the nurse to notify the health care provider?

- A. Loss of sensation in tongue
- B. Alternates smiling and grimacing
- C. Wrinkles brows on command
- D. Holds eyes shut as the nurse pulls gently on the eyebrows

Patients who have undergone **parotidectomy** (surgical removal of the parotid glands) or submandibular gland surgery are at risk for weakness or loss of function of the facial nerve because the nerve courses directly through the gland. Facial nerve repair with grafting can be done at the time of surgery. A combination of surgery followed by radiation is common for advanced disease. Care for patients after parotidectomy is similar to that required for those having oral cancer surgery, which is described in the Surgical Management discussion in the Oral Cavity Disorders section.

# Get Ready for the NCLEX® Examination!

## Key Points

Review these key points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Be aware that airway management is the priority of care for patients having surgery for oral cancer. **QSEN: Safety**
- Place patients having oral cancer surgery in a high-Fowler's position to facilitate breathing and prevent aspiration. **QSEN: Safety**
- Assess for swallowing ability to prevent aspiration by checking the gag reflex before offering liquids or food to the patient who has had oral cancer surgery. **QSEN: Safety**
- Plan transition management to meet the patients' needs when they are transferred from the hospital to community-based agencies. **QSEN: Teamwork and Collaboration**

### Health Promotion and Maintenance

- Remind adults to visit their dentist regularly for dental hygiene and oral examinations and to seek medical or dental attention for oral lesions that do not heal.
- Follow the best practice recommendations for maintaining oral health as listed in [Chart 53-1](#).
- Instruct patients to avoid harsh commercial mouthwashes if they have oral lesions.
- In keeping with The Joint Commission (TJC) Core Measures TOB-2, teach adults to avoid tobacco or offer a cessation plan, alcohol, and sun exposure to decrease their chance of having oral cancer. **QSEN: Evidence-Based Practice**
- Instruct patients with acute sialadenitis to use sialagogues to stimulate saliva, such as citrus foods or candies.

### Psychosocial Integrity

- Assess the patient's and family's response to an oral cancer diagnosis, which may include feelings of anger, depression, anxiety, and/or fear. **QSEN: Patient-Centered Care**
- Help the patient and family identify and use strengths and coping mechanisms to deal with changes in body image and altered self-esteem. **QSEN: Patient-Centered Care**
- Refer patients with oral cancer to support groups, such as those available through the American Cancer Society.

### Physiological Integrity

- Remember that stomatitis usually begins as painful single or multiple ulcerations within the mouth.
- Recognize that stomatitis can be caused by a variety of organisms; *Candida* infections are common in patients who receive antibiotic therapy and in those who are immunocompromised.
- Provide gentle oral care for patients with oral lesions by using chemobrushes and warm saline or sodium bicarbonate solution. **QSEN: Safety**
- Be aware that patients with stomatitis receive antimicrobials, anti-inflammatory agents, immune modulators, and topical agents for relief of symptoms. **QSEN: Evidence-Based Practice**
- Differentiate leukoplakia and erythroplakia: leukoplakia presents as thin, white patches; and erythroplakia presents as red, velvety lesions. **Clinical Judgment**
- Be aware that patients with oral cancer may undergo chemotherapy, radiation, surgery, or a combination of these treatment methods.

- Recognize that sialadenitis can occur as a result of radiation therapy.
- Assess for facial nerve involvement for patients with salivary gland tumors. **QSEN: Safety**
- Remember that a parotidectomy involves the removal of the salivary glands; postoperative care is similar to that for patients who have oral cancer surgery.

## CHAPTER 54

# Care of Patients With Esophageal Problems

Tracy Taylor

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is NUTRITION.**

✚ The NUTRITION concept exemplars for this chapter are:

- Gastroesophageal Reflux Disease (GERD), below
- Esophageal Tumors, p. 1095

**The interrelated concept for this chapter is COMFORT.**

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to protect the patient with esophageal problems from injury and infection.
2. Identify appropriate community resources to ensure appropriate transition management for patients with esophageal problems.

### Health Promotion and Maintenance

3. Teach patients about lifestyle changes that decrease gastroesophageal reflux disease (GERD) and alterations in COMFORT associated with hiatal hernias.

### Psychosocial Integrity

4. Implement nursing interventions to minimize stressors for the patient and family who have received a diagnosis of esophageal cancer.

### Physiological Integrity

5. Apply knowledge of anatomy, physiology, pathophysiology, genetic risk, age-related changes, and psychomotor skills to perform a focused assessment for patients with esophageal health problems.
6. Evaluate the impact of esophageal problems on the patient's NUTRITION status.
7. Prioritize care for patients with esophageal problems.
8. Develop an evidence-based postoperative teaching plan for the patient who has had esophageal surgery.

The esophagus moves partially digested food from the mouth to the stomach. Without this process, adults cannot meet their basic human need for NUTRITION. Food nutrients are necessary for normal body cell function. Common esophageal problems that can interfere with digestion and NUTRITION are caused by inflammation, structural defects or obstruction, and cancer. Interprofessional collaborative care involves dietary and lifestyle changes and may include medical and surgical therapies.

# Nutrition Concept Exemplar Gastroesophageal Reflux Disease (GERD)

## Pathophysiology

**Gastroesophageal reflux disease (GERD)**, the most common upper GI disorder in the United States, occurs most often in middle-age and older adults but can affect people of any age.

**Gastroesophageal reflux (GER)** occurs as a result of backward flow of stomach contents into the esophagus. GERD is the chronic and more serious condition that arises from persistent GER.

Reflux produces symptoms by exposing the esophageal mucosa to the irritating effects of gastric or duodenal contents, resulting in inflammation. A patient with acute symptoms of inflammation is often described as having mild or severe **reflux esophagitis** (McCance et al., 2014).

The reflux of gastric contents into the esophagus is normally prevented by the presence of two high-pressure areas that remain contracted at rest. A 1.2-inch (3-cm) segment at the proximal end of the esophagus is called the *upper esophageal sphincter (UES)*, whereas another small portion at the gastroesophageal junction (near the cardiac sphincter) is called the **lower esophageal sphincter (LES)**. The function of the LES is supported by its anatomic placement in the abdomen, where the surrounding pressure is significantly higher than in the low-pressure thorax. Sphincter function is also supported by the acute angle (angle of His) that is formed as the esophagus enters the stomach.

The most common cause of GERD is excessive relaxation of the LES, which allows the reflux of gastric contents into the esophagus and exposure of the esophageal mucosa to acidic gastric contents. Patients who are overweight or obese are at highest risk for development of GERD because increased weight increases intra-abdominal pressure, which contributes to reflux of stomach contents into the esophagus. Nighttime reflux tends to cause prolonged exposure of the esophagus to acid because lying supine decreases peristalsis and the benefit of gravity. **Hiatal hernias** also increase the risk for development of GERD due to the creation of increased intra-abdominal pressure. *Helicobacter pylori* may contribute to reflux (McCance et al., 2014) by causing gastritis and thus poor gastric emptying. This increases frequency of GER events and acid exposure to the esophagus.

A person having reflux may be asymptomatic. However, the esophagus has limited resistance to the damaging effects of the acidic GI contents. The pH of acid secreted by the stomach ranges from 1.5 to 2.0, whereas the pH of the distal esophagus is normally neutral (6.0 to 7.0).

Refluxed material is returned to the stomach by a combination of gravity, saliva, and peristalsis. The inflamed esophagus cannot eliminate the refluxed material as quickly as a healthy one; therefore the length of exposure increases with each reflux episode. Hyperemia (increased blood flow) and **erosion** (ulceration) occur in the esophagus in response to the chronic inflammation. Gastric acid and pepsin injure tissue. Minor capillary bleeding often occurs with erosion, but hemorrhage is rare.

During the process of healing, the body may substitute **Barrett's epithelium** (columnar epithelium) for the normal squamous cell epithelium of the lower esophagus. Although this new tissue is more resistant to acid and therefore supports esophageal healing, it is considered premalignant and is associated with an increased risk for cancer in patients with prolonged GERD. The fibrosis and scarring that accompany the healing process can produce **esophageal stricture** (narrowing of the esophageal opening). The stricture leads to progressive difficulty swallowing. Uncontrolled esophageal reflux also increases the risk for other complications such as asthma, laryngitis, dental decay, cardiac disease, as well as serious concerns for hemorrhage and aspiration pneumonia.

Gastric distention caused by eating very large meals or delayed gastric emptying predisposes the patient to reflux. Certain foods and drugs, smoking, and alcohol influence the tone function of the LES (Table 54-1).

**TABLE 54-1**

**Factors Contributing to Decreased Lower Esophageal Sphincter Pressure**

<ul style="list-style-type: none"><li>• Caffeinated beverages, such as coffee, tea, and cola</li><li>• Chocolate</li><li>• Citrus fruits</li></ul>	<ul style="list-style-type: none"><li>• Nitrates</li><li>• Peppermint, spearmint</li><li>• Alcohol</li></ul>
--	--

- Tomatoes and tomato products
- Smoking and use of other tobacco products
- Calcium channel blockers

- Anticholinergic drugs
- High levels of estrogen and progesterone
- Nasogastric tube placement

Patients who have a nasogastric tube also have decreased esophageal sphincter function. The tube keeps the cardiac sphincter open and allows acidic contents from the stomach to enter the esophagus. Other factors that increase intra-abdominal and intragastric pressure (e.g., pregnancy, wearing tight belts or girdles, bending over, ascites) overcome the gastroesophageal pressure gradient maintained by the LES and allow reflux to occur. Many patients with obstructive sleep apnea report frequent episodes of GERD. Patients with hiatal hernias often have reflux because the upper portion of the stomach protrudes through the diaphragm into the thorax, which allows acid to reach the esophagus (see later discussion of hiatal hernia).

## Health Promotion and Maintenance

Adults who have gastroesophageal reflux (GER) may initially be asymptomatic. Teach patients to engage in healthy eating habits that include consuming small, frequent meals and limiting intake of fried, fatty, and spicy foods, and caffeine. Sitting upright for at least 1 hour after eating can promote proper digestion and reduce the risk for reflux.

### NCLEX Examination Challenge 54-1

#### Health Promotion and Maintenance

On assessment of a client with GERD, which statement requires nursing intervention?

- A. "I quit smoking several years ago."
- B. "Sometimes I wake up gasping for air in the middle of the night."
- C. "My family likes to eat small meals every 3 to 4 hours throughout the day."
- D. "When I buy meat, I ask for the leanest cut that is available."

### Interprofessional Collaborative Care

Care for the patient with GERD usually takes place in the community setting. Only infrequently is surgery needed to correct the problem. The interprofessional team that usually collaborates to care for this patient includes the primary health care provider, nurse, and dietician.

#### Assessment: Noticing

Ask the patient about a history of heartburn or atypical chest pain associated with the reflux of GI contents. Ask whether he or she has been newly diagnosed with asthma or has experienced morning hoarseness or pneumonia. These symptoms may indicate severe reflux reaching the pharynx or mouth or pulmonary aspiration.

#### Physical Assessment/Signs and Symptoms.

**Dyspepsia**, also known as *indigestion*, and regurgitation are the main symptoms of GERD, although symptoms may vary in severity (Chart 54-1). Symptoms associated with "indigestion" may include abdominal discomfort, feeling uncomfortably full, nausea, and burping. Because indigestion might not be viewed as a serious concern, patients may delay seeking treatment. The symptoms typically worsen when the patient bends over, strains, or lies down. If the indigestion is severe, the pain may radiate to the neck or jaw or may be referred to the back, mimicking cardiac pain. Patients may come to the emergency department (ED) fearing that they are having a myocardial infarction ("heart attack").

#### Chart 54-1

### Key Features

## Gastroesophageal Reflux Disease

- Dyspepsia (indigestion)
- Regurgitation (may lead to aspiration or bronchitis)
- Coughing, hoarseness, or wheezing at night
- Water brash (hypersalivation)
- Dysphagia
- Odynophagia (painful swallowing)
- Epigastric pain
- Generalized abdominal pain
- Belching
- Flatulence
- Nausea
- Pyrosis (heartburn)
- Globus (feeling of something in back of throat)
- Pharyngitis
- Dental caries (severe cases)

With severe GERD, pain generally occurs after each meal and lasts for 20 minutes to 2 hours. Discomfort may worsen when the patient lies down. Drinking fluids, taking antacids, or maintaining an upright posture usually provides prompt relief.

**Regurgitation** (backward flow into the throat) of food particles or fluids is common. Risk for aspiration is increased if regurgitation occurs when the patient is lying down. Even if the patient is in an upright position, he or she may experience warm fluid traveling up the throat without nausea. If the fluid reaches the level of the pharynx, he or she notes a sour or bitter taste in the mouth. A reflex salivary hypersecretion known as **water brash** occurs in response to reflux. Water brash is different from regurgitation. The patient reports a sensation of fluid in the throat, but unlike with regurgitation, there is no bitter or sour taste.

Ask the patient if he or she experiences **eructation** (belching), **flatulence** (gas), and bloating after eating; these are other common symptoms. Nausea and vomiting rarely occur; unplanned weight loss is not common.

Assess for crackles in the lung, which can be an indication of associated aspiration. Patients who have had long-term regurgitation may experience coughing, hoarseness, or wheezing at night, which may be associated with bronchitis.

Chronic GERD can cause **dysphagia** (difficulty swallowing), a narrowing of the esophagus because of stricture or inflammation, which can interfere with NUTRITION. Assess the patient for degree of dysphagia, whether ingesting solids and/or liquids induces dysphagia, and whether dysphagia occurs intermittently or with each swallowing effort. See [Chapter 53](#) for more information on assessing for dysphagia.

**Odynophagia** (painful swallowing) can also occur with chronic GERD, but it is rare in patients with uncomplicated reflux disease. Severe and long-lasting chest pain may be present if esophageal spasms cause the muscle to contract with excess force. The resulting pain can be agonizing and may last for hours.

Other symptoms include atypical chest pain, symptoms of asthma, and chronic cough that occurs mostly at night or when the patient is lying down. Cough and symptoms of asthma occur when

refluxed acid is spilled over into the tracheobronchial tree. *Atypical chest pain* is thought to be caused by stimulation of pain receptors in the esophageal wall and by esophageal spasm. This type of chest pain can mimic angina and needs to be carefully distinguished from cardiac pain.

## Considerations for Older Adults

### Patient-Centered Care QSEN

Older adults are at risk for developing severe complications associated with GERD caused by age-related physiologic changes, medication side effects, and an increased prevalence of hiatal hernias (Solomon & Reynolds, 2012). Instead of heartburn associated with GERD, this population experiences more severe complications of the disease such as atypical chest pain; ear, nose, and throat infections; and pulmonary problems, such as aspiration pneumonia, sleep apnea, and asthma. Barrett's esophagus and esophageal erosions are also more common in older adults.

### Diagnostic Assessment.

A definitive diagnostic test for GERD does not exist; however, health care providers may use one or more options to attempt to establish a diagnosis when GERD is suspected (The Ohio State University Wexner Medical Center [OSUWMC], 2017).

Patients may drink a solution and then have x-rays performed as part of a *barium swallow*, which shows hiatal hernias, strictures, and other structural or anatomic esophageal problems. Although this test, when conducted by itself, does not confirm GERD, it can be helpful when used in combination with other diagnostic procedures.

**Upper endoscopy** (also called **esophagogastroduodenoscopy [EGD]**) involves insertion of an endoscope (a flexible plastic tube equipped with a light and lens) down the throat, which allows the health care provider to see the esophagus and look for abnormalities. A biopsy can be taken while the patient undergoes endoscopy (see Chapter 52) (OSUWMC, 2017). This test requires the use of moderate sedation during the procedure, and patients must have someone accompany them home after recovery.

A **pH monitoring examination** is the most accurate method of diagnosing GERD. This involves either (1) placing a small catheter through the nose into the distal esophagus or (2) temporarily attaching a small capsule to the wall of the esophagus during an upper endoscopy (the 48-hour Bravo esophageal pH test). The patient is asked to keep a diary of activities and symptoms over 24 to 48 hours (depending on diagnostic method), and the pH is continuously monitored and recorded. Ambulatory pH monitoring is especially useful in diagnosing patients with atypical symptoms. A wireless monitoring device may be used to promote patient COMFORT (OSUWMC, 2017).

Although not as common, *esophageal manometry*, or motility testing, may be performed when the diagnosis is uncertain. Water-filled catheters are inserted in the patient's nose or mouth and slowly withdrawn while measurements of LES pressure and peristalsis are recorded. When used alone, manometry is not sensitive or specific enough to establish a diagnosis of GERD (National Institutes of Health, 2015). A Gastric Emptying Study can also be done while a patient is in the radiology/nuclear medicine department. He or she is given a meal mixed with radiolucent dye, and imaging is performed to determine how well the stomach empties over the next few hours. If food stays too long in the stomach, it can reflux back into the esophagus, causing symptoms. Imaging of the lungs can also be conducted 24 hours later to visualize whether the patient has aspirated stomach contents.

### ◆Analysis: Interpreting

The priority collaborative problems for the patient with gastroesophageal reflux disease (GERD) include:

1. Potential for compromised NUTRITION status due to dietary selection
2. Acute pain due to reflux of gastric contents

### ◆Planning and Implementation: Responding

## Balancing Nutrition

### Planning: Expected Outcomes.

The patient with imbalanced NUTRITION is expected to have improvement in nutrition status, which allows esophagitis to heal and prevents complications such as strictures or Barrett's esophagus. Indicators include:

- Selection of food items that minimize symptoms of GERD
- No report of reflux after eating

### Interventions.

Interventions are designed to optimize NUTRITION status, decrease symptoms experienced with GERD, and prevent complications. Nursing care priorities focus on teaching the patient about proper dietary selections that provide optimum nutrients and that do not contribute to reflux.

### Nonsurgical Management.

For most patients, GERD can be controlled by NUTRITION therapy, lifestyle changes, and drug therapy. *The most important role of the nurse is patient and family education. Teach the patient that GERD is a chronic disorder that requires ongoing management. The disease should be treated more aggressively in older adults.*

NUTRITION therapy is used to relieve symptoms in patients with relatively mild GERD. Ask about the patient's basic meal patterns and food preferences. Coordinate with the dietitian, patient, and family about how to adapt to changes in eating that may decrease reflux symptoms.

Teach the patient to limit or eliminate foods that decrease LES pressure and irritate inflamed tissue, causing heartburn, such as peppermint, chocolate, alcohol, fatty foods (especially fried), caffeine, and carbonated beverages. The patient should also restrict spicy and acidic foods (e.g., orange juice, tomatoes) until esophageal healing can occur. Patients who are smart phone users may find different types of applications ("apps") that can help them follow a healthier diet, such as MyFitnessPal ([www.myfitnesspal.com](http://www.myfitnesspal.com)). In keeping with The Joint Commission Core Measures, teach patients that smoking and alcohol use should also be avoided, because these can also decrease LES pressure. Explore the possibility and methods for smoking cessation and make appropriate referrals. Ask the patient about his or her use of alcoholic beverages and, if appropriate, help the patient find alcohol-cessation programs.

Large meals increase the volume of and pressure in the stomach and delay gastric emptying. Remind the patient to eat four to six small meals each day rather than three large ones. Encourage patients to avoid eating at least 3 hours before going to bed because reflux episodes are most damaging at night. Advise the patient to eat slowly and chew thoroughly to facilitate digestion and prevent eructation (belching).

## Considerations for Older Adults

### Patient-Centered Care QSEN

Research has also found that long-term use of proton pump inhibitors (PPIs) may increase the risk for hip fracture, especially in older adults. PPIs can interfere with calcium absorption and protein digestion and therefore reduce available calcium to bone tissue. Decreased calcium makes bones more brittle and likely to fracture, especially as adults age.

## NCLEX Examination Challenge 54-2

### Health Promotion and Maintenance

A client reports ongoing episodes of heartburn. The nurse educates the client on prevention and control of reflux by recommending dietary elimination of which food item?

- A. Lean steak

- B. Carrot sticks
- C. Chocolate candy
- D. Air-popped popcorn

## Improving Comfort

### Planning: Expected Outcomes.

The patient with alterations in COMFORT is expected to have relief of signs and symptoms of pain. Indicators include:

- Decrease in level of reported pain

### Interventions.

Interventions are designed to optimize the patient's perceived level of COMFORT. Nursing care priorities focus on teaching the patient about lifestyle modifications that will alleviate pain.

### Nonsurgical Management.

In addition to appropriate dietary selections that promote NUTRITION and allow esophageal tissues to heal, patients should be empowered to adhere to other methods of controlling symptoms associated with GERD to minimize COMFORT alterations.

### Lifestyle Changes.

The control of GERD involves *lifestyle changes* to promote health and control reflux ([Chart 54-2](#)). Teach the patient to elevate the head of the bed by 6 to 12 inches for sleep to prevent nighttime reflux. This can be done by placing blocks under the head of the bed or by using a large, wedge-style pillow instead of a standard pillow. Teach the patient to sleep in the right side-lying position to promote gas exchange and to swallow frequently to clear the esophagus. Help the patient examine approaches to weight reduction. Decreasing intra-abdominal pressure often reduces reflux symptoms. Teach the patient to avoid wearing constrictive clothing, lifting heavy objects or straining, and working in a bent-over or stooped position. Emphasize that these general adaptations are an essential and effective part of disease management and can produce prompt results in uncomplicated cases.

## Chart 54-2

# Patient and Family Education: Preparing for Self-Management

## Health Promotion and Lifestyle Changes to Control Reflux

- Eat four to six small meals a day.
- Limit or eliminate fatty foods, coffee, tea, cola, and chocolate.
- Reduce or eliminate from your diet any food or spice that increases gastric acid and causes pain.
- Limit or eliminate alcohol and tobacco and reduce exposure to secondhand smoke.
- Do not snack in the evening and do not eat for 2 to 3 hours before you go to bed.
- Eat slowly and chew your food thoroughly to reduce belching.
- Remain upright for 1 to 2 hours after meals, if possible.
- Elevate the head of your bed 6 to 12 inches using wooden blocks or elevate your head using a foam wedge. Never sleep flat in bed.

- If you are overweight, lose weight.
- Do not wear constrictive clothing.
- Avoid heavy lifting, straining, and working in a bent-over position.
- Chew “chewable” antacids thoroughly and follow with a glass of water.

Patients with obesity often have both obstructive sleep apnea and GERD. Those who receive continuous positive airway pressure (CPAP) treatment report improved sleeping and decreased episodes of reflux at night. See [Chapter 29](#) for a discussion of CPAP.

### Drug Therapy.

Some drugs lower LES pressure and *cause* reflux, such as oral contraceptives, anticholinergic agents, sedatives, NSAIDs (e.g., ibuprofen), nitrates, and calcium channel blockers. The possibility of eliminating the drugs causing reflux should be explored with the primary health care provider. Drug therapy for GERD management includes three major types: antacids, histamine blockers, and proton pump inhibitors. These drugs, which are also used for peptic ulcer disease, have one or more of these functions (see [Chart 55-3](#)).

- Inhibit gastric acid secretion
- Accelerate gastric emptying
- Protect the gastric mucosa

In response to these actions, the pain or discomfort that a patient experiences should decrease. In uncomplicated cases of GERD, *antacids* may be effective for *occasional* episodes of heartburn discomfort. Antacids act by elevating the pH level of the gastric contents, thereby deactivating pepsin. They are not helpful in controlling frequent symptoms because their length of action is too short and their nighttime effectiveness is minimal. They also *increase* LES pressure and therefore are not given for long-term use.

Antacids containing aluminum hydroxide or magnesium hydroxide may be used. Maalox and Mylanta consist of a combination of these two agents. Patients often tolerate them better because they produce fewer side effects, such as constipation and diarrhea. Liquid forms of these medications are preferred, since they coat the esophagus to provide pain relief and buffer acid. Teach the patient to take the antacid 1 hour before and 2 to 3 hours after each meal.

Gaviscon, a combination of alginic acid and sodium bicarbonate, is often a very effective drug for GERD. It forms thick foam that floats on top of the gastric contents and theoretically decreases the incidence of reflux. If reflux occurs, the foam enters the esophagus first and buffers the acid in the refluxed material, causing less pain and decreasing the risk for further mucosal irritation. Remind the patient to take this drug when food is in the stomach.

*Histamine receptor antagonists*, commonly called *histamine blockers*, such as famotidine (Pepcid), cimetidine (Tagamet), and ranitidine (Zantac), decrease acid, are long acting, have fewer side effects, and allow less-frequent dosing. Although these drugs do not affect the occurrence of reflux directly, they do reduce gastric acid secretion, improve symptoms, and promote healing of inflamed esophageal tissue so COMFORT is improved. With these drugs available over-the-counter (OTC) and widely advertised for heartburn, many patients self-medicate before seeking professional assistance from their primary health care provider. Encourage patients to speak with their primary health care provider to determine whether long-term use of these medications is appropriate.

*Proton pump inhibitors (PPIs)*, such as omeprazole (Prilosec), rabeprazole (AcipHex), pantoprazole (Protonix), lansoprazole (Prevacid), and esomeprazole (Nexium), are the *main* treatment for more severe GERD. Some PPIs are available as OTC drugs. These agents provide effective, long-acting inhibition of gastric acid secretion by affecting the proton pump of the gastric parietal cells. PPIs reduce gastric acid secretion and can be given in a single daily dose. If once-a-day dosing fails to control symptoms, twice-daily dosing may be used ([National Guideline Clearinghouse \[NGC\], 2013](#)). An omeprazole/sodium bicarbonate combination, Zegerid, is the first immediate-release PPI and is designed for short-term use. Dexlansoprazole (Kapidex) is a dual-release (delayed-release) drug that is available in several dosages but has more side and adverse effects than other PPIs.

Some PPIs, such as Nexium and Protonix, may be administered in IV form for short-term use to treat or prevent stress ulcers that can result from surgery. PPIs promote rapid tissue healing, but

recurrence is common when the drug is stopped. Long-term use may mask reflux symptoms, and stopping the drug determines if reflux has been resolved. Long-term use may also cause community-acquired pneumonia and GI infections such as those caused by *Clostridium difficile*.

### Endoscopic Therapies.

The Stretta procedure, a nonsurgical method, can replace surgery for GERD when other measures are not effective. Patients who are very obese or have severe symptoms may not be candidates for this procedure. In the Stretta procedure, the physician applies radiofrequency (RF) energy through the endoscope using needles placed near the gastroesophageal junction. The RF energy decreases vagus nerve activity, thus reducing discomfort for the patient. Postoperative instructions for patients who have undergone the Stretta procedure can be found in [Chart 54-3](#).

#### **Chart 54-3**

## Patient and Family Education: Preparing for Self-Management

### Postoperative Instructions for Patients Having Stretta Procedure

- Remain on clear liquids for 24 hours after the procedure.
- After the first day, consume a soft diet, such as custard, pureed vegetables, mashed potatoes, and applesauce.
- Avoid NSAIDs and aspirin for 10 days.
- Continue drug therapy as prescribed, usually proton pump inhibitors.
- Use liquid medications whenever possible.
- Do not allow nasogastric tubes for at least 1 month because the esophagus could be perforated.
- Contact the health care provider immediately if these problems occur:
  - Chest or abdominal pain
  - Bleeding
  - Dysphagia
  - Shortness of breath
  - Nausea or vomiting

### Surgical Management.

A very small percentage of patients with GERD require anti-reflux surgery. It is usually indicated for otherwise healthy patients who have failed to respond to medical treatment or have developed complications related to GERD. Various surgical procedures may be used through conventional open techniques or laparoscope.

Laparoscopic Nissen fundoplication (LNF) is a minimally invasive surgery (MIS) and is the standard surgical approach for treatment of severe GERD ([Buckley, 2016](#)). Information about this procedure can be found in the next section ([Hiatal Hernia](#)) in the Surgical Management discussion. Patients who have surgery are encouraged to continue following the basic anti-reflux regimen of antacids and NUTRITION therapy because the rate of recurrence is high.

## Care Coordination and Transition Management

Patients with nonsurgical GERD are usually managed in the community setting. Nursing interventions focus on helping the patient and family with current treatment and reducing risk for continuing symptoms and complications.

### Home Care Management.

Remind the patient to make appropriate dietary selections that enhance NUTRITION and decrease symptoms associated with GERD.

### Self-Management Education.

For patients with nonsurgical GERD, teach about signs and symptoms of more serious complications such as esophageal stricture and Barrett's esophagus.

### Health Care Resources.

Patients may find it helpful to work with a dietitian or a support group for meal-planning purposes. Refer the patient to a dietitian as necessary. Inform him or her of local support groups for patients with GERD and also of credible online communities that provide a forum for ongoing management of this condition.

### ◆ Evaluation: Reflecting

Evaluate the care of the patient with GERD on the basis of adherence to plan of care, reduction of symptoms, and prevention of complications. The expected outcomes include that the patient will:

- Exhibit adherence to choosing appropriate dietary selections, taking drugs as prescribed, and making appropriate lifestyle modifications
- Report decrease of reflux signs and symptoms associated with GERD
- Avoid complications resulting from GERD

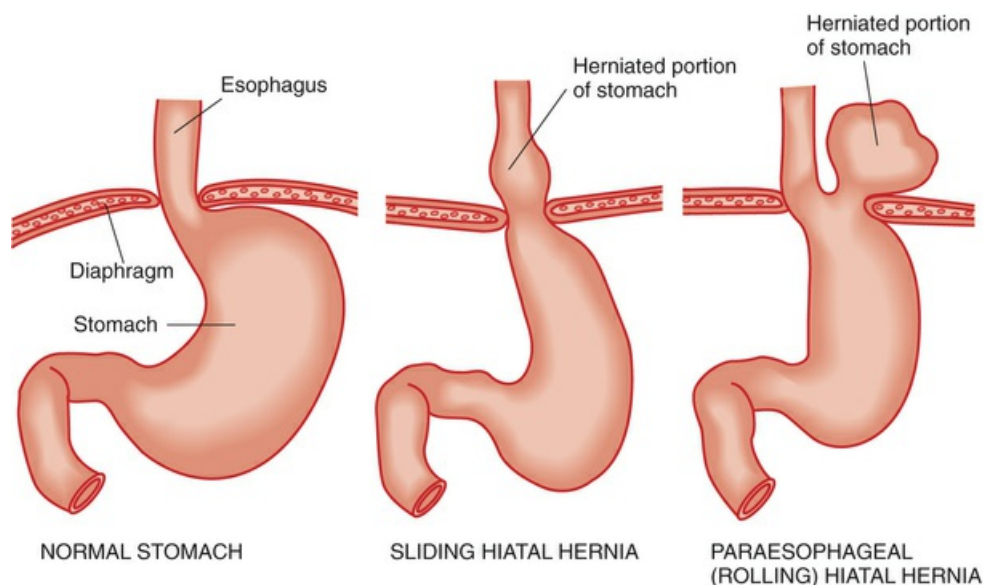

## Hiatal Hernias

**Hiatal hernias**, also called *diaphragmatic hernias*, involve the protrusion of the stomach through the esophageal hiatus of the diaphragm into the chest. The esophageal hiatus is the opening in the diaphragm through which the esophagus passes from the thorax to the abdomen. Most patients with hiatal hernias are asymptomatic, but some may have daily symptoms similar to those with GERD (McCance et al., 2014).

### ❖ Pathophysiology

The two major types of hiatal hernias are sliding hernias (which are most common) and paraesophageal (rolling) hernias. The esophagogastric junction and a portion of the fundus of the stomach slide upward through the esophageal hiatus into the chest, usually as a result of weakening of the diaphragm (Fig. 54-1). The hernia generally moves freely and slides into and out of the chest during changes in position or intra-abdominal pressure. Although **volvulus** (twisting of a GI structure) and obstruction do occur rarely, the major concern for a sliding hernia is the development of esophageal reflux and associated complications (see the Gastroesophageal Reflux Disease section earlier in this chapter). The development of reflux is related to chronic exposure of the lower esophageal sphincter (LES) to the low pressure of the thorax, which significantly reduces the effectiveness of the LES. Symptoms associated with decreased LES pressure are worsened by positions that favor reflux, such as bending or lying supine. Coughing, obesity, and ascites also increase reflux symptoms.

**FIG. 54-1** Comparison of the normal stomach and sliding and paraesophageal (rolling) hiatal hernias.

With *rolling hernias*, also known as *paraesophageal hernias*, the gastroesophageal junction remains in its normal intra-abdominal location; but the fundus (and possibly portions of the stomach's greater curvature) rolls through the esophageal hiatus and into the chest beside the esophagus (see Fig. 54-1). The herniated portion of the stomach may be small or quite large. In rare cases, the stomach completely inverts into the chest. Reflux is not usually present because the LES remains anchored below the diaphragm. However, the risks for volvulus (twisting of a GI structure), obstruction (blockage), and strangulation (stricture) are high. The development of iron deficiency anemia is common because slow bleeding from venous obstruction causes the gastric mucosa to become engorged and ooze. Significant bleeding or hemorrhage is rare.

Rolling hernias are thought to develop from an anatomic defect occurring when the stomach is not properly anchored below the diaphragm rather than from muscle weakness. They can also be caused by previous esophageal surgeries, including sliding hernia repair.

## ❖ Interprofessional Collaborative Care

Care for the patient with a hiatal hernia usually takes place in the community setting, unless surgery is needed to correct the problem. The interprofessional team that collaborates to care for this patient includes the health care provider, nurse, surgeon, dietitian, and spiritual leader of the patient's choice if surgery is needed.

### ◆ Assessment: Noticing

Ask the patient if he or she has heartburn, regurgitation (backward flow of food into the throat), pain, dysphagia (difficulty swallowing), and eructation (belching). Assess general physical appearance and NUTRITION status. Note the location, onset, duration, and quality of pain and factors that relieve it or make it worse. The primary symptoms of sliding hiatal hernias are associated with reflux. Auscultate the lungs because pulmonary symptoms similar to those of asthma may be triggered by episodes of aspiration, particularly at night. A detailed history is crucial in attempting to differentiate angina from noncardiac chest pain caused by reflux. Symptoms resulting from hiatal hernia typically worsen after a meal or when the patient is in a supine position (Chart 54-4).

### ▶ Chart 54-4

## Key Features

### Hiatal Hernias

#### Sliding Hiatal Hernias

- Heartburn
- Regurgitation
- Chest pain
- Dysphagia
- Belching

#### Paraesophageal Hernias

- Feeling of fullness after eating
- Breathlessness after eating
- Feeling of suffocation
- Chest pain that mimics angina
- Worsening of manifestations in a recumbent position

In those with rolling hernias, assess for symptoms related to stretching or displacement of thoracic contents by the hernia. Patients may report a feeling of fullness after eating or have breathlessness or a feeling of suffocation if the hernia interferes with breathing. Some may experience chest pain associated with reflux that mimics angina.

The *barium swallow study with fluoroscopy* is the most specific diagnostic test for identifying hiatal hernia. Rolling hernias are usually clearly visible, and sliding hernias can often be observed when the patient moves through a series of positions that increase intra-abdominal pressure. To visualize sliding hernias, an esophagogastroduodenoscopy (EGD) may be performed to view both the esophagus and gastric lining (see Chapter 52).

### ◆ Interventions: Responding

Patients with hiatal hernias may be managed either medically or surgically. Collaborative care is

based on the severity of symptoms and the risk for serious complications. Sliding hiatal hernias are most commonly treated medically. Large rolling hernias can become strangulated or obstructed; therefore early surgical repair is preferred.

### **Nonsurgical Management.**

The collaborative interventions for patients with hiatal hernia are similar to those for GERD and include drug therapy, NUTRITION therapy, and lifestyle changes. The primary health care provider typically recommends antacids and a proton-pump inhibitor such as lansoprazole (Prevacid), omeprazole (Prilosec), or esomeprazole (Nexium) in an attempt to control reflux and its symptoms. NUTRITION therapy is also important and follows the guidelines discussed earlier for GERD.

## **Nursing Safety Priority** QSEN

### **Action Alert**

The most important role of the nurse in caring for a patient with a hiatal hernia is health teaching. Encourage the patient to avoid eating in the late evening and avoid foods associated with reflux. Teach the patient and family that the patient should follow a restricted diet and exercise regularly. Reducing body weight is beneficial because obesity increases intra-abdominal pressure and worsens both the hernia and the symptoms of reflux. Teach about positioning, including:

- Sleep at night with the head of the bed elevated 6 inches
- Remain upright for several hours after eating
- Avoid straining or excessive vigorous exercise
- Refrain from wearing clothing that is tight or constrictive around the abdomen

### **Surgical Management.**

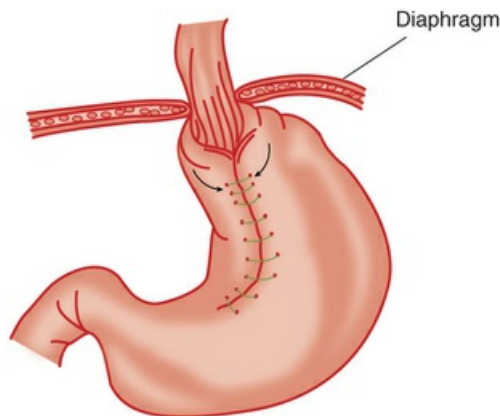

Surgery may be required when the risk for complications is high or when damage from chronic reflux becomes severe.

### **Preoperative Care.**

If the surgery is not urgent, the surgeon instructs patients who are overweight to lose weight before surgery. They are also advised to quit or significantly reduce smoking. As part of preoperative teaching, reinforce the surgeon's instructions and prepare the patient for what to expect after surgery.

### **Operative Procedures.**

Several types of hiatal hernia repair procedures are used, each of which involves reinforcement of the lower esophageal sphincter (LES) by fundoplication. The surgeon wraps a portion of the stomach fundus around the distal esophagus to anchor it and reinforce the LES (Fig. 54-2).

**FIG. 54-2** Open surgical approach for Nissen fundoplication for gastroesophageal reflux disease or hiatal hernia repair.

Laparoscopic Nissen fundoplication (LNF) is a minimally invasive surgery commonly used for hiatal hernia repair (Buckley, 2016). Complications after LNF occur less frequently compared with those seen in patients having the more traditional open surgical approach. A small percentage of patients are not candidates for LNF and therefore require a conventional open fundoplication.

For the trans-thoracic surgical approach, teach the patient about chest tubes. Inform him or her that a nasogastric tube will be inserted during surgery and will remain in place for several days. Oral intake is started gradually with clear liquids after peristalsis is re-established or to stimulate peristalsis. Instruct the patient how to deep breathe and use the incentive spirometer. These measures are essential to prevent postoperative respiratory complications. The high incision makes deep breathing extremely painful. Teach the patient about postoperative pain and assure him or her that adequate postoperative analgesic will be given promptly. Pain levels must be monitored continuously.

In paraesophageal repair (a laparoscopic surgery), several  $\frac{1}{2}$ -inch incisions are made in the abdomen, through which the hernia is closed and typically reinforced using mesh. Less commonly, a conventional open procedure is used in which the surgeon uses a high trans-thoracic approach that requires a large chest incision for access to the surgical area.

### Postoperative Care.

Patients having the *LNF procedure* or paraesophageal repair via laparoscope are at risk for bleeding and infection, although these problems are not common. *The nursing care priority is to observe for these complications and provide health teaching as described in Chart 54-5.*

### **Chart 54-5**

## **Patient and Family Education: Preparing for Self-Management**

### **Postoperative Instructions for Patients Having Laparoscopic Nissen Fundoplication (LNF) or Paraesophageal Repair via Laparoscope**

- Stay on a soft diet for about a week, including mashed potatoes, puddings, custard, and milkshakes; avoid carbonated beverages, tough foods, and raw vegetables that are difficult to swallow.
- Remain on anti-reflux medications as prescribed for at least a month.
- Do not drive for a week after surgery; do not drive if taking opioid pain medication.
- Walk every day but do not do any heavy lifting.
- Remove small dressings 2 days after surgery and shower; do not remove Steri-Strips until 10 days

after surgery.

- Wash incisions with soap and water, rinse well, and pat dry; report any redness or drainage from the incisions to your surgeon.
- Report fever above 101° F (38.3° C), nausea, vomiting, or uncontrollable bloating or pain. For patients older than 65 years, report elevations above 100° F (37.8° C).
- Schedule an appointment for follow-up with your surgeon in 3 to 4 weeks.

Postoperative care after *conventional open repair* closely follows that required after any esophageal surgery. Complications after open surgery are more common and potentially serious. Carefully assess for complications of open fundoplication surgery, described next, and report any complications to the health care provider (Chart 54-6).

### Chart 54-6

## Best Practice for Patient Safety & Quality Care QSEN

### Assessment of Postoperative Complications Related to Fundoplication Procedures

COMPLICATION	ASSESSMENT FINDINGS
Temporary dysphagia	The patient has difficulty swallowing when oral feeding begins.
Gas bloat syndrome	The patient has difficulty belching to relieve distention.
Atelectasis, pneumonia	The patient experiences dyspnea, chest pain, or fever.
Obstructed nasogastric tube	The patient experiences nausea, vomiting, or abdominal distention. The nasogastric tube does not drain.

## Nursing Safety Priority QSEN

### Action Alert

The primary focus of care after conventional surgery for a hiatal hernia repair is the prevention of respiratory complications. Elevate the head of the patient's bed at least 30 degrees to lower the diaphragm and promote lung expansion. Assist the patient out of bed and begin ambulation as soon as possible. Be sure to support the incision during coughing to reduce pain and prevent excessive strain on the suture line, especially with obese patients.

Incentive spirometry and deep breathing are routinely used after surgery to maintain patency of the airways and lung expansion. Adequate pain control with analgesics is essential for postoperative deep breathing and coughing. Patients with a smoking history or chronic airway limitation (e.g., chronic obstructive pulmonary disease, asthma) require more aggressive management by the respiratory therapist to prevent atelectasis and pneumonia. Patients with large hiatal hernias are at the highest risk for developing respiratory complications.

For patients who have extensive head-neck cancer or who have had trauma to this area, a gastric feeding tube may have been placed through the abdominal wall to provide a temporary or permanent means for NUTRITION intake. This can be preferable to a nasogastric (NG) tube since it can provide longer-term access for nutrition intake. It can be placed percutaneously by an interventional radiologist, through an open incision, or endoscopically by a surgeon, into the stomach, stomach and jejunum, or jejunum only. Patients with this type of catheter can receive feedings through this tube by a family member or home health nurse with minimal care needed.

Alternately, the patient having the conventional surgery usually has a large-bore (diameter) nasogastric (NG) tube to prevent the fundoplication wrap from becoming too tight around the esophagus. Initially the NG drainage should be dark brown with old blood. The drainage should become normal yellowish green within the first 8 hours after surgery. Check the NG tube every 4 to 8 hours for proper placement in the stomach. It should be properly anchored so it is not displaced, because reinsertion could perforate the fundoplication. Follow the surgeon's directions for care of the patient with an NG tube.

Monitor patency of the NG tube to keep the stomach decompressed. This prevents retching or vomiting, which can strain or rupture the stomach sutures. The NG tube is irritating. Therefore

provide frequent oral hygiene to increase COMFORT. Assess the patient's hydration status regularly, including accurate measures of intake and output. Adequate fluid replacement helps thin respiratory secretions.

After open fundoplication, the patient may begin clear fluids when peristalsis is re-established or in an effort to stimulate peristalsis. Some surgeons create a temporary gastrostomy for feeding to allow for undisturbed healing of the repair. The patient gradually progresses to a near-normal diet during the first 4 to 6 weeks. Some foods, especially caffeinated or carbonated beverages and alcohol, are either restricted or eliminated. The food storage area of the stomach is reduced by the surgery, and meals need to be both smaller and more frequent.

*Carefully supervise the first oral feedings because temporary dysphagia is common.* Continuous dysphagia usually indicates that the fundoplication is too tight, and dilation may be required.

Another common complication of this surgery is *gas bloat syndrome*, in which patients are unable to voluntarily eructate (belch). The syndrome is usually temporary but may persist, even in those who have the laparoscopic approach. Teach the patient to avoid drinking carbonated beverages and eating gas-producing foods (especially high-fat foods), chewing gum, and drinking with a straw.

Other patients have *aerophagia* (air swallowing) from attempting to reverse or clear acid reflux. Teach them to relax consciously before and after meals, to eat and drink slowly, and to chew all food thoroughly. Air in the stomach that cannot be removed by belching can be extremely uncomfortable. Frequent position changes and ambulation are often effective interventions for eliminating air from the GI tract. If gas pain is still present, patients are taught to take simethicone, which dissolves in the mouth.

### Care Coordination and Transition Management

Patients undergoing one of the open surgical repairs require activity restrictions during the 3- to 6-week postoperative recovery period. For laparoscopic surgery, activity is typically restricted for a shorter time, and the patient can return to his or her usual lifestyle more quickly, usually in a few days to a week.

For long-term management, teach the patient and family about appropriate NUTRITION modifications. The use of stool softeners or bulk laxatives is recommended for the first postoperative weeks until healing is complete. Instruct the patient to avoid straining and prevent constipation. Teach him or her to inspect the healing incision daily and notify the health care provider if swelling, redness, tenderness, discharge, or fever occurs. Advise the patient to avoid contact with individuals with a respiratory infection and to contact the health care provider if symptoms of a cold or influenza develop. Continuous coughing can cause the incision or the fundoplication to dehiscence ("break open").

If needed, collaborate with the dietitian to educate the patient and family about dietary changes. Encourage the patient to eat smaller and more frequent meals. Few ongoing diet restrictions are needed, but overeating or eating the wrong types of foods can produce discomfort if the patient cannot belch. Instruct the patient to report reflux symptoms to the primary health care provider.

Although severe surgical complications are rare, conditions such as gas bloat syndrome and dysphagia may continue. Prepare the patient for these problems and for the potential that reflux may not be completely controlled or may occur again. Although surgery controls the condition, a cure is rare, and lifestyle modifications need to be ongoing.

## ❏ Nutrition Concept Exemplar Esophageal Tumors

### ❖ Pathophysiology

Although esophageal tumors can be benign, most are malignant (cancerous), and the majority arise from the epithelium. Squamous cell carcinomas of the esophagus are located in the upper two thirds of the esophagus. Adenocarcinomas are more commonly found in the distal third and at the gastroesophageal junction and are now the most common type of esophageal cancer (McCance et al., 2014). Esophageal tumors grow rapidly because there is no serosal layer to limit their extension. Because the esophageal mucosa is richly supplied with lymph tissue, there is early spread of tumors to lymph nodes. Esophageal tumors can protrude into the esophageal lumen and can cause thickening or invade deeply into surrounding tissue. In rare cases, the lesion may be confined to the epithelial layer (in situ). In most cases, the tumor is large and well established on diagnosis. More than half of esophageal cancers **metastasize** (spread throughout the body).

Primary risk factors associated with the development of esophageal cancer are smoking and obesity. The compounds in tobacco smoke may be responsible for the genetic mutations seen in many squamous cell carcinomas of the esophagus. Increased abdominal pressure associated with obesity is linked to reflux and Barrett's esophagus (a premalignant condition). Both conditions can contribute to changes in cellular structure in the esophagus, increasing the potential for adenocarcinoma of the esophagus (ACS, 2016c). In addition to these primary risk factors, malnutrition, untreated gastroesophageal reflux disease (GERD), and excessive alcohol intake are also associated with esophageal cancer. **Barrett's esophagus** results from exposure to acid and pepsin, which leads to the replacement of normal distal squamous mucosa with columnar epithelium as a response to tissue injury. This tissue undergoes dysplasia (cell appearance changes) and ultimately becomes cancerous. In parts of the world where esophageal cancer is more common, the incidence of squamous cell carcinoma appears to be linked to high levels of nitrosamines (which are found in pickled and fermented foods) and foods high in nitrate. Diets that are chronically deficient in fresh fruits and vegetables have also been implicated in the development of squamous cell carcinoma.

## ❏ Genetic/Genomic Considerations

### Patient-Centered Care QSEN

Certain genetic factors may have a role in the development of esophageal cancers. It is thought that these cancers result from mutations in tumor suppressor genes. Tumor suppressor genes are normal genes that control cell growth and division. When this type of gene is mutated and does not work properly, cells are unable to stop growing and dividing, and tumors can result. (See Chapter 21 for discussion of suppressor gene activity.)

Overexpression and mutations of the *Tp53*, *Tp16* and tumor suppressor genes have been found in patients with esophageal cancer (National Center for Biotechnology Information, 2017). In addition, the presence of the mutated *Tp53* gene may be an indication of advanced disease, especially in those with adenocarcinomas.

Overexpression of *cyclin D1*, a protein that promotes cell growth and division, has also been found in patients with esophageal squamous cell cancers. Cyclins are products of oncogenes, which are normal genes involved in cell division and are controlled by suppressor genes. Prolonged exposure to carcinogens, such as tobacco, can cause oncogenes to escape the control of suppressor genes, leading to overexpression of cyclins and uncontrolled cell growth (cancer).

## ❏ NCLEX Examination Challenge 54-3

### Health Promotion and Maintenance

The community clinic nurse is discussing risk factors for esophageal cancer with a group of clients. Which client behavior requires **further** teaching?

- A. Smokes one pack of cigarettes daily
- B. Walks at the shopping mall three times weekly
- C. Elevates pillows at night
- D. Eats a small snack each night before bedtime

## ❖ Interprofessional Collaborative Care

Care for the patient with esophageal tumors usually takes place in the hospital, followed by the community setting. The interprofessional team that collaborates to care for this patient generally includes the health care provider, nurse, surgeon, dietitian, respiratory therapist, social worker, and spiritual leader of the patient's choice.

### ◆ Assessment: Noticing

#### History.

Assess for risk factors related to the development or symptoms of esophageal cancer, such as gender, history of alcohol consumption, tobacco use, dietary habits, and other esophageal problems (e.g., dysphagia, reflux). In the United States, adenocarcinoma of the esophagus is more common than squamous cell carcinoma ([National Cancer Institute at the National Institutes of Health, 2014](#)). Men, regardless of race or ethnicity, have higher incidence and mortality rates associated with esophageal cancer ([National Cancer Institute, 2014](#)). Ask the patient about consumption of smoked and/or pickled foods, changes in appetite, changes in taste, or weight loss.

#### Physical Assessment/Signs and Symptoms.

Cancer of the esophagus is a silent tumor in its early stages, with few observable signs. By the time the tumor causes symptoms, it usually has spread extensively.

**Dysphagia** (*difficulty swallowing*) is the most common symptom of esophageal cancer, but it may not be present until the esophageal opening has gotten much smaller. Dysphagia is persistent and progressive when **stricture** (narrowing) occurs. It is initially associated with swallowing solids, particularly meat, and then progresses rapidly over a period of weeks or months to difficulty swallowing soft foods and liquids. Late in the disease, even saliva can cause choking. Patients usually report a sensation of food sticking in the throat or in the substernal area. Careful assessment of dysphagia is important because dysphagia associated with other esophageal disorders is not usually continuous. Weight loss often accompanies dysphagia and can exceed 20 lb over several months.

**Odynophagia** (painful swallowing) is reported by many patients as a steady, dull, substernal pain that may radiate. It occurs most often when the patient drinks cold liquids. The presence of severe or persistent pain often indicates tumor invasion of the mediastinal structures. Assess for regurgitation, vomiting, **halitosis** (foul breath), and chronic hiccups, which often accompany advanced disease. In most patients, pulmonary problems develop. Assess for chronic cough, increased secretions, and a history of recent infections. Tumors in the upper esophagus may involve the larynx and thus cause hoarseness. [Chart 54-7](#) summarizes the common clinical symptoms of esophageal tumors.

### ▶ Chart 54-7

## Key Features

### Esophageal Tumors

- Persistent and progressive dysphagia (most common feature)
- Feeling of food sticking in the throat
- Odynophagia (painful swallowing)

- Severe, persistent chest or abdominal pain or discomfort
- Regurgitation
- Chronic cough with increasing secretions
- Hoarseness
- Anorexia
- Nausea and vomiting
- Weight loss (often more than 20 lb)
- Changes in bowel habits (diarrhea, constipation, bleeding)

### Psychosocial Assessment.

The diagnosis of esophageal cancer causes high patient anxiety. The disease is accompanied by distressing symptoms and is often terminal. The fear of choking can place unusual stress, especially at mealtimes. The loss of pleasure and social aspects of eating may affect relationships with family and friends. Assess the patient's response to the diagnosis and prognosis. Ask about his or her usual coping strengths and resources. Assess the impact of the disease on the patient's usual daily activity routine. Determine the availability of support systems and the potential financial impact of the disease and its treatment. Refer the patient and family members to psychological counseling, pastoral care, and/or the social worker or case manager as needed. [Chapter 7](#) describes end-of-life care for patients in the terminal stage of the disease.

## NCLEX Examination Challenge 54-4

### Psychosocial Integrity

The nurse is caring for a client who has been diagnosed with esophageal cancer. The client appears anxious and asks the nurse, "Does this mean I'm going to die?" Which nursing responses are appropriate? **Select all that apply.**

- A. "No, surgery can cure you."
- B. "It sounds like death frightens you."
- C. "Let me call the hospital chaplain to talk with you."
- D. "You can beat this disease if you just put your mind to it."
- E. "Let me sit with you for a while and we can discuss how you're feeling about this."

### Diagnostic Assessment.

A *barium swallow* study with fluoroscopy may be the first diagnostic test requested to evaluate dysphagia. In a barium swallow, the margins of a tumor may be seen. The definitive diagnosis of esophageal cancer is made by *esophageal ultrasound (EUS)* with fine-needle aspiration to examine the tumor tissue. An *esophagogastroduodenoscopy (EGD)* may also be performed to inspect the esophagus and obtain tissue specimens for cell studies and disease staging. A complete cancer staging workup is performed to determine the extent of the disease and plan appropriate therapy.

*Positron emission tomography (PET)* may identify metastatic disease with more accuracy than a CT scan. PET can also help evaluate response to chemotherapy to treat the cancer.

### ◆Analysis: Interpreting

The most specific common problem for patients with esophageal cancer is *Potential for compromised*

*nutrition due to impaired swallowing and possible metastasis.* Many patients with cancer also have pain and are fearful because of the diagnosis of cancer. [Chapter 22](#) describes problems that are typically seen with any patient with cancer.

## ◆ **Planning and Implementation: Responding**

### **Promoting Nutrition**

#### **Planning: Expected Outcomes.**

The major concern for a patient with esophageal cancer is weight loss secondary to dysphagia. Therefore he or she is expected to maintain adequate nutrient intake and weight either orally or via an alternative method.

#### **Interventions.**

Interventions to maintain or improve NUTRITION status focus on treatments that remove or shrink the obstructive tumor. Methods to reduce the effects of treatment that can impact NUTRITION are also a priority. Surgery is the most definitive intervention for esophageal cancer.

#### **Nonsurgical Management.**

The treatment of esophageal cancer often involves a combination of therapies. Patients with cancer of the esophagus experience many physical problems, and symptom management becomes essential.

Nonsurgical treatment options for cancer of the esophagus that can assist in both disease and NUTRITION management include:

- Nutrition therapy
- Swallowing therapy
- Chemotherapy
- Radiation therapy
- Chemoradiation
- Targeted therapies
- Photodynamic therapy
- Esophageal dilation
- Endoscopic therapies

#### **Nutrition and Swallowing Therapy.**

*The purpose of NUTRITION therapy is to administer food and fluids to support the patient who is malnourished or at high risk for becoming malnourished.* Conduct a screening assessment to provide information about the patient's NUTRITION status. The dietitian determines the caloric needs of the patient to meet daily requirements. Be sure that the patient is weighed daily before breakfast on the same scale each day. To keep the esophagus patent, careful positioning is essential for a patient who is experiencing frequent reflux or who has tubes. Teach him or her to remain upright for several hours after meals and avoid lying completely flat. Remind unlicensed assistive personnel (UAP) and other health care team members to keep the head of the bed elevated to a 30-degree angle or more to prevent reflux.

Semisoft foods and thickened liquids are preferred because they are easier to swallow. Record the amount of food and fluid intake every day to monitor progress in meeting desired NUTRITION outcomes. Liquid NUTRITION supplements (e.g., Boost, Ensure) are used between feedings to increase caloric intake. Ongoing efforts are made to preserve the ability to swallow, but enteral feedings (tube feedings) may be needed temporarily when dysphagia is severe. In patients with complete esophageal obstruction or life-threatening fistulas, the surgeon may create a gastrostomy or jejunostomy for feeding. Encourage the patient and family to meet with the dietitian for diet teaching and planning. [Chapter 60](#) describes care for patients receiving enteral feeding.

Collaborate with the speech-language pathologist (SLP) to assist the patient with oral exercises to improve swallowing (*swallowing therapy*) and with the occupational therapist (OT) for feeding therapy. Ask the patient to suck on a lollipop to enhance tongue strength. Teach him or her to reach

for food particles on the lips or chin using the tongue. In preparation for swallowing, remind the patient to position the head in forward flexion (chin tuck). Then tell him or her to place food at the back of the mouth. Monitor the patient for sealing of the lips and tongue movements while eating. Check for pocketing of food in the cheeks after swallowing.

## Nursing Safety Priority QSEN

### Critical Rescue

When the patient with an esophageal tumor is eating or drinking, recognize that you must monitor for signs and symptoms of aspiration, such as choking or coughing. Food aspiration can cause airway obstruction, pneumonia, or both, especially in older adults. In coordination with the SLP, teach family members and caregivers how to feed the patient, if needed. Teach them how to monitor for aspiration and how to respond quickly to implement appropriate measures if choking occurs.

### Chemotherapy and Radiation.

The use of *chemotherapy* in the treatment of esophageal cancer has been only moderately effective. It can be given as a primary treatment if the patient is not a candidate for surgery or given for palliation (control of symptoms). However, in most cases, chemotherapy is given in combination with radiation therapy to provide the patient the best chance of cure. The rationale for this approach is to shrink the primary tumor and eliminate any other tumor that may be in the local lymph nodes, improving the odds for a complete surgical resection. The most commonly used paired chemotherapeutic agents for esophageal cancer are carboplatin and paclitaxel (Taxol) or cisplatin and 5-fluorouracil (5-FU). These drugs are often combined with radiation because they make the tumor cells more sensitive to radiation effects ([American Cancer Society \[ACS\], 2016a](#)). Because chemotherapeutic drugs affect both healthy cells and cancer cells, they have many side effects that cause discomfort to the patient. [Chapter 22](#) describes chemotherapy in detail and discusses the role of the nurse in caring for patients receiving these drugs.

*Radiation therapy* to manage esophageal cancer is only moderately effective and can be used alone or in combination with other treatments. Radiation alone can provide palliation of symptoms by shrinking the tumor. It is contraindicated for patients with tracheoesophageal fistula, mediastinitis, mediastinal hemorrhage, or infiltration of the cancer to the trachea or bronchus. Normal esophageal tissue is very sensitive to the effects of radiation. Although high doses of radiation demonstrate the best results for tumor shrinkage, esophageal stricture or stenosis can result in many patients, which then requires esophageal dilation. [Chapter 22](#) describes radiation methods and the general nursing care for the patient having radiation therapy.

*Chemoradiation* is a treatment for esophageal cancer that involves the use of chemotherapy at the same time as radiation therapy. One cycle of chemotherapy is given during the first week of radiation, and another is delivered during the fifth week of radiation. Additional drug cycles are given after radiation therapy is complete.

### Other Therapies.

Targeted therapies may be used in combination with radiation and chemotherapy. Unlike chemotherapy, these therapies interfere with cancer cell growth in a variety of ways with less impact on healthy cells. Many of these drugs focus on proteins that are involved in signaling cells when to grow and divide. A key to success with targeted therapy is that the cancer cells must overexpress the targeted protein. Thus each patient's cancer cells are first examined for the overexpression to determine if targeted therapy is appropriate and which drug to use. Trastuzumab (Herceptin) is a commonly used drug that is used for patients whose esophageal cancer tests positive for an excess of the *HER2* protein on the cell surface. It is given by IV injection once every 3 weeks, in addition to chemotherapy ([ACS, 2016b](#)). [Chapter 22](#) describes targeted therapies in detail, including nursing implications for patient safety and quality care.

*Photodynamic therapy (PDT)* is used as a palliative treatment for patients with advanced esophageal cancer who are not candidates for surgery. It may be used also as a cure for patients who have very small, localized tumors. The patient is injected with porfimer sodium (Photofrin), a light-sensitive drug that collects in cancer cells. Two days after the injection, a fiberoptic probe with

a light at the tip is threaded into the esophagus through an endoscope. The light activates the Photofrin, destroying only cancer cells. PDT is far less invasive than surgery and is performed on an ambulatory care basis under moderate sedation. Endoscopy nurses observe the patient's rate and depth of respirations and monitor his or her oxygen saturation and end-tidal (exhaled) carbon dioxide to ensure adequate gas exchange.

The side effects of Photofrin are rare but include nausea, fever, and constipation. Before the procedure, the patient is given written guidelines concerning photosensitivity measures. Remind him or her to avoid exposure to sunlight for 1 to 3 months. Sunglasses and protective clothing that covers all exposed body areas are essential. The patient may experience chest pain secondary to tissue damage and will require pain relief with opioid analgesics for a short time. Teach the patient to follow a clear liquid diet for 3 to 5 days after the procedure and advance to full liquids as tolerated. Warn the patient that tissue particles may release from the tumor site and be present in the sputum. [Chapter 22](#) describes in detail the health teaching needed to promote patient safety associated with PDT.

*Esophageal dilation* may be performed as necessary throughout the course of the disease to achieve temporary but immediate relief of dysphagia. It is usually performed on an ambulatory care basis. Dilators are used to tear soft tissue, thereby widening the esophageal lumen (opening). In most cases, malignant tumors can be dilated safely, but perforation remains a significant risk. Large metal stents may be used to keep the esophagus open for longer periods. A stent covered with graft material can be used to seal a perforation. Bacteremia can also occur. To reduce the risk for endocarditis, antibiotics are given. The treatment is repeated as often as needed to preserve the patient's ability to swallow. Prolonged stent embedment into benign esophageal tissue can cause ulceration, bleeding, fistula, dysphagia, and formation of a new stricture if the stent is not removed ([Patel & Siddiqui, 2013](#)).

When patients are not candidates for surgery or the tumor is too large to remove surgically, laser therapy or electrocoagulation using endoscopy may be performed as a palliative measure. Both of these methods destroy some cancer cells and reduce tumor size to improve swallowing. The procedures are done in ambulatory care settings or same-day surgery centers using moderate sedation.

### **Surgical Management.**

The purposes of surgical resection vary from palliation to cure. **Esophagectomy** is the removal of all or part of the esophagus. An **esophagogastrostomy** involves the removal of part of the esophagus and proximal stomach. The remaining stomach may be “pulled up” to take the place of the esophagus, or a section of the jejunum or colon may be placed as a conduit. Conventional open surgical techniques are lengthy and associated with many complications or death. Fistula formation between the trachea and esophagus, abscess, and respiratory complications are common.

For patients with early-stage cancer, a laparoscopic-assisted **minimally invasive esophagectomy (MIE)** may be performed. However, most patients require the conventional open surgery because of tumor size and metastasis by the time they are diagnosed with the disease.

### **Preoperative Care.**

Preoperative preparation for patients undergoing esophagectomy or esophagogastrostomy can be quite extensive, especially before conventional techniques. Advise the patient to stop smoking 2 to 4 weeks before surgery to enhance pulmonary function. Patient preparation may include 5 days to 2 to 3 weeks of NUTRITION support to decrease the risk for postoperative complications. Ideally this supplementation is given orally, but many patients require tube feeding or parenteral NUTRITION. Teach the patient and family to monitor the patient's weight and intake and output. A preoperative evaluation may be required to treat dental disease. Teach the patient to practice meticulous oral care four times daily to decrease the risk for postoperative infection.

Preoperative nursing care focuses on teaching and psychological support regarding the surgical procedure and preoperative and postoperative instructions. Teach the patient about:

- The number and sites of all incisions and drains
- The placement of a jejunostomy tube for initial enteral feedings
- The need for chest tubes if the pleural space is entered
- The purpose of the nasogastric tube

- The need for IV infusion

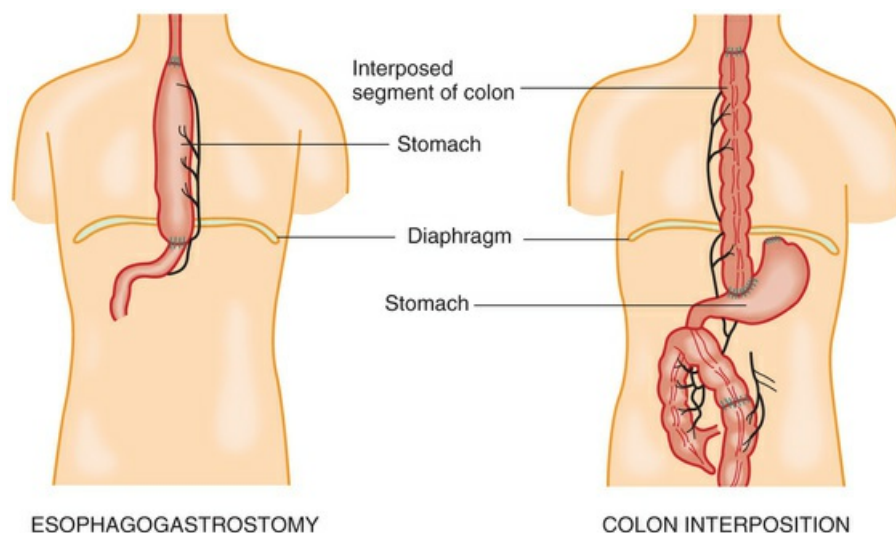

Teach the patient about regularly turning, coughing, deep breathing, and having chest physiotherapy. Emphasize the crucial nature of postoperative respiratory care. If colon interposition (resecting a piece of colon and creating an esophagus) is planned, the patient also has a complete bowel preparation before surgery.

The patient facing a serious illness and extensive surgery can be expected to experience grief and anxiety. Encourage him or her to talk about personal feelings and fears and involve the family or significant others in all preoperative teaching and discussions. A social worker, certified hospital chaplain, or case manager can be extremely helpful in providing continuity of care and support to the entire family.

### Operative Procedures.

In the MIE procedure, the surgeon makes four or five small incisions in the chest and abdomen using a video-assisted thoracoscope and laparoscope. The lower esophagus and gastric fundus are removed. The remaining portion of the esophagus is then anastomosed (reconnected) to the stomach.

For most patients, the surgeon performs an open subtotal or total esophagectomy because tumors are often large and involve distant lymph nodes. For a subtotal (partial) removal, the diseased portion of the esophagus is removed, and the cervical portion is anastomosed (connected) to the stomach (Fig. 54-3). A **pyloromyotomy** is done by cutting and suturing the pylorus. Finally, a jejunostomy tube may be placed for postoperative enteral feeding.

**FIG. 54-3** Open surgical approaches to the treatment of esophageal cancer.

For patients with early-stage tumors of the lower third of the esophagus, a transhiatal esophagectomy is the preferred surgical approach. The surgery is performed through an upper midline cervical incision. With this approach, the pleural space is not entered, reducing respiratory complications. For patients with tumors in the upper esophagus, a radical neck dissection and laryngectomy may also be needed if the disease has spread to the larynx. Chapter 29 discusses the care of patients having these procedures.

The surgeon may perform a **colon interposition** when the tumor involves the stomach or the stomach is otherwise unsuitable for anastomosis. A section of right or left colon is removed and brought up into the thorax to substitute for the esophagus (see Fig. 54-3).

### Postoperative Care.

The patient requires intensive postoperative care and is at risk for multiple serious complications. The patient having an MIE has the same risk for postoperative complications as one having the open procedure. The advantages of MIE include:

- Less blood loss during surgery; fewer blood transfusions

- Decreased healing and recovery time
- Decreased trauma to the body
- No large incisions
- Less postoperative pain
- Shorter hospital stay (5 to 7 days rather than 7 to 10 days)

## Nursing Safety Priority QSEN

### Action Alert

Respiratory care is the highest postoperative priority for patients having an esophagectomy. For those who had traditional surgery, intubation with mechanical ventilation is needed for at least the first 16 to 24 hours. Pulmonary complications include atelectasis and pneumonia. The risk for postoperative pulmonary complications is increased in the patient who has received preoperative radiation. Once the patient is extubated, begin deep breathing, turning, and coughing every 1 to 2 hours. Assess the patient for decreased breath sounds and shortness of breath every 1 to 2 hours. Provide incisional support and adequate analgesia for effective coughing.

Remind all staff to keep the patient in a semi-Fowler's or high-Fowler's position to support ventilation and prevent reflux. The health care provider prescribes prophylactic antibiotics and supplemental oxygen. *Ensure the patency of the chest tube drainage system and monitor for changes in the volume or color of the drainage.*

*Cardiovascular complications*, particularly hypotension during surgery, can occur as a result of pressure placed on the posterior heart and usually respond well to IV fluid administration.

## Nursing Safety Priority QSEN

### Action Alert

Monitor for symptoms of fluid volume overload, particularly in older patients and those who have undergone lymph node dissection. Assess for edema, crackles in the lungs, and increased jugular venous pressure. In the immediate postoperative phase, the patient is often admitted to the intensive care unit. Critical care nurses assess hemodynamic parameters such as cardiac output, cardiac index, and systemic vascular resistance every 2 hours to monitor for myocardial ischemia. Observe for atrial fibrillation that results from irritation of the vagus nerve during surgery and manage according to agency protocol.

The patient with poor NUTRITION or prior radiation or chemotherapy is at risk for infection. For those who undergo more radical surgical procedures, there is a serious risk for leakage at the anastomosis (surgical connection) sites. This situation is especially true with colon interpositions because several sites are stressed by the effects of tension, poor blood supply, and delayed healing. *Mediastinitis* (inflammation of the mediastinum) resulting from an anastomotic leak can lead to fatal sepsis.

*Wound management* is another major postoperative concern for conventional surgery because the patient typically has multiple incisions and drains. *Provide direct support to the incision during turning and coughing to prevent dehiscence.* Wound infection can occur 4 to 5 days after surgery. Leakage from the site of anastomosis is a dreaded complication that can appear 2 to 10 days after surgery. If an anastomotic leak occurs, all oral intake is discontinued and is not resumed until the site of the leak has healed.

## Nursing Safety Priority QSEN

### Critical Rescue

After esophageal surgery, recognize if the patient has signs of fever, fluid accumulation, signs of

inflammation, and symptoms of early shock (e.g., tachycardia, tachypnea). Respond immediately by reporting any of these findings to the surgeon **and** Rapid Response Team!

A nasogastric (NG) tube is placed intraoperatively to decompress the stomach to prevent tension on the suture line. Monitor the NG tube for patency and carefully secure the tube to prevent dislodgment, which can disrupt the sutures at the anastomosis. *Do not irrigate or reposition the NG tube in patients who have undergone esophageal surgery unless requested by the surgeon!* The initial nasogastric drainage is bloody but should change to a greenish-yellow color by the end of the first postoperative day. The continued presence of blood may indicate internal bleeding at the suture line. Commonly an antacid will be prescribed to support the patient's healing. Provide oral hygiene for the patient every 2 to 4 hours while the tube is in place or delegate and appropriately supervise this activity (Chart 54-8).

### Chart 54-8

## Best Practice for Patient Safety & Quality Care

### Managing the Patient With a Nasogastric Tube After Esophageal Surgery

- Check for tube placement every 4 to 8 hours.
- Ensure that the tube is patent (open) and draining; drainage should turn from bloody to yellowish green by the end of the first postoperative day.
- Secure the tube well to prevent dislodgment.
- Do not irrigate or reposition the tube without a physician's request.
- Provide meticulous oral and nasal hygiene every 2 to 4 hours.
- Keep the head of the bed elevated to at least 30 degrees.
- When the patient is permitted to have a small amount of water, place him or her in an upright position and observe for dysphagia (difficulty swallowing).
- Observe for leakage from the anastomosis site, as indicated by fever, fluid accumulation, and manifestations of early shock (tachycardia, tachypnea, altered mental status).

NUTRITION management of the patient who has undergone esophageal surgery is an early postoperative concern. After conventional surgery, on the second postoperative day, initial feedings usually begin through the jejunostomy tube (J tube). Do not aspirate for residual because this increases the risk for mucosal tearing. Feedings are slowly increased over the next several days. Feeding by this method can be discontinued once the patient is taking adequate oral NUTRITION.

Before beginning oral feedings, a cine-esophagram study is performed to detect any anastomotic leaks, strictures, or signs of aspiration. If no leaks are seen, a liquid diet is started. If liquids are well tolerated, the patient's diet is advanced to include semi-solid foods and then solid foods.

Place the patient in an upright position and supervise all initial swallowing efforts. The food storage area of the stomach has been radically decreased, and gravity is the only defense against reflux. *Teach the patient and/or family the importance of the patient eating six to eight small meals per day. Fluids should be taken between, rather than with, meals to prevent diarrhea.* Diarrhea can occur 20 minutes to 2 hours after eating and can be managed with loperamide (Imodium) before meals. The diarrhea is thought to be the result of *vagotomy syndrome*, which develops as a result of interrupted vagal fibers to the abdominal organs during surgery.

### Care Coordination and Transition Management

Patients with esophageal cancer have many challenges to face once they are discharged home. The combination treatment regimens cause long-lasting side effects, such as fatigue and weakness.

These complex treatments also require the patient and family to be knowledgeable about symptom management and to know when to report concerns to the health care provider.

### Home Care Management.

Once the patient is discharged to home, ongoing respiratory care remains a priority. Give the patient and family instructions for ambulation and incentive spirometer use. Encourage the patient to be as active as possible and avoid excessive bedrest because this can lead to complications of immobility. **In accordance with The Joint Commission National Patient Safety Goals for 2017, teach the family to protect the patient from infection by following the World Health Organization (WHO) or the Centers for Disease Control (CDC) handwashing guidelines and to contact the health care provider immediately if signs of respiratory infection develop. Patients should stay away from individuals with infections and avoid large crowds.**

### Self-Management Education.

Remind the patient and family to wash their hands frequently and teach them to inspect the incisions daily for redness, tenderness, swelling, odor, and discharge because proper wound healing is still a concern at the time of discharge. Instruct them to report a temperature greater than 101° F (38.3° C), or 100° F (37.8° C) for older adults, which may be a sign of infection. Prepare written instructions about the signs of anastomosis leakage. *Teach the patient or family to immediately report to the health care provider the presence of fever and a swollen, painful neck incision.*

NUTRITION support is important. Encourage the patient to continue increasing oral feedings as tolerated. Remind him or her to eat small, frequent meals containing high-calorie, high-protein foods that are soft and easily swallowed. Teach the value of using supplemental milkshakes between meals and instruct the patient to eat slowly. Patients who have undergone esophageal resection can lose up to 10% of their body weight. Teach the patient to monitor his or her weight at home and to report a weight loss of 5 lb or more in 1 month. If sufficient oral intake is not possible, the patient and family may need instruction about tube feedings or parenteral NUTRITION at home.

Emphasize the importance of remaining upright after meals. Dysphagia or odynophagia may recur because of stricture, reflux, or cancer recurrence. These symptoms should be reported to the health care provider promptly. Despite radical surgery, the patient with cancer of the esophagus often still has a terminal illness and a relatively short life expectancy. Emphasis is placed on maximizing quality of life. Realistic planning is important as the patient's condition eventually worsens and the patient and family are assisted to plan for the future together. Help family members explore formal and informal sources of support. Help the family or significant others arrange for hospice care when it is needed. [Chapter 7](#) describes end-of-life care, including hospice.

### Health Care Resources.

Referrals to community or home care organizations help the family provide care in the home. The patient may need transportation to the radiation treatment center five times per week for up to 6 weeks. Oncology nursing care may be needed to monitor and evaluate the patient who is receiving chemotherapy at home through venous access devices or portable infusion pumps. Inform the patient and family about the services available through the American Cancer Society ([www.cancer.org](http://www.cancer.org)), including support groups and transportation. Familiarize the family with area hospice services for future planning. Coordinate resource referrals with the case manager or home care agency.

### ◆Evaluation: Reflecting

Evaluate the care of the patient with esophageal cancer based on the identified priority patient problems. The major expected outcome is that the patient will be able to consume adequate NUTRITION and maintain a stable weight.

## Clinical Judgment Challenge 54-1

### Teamwork and Collaboration; Safety; Evidence-Based Practice QSEN

A 58-year-old patient has undergone a Laparoscopic Nissen Fundoplication (LNF) for a hiatal

hernia. Before discharge, you are preparing to teach the patient and family about self-management.

1. For what postoperative complications will you monitor, and why could they occur after this surgery?
2. What type of diet will the patient need to eat, and for how long will the diet be recommended?
3. What types of activities will you recommend for the patient? Are there any restrictions in activity that you should teach the patient?
4. The patient will have a postoperative incision. What will you teach the patient about wound care?
5. What type of follow-up instructions will you provide?

## Esophageal Diverticula

**Diverticula** are sacs resulting from the herniation of esophageal mucosa and submucosa into surrounding tissue. They may develop anywhere along the length of the esophagus. No environmental risk factors are known to be involved in their development. The incomplete or late opening of swallowing muscles can cause high pressure in the hypopharynx and lead to *Zenker's diverticula*, the most common form. This type occurs most often in older adults. Patients report dysphagia (difficulty swallowing), regurgitation (reflux), nocturnal cough, and halitosis (bad breath). They can also be at risk for perforation because the mucosa is without the protection of the normal esophageal muscle layer.

Esophageal diverticula are diagnosed most often by *esophagogastroduodenoscopy (EGD)*. This procedure must be performed with strict care because of the risk for perforation. NUTRITION therapy and positioning are the major interventions for controlling symptoms related to diverticula. Collaborate with the dietitian to help the patient explore variations in the size and frequency of meals and food texture and consistency. Semisoft foods and smaller meals are often best tolerated and may reduce or relieve the symptoms of pressure and reflux. Nocturnal reflux associated with diverticula is managed by teaching the patient to sleep with the head of the bed elevated and to avoid the supine position for at least 2 hours after eating. Advise the patient to avoid vigorous exercise after meals. Teach him or her to avoid restrictive clothing and frequent stooping or bending.

Surgical management is aimed at removing the diverticula. After surgery, the patient is NPO status for several days to promote healing. During that period, he or she receives IV fluids for hydration and tube feedings; after that, he or she is given oral fluid and food. Provide pain relief measures and monitor for complications such as bleeding or perforation. *A nasogastric (NG) tube is placed during surgery for decompression and is not irrigated or repositioned unless specifically requested by the surgeon.*

Care coordination and transition management include teaching the patient and family about:

- Nutrition therapy
- Positioning guidelines to prevent reflux
- Warning signs of complications, such as bleeding or infection

## Esophageal Trauma

Trauma to the esophagus can result from blunt injuries, chemical burns, surgery or endoscopy (rare), or the stress of continuous severe vomiting (Table 54-2). Trauma may affect the esophagus directly, impairing swallowing and NUTRITION, or it may create problems in related structures such as the lungs or mediastinum. The incidence of most forms of esophageal trauma is low in adults. When excessive force is exerted on the esophageal mucosa, it may perforate or rupture, allowing the caustic acid secretions to enter the mediastinal cavity. These tears are associated with a high mortality rate related to shock, respiratory impairment, or sepsis.

---

**TABLE 54-2**  
**Common Causes of Esophageal Perforation**

---

<ul style="list-style-type: none"><li>• Straining</li><li>• Seizures</li><li>• Trauma</li><li>• Foreign objects</li></ul>	<ul style="list-style-type: none"><li>• Instrument or tubes</li><li>• Chemical injury</li><li>• Complications of esophageal surgery</li><li>• Ulcers</li></ul>
---	--

Chemical injury is usually a result of the accidental or intentional ingestion of caustic substances. The damage to the mouth and esophagus is rapid and severe. Acid burns tend to affect the superficial mucosal lining, whereas alkaline substances cause deeper penetrating injuries. Strong alkalis can cause full perforation of the esophagus within 1 minute. Additional problems may include aspiration pneumonia and hemorrhage. Esophageal strictures may develop as scar tissue forms.

Patients with esophageal trauma are initially evaluated and treated in the emergency department. Assessment focuses on the nature of the injury and the circumstances surrounding it. *Assess for airway patency, breathing, chest pain, dysphagia, vomiting, and bleeding as the priorities for patient care.* If the risk for extending the damage is not excessive, an endoscopic study may be requested to evaluate tears or perforation. A CT scan of the chest can be done to assess for the presence of mediastinal air.

After the injury, keep the patient NPO to prevent further leakage of esophageal secretions. Esophageal and gastric suction can be used for drainage and to rest the esophagus. Esophageal rest is maintained for more than a week after injury to allow for initial healing of the mucosa. Total parenteral NUTRITION (TPN) is prescribed to provide calories and protein for wound healing while the patient is not eating.

To prevent sepsis, the health care provider prescribes broad-spectrum antibiotics. High-dose corticosteroids may be administered to suppress inflammation and prevent strictures (esophageal narrowing). In addition, opioid and nonopioid analgesics are prescribed for pain management. When caustic burns involve the mouth, topical agents such as lidocaine (Xylocaine Viscous) may be used for analgesia and local anti-inflammatory action.

If nonsurgical management is not effective in healing traumatized esophageal tissue, the patient may need surgery to remove the damaged tissue. Those with severe injuries may require resection of part of the esophagus with a gastric pull-through and repositioning or replacement by a bowel segment; also, gastrostomy tube (G-tube) placement may be needed to meet NUTRITION needs while healing.

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Consult with the dietitian, patient, and family regarding NUTRITION modifications for patients with GERD. **QSEN: Teamwork and Collaboration**
- Collaborate with the interprofessional team to care for the patient with impaired swallowing and/or limited NUTRITION. **QSEN: Teamwork and Collaboration**
- Teach the patient and family to recognize the symptoms of dysphagia. **QSEN: Safety**
- Remain with the patient with dysphagia during meals to prevent choking episodes or intervene quickly. **QSEN: Safety**

### Health Promotion and Maintenance

- Teach the patient oral exercises to improving swallowing.
- Stress the importance of controlling reflux through NUTRITION and drug therapy to avoid further esophageal damage that could lead to Barrett's esophagus. **QSEN: Safety**
- Teach the patient to elevate the head of the bed by 6 inches for sleep and to lie in the right side-lying position to minimize or prevent nighttime reflux. **QSEN: Evidence-Based Practice**
- Teach the patient with esophageal cancer to monitor body weight and to notify the health care provider of weight loss.
- Teach the patient to avoid alcoholic beverages, smoking, and other substances listed in [Chart 54-2](#) because they lead to increased gastroesophageal reflux. **QSEN: Evidence-Based Practice**
- Teach the patient to prevent gas bloat syndrome by avoiding carbonated beverages and gas-producing foods, chewing gum, and drinking with a straw.
- Review postprocedure instructions for patients having the Stretta procedure for GERD as outlined in [Chart 54-3](#). **QSEN: Safety**

### Psychosocial Integrity

- Allow the patient the opportunity to express fear or anxiety regarding the diagnosis of esophageal cancer. **QSEN: Patient-Centered Care**
- Explain all procedures, restrictions, drug therapy, and follow-up care to the patient and family. **Ethics**
- Refer the patient or family members to psychological counseling, hospice, spiritual care, and the case manager as needed. **QSEN: Teamwork and Collaboration**

### Physiological Integrity

- For patients with GERD, teach the importance of strict adherence to anti-reflux agents in preventing esophageal damage (see [Chart 55-3](#)). **QSEN: Evidence-Based Practice**
- Assess for complications and provide postoperative care for patients having the common surgical procedures for esophageal problems, as described in [Chart 54-6](#). **QSEN: Safety**
- Be sure to frequently monitor the NUTRITION status of the patient with esophageal cancer. **Clinical Judgment**
- Teach the patient having open conventional esophageal surgery about incisions, drains, and jejunostomy tube placement before he or she undergoes surgery for esophageal cancer.
- For the patient with a nasogastric (NG) tube, check the NG tube every 4 to 8 hours for proper

placement and anchorage; follow guidelines outlined in [Chart 54-8](#).

- Assess patients for key features of esophageal tumors listed in [Chart 54-7](#). **Clinical Judgment**

## CHAPTER 55

# Care of Patients With Stomach Disorders

Lara Carver

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is IMMUNITY.**

✚ The IMMUNITY concept exemplar for this chapter is Peptic Ulcer Disease (PUD), p. 1107.

**The interrelated concepts for this chapter are:**

- NUTRITION
- COMFORT

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to protect the patient with a stomach disorder from injury and infection.
2. Identify community resources to ensure appropriate transition management for patients with stomach disorders.

### Health Promotion and Maintenance

3. Teach adults how to promote GI health and prevent gastritis.
4. Teach patients with a stomach disorder how to enhance NUTRITION, promote digestion, and minimize disturbances in COMFORT.

### Psychosocial Integrity

5. Implement nursing interventions to minimize stressors for the patient with a stomach disorder.
6. Identify end-of-life care needs for patients with advanced gastric cancer.

### Physiological Integrity

7. Apply knowledge of anatomy, physiology, pathophysiology, genetic risk, age-related changes, and psychomotor skills to perform a focused assessment of the GI system.
8. Describe interprofessional care and educational needs to promote NUTRITION for the patient with a stomach disorder.
9. Prioritize care and educational needs for the patient with a stomach disorder to prevent complications associated with altered IMMUNITY.
0. Develop an evidence-based plan of care for the patient undergoing gastric surgery.

The stomach is part of the upper GI system that is responsible for a large part of the digestive process. It is only affected by a few diseases, including gastritis, peptic ulcer disease (PUD), and cancer, yet these conditions can be very serious and sometimes life threatening. Each of these health problems can result in impaired or altered *digestion* and NUTRITION. Inflammation and infection can create disturbances in COMFORT. Interprofessional collaborative care for stomach disorders often includes therapies to meet the patient's need for adequate nutrition.

## Gastritis

**Gastritis** is the inflammation of gastric mucosa (stomach lining) (see discussion of Inflammation in Chapter 17). Inflammation, an alteration in IMMUNITY, can be scattered or localized; thus gastritis can be classified according to cause, cellular changes, or distribution of the lesions. It can be erosive (causing ulcers) or nonerosive. Although the mucosal changes that result from *acute* gastritis typically heal after several months, this is not true for *chronic* gastritis.

### ❖Pathophysiology

Prostaglandins provide a protective mucosal barrier that prevents the stomach from digesting itself by a process called acid **autodigestion**. If there is a break in the protective barrier, mucosal injury occurs. The resulting injury is worsened by histamine release and vagus nerve stimulation. Hydrochloric acid can then diffuse back into the mucosa and injure small vessels. This back-diffusion causes edema, hemorrhage, and erosion of the stomach's lining, which alters IMMUNITY. The pathologic changes of gastritis include vascular congestion, edema, acute inflammatory cell infiltration, and degenerative changes in the superficial epithelium of the stomach lining.

### Types of Gastritis

Inflammation of the gastric mucosa or submucosa after exposure to local irritants or other causes can result in **acute gastritis**. The early pathologic manifestation of gastritis is a thickened, reddened mucous membrane with prominent **rugae**, or folds. Various degrees of mucosal necrosis and inflammatory reaction occur in acute disease. The diagnosis cannot be based solely on clinical symptoms. Complete regeneration and healing usually occur within a few days. If the stomach muscle is not involved, complete recovery usually occurs with no residual evidence of gastric inflammatory reaction. If the muscle is affected, hemorrhage may occur during an episode of acute gastritis.

**Chronic gastritis** appears as a patchy, diffuse (spread out) inflammation of the mucosal lining of the stomach. As the disease progresses, the walls and lining of the stomach thin and atrophy. With progressive gastric atrophy from chronic mucosal injury, the function of the parietal (acid-secreting) cells decreases, and the source of intrinsic factor is lost. Intrinsic factor is critical for absorption of vitamin B<sub>12</sub>. When body stores of vitamin B<sub>12</sub> are eventually depleted, **pernicious anemia** results. The amount and concentration of acid in stomach secretions gradually decrease until the secretions consist of only mucus and water.

Chronic gastritis is associated with an increased risk for gastric cancer. The persistent inflammation extends deep into the mucosa, causing alteration in IMMUNITY by destruction of the gastric glands and cellular changes. Chronic gastritis may be categorized as type A, type B, or atrophic (McCance et al., 2014).

Type A (nonerosive) chronic gastritis refers to an inflammation of the glands and the fundus and body of the stomach. Type B chronic gastritis usually affects the glands of the antrum but may involve the entire stomach. In atrophic chronic gastritis, diffuse inflammation and destruction of deeply located glands accompany the condition. Chronic atrophic gastritis affects all layers of the stomach, thus decreasing the number of cells. The muscle thickens, and inflammation is present. Chronic atrophic gastritis is characterized by total loss of fundal glands, minimal inflammation, thinning of the gastric mucosa, and intestinal metaplasia (abnormal tissue development). These cellular changes can lead to peptic ulcer disease (PUD) and gastric cancer (McCance et al., 2014).

### Etiology and Genetic Risk

The onset of infection with *Helicobacter pylori* can result in acute gastritis. *H. pylori* is a gram-negative bacterium that penetrates the mucosal gel layer of the gastric epithelium. Although less common, other forms of bacterial gastritis from organisms such as staphylococci, streptococci, *Escherichia coli*, or salmonella can cause life-threatening problems such as sepsis and extensive tissue necrosis (death), greatly altering a patient's IMMUNITY.

Long-term NSAID use creates a high risk for acute gastritis. NSAIDs inhibit prostaglandin production in the mucosal barrier. Other risk factors include use of alcohol, coffee, caffeine, and corticosteroids. Acute gastritis is also caused by local irritation from radiation therapy and

accidental or intentional ingestion of corrosive substances, including acids or alkalis (e.g., lye and drain cleaners).

**Type A gastritis** has been associated with the presence of antibodies to parietal cells and intrinsic factor. Therefore an autoimmune cause for this type of gastritis is likely. Parietal cell antibodies have been found in most patients with pernicious anemia and in more than one half of those with type A gastritis. A genetic link to this disease, with an autosomal-dominant pattern of inheritance, has been found in the relatives of patients with pernicious anemia (McCance et al., 2014).

The most common form of chronic gastritis is **type B gastritis**, caused by *H. pylori* infection. A direct correlation exists between the number of organisms and the degree of cellular abnormality present. The host response to the *H. pylori* infection is activation of lymphocytes and neutrophils. Release of inflammatory cytokines, such as interleukin (IL)-1, IL-8, and tumor necrosis factor (TNF)-alpha, damages the gastric mucosa (McCance et al., 2014).

Chronic local irritation and toxic effects caused by alcohol ingestion, radiation therapy, and smoking have been linked to chronic gastritis. Surgical procedures that involve the pyloric sphincter, such as a pyloroplasty, can lead to gastritis by causing reflux of alkaline secretions into the stomach. Other systemic disorders such as Crohn's disease, graft-versus-host disease, and uremia can also precipitate the development of chronic gastritis.

**Atrophic gastritis** is a type of chronic gastritis that is seen most often in older adults. It can occur after exposure to toxic substances in the workplace (e.g., benzene, lead, nickel) or *H. pylori* infection, or it can be related to autoimmune factors. Atrophic gastritis can lead to two types of cancer: gastric cancer and gastric mucosa-associated lymphoid tissue (MALT) lymphoma. See **Gastric Cancer** later in this chapter for a more detailed explanation.

## Health Promotion and Maintenance

Gastritis is a very common health problem in the United States. A balanced diet, regular exercise, and stress-reduction techniques can help prevent it (Chart 55-1). A balanced diet includes following the recommendations of the U.S. Department of Agriculture (USDA) and limiting intake of foods and spices that can cause gastric distress, such as caffeine, chocolate, mustard, pepper, and other strong or hot spices. Alcohol and tobacco should also be avoided. Regular exercise maintains peristalsis, which helps prevent gastric contents from irritating the gastric mucosa. Stress-reduction techniques can include aerobic exercise, meditation, reading, and/or yoga, depending on individual preferences.

### Chart 55-1

## Patient and Family Education: Preparing for Self-Management

### Gastritis Prevention

- Eat a well-balanced diet.
- Avoid drinking excessive amounts of alcoholic beverages.
- Use caution in taking large doses of aspirin, other NSAIDs (e.g., ibuprofen), and corticosteroids.
- Avoid excessive intake of coffee (even decaffeinated).
- Be sure that foods and water are safe to avoid contamination.
- Manage stress levels using complementary and integrative therapies such as relaxation and meditation techniques.
- Stop smoking.
- Protect yourself against exposure to toxic substances in the workplace such as lead and nickel.

- Seek medical treatment if you are experiencing symptoms of esophageal reflux (see Chapter 54).

Excessive use of aspirin and other NSAIDs should also be avoided. If a family member has *H. pylori* infection or has had it in the past, patient testing should be considered. This test can identify the bacteria before they cause gastritis.

## ❖ Interprofessional Collaborative Care

Care of the patient with gastritis usually takes place in the community setting. However, if symptoms are severe, the patient may be hospitalized. The interprofessional team that collaborates to care for this patient generally includes the primary health care provider and nurse.

### ◆ Assessment: Noticing

Symptoms of *acute* gastritis range from mild to severe. The patient may report epigastric alterations in COMFORT or pain, anorexia, cramping, nausea, and vomiting (Chart 55-2). Assess for abdominal tenderness and bloating, **hematemesis** (vomiting blood), or **melena** (dark, sticky feces, as evidence of blood in the stool). Symptoms last only a few hours or days and vary with the cause.

Aspirin/NSAID-related gastritis may result in **dyspepsia** (heartburn). Gastritis or food poisoning caused by endotoxins, such as staphylococcal endotoxin, has an abrupt onset. Severe nausea and vomiting often occur within 5 hours of ingestion of the contaminated food. *In some cases gastric hemorrhage is the presenting symptom, which is a life-threatening emergency.*

## ▶ Chart 55-2

### Key Features

#### Gastritis

##### Acute Gastritis

- Rapid onset of epigastric pain or discomfort
- Nausea and vomiting
- Hematemesis (vomiting blood)
- Gastric hemorrhage
- Dyspepsia (heartburn)
- Anorexia

##### Chronic Gastritis

- Vague report of epigastric pain that is relieved by food
- Anorexia
- Nausea or vomiting
- Intolerance of fatty and spicy foods
- Pernicious anemia

Chronic gastritis causes few symptoms unless ulceration occurs. Patients may report nausea, vomiting, or upper abdominal discomfort. Periodic epigastric pain may occur after a meal. Some patients have anorexia (see Chart 55-2).

Esophagogastroduodenoscopy (EGD) via an endoscope with biopsy is the gold standard for diagnosing gastritis. (See Chapter 52 for discussion of nursing care associated with this diagnostic

procedure.) The physician performs a biopsy to establish a definitive diagnosis of the type of gastritis. If lesions are patchy and diffuse, biopsy of several suspicious areas may be necessary to avoid misdiagnosis. A *cytologic examination* of the biopsy specimen is performed to confirm or rule out gastric cancer. Tissue samples can also be taken to detect *H. pylori* infection using *rapid urease testing*. The results of these tests are more reliable if the patient has discontinued taking antacids for at least a week (Pagana et al., 2017).

### ◆ Interventions: Responding

Patients with gastritis are not often seen in the acute care setting unless they have an exacerbation (“flare-up”) of acute or chronic gastritis that results in fluid and electrolyte imbalance, bleeding, or increased pain. Collaborative care is directed toward supportive care for relieving the symptoms and removing or reducing the cause of discomfort.

*Acute* gastritis is treated symptomatically and supportively because the healing process is spontaneous, usually occurring within a few days. When the cause is removed, pain and discomfort usually subside. If bleeding is severe, a blood transfusion may be necessary. Fluid replacement is prescribed for patients with severe fluid loss. Surgery, such as partial gastrectomy, pyloroplasty, and/or vagotomy, may be needed for patients with major bleeding or ulceration. Treatment of *chronic* gastritis varies with the cause. The approach to management includes the elimination of causative agents, treatment of any underlying disease (e.g., uremia, Crohn's disease), avoidance of toxic substances (e.g., alcohol, tobacco), and health teaching.

Eliminating the causative factors, such as *H. pylori* infection if present, is the primary treatment approach. Drugs and nutritional therapy are also used. In the *acute* phase the primary health care provider prescribes drugs that block and buffer gastric acid secretions to relieve pain.

**H<sub>2</sub>-receptor antagonists**, such as famotidine (Pepcid) and nizatidine (Axid), are typically used to block gastric secretions. Sucralfate (Carafate, Sulcrate), a *mucosal barrier fortifier*, may also be prescribed. *Antacids* used as buffering agents include aluminum hydroxide combined with magnesium hydroxide (Maalox) and aluminum hydroxide combined with simethicone and magnesium hydroxide (Mylanta). Antisecretory agents (**proton pump inhibitors [PPIs]**) such as omeprazole (Prilosec) or pantoprazole (Protonix) may be prescribed to suppress gastric acid secretion (Chart 55-3).

### Chart 55-3

## Common Examples of Drug Therapy

### Peptic Ulcer Disease

CLASS AND COMMON EXAMPLES	SELECTED NURSING IMPLICATIONS
<b>Antacids</b> —Increase pH of gastric contents by deactivating pepsin Magnesium hydroxide with aluminum hydroxide	Give 2 hours after meals and at bedtime. <i>Hydrogen ion load is high after ingestion of foods.</i> Use liquid rather than tablets. <i>Suspensions are more effective than chewable tablets.</i> Do not give other drugs within 1-2 hours of antacids. <i>Antacids interfere with absorption of other drugs.</i> Assess patients for a history of renal disease. <i>Hypermagnesemia may result, especially in patients with poorly functioning kidneys, thus causing toxicity.</i> Assess the patient for a history of heart failure. <i>Inadequate renal perfusion from heart failure decreases the ability of the kidneys to excrete magnesium, thus causing toxicity.</i> Observe the patient for the side effect of diarrhea. <i>Magnesium often causes diarrhea.</i>
Aluminum hydroxide (Gaviscon, Alugel 🇨🇦)	Give 1 hour after meals and at bedtime. <i>Hydrogen ion load is high after ingestion of food.</i> Use liquid rather than tablets if palatable. <i>Suspensions are more effective than chewable tablets.</i> Do not give other drugs within 1-2 hours of antacids. <i>Antacids interfere with absorption of other drugs.</i> Observe patients for the side effect of constipation. If constipation occurs, consider alternating with magnesium antacid. <i>Aluminum causes constipation, and magnesium has a laxative effect.</i> Use for patients with renal failure. <i>Aluminum binds with phosphates in the GI tract. This antacid does not contain magnesium.</i>
<b>H<sub>2</sub> Antagonists (Blockers)</b> —Decrease gastric acid secretions by blocking histamine receptors in parietal cells Ranitidine (Zantac) Famotidine (Pepcid) Nizatidine (Axid) NOTE: IV famotidine or IV ranitidine may also be given to prevent surgical stress ulcers.	Give single dose at bedtime for treatment of GI ulcers, heartburn, and PUD. <i>Bedtime administration suppresses nocturnal acid production.</i>
<b>Mucosal Barrier Fortifiers</b> —Protect stomach mucosa Sucralfate (Carafate, Sulcrate 🇨🇦)	Give 1 hr before and 2 hr after meals and at bedtime. <i>Food may interfere with drug's adherence to mucosa.</i> Do not give within 30 min of giving antacids or other drugs. <i>Antacids may interfere with effect.</i>
Bismuth subsalicylate (Pepto-Bismol)	Remind patient to refrain from taking aspirin while on this drug. <i>Aspirin is a salicylic acid and can lead to overdose.</i>
<b>Proton Pump Inhibitors</b> —Suppress H <sup>+</sup> K-ATPase enzyme system of gastric acid secretion	

Omeprazole (Prilosec, Losec 🍀, Olex 🍀)	Have patients take capsule whole; do not crush. Delayed-release capsules allow absorption after granules leave the stomach. Give 30 minutes before the main meal of the day. The proton pump is activated by the presence of food. Therefore the drug needs a chance to work before the patient eats.
Lansoprazole (Prevacid)	Give 30 min before the main meal of the day. The proton pump is activated by the presence of food. Therefore the drug needs a chance to work before the patient eats.
Rabeprazole (Aciphex, Pariet 🍀)	Take after the morning meal. This drug promotes healing and symptom relief of duodenal ulcers. Do not crush capsule. This drug is a sustained-release capsule.
Pantoprazole (Protonix, Pantoloc 🍀, Panto IV 🍀, Tecta 🍀)	Do not crush. This drug is enteric coated. IV form must be given on a pump with a filter and in a separate line. Given IV, this drug precipitates easily. Do not give Protonix IV with other IV drugs. Monitor for adverse drug interactions if patient is on other medications. The IV form is not compatible with most other drugs. This drug will alter how other drugs are metabolized, either increasing or decreasing their effectiveness.
Esomeprazole (Nexium)	Assess for hepatic impairment. Patients with severe hepatic problems need a low dose. Do not give Nexium IV with other IV drugs. The IV form is not compatible with most other drugs. Monitor for adverse drug interactions if patient is on other medications. This drug will alter how other drugs are metabolized, either increasing or decreasing the effectiveness.
<b>Prostaglandin Analogs</b> —Stimulate mucosal protection and decrease gastric acid secretions	
Misoprostol (Cytotec)	Avoid magnesium-containing antacids. Misoprostol and magnesium-containing antacids can cause diarrhea. Do not administer to pregnant women. This drug can cause abortion, premature birth, or birth defects.
<b>Antimicrobials</b> —Treat <i>H. pylori</i> infection	
Clarithromycin (Biaxin)	Give with caution to patients with renal impairment; monitor renal function laboratory values. This drug can increase the patient's BUN level and should be monitored.
Amoxicillin (Amoxil, Novamoxin 🍀)	Teach patients to take the drug with food or immediately after a meal. This drug can cause GI disturbances, including nausea, vomiting, and diarrhea.
Tetracycline	Teach patients to take the drug at least 1 hour before meals or 2 hours after meals. Dairy products and other foods may interfere with drug absorption. Teach patients to avoid direct sunlight and wear sunscreen when outdoors. This drug can cause the skin to burn as a result of photosensitivity.
Metronidazole (Flagyl, Nidagel 🍀, Novo-Nidazol 🍀)	Teach patients to take the drug with food. This drug can cause GI disturbances, especially nausea. Teach patients to avoid alcohol during drug therapy and for at least 3 days after therapy is completed. The patient can experience a drug-alcohol reaction, including severe nausea, vomiting, and headache.

BUN, Blood urea nitrogen.

## Nursing Safety Priority QSEN

### Drug Alert

Teach the patient to monitor for symptom relief and side effects of drugs to treat gastritis and to notify the primary health care provider of any adverse effects or worsening of gastric distress. The dose, frequency, or type of drug may need to be changed if symptoms of gastric irritation appear or persist. *Remind patients not to take additional over-the-counter (OTC) drugs such as Pepcid AC or Axid AR if they are taking similar prescribed drugs.*

Patients with *chronic* gastritis may require vitamin B<sub>12</sub> for prevention or treatment of pernicious anemia. If *H. pylori* is found, the primary health care provider treats the infection. Current practice for infection treatment is described in the Drug Therapy discussion in the Peptic Ulcer Disease section.

The nurse, primary health care provider, or pharmacist teaches patients to avoid drugs and other irritants that are associated with gastritis episodes, if possible. These drugs include corticosteroids, erythromycin (E-Mycin, Erythro-ES 🍀), ASA (aspirin), and NSAIDs such as naproxen (Naprosyn, Maxidol 🍀) and ibuprofen (Motrin, Advil). NSAIDs are also available as OTC drugs and should not be used. Teach patients to read all OTC drug labels because many preparations contain aspirin or other NSAID.

## NCLEX Examination Challenge 55-1

### Safe and Effective Care Environment

The nurse is performing medication reconciliation for a newly admitted client. The nurse recognizes which drugs contribute to signs and symptoms of gastritis? **Select all that apply.**

- A. Aspirin, taken once daily to prevent cardiac concerns
- B. Naproxen, taken once daily for joint pain associated with arthritis
- C. Amoxicillin, taken over a 10-day period for an acute sinus infection

D. Bacitracin ointment (over the counter), applied to minor scrapes on arms and legs

E. Prednisone, tapered over a 14-day period to decrease inflammation associated with an acute sinus infection

Teach the patient to limit intake of any foods and spices that cause distress, such as those that contain caffeine or high acid content (e.g., tomato products, citrus juices) or those that are heavily seasoned with strong or hot spices. Bell peppers and onions are also commonly irritating foods. Most patients seem to progress better with a bland, nonspicy diet and smaller, more frequent meals. Alcohol and tobacco should also be avoided.

Teach the patient about various techniques that reduce stress and discomfort, such as progressive relaxation, cutaneous stimulation, guided imagery, and distraction. [Table 55-1](#) lists commonly used complementary and integrative therapies for gastritis and peptic ulcer disease.

**TABLE 55-1**

**Commonly Used Complementary and Integrative Therapies for Gastritis and Peptic Ulcer Disease (PUD)**

<b>Herbs and Vitamins</b>
<ul style="list-style-type: none"><li>• Cranberry</li><li>• Deglycyrrhizinated licorice (DGL)</li><li>• Ginger</li><li>• Probiotics</li><li>• Slippery elm</li><li>• Vitamin C</li></ul>
<b>Homeopathy</b>

## Immunity Concept Exemplar Peptic Ulcer Disease (PUD)

A **peptic ulcer** is a mucosal lesion of the stomach or duodenum. **Peptic ulcer disease (PUD)** results when mucosal defenses become impaired and no longer protect the epithelium from the effects of acid and pepsin.

### Pathophysiology

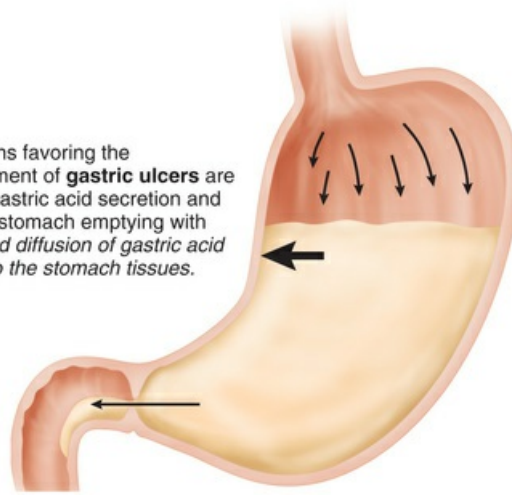

#### Types of Ulcers

Three types of ulcers may occur: gastric ulcers, duodenal ulcers, and stress ulcers (less common). Many ulcers are caused by *H. pylori* infection ([National Institute of Diabetes and Digestive and Kidney Diseases, 2017](#)). Although it is not certain how *H. pylori* is transmitted, it is believed to be spread through contaminated food or water. Studies have also suggested that interpersonal transmission appears to be the main route of transmission ([Eusebi et al., 2014](#)).

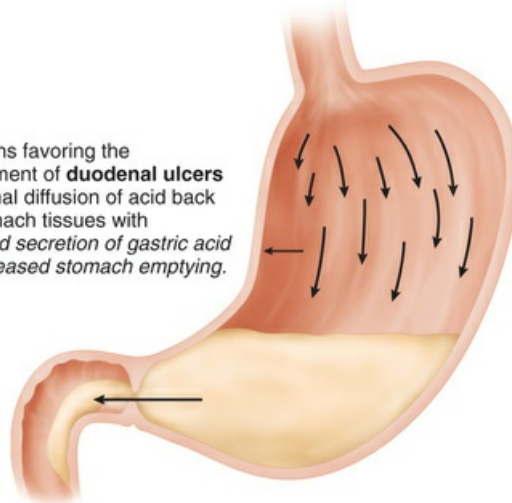

As a response to the bacteria, cytokines, neutrophils, and other substances are activated and cause epithelial cell necrosis. These bacteria produce substances that damage the mucosa. Urease produced by *H. pylori* breaks down urea into ammonia, which neutralizes the acidity of the stomach. Urease can be detected through laboratory testing to confirm the *H. pylori* infection. In addition, the helical shape of *H. pylori* allows the bacterium to burrow into the mucus layer of the stomach and become undetectable by the body's immune cells. Although this bacterium does not cause illness in most individuals, it is a major risk factor for peptic and duodenal ulcers and gastric cancer ([McCance et al., 2014](#)).

*Gastric ulcers* usually develop in the antrum of the stomach near acid-secreting mucosa. When a break in the mucosal barrier occurs (such as that caused by *H. pylori* infection), hydrochloric acid injures the epithelium. Gastric ulcers may then result from back-diffusion of acid or dysfunction of the pyloric sphincter ([Fig. 55-1](#)). Without normal functioning of the pyloric sphincter, bile refluxes (backs up) into the stomach. This reflux of bile acids may break the integrity of the mucosal barrier, which leads to mucosal inflammation and compromise in IMMUNITY. Toxic agents and bile then destroy the membrane of the gastric mucosa.

Conditions favoring the development of **gastric ulcers** are normal gastric acid secretion and delayed stomach emptying with *increased diffusion of gastric acid back into the stomach tissues.*

Conditions favoring the development of **duodenal ulcers** are normal diffusion of acid back into stomach tissues with *increased secretion of gastric acid and increased stomach emptying.*

**FIG. 55-1** Pathophysiology of peptic ulcer.

Gastric emptying is often delayed in patients with gastric ulceration. This causes regurgitation of duodenal contents, which worsens the gastric mucosal injury. Decreased blood flow to the gastric mucosa may also alter the defense barrier and thereby allow ulceration to occur. Gastric ulcers are deep and penetrating, and they usually occur on the lesser curvature of the stomach, near the pyloric sphincter (Fig. 55-2).

**FIG. 55-2** Most common sites for peptic ulcers.

Most *duodenal ulcers* occur in the upper portion of the duodenum. They are deep, sharply demarcated lesions that penetrate through the mucosa and submucosa into the muscularis propria (muscle layer). The floor of the ulcer consists of a necrotic area residing on granulation tissue and surrounded by areas of fibrosis (McCance et al., 2014).

The main feature of a duodenal ulcer is high gastric acid secretion, although a wide range of secretory levels are found. In patients with duodenal ulcers, pH levels are low (excess acid) in the duodenum for long periods. Protein-rich meals, calcium, and vagus nerve excitation stimulate acid secretion. Combined with hypersecretion, a rapid emptying of food from the stomach reduces the buffering effect of food and delivers a large acid bolus to the duodenum. Inhibitory secretory mechanisms and pancreatic secretion may be insufficient to control the acid load.

*Stress ulcers* are acute gastric mucosal lesions occurring after an acute medical crisis or trauma, such as sepsis or a head injury. In the patient who is NPO for major surgery, gastritis may lead to **stress ulcers**, which are multiple shallow erosions of the stomach and occasionally the proximal duodenum. Patients who are critically ill, especially those with extensive burns (**Curling's ulcer**), sepsis (ischemic ulcer), or increased intracranial pressure (**Cushing's ulcer**), are also susceptible to these ulcers.

*Bleeding caused by gastric erosion is the main manifestation of acute stress ulcers.* Multifocal lesions associated with stress ulcers occur in the stomach and proximal duodenum. These lesions begin as areas of ischemia and evolve into erosions and ulcerations that may progress to massive hemorrhage. Little is known of the exact etiology of stress ulcers. Stress ulcers are associated with lengthened hospital stay and increased mortality rates. Therefore most patients who have major trauma or surgery receive IV drug therapy (e.g., PPI) to prevent stress ulcer development.

### Complications of Ulcers

The most common complications of PUD are hemorrhage, perforation, pyloric obstruction, and intractable disease. *Hemorrhage is the most serious complication.* It tends to occur more often in patients with *gastric ulcers* and in older adults. Many patients have a second episode of bleeding if underlying infection with *H. pylori* remains untreated or if therapy does not include an H<sub>2</sub> antagonist. With massive bleeding the patient vomits bright red or coffee-ground blood (**hematemesis**). Hematemesis usually indicates bleeding at or above the duodenojejunal junction (upper GI bleeding) (Chart 55-4).

#### Chart 55-4

## Key Features

### Upper GI Bleeding

- Bright red or coffee-ground vomitus (hematemesis)
- Melena (tarry or dark, sticky) stools
- Decreased blood pressure
- Increased heart rate
- Weak peripheral pulses
- Acute confusion (in older adults)
- Vertigo
- Dizziness or light-headedness
- Syncope (loss of consciousness)
- Decreased hemoglobin and hematocrit

Minimal bleeding from ulcers is manifested by occult blood in a dark, “tarry” stool (**melena**). The digestion of blood within the duodenum and small intestine may result in this black stool. Melena may occur in patients with gastric ulcers but is more common in those with duodenal ulcers. Gastric acid digestion of blood typically results in a granular dark vomitus (*coffee-ground appearance*).

Gastric and duodenal ulcers can perforate and bleed (**Fig. 55-3**). *Perforation* occurs when the ulcer becomes so deep that the entire thickness of the stomach or duodenum is worn away. The stomach or duodenal contents can then leak into the peritoneal cavity. Sudden, sharp pain begins in the mid-epigastric region and spreads over the entire abdomen. The amount of pain correlates with the amount and type of GI contents spilled. The classic pain causes the patient to be apprehensive. The abdomen is tender, rigid, and boardlike (**peritonitis**). The patient often assumes a “fetal” position to decrease the tension on the abdominal muscles. He or she can become severely ill within hours. Bacterial septicemia and hypovolemic shock follow. Peristalsis diminishes, and paralytic ileus develops. *Peptic ulcer perforation is a surgical emergency and can be life threatening!*

FIG. 55-3 Common causes of upper GI bleeding.

## NCLEX Examination Challenge 55-2

### Safe and Effective Care Environment

When caring for a patient who has just had an upper GI endoscopy, the nurse assesses that the client has developed a temperature of 101.8° F (38.8° C). What is the **appropriate** nursing intervention?

- A. Promptly assess the client for potential perforation.
- B. Ask the nursing assistant to bathe the client with tepid water.
- C. Administer acetaminophen (Tylenol) to lower the temperature.
- D. Delegate to an unlicensed assistive personnel (UAP) to retake the temperature.

*Pyloric (gastric outlet) obstruction* (blockage) occurs in a small percentage of patients and is manifested by vomiting caused by stasis and gastric dilation. Obstruction occurs at the pylorus (the gastric outlet) and is caused by scarring, edema, inflammation, or a combination of these factors.

Symptoms of obstruction include abdominal bloating, nausea, and vomiting. When vomiting persists, the patient may have hypochloremic (metabolic) alkalosis from loss of large quantities of acid gastric juice (hydrogen and chloride ions) in the vomitus. Hypokalemia may also result from the vomiting or metabolic alkalosis.

Many patients with ulcers have a single episode with no recurrence. However, *intractability* may develop from complications of ulcers, excessive stressors in the patient's life, or an inability to adhere to long-term therapy. He or she no longer responds to conservative management, or recurrences of symptoms interfere with ADLs. In general, the patient continues to have recurrent pain and alteration in COMFORT, despite treatment. Those who fail to respond to traditional treatments or who have a relapse after discontinuation of therapy are referred to a gastroenterologist.

### Etiology and Genetic Risk

Peptic ulcer disease is caused most often by bacterial infection with *H. pylori* and NSAIDs. NSAIDs (e.g., ibuprofen) break down the mucosal barrier and disrupt the mucosal protection mediated systemically by cyclooxygenase (COX) inhibition. COX-2 inhibitors (celecoxib [Celebrex]) are less

likely to cause mucosal damage but place patients at high risk for cardiovascular events, such as myocardial infarction. In addition, NSAIDs cause decreased endogenous prostaglandins, resulting in local gastric mucosal injury (Lilley et al., 2017). GI complications from NSAID use can occur at any time, even after long-term uncomplicated use. NSAID-related ulcers are difficult to treat, even with long-term therapy, because they have a high rate of recurrence.

Certain substances may contribute to gastroduodenal ulceration by altering gastric secretion, which produces localized damage to mucosa and interferes with the healing process. For example, corticosteroids (e.g., prednisone), theophylline (Theo-Dur), and caffeine stimulate hydrochloric acid production. Patients receiving radiation therapy may also develop GI ulcers. Other risk factors for PUD are the same as for gastritis (see Chart 55-1).

### **Incidence and Prevalence**

PUD affects millions of adults across the world. However, health care provider visits, hospitalizations, and the mortality rate for PUD have decreased in the past few decades due in part to the use of proton pump inhibitors and earlier treatment for *H. pylori*.

### **❖ Interprofessional Collaborative Care**

Care of the patient with PUD generally takes place in the community setting, unless the patient develops a more serious condition such as upper GI bleeding, which requires hospitalization for management. The interprofessional team that collaborates to care for this patient generally includes the primary or specialty health care provider and nurse and may include the surgeon, case manager, and dietitian if the patient requires surgery.

### **◆ Assessment: Noticing**

#### **History.**

Collect data related to the causes and risk factors for peptic ulcer disease (PUD). Question the patient about factors that can influence the development of PUD, including alcohol intake and tobacco use. Note if certain foods such as tomatoes or caffeinated beverages precipitate or worsen symptoms. Information regarding actual or perceived daily stressors should also be obtained.

A history of current or past medical conditions focuses on GI problems, particularly any history of diagnosis or treatment for *H. pylori* infection. Review all prescription and OTC drugs the patient is taking. Specifically inquire whether the patient is taking corticosteroids, chemotherapy, or NSAIDs. Also ask whether he or she has ever undergone radiation treatments. Assess whether the patient has had any GI surgeries, especially a partial gastrectomy, which can cause chronic gastritis.

A history of GI upset, pain and its relationship to eating and sleep patterns, and actions taken to relieve pain are also important. Inquire about any changes in the character of the pain because this may signal the development of complications. For example, if pain that was once intermittent and relieved by food and antacids becomes constant and radiates to the back or upper quadrant, the patient may have ulcer perforation. However, many adults with active duodenal or gastric ulcers report having no ulcer symptoms.

#### **Physical Assessment/Signs and Symptoms.**

Physical assessment findings may reveal epigastric tenderness, usually located at the midline between the umbilicus and the xiphoid process. *If perforation into the peritoneal cavity is present, the patient typically has a rigid, boardlike abdomen accompanied by rebound tenderness and pain.* Initially, auscultation of the abdomen may reveal hyperactive bowel sounds, but these may diminish with progression of the disorder.

**Dyspepsia** (*indigestion*) is the most commonly reported symptom associated with PUD. It is typically described as sharp, burning, or gnawing pain. Some patients may perceive discomfort as a sensation of abdominal pressure or of fullness or hunger. Specific differences between gastric and duodenal ulcers are listed in Table 55-2.

---

**TABLE 55-2**  
**Differential Features of Gastric and Duodenal Ulcers**

---

FEATURE	GASTRIC ULCER	DUODENAL ULCER
Age	Usually 50 yr or older	Usually 50 yr or older
Gender	Male/female ratio of 1.1 : 1	Male/female ratio of 1 : 1
Blood group	No differentiation	Most often type O
General nourishment	May be malnourished	Usually well nourished
Stomach acid production	Normal secretion or hyposecretion	Hypersecretion
Occurrence	Mucosa exposed to acid-pepsin secretion	Mucosa exposed to acid-pepsin secretion
Clinical course	Healing and recurrence	Healing and recurrence
Pain	Occurs 30-60 min after a meal; at night: rarely Worsened by ingestion of food	Occurs $\frac{1}{2}$ - 3 hr after a meal; at night: often awakens patient between 1 and 2 AM Relieved by ingestion of food
Response to treatment	Healing with appropriate therapy	Healing with appropriate therapy
Hemorrhage	Hematemesis more common than melena	Melena more common than hematemesis
Malignant change	Perhaps in less than 10%	Rare
Recurrence	Tends to heal and recurs often in the same location	60% recur within 1 yr; 90% recur within 2 yr
Surrounding mucosa	Atrophic gastritis	No gastritis

Gastric ulcer pain often occurs in the upper epigastrium with localization to the left of the midline and is aggravated by food. Duodenal ulcer pain is usually located to the right of or below the epigastrium. The pain associated with a duodenal ulcer occurs 90 minutes to 3 hours after eating and often awakens the patient at night (McCance et al., 2014). Pain may also be exacerbated (made worse) by certain foods (e.g., tomatoes, hot spices, fried foods, onions, alcohol, caffeine drinks) and certain drugs (e.g., NSAIDs, corticosteroids). Perform a comprehensive pain assessment.

Nausea and vomiting may be symptoms accompanying ulcer disease, most commonly with pyloric sphincter dysfunction. It may result from gastric stasis associated with pyloric obstruction. Appetite is generally maintained in patients with a peptic ulcer unless pyloric obstruction is present.

To assess for fluid volume deficit that occurs from bleeding, take orthostatic blood pressure and monitor for signs and symptoms of dehydration. Also assess for dizziness, especially when the patient is upright, because this is a symptom of fluid volume deficit. Older adults often experience dizziness when they get out of bed and are at risk for falls.

## NCLEX Examination Challenge 55-3

### Physiological Integrity

The nurse is caring for a client with a bleeding duodenal ulcer who was admitted to the hospital after vomiting bright, red blood. Which condition does the nurse anticipate when the client develops a sudden, sharp pain in the mid-epigastric region and a rigid, board-like abdomen?

- A. Pancreatitis
- B. Ulcer perforation
- C. Small bowel obstruction
- D. Development of additional ulcers

### Psychosocial Assessment.

Assess the impact of ulcer disease on the patient's lifestyle, occupation, family, and social and leisure activities. Evaluate the impact that lifestyle changes will have on the patient and family. This assessment may reveal information about the patient's ability to adhere to the prescribed treatment regimen and obtain the needed social support to alter his or her lifestyle.

### Laboratory Assessment.

There are three simple, noninvasive tests to detect *H. pylori* in the patient's blood, breath, or stool. Although the breath and stool tests are considered more accurate, serologic testing for *H. pylori* antibodies is the most common method to confirm *H. pylori* infection. The urea breath test involves swallowing a capsule, liquid, or pudding that contains urea with a special carbon atom. After a few minutes the patient exhales; and, if the special carbon atom is found, the bacterium is present. The stool antigen test is performed on a stool sample provided by the patient and is tested for *H. pylori* antigens. Patients who have venous bleeding from a peptic ulcer may have decreased hemoglobin and hematocrit values. The stool may also be positive for occult (not seen) blood if bleeding is present (Pagana et al., 2017).

## Imaging Assessment.

If perforation is suspected, the health care provider may request a *chest and abdomen x-ray series*, but other diagnostic tests are more helpful in diagnosis.

## Other Diagnostic Assessment.

The major diagnostic test for PUD is *esophagogastroduodenoscopy (EGD)*, which is the most accurate means of establishing a diagnosis. Direct visualization of the ulcer crater by EGD allows the health care provider to take specimens for *H. pylori* testing and biopsy and cytologic studies for ruling out gastric cancer. The rapid urease test can confirm a quick diagnosis because urease is produced by the bacteria in the gastric mucosa. EGD may be repeated at 4- to 6-week intervals while the health care provider evaluates the progress of healing in response to therapy. [Chapter 52](#) describes this test in more detail.

GI bleeding may be tested using a *nuclear medicine scan*. No special preparation is required for this scan. The patient is injected with a contrast medium (usually  $^{99m}\text{Tc}$ ), and the GI system is scanned for the presence of bleeding after a waiting period. A second scan may be done 1 to 2 days after the bleeding is treated to determine if the interventions were effective.

### ◆Analysis: Interpreting

The priority collaborative problems for patients with peptic ulcer disease (PUD) include:

1. Acute pain or chronic noncancer pain due to gastric and/or duodenal ulceration
2. Potential for upper GI bleeding due to gastric and/or duodenal ulceration

### ◆Planning and Implementation: Responding

## Managing Acute Pain or Chronic Noncancer Pain

### Planning: Expected Outcomes.

The patient with PUD is expected to report pain control as evidenced by no more than a 3 on a 0-to-10 pain intensity scale.

### Interventions.

PUD causes significant discomfort that impacts many aspects of daily living. Interventions to manage pain focus on drug therapy and dietary changes.

### Drug Therapy.

The primary purposes of drug therapy in the treatment of PUD are to (1) provide pain relief, (2) eliminate *H. pylori* infection, (3) heal ulcerations, and (4) prevent recurrence. Several different regimens can be used. In selecting a therapeutic drug regimen, the health care provider considers the efficacy of the treatment, the anticipated side effects, the ability of the patient to adhere to the regimen, and the cost of the treatment.

Although numerous drugs have been evaluated for the treatment of *H. pylori* infection, no single agent has been used successfully against the organism. A common drug regimen for *H. pylori* infection is PPI–triple therapy, which includes a proton pump inhibitor (PPI) such as lansoprazole (Prevacid) plus two antibiotics such as metronidazole (Flagyl, Novonidazol) and tetracycline (Ala-Tet, Panmycin, Nu-Tetra) or clarithromycin (Biaxin, Biaxin XL) and amoxicillin (Amoxil, Amoxi) for 10 to 14 days. Some health care providers may prefer to use quadruple therapy, which contains combination of a proton pump inhibitor (PPI), any two commonly used antibiotics as described previously, with the addition of bismuth (Pepto-Bismol). Bismuth therapy is often used in patients who are allergic to penicillin-based medications.

## Considerations for Older Adults

### Patient-Centered Care QSEN

Many older adults have *H. pylori* infection that is undiagnosed because of vague symptoms associated with physiologic changes of aging and comorbidities that mask dyspepsia. Because the average age of gastric cancer diagnosis is 70 years, it is important to teach older adults about the symptoms of PUD and to consider *H. pylori* screening. Early detection and aggressive treatment can prevent PUD and gastric cancer.

Hyposecretory drugs reduce gastric acid secretions and are therefore used for both peptic ulcer disease (PUD) and gastritis management. The primary prescribed drugs include proton pump inhibitors and H<sub>2</sub>-receptor antagonists (see [Chart 55-3](#)).

*Proton pump inhibitor (PPI) is the drug class of choice for treating patients with acid-related disorders.* Examples include omeprazole (Prilosec), lansoprazole (Prevacid), rabeprazole (Aciphex), pantoprazole (Protonix), and esomeprazole (Nexium). These drugs suppress the HK-ATPase enzyme system of gastric acid production, and several of them are available as over-the-counter (OTC) drugs ([Lilley et al., 2017](#)).

Omeprazole, lansoprazole, and esomeprazole are each available as delayed-release capsules designed to release their contents after they pass through the stomach. Omeprazole and lansoprazole may be dissolved in a sodium bicarbonate solution and given through any feeding tube. Bicarbonate protects the dissolved omeprazole and lansoprazole granules in gastric acid. Therefore the drugs are still absorbed correctly. These capsules can also be opened. The enteric-coated capsules can be put in apple juice or orange juice and given through a large-bore feeding tube. Rabeprazole (Aciphex) and pantoprazole (Protonix) are enteric-coated tablets that quickly dissolve after the tablet has moved through the stomach and should not be crushed before giving them. Several of the PPIs are also available in an IV form, which may be helpful for patients who are NPO.

Some patients use PPIs for years and perhaps a lifetime; these patient should be assessed periodically to determine the necessity of PPI use. Some studies have suggested there may be an increased risk of osteoporotic fractures related to long-term PPI use, yet current research is ongoing to determine if there is a definitive link between the two ([Mulcahy, 2015](#)). Omeprazole (Prilosec and Prilosec OTC) reduces the effect of clopidogrel (Plavix), an antiplatelet drug. Teach patients to tell their health care provider if they are taking clopidogrel. PPIs should not be discontinued abruptly to prevent rebound activation of the proton pump. Therefore a step-down approach over several days is recommended ([Haastrup et al., 2014](#)).

*H<sub>2</sub>-receptor antagonists* are drugs that block histamine-stimulated gastric secretions. These drugs may also be used for indigestion and gastritis. Lower-dose forms are available in over-the-counter (OTC) products. H<sub>2</sub>-receptor antagonists block the action of the H<sub>2</sub> receptors of the parietal cells, thus inhibiting gastric acid secretion. Two of the most common drugs are famotidine (Pepcid) and nizatidine (Axid) and are available as Pepcid OTC and Axid AR in OTC form. These drugs are typically administered in a single dose at bedtime and are used for 4 to 6 weeks in combination with other therapy.

*Antacids* buffer gastric acid and prevent the formation of pepsin. They may help small duodenal ulcers heal but are usually not used alone as drug therapy. Liquid suspensions are the most therapeutic form, but tablets may be more convenient and enhance adherence. The most widely used preparations are mixtures of aluminum hydroxide and magnesium hydroxide. This combination overcomes the unpleasant GI side effects of either of these preparations when used alone. Mylanta and Maalox are examples of this type of combination antacid formulation. The aluminum and magnesium hydroxide combination products neutralize well at small doses. These products must be administered cautiously to patients with renal impairment because elimination is reduced and excessive amounts are retained in the body.

## Nursing Safety Priority QSEN

### Drug Alert

Teach the patient that, to achieve a therapeutic effect, sufficient antacid must be ingested to neutralize the hourly production of acid. For optimal effect, take antacids about 2 hours after meals to reduce the hydrogen ion load in the duodenum. Antacids may be effective from 30 minutes to 3

hours after ingestion. If taken on an empty stomach, they are quickly evacuated. Thus the neutralizing effect is reduced (Lilley et al., 2017).

Calcium carbonate (Tums) is a potent antacid, but it triggers gastrin release, causing a rebound acid secretion. Therefore its use in acid inhibition is not recommended.

Antacids can interact with certain drugs such as phenytoin (Dilantin), tetracycline (Ala-Tet, Nu-Tetra), and ketoconazole (Nizoral) and interfere with their effectiveness. Ask what other drugs the patient is using before a specific antacid is prescribed. Other drugs are given 1 to 2 hours before or after the antacid. Inform the patient that flavored antacids, especially wintergreen, should be avoided. The flavoring increases the emptying time of the stomach. Thus the desired effect of the antacid is negated.

Teach the patient with past or present heart failure to avoid antacids with high sodium content, such as aluminum hydroxide, magnesium hydroxide, sodium bicarbonate, and simethicone combination products (Gelusil and Mylanta). Magaldrate (Riopan) has the lowest sodium concentration.

Sucralfate (Carafate) is a *mucosal barrier fortifier* (protector) that forms complexes with proteins at the base of a peptic ulcer. This protective coat prevents further digestive action of both acid and pepsin. Sucralfate does not inhibit acid secretion. Rather, it binds bile acids and pepsins, reducing injury from these substances. The drug may be used in conjunction with H<sub>2</sub>-receptor antagonists and antacids but should not be administered within 1 hour of the antacid. Sucralfate is given on an empty stomach 1 hour before each meal and at bedtime. The main side effect of this drug is constipation.

Bismuth subsalicylate (Pepto-Bismol) inhibits *H. pylori* from binding to the mucosal lining and stimulates mucosal protection and prostaglandin production. Teach patients that they cannot take aspirin while on this drug because aspirin is a salicylic acid and could cause an overdose of salicylates. Patients should also be taught that this medication may cause the stools to be discolored black. This discoloration is temporary and harmless.

### Nutrition Therapy.

The role of diet in the management of ulcer disease is controversial. There is no evidence that dietary restriction reduces gastric acid secretion or promotes tissue healing, although a bland diet may assist in relieving symptoms. Food itself acts as an antacid by neutralizing gastric acid for 30 to 60 minutes. An increased rate of gastric acid secretion, called *rebound*, may follow.

## Nursing Safety Priority QSEN

### Action Alert

Teach the patient with peptic ulcer disease to avoid substances that increase gastric acid secretion. This includes caffeine-containing beverages (coffee, tea, cola). Both caffeinated and decaffeinated coffees should be avoided because coffee contains peptides that stimulate gastrin release (McCance et al., 2014).

Teach the patient to exclude any foods that cause discomfort. A bland, nonirritating diet is recommended during the acute symptomatic phase. Bedtime snacks are avoided because they may stimulate gastric acid secretion. Eating six smaller meals daily may help, but this regimen is no longer a regular part of therapy. No evidence supports the theory that eating six meals daily promotes healing of the ulcer. This practice may actually stimulate gastric acid secretion. Patients should avoid alcohol and tobacco because of their stimulatory effects on gastric acid secretion.

### Complementary and Integrative Health.

Teach patients about complementary and integrative therapies that can reduce stress, including hypnosis and imagery. For example, the use of yoga and meditation techniques has demonstrated a beneficial effect on anxiety disorders. Many have suggested that GI disorders result from the dysfunction of both the GI tract itself and the brain. This means that emotional stress is thought to worsen GI disorders such as peptic ulcer disease. Yoga may alter the activities of the central and

autonomic nervous systems.

Many herbs, such as powders of slippery elm and marshmallow root, quercetin, and licorice, are used commonly by patients with gastritis and PUD. These herbs may help heal inflamed tissue and increase blood flow to the gastric mucosa. Other substances include zinc, vitamin C, essential fatty acids, acidophilus, vitamin A, and glutamine. Table 55-1 provides a list of therapies that have been used by many patients with gastric disorders. Many of them have been scientifically supported in animal studies but have not been thoroughly studied in humans.

## Nursing Safety Priority QSEN

### Action Alert

Teach the patient who has peptic ulcer disease to seek immediate medical attention if experiencing any of these symptoms:

- Sharp, sudden, persistent, and severe epigastric or abdominal pain
- Bloody or black stools
- Bloody vomit or vomit that looks like coffee grounds

## Managing Upper GI Bleeding

### Planning: Expected Outcomes.

The patient with upper GI bleeding (often called *upper GI hemorrhage* or *UGH*) is expected to have bleeding promptly and effectively controlled and vital signs within normal limits.

### Interventions.

Blood loss from PUD results in high morbidity and mortality. Fluid volume loss secondary to vomiting can lead to dehydration and electrolyte imbalances. Interventions aimed at managing complications associated with PUD include prevention and/or management of bleeding, perforation, and gastric outlet obstruction. In some cases surgical treatment of complications becomes necessary.

### Nonsurgical Management.

Because prevention or early detection of complications is needed to obtain a positive clinical outcome, monitor the patient carefully and immediately report changes to the health care provider. The type of intervention selected will depend on the type and severity of the complication.

### Emergency: Upper GI Bleeding.

The patient who is actively bleeding has a life-threatening emergency. He or she needs supportive therapy to prevent hypovolemic shock and possible death.

## Nursing Safety Priority QSEN

### Critical Rescue

Recognize that your priority for care of the patient with upper GI bleeding is to maintain airway, breathing, and circulation (ABCs). Respond to these needs by providing oxygen and other ventilatory support as needed, starting two large-bore IV lines for replacing fluids and blood, and monitoring vital signs, hematocrit, and oxygen saturation.

The purpose of managing hypovolemia is to expand intravascular fluid in a patient who is volume depleted. Carefully monitor the patient's fluid status, including intake and output. *Fluid replacement in older adults should be closely monitored to prevent fluid overload.* Serum electrolytes are also assessed because depletions from vomiting or nasogastric suctioning must be replaced. Volume

replacement with isotonic solutions (e.g., 0.9% normal saline solution, lactated Ringer's solution) should be started immediately. The health care provider may prescribe blood products such as packed red blood cells to expand volume and correct a low hemoglobin and hematocrit. For patients with active bleeding, fresh frozen plasma may be given if the prothrombin time is 1.5 times higher than the midrange control value.

Continue to monitor the patient's hematocrit, hemoglobin, and coagulation studies for changes from the baseline measurements. With mild bleeding (less than 500 mL), slight feelings of weakness and mild perspiration may be present. When blood loss exceeds 1 L/24 hr, manifestations of shock may occur, such as hypotension, chills, palpitations, diaphoresis, and a weak, thready pulse.

A combination of several different treatments, including nasogastric tube (NGT) placement and lavage, endoscopic therapy, interventional radiologic procedures, and acid suppression, can be used to control acute bleeding and prevent rebleeding. If the patient is actively bleeding at home, he or she is usually admitted to the emergency department for GI lavage. If the patient is already a patient in the hospital, lavage can be done at the bedside. After the bleeding has stopped, H<sub>2</sub>-receptor antagonists, proton pump inhibitors, and antacids are the primary drugs used.

### Nasogastric Tube Placement and Lavage.

Upper GI bleeding often requires the primary care provider or nurse to insert a large-bore NGT to:

- Determine the presence or absence of blood in the stomach
- Assess the rate of bleeding
- Prevent gastric dilation
- Administer lavage

Although not performed as commonly today, **gastric lavage** requires the insertion of a large-bore NGT with instillation of a room-temperature solution in volumes of 200 to 300 mL. There is no evidence that sterile saline or sterile water is better than tap water for this procedure. Follow agency protocol for the solution that is required. The solution and blood are repeatedly withdrawn manually until returns are clear or light pink and without clots. Instruct the patient to lie on the left side during this procedure. The NGT may remain in place for a few days or be removed after lavage.

### Endoscopic Therapy.

Endoscopic therapy via an esophagogastroduodenoscopy (EGD) can assist in achieving homeostasis during an acute hemorrhage by isolating the bleeding artery to embolize (clot) it. A physician can insert instruments through the endoscope during the procedure to stop bleeding in three different ways: (1) inject chemicals into the bleeding site; (2) treat the bleeding area with heat, electric current, or laser; or (3) close the affected blood vessels with a band or clip. During the EGD, a specialized endoscopy nurse and technician assist the physician with the procedure.

Pre-EGD nursing care involves inserting one or two large-bore IV catheters if they are not in place. A large catheter allows the patient to receive IV moderate sedation (e.g., midazolam [Versed] and an opioid) and possibly a blood transfusion. Keep the patient NPO for 4 to 6 hours before the procedure. This prevents the risk for aspiration and allows the endoscopist to view and treat the ulcer. A patient must sign a consent form before the EGD *after* the physician informs him or her about the procedure.

## Nursing Safety Priority QSEN

### Action Alert

After esophagogastroduodenoscopy (EGD), monitor vital signs, heart rhythm, and oxygen saturation frequently until they return to baseline. In addition, frequently assess the patient's ability to swallow saliva. The patient's gag reflex may initially be absent after an EGD because of anesthetizing (numbing) the throat with a spray before the procedure. *After the procedure, do not allow the patient to have food or liquids until the gag reflex is intact!*

Endoscopic therapy is beneficial for most patients with active bleeding. However, ulcers that continue to bleed or continue to rebleed despite endoscopic therapy may require an interventional

radiologic procedure or surgical repair.

### Interventional Radiologic Procedures.

For patients with persistent, massive upper GI bleeding or those who are not surgical candidates, catheter-directed embolization may be performed. This endovascular procedure is usually done if endoscopic procedures are not successful or available. A femoral approach is most often used, but brachial access may be used. An arteriogram is performed to identify the arterial anatomy and find the exact location of the bleeding. The physician injects medication or other material into the blood vessels to stop the bleeding. Care of the patient following an arteriogram is similar to care following a percutaneous vascular intervention, which is described in [Chapters 36](#) and [38](#). Post-arteriogram nursing care should be provided after the procedure.

### Acid Suppression.

*Aggressive acid suppression is used to prevent rebleeding.* When acute bleeding is stopped and clot formation has taken place within the ulcer crater, the clot remains in contact with gastric contents. Acid-suppressive agents are used to stabilize the clot by raising the pH level of gastric contents. Several types of drugs are used. H<sub>2</sub>-receptor antagonists prevent acid from being produced by parietal cells. Proton pump inhibitors prevent the transport of acid across the parietal cell membrane, whereas antacids buffer acid produced in the stomach.

*Perforation* is managed by immediately replacing fluid, blood, and electrolytes, administering antibiotics, and keeping the patient NPO. Maintain nasogastric suction to drain gastric secretions and thus prevent further peritoneal spillage. Carefully monitor intake and output and check vital signs at least hourly. Monitor the patient for signs and symptoms of septic shock, such as fever, alterations in COMFORT, tachycardia, lethargy, or anxiety.

*Pyloric obstruction* is caused by edema, spasm, or scar tissue. Symptoms of obstruction related to difficulty in emptying the stomach include feelings of fullness, distention, or nausea after eating, as well as vomiting copious amounts of undigested food.

Treatment of obstruction is directed toward restoring fluid and electrolyte balance and decompressing the dilated stomach. Obstruction related to edema and spasm generally responds to medical therapy. First, the stomach must be decompressed with nasogastric suction. Next, interventions are directed at correcting metabolic alkalosis and dehydration. The NGT is clamped after about 72 hours. Check the patient for retention of gastric contents. If the amount retained is not more than 50 mL in 30 minutes, the health care provider may allow oral fluids. In some cases, surgical intervention may be required to treat PUD.

### Surgical Management.

Evidence-based guidelines for the treatment of PUD that include *H. pylori* treatment and the development of nonsurgical means of controlling bleeding have led to a decline in the need for surgical intervention. In PUD, surgical intervention may be used to:

- Treat patients who do not respond to medical therapy or other nonsurgical procedures
- Treat a surgical emergency that develops as a complication of PUD, such as perforation

Two general surgical approaches are available for PUD: minimally invasive surgery and conventional open surgery.

*Minimally invasive surgery (MIS)* via laparoscopy (a type of endoscope) may be used to remove a chronic gastric ulcer or treat hemorrhage from perforation. Several small incisions allow access to the stomach and duodenum. The patient may have partial stomach removal (subtotal gastrectomy), pyloroplasty (to open the pylorus), and/or a vagotomy (vagus nerve cutting) to control acid secretion. Acid-reduction surgery may not be necessary because of the increased use of PPIs and endoscopic procedures in the treatment of PUD. The advantages of MIS over traditional open surgical procedures include a shorter hospital stay, fewer complications, less pain, and better, quicker recovery.

## Clinical Judgment Challenge 55-1

### Safety; Teamwork and Collaboration OSEN

You are caring for a 55-year-old woman who was admitted after vomiting bright red blood this morning. She states that she has a history of a stomach problem and hypertension and takes medication for both. She cannot provide the names of the medications yet does report that she had “a couple of alcoholic drinks” this morning “to settle her nerves.” Vital signs show blood pressure of 150/90, pulse of 108/minute, respirations of 22/minute, and temperature of 98.6° F. Assessment findings include dry, pale skin and a slightly distended abdomen with mid-epigastric moderate pain (5 out of 10). She is alert and oriented. Her husband states that she reported feeling light-headed and tired over the past few days.

1. What additional assessment questions will you ask the patient and her husband?
2. Which tasks can you appropriately delegate to the unlicensed assistive personnel (UAP) working with you?
3. What assessment findings would you immediately report to the health care provider?
4. What treatments do you anticipate that the health care provider will order if the patient experiences perforation?

### Care Coordination and Transition Management

Patients may be discharged from the hospital if there is no evidence of ongoing bleeding, orthostatic changes, or cardiopulmonary distress or compromise. Those discharged after treatment for peptic ulcer disease (PUD) and/or complications secondary to the disease must face several challenges to manage the disease successfully. Long-term adherence to drug therapy may require the patient to take several drugs each day. Permanent lifestyle alterations in NUTRITION habits must also be made.

### Home Care Management.

Most patients are discharged to home to continue their recovery. Those who have had major surgery or complications, such as hemorrhage, may require one or two visits from a home care nurse to assess clinical progress, especially if the patient is an older adult ([Chart 55-5](#)).

#### Chart 55-5

### Home Care Assessment

#### The Patient With Ulcer Disease

Assess gastrointestinal and cardiovascular status, including:

- Vital signs, including orthostatic vital signs
- Skin color
- Presence of abdominal pain (location, severity, character, duration, precipitating factors, and relief measures)
- Character, color, and consistency of stools
- Changes in bowel elimination pattern
- Hemoglobin and hematocrit
- Bowel sounds; palpate for areas of tenderness

Assess nutritional status, including:

- Dietary patterns and habits
- Intake of coffee and alcohol

- Relationship of food ingestion to symptoms

Assess medication history:

- Use of steroids
- Use of NSAIDs
- Use of over-the-counter medications

Assess patient's coping style:

- Recent stressors
- Past coping style

Assess patient's understanding of illness and ability to adhere to the therapeutic regimen:

- Symptoms to report to health care provider
- Expected and side effects of medications
- Food and drug interactions
- Need for smoking cessation

### Self-Management Education.

The primary focus of home care preparation is patient and family teaching regarding risk factors for the recurrence of PUD. Teach them how to recognize new complications and what to do if they occur, especially abdominal pain; nausea and vomiting; black, tarry stools; and weakness or dizziness.

Help the patient plan ways to make needed lifestyle changes. For postsurgical patients, especially those who have undergone partial stomach removal, smaller meals may be required. Other postoperative nutrition changes are described in the [Self-Management Education](#) discussion in the [Gastric Cancer](#) section.

## Nursing Safety Priority QSEN

### Action Alert

Teach the patient who has had surgery for PUD to avoid any OTC product containing aspirin or other NSAID. Emphasize the importance of following the treatment regimen for *H. pylori* infection and healing the ulcer and of keeping all follow-up appointments. Help the patient identify situations that cause stress, describe feelings during stressful situations, and develop a plan for coping with stressors.

### Health Care Resources.

If needed, refer the patient and family to the National Digestive Diseases Information Clearinghouse ([www.digestive.niddk.nih.gov/](http://www.digestive.niddk.nih.gov/)). This group provides information and support to patients who have digestive disorders.

### ◆ Evaluation: Reflecting

Evaluate the care of the patient with peptic ulcer disease (PUD) based on the identified priority patient problems. The expected outcomes are that the patient:

- Does not have active PUD or associated complications
- Verbalizes relief or control of pain and alterations in COMFORT
- Adheres to the drug regimen and lifestyle changes to prevent recurrence and heal the ulcer

- Does not experience an upper GI bleed; if bleeding occurs, it will be promptly and effectively managed

## Gastric Cancer

Most cancers of the stomach are adenocarcinomas. This type of cancer develops in the mucosal cells that form the innermost lining of any portion or all of the stomach. *Often there are no symptoms in the early stages, and the disease is advanced when detected.*

### ❖Pathophysiology

Gastric cancer usually begins in the glands of the stomach mucosa. Atrophic gastritis and intestinal metaplasia (abnormal tissue development) are precancerous conditions. Inadequate acid secretion in patients with atrophic gastritis creates an alkaline environment that allows bacteria (especially *H. pylori*) to multiply. This infection causes mucosa-associated lymphoid tissue (MALT) lymphoma, which starts in the stomach (McCance et al., 2014).

Gastric cancers spread by direct extension through the gastric wall and into regional lymphatics, which carry tumor deposits to lymph nodes. Direct invasion of and adherence to adjacent organs (e.g., the liver, pancreas, and transverse colon) may also result. Hematogenous spread via the portal vein to the liver and via the systemic circulation to the lungs and bones is the most common mode of metastasis. Peritoneal seeding of cancer cells from the tumor areas to the omentum, peritoneum, ovary, and pelvic cul-de-sac can also occur.

In adults with *advanced* gastric cancer, there is invasion of the muscularis (stomach muscle) or beyond. These lesions are not cured by surgical resection. The overall 5-year survival rate of adults with stomach cancer in the United States is poor because most patients have no symptoms until the disease advances.

### Etiology and Genetic Risk

Infection with *H. pylori* is the largest risk factor for gastric cancer because it carries the cytotoxin-associated gene A (*CagA*) gene. Patients with pernicious anemia, gastric polyps, chronic atrophic gastritis, and **achlorhydria** (absence of secretion of hydrochloric acid) are two to three times more likely to develop gastric cancer.

The disease also seems to be positively correlated with eating pickled foods, nitrates from processed foods, and salt added to food. The ingestion of these foods over a long period can lead to atrophic gastritis, a precancerous condition. A low intake of fruits and vegetables is also a risk factor for cancer (McCance et al., 2014).

Gastric surgery seems to increase the risk for gastric cancer because of the eventual development of atrophic gastritis, which results in changes to the mucosa. Patients with Barrett's esophagus from prolonged or severe gastroesophageal reflux disease (GERD) have an increased risk for cancer in the cardia (at the point where the stomach connects to the esophagus).

### Incidence and Prevalence

Generally, stomach cancer is more common in males than in females, and there is a sharp increase in adults over 50, with most diagnosed between ages 60 and 80. Across the world, the highest incidence rates are in Japan, China, Southern and Eastern Europe, and South and Central America. In the United States, according to ethnicity, Hispanic Americans, African Americans, and Asian/Pacific Islanders have more incidence of stomach cancer than non-Hispanic whites. The average age for an adult diagnosed with gastric cancer is 69 years old (American Cancer Society, 2017).

Nurses are uniquely positioned to improve gastric cancer survival rates by ensuring that patients with high risk and suspicious symptoms are assessed and diagnosed early. Maintaining functional status and quality of life during gastric cancer care is a priority for nursing care.

### Health Promotion and Maintenance

Teach patients with gastritis and/or *H. pylori* infection to follow the treatment regimen to ensure that gastritis heals and *H. pylori* infection is eliminated. *Stress the need for eating a well-balanced diet and limiting pickled, salted, and processed foods to help prevent gastric cancer.*

## ❖ Interprofessional Collaborative Care

Care of the patient with gastric cancer takes place in all settings, ranging from the home and community environment to the inpatient setting, depending on the stage of disease and the immediate course of treatment. The interprofessional team that collaborates to care for this patient generally includes the surgeon, nurse, case manager, dietitian, social worker, and spiritual leader of the patient's choice.

### ◆ Assessment: Noticing

Question the patient about known risk factors for the development of gastric cancer. Ask about preferred foods, especially pickled, salted, or smoked foods. Inquire whether the patient has ever been diagnosed with or treated for *H. pylori* infection, gastritis, or pernicious anemia. Note whether he or she has a history of gastric surgery or polyps. Also ask whether any of the patient's immediate relatives have gastric cancer.

Although patients with *early* gastric cancer may be asymptomatic, indigestion (heartburn) and abdominal discomfort are the *most* common symptoms (Chart 55-6). However, these symptoms are often ignored, or a change in diet or use of antacids relieves them. As the tumor grows, these symptoms become more severe and do not respond to nutrition changes or antacids. Epigastric or back pain is also an early symptom that may go unrecognized.

### ▶ Chart 55-6

## Key Features

### Early versus Advanced Gastric Cancer

#### Early Gastric Cancer\*

- Indigestion
- Abdominal discomfort initially relieved with antacids
- Feeling of fullness
- Epigastric, back, or retrosternal pain

#### Advanced Gastric Cancer

- Nausea and vomiting
- Obstructive symptoms
- Iron deficiency anemia
- Palpable epigastric mass
- Enlarged lymph nodes
- Weakness and fatigue
- Progressive weight loss

**Note:** Many patients with early gastric cancer have no signs or symptoms.

In *advanced* gastric cancer, progressive weight loss, nausea, and vomiting can occur. Vomiting represents pronounced dilation, thickening of the stomach wall, or pyloric obstruction. Obstructive symptoms appear earlier with tumors located near the pylorus than with those in the fundus. Patients with advanced disease may have weakness, fatigue, and anemia. Physical assessment

findings in advanced disease may be absent, or a palpable epigastric mass may suggest hepatomegaly (liver enlargement) from metastatic disease. Hard, enlarged lymph nodes in the left supraclavicular chain, left axilla, or umbilicus result from metastasis from gastric cancer. Masses on the right suggest metastasis in the perigastric lymph nodes or liver.

In patients with advanced disease, anemia is evidenced by *low hematocrit* and hemoglobin values. Patients may have macrocytic or microcytic anemia associated with decreased iron or vitamin B<sub>12</sub> absorption. *The stool may be positive for occult blood. Hypoalbuminemia and abnormal results of liver tests* (e.g., bilirubin and alkaline phosphatase) occur with advanced disease and hepatic metastasis. The level of carcinoembryonic antigen (CEA) is elevated in advanced cancer of the stomach (Pagana et al., 2017).

The health care provider uses esophagogastroduodenoscopy (EGD) with biopsy for definitive diagnosis of gastric cancer. (See Chapter 52 for a discussion of nursing care associated with this diagnostic test.) The lesion can be viewed directly, and biopsies of all visible lesions can be obtained to determine the presence of cancer cells. During the endoscopy, an endoscopic (endoluminal) ultrasound (EUS) of the gastric mucosa can also be performed. This technology allows the health care provider to evaluate the depth of the tumor and the presence of lymph node involvement, which permits more accurate staging of the disease. CT, positron emission tomography (PET), and MRI scans of the chest, abdomen, and pelvis are used in determining the extent of the disease and planning therapy.

### ◆ **Interventions: Responding**

Management of gastric cancer includes drug therapy, radiation, and/or surgery. Drug therapy and radiation may be used instead of surgery or as an adjunct before and/or after surgery.

### **Nonsurgical Management.**

The treatment of gastric cancer depends highly on the stage of the disease. Radiation and chemotherapy commonly prolong survival of patients with advanced gastric disease.

Combination *chemotherapy* with multiple cycles of drugs such as cisplatin (Platinol) and epirubicin (Ellence) before and after surgery may be given. Bone marrow suppression, nausea, and vomiting are common adverse drug effects. Chapter 22 discusses the general nursing care of patients receiving chemotherapy.

Although gastric cancers are somewhat sensitive to the effects of radiation, the use of this treatment is limited because the disease is often widely spread to other abdominal organs on diagnosis. Organs such as the liver, kidneys, and spinal cord can endure only a limited amount of radiation. Intraoperative radiotherapy (IORT) is available in large tertiary care health care systems. Radiation may be used for palliative management when surgery is not an option.

The most common side effects of radiation include impaired skin integrity, fatigue, and anorexia. Nausea, vomiting, and diarrhea may occur about 1 week after treatment is initiated and diminish a month or more after treatment ends. (See Chapter 22 for more information on radiation therapy.)

### **Surgical Management.**

*Surgical resection by removing the tumor is the preferred method for treating gastric cancer.* The primary surgical procedures for the treatment of gastric cancer are total and subtotal (partial) gastrectomy. In early stages, laparoscopic surgery (minimally invasive surgery [MIS]) plus adjuvant chemotherapy or radiation may be curative. Patients having MIS have less pain, shorter hospital stays, rare postoperative complications, and quicker recovery. However, MIS is seldom performed because very few patients are diagnosed in the early stage of the disease.

Most patients with advanced disease are candidates for palliative surgical treatment. Metastasis in the supraclavicular lymph nodes, inguinal lymph nodes, liver, umbilicus, or perirectal wall indicates that the opportunity for cure by resection has been lost. Palliative resection may significantly improve the quality of life for a patient suffering from obstruction, hemorrhage, or pain.

### **Preoperative Care.**

Before conventional open-approach surgery, a nasogastric tube (NGT) is often inserted and connected to suction to remove secretions and empty the stomach. This allows surgery to take place without contamination of the peritoneal cavity by gastric secretions. The NGT remains in place for a

few days *after surgery* to prevent the accumulation of secretions, which may lead to vomiting or GI distention and pressure on the incision. Patients having laparoscopic surgery (minimally invasive surgery [MIS]) do not require an NGT.

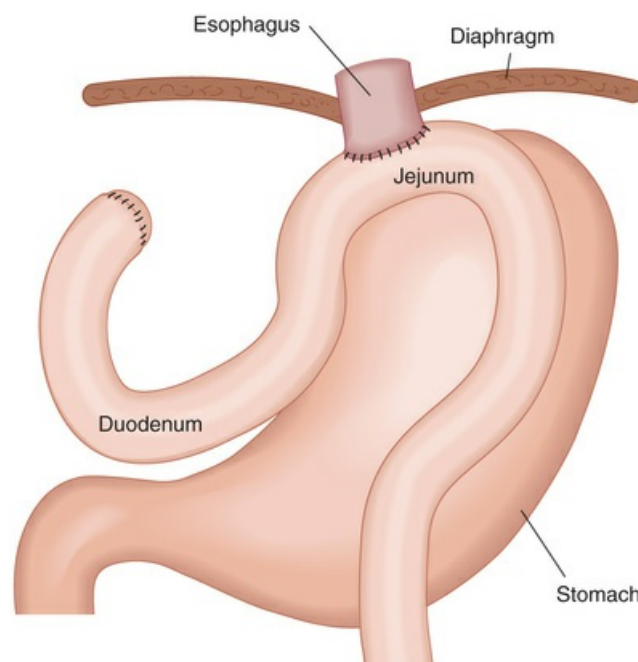

Because weight loss is problematic for patients with gastric cancer, NUTRITION therapy is a vital aspect of preoperative and postoperative management. Before surgery, compression by the tumor can prevent adequate nutritional intake. To correct malnutrition before surgery, the health care provider may prescribe enteral supplements to the diet and/or total parenteral nutrition (TPN). Vitamin, mineral, iron, and protein supplements are essential to correct nutritional deficits.

Other preoperative nursing measures for the patient undergoing open gastric surgery are the same as those for any patient undergoing abdominal surgery and general anesthesia (see [Chapter 14](#)).

### Operative Procedures.

The surgeon usually removes part or all of the stomach to take out the tumor. When the tumor is located in the mid-portion or distal (lower) portion of the stomach, a subtotal (partial) gastrectomy is typically performed. The omentum, spleen, and relevant nodes are also removed. The surgery may be performed as an MIS procedure or as an open conventional surgical technique, with or without robotic assistance.

For the patient with a removable growth in the proximal (upper) third of the stomach, a total gastrectomy is performed ([Fig. 55-4](#)). In this procedure the surgeon removes the entire stomach along with the lymph nodes and omentum. The surgeon sutures the esophagus to the duodenum or jejunum to reestablish continuity of the GI tract. More radical surgery involving removal of the spleen and distal pancreas is controversial, although the Whipple procedure may be used to prolong life. However, the complications of this drastic surgery are very serious and common. For patients with advanced disease, total gastrectomy is performed only when gastric bleeding or obstruction is present.

**FIG. 55-4** Total gastrectomy with anastomosis of the esophagus to the jejunum (esophagojejunostomy) is the principal surgical intervention for extensive gastric cancer.

Patients with tumors at the gastric outlet who are not candidates for subtotal or total gastrectomy may undergo gastroenterostomy for palliation. The surgeon creates a passage between the body of the stomach and the small bowel, often the duodenum.

### Postoperative Care.

Provide the usual postoperative care for patients who have had general anesthesia to prevent

atelectasis, paralytic ileus, wound infection, and peritonitis (see [Chapter 16](#)). Document and report any signs and symptoms of these complications immediately to the surgeon. Patients who have laparoscopic surgery usually have less postoperative pain, fewer complications, and a shorter stay in the hospital.

Auscultate the lungs for adventitious sounds (crackles or reduced breath sounds) and monitor for the return of bowel sounds. Take vital signs as appropriate to detect signs of infection or bleeding. Aggressive pulmonary exercises and early ambulation can help prevent respiratory complications and deep vein thrombosis. Also inspect the operative site every 8 to 12 hours for the presence of redness, swelling, or drainage, which indicate wound infection. Keep the head of the bed elevated to prevent aspiration from reflux.

Decreased patency caused by a clogged NGT can result in *acute gastric dilation* after surgery. This problem is characterized by epigastric pain and a feeling of fullness, hiccups, tachycardia, and hypotension. Notify the surgeon to obtain an order for irrigation or replacement of the NGT to relieve these symptoms.

**Dumping syndrome** is a term that refers to a group of vasomotor symptoms that occur after eating. This syndrome is believed to occur as a result of the rapid emptying of food contents into the small intestine, which shifts fluid into the gut, causing abdominal distention. Observe for *early* manifestations of this syndrome, which typically occur within 30 minutes of eating. Symptoms include vertigo, tachycardia, syncope, sweating, pallor, palpitations, and the desire to lie down. Report these manifestations to the surgeon, and encourage the patient to lie down. Monitor the patient for late symptoms.

*Late* dumping syndrome, which occurs 90 minutes to 3 hours after eating, is caused by a release of an excessive amount of insulin. The insulin release follows a rapid rise in the blood glucose level that results from the rapid entry of high-carbohydrate food into the jejunum. Observe for manifestations, including dizziness, light-headedness, palpitations, diaphoresis, and confusion.

Dumping syndrome is managed by nutrition changes that include decreasing the amount of food taken at one time and eliminating liquids ingested with meals. In collaboration with the dietitian, teach the patient to eat a high-protein, high-fat, low- to moderate-carbohydrate diet ([Table 55-3](#)). Acarbose may be used to decrease carbohydrate absorption. A somatostatin analog, octreotide (Sandostatin), 50 mcg subcutaneously two or three times daily 30 minutes before meals, may be prescribed in severe cases. This drug decreases gastric and intestinal hormone secretion and slows stomach and intestinal transit time.

**TABLE 55-3**  
**Diet for Dumping Syndrome**

FOOD GROUP	FOODS ALLOWED OR ENCOURAGED	FOODS TO USE WITH CAUTION	FOODS THAT MUST BE EXCLUDED
Soups		Fluids 1 hr before and after meals	Spicy soups
Meat and meat substitutes	8 oz or more per day: fish, poultry, beef, pork, veal, lamb, eggs, cheese, and peanut butter		Spicy meats or meat substitutes
Potatoes	Potato, rice, pasta, starchy vegetables (small amount)		Highly spiced potatoes or potato substitutes
Bread and cereal	White bread, rolls, muffins, crackers, and cereals (small amount)	Whole-grain bread, rolls, crackers, and cereals	Breads with frosting or jelly, sweet rolls, and coffee cake
Vegetables	Two or more cooked vegetables	Gas-producing vegetables, such as cabbage, onions, broccoli, or raw vegetables	
Fruits	Limit three per day: unsweetened cooked or canned fruits	Unsweetened juice or fruit drinks 30-45 min after meals; fresh fruit	Sweetened fruit or juice
Beverages	Dietetic drinks	Limit to 1 hr after meals; caffeine-containing beverages, such as coffee, tea, and cola; if tolerated, diet carbonated beverages	Milk shakes, malts, and other sweet drinks; regular carbonated beverages and alcohol
Fats	Margarine, oils, shortening, butter, bacon, and salad dressings	Mayonnaise	Any fats with milk products
Desserts	Fruit (see Fruits)	Sugar-free gelatin, pudding, and custard	All sweets, cakes, pies, cookies, candy, ice cream, and sherbet
Seasonings and miscellaneous	Diet jelly, diet syrups, sugar substitutes	Excessive amounts of salt	Excessive amounts of spices, sugar, jelly, honey, syrup, or molasses
<b>General Principles for Patients to Follow</b>			
<ul style="list-style-type: none"> <li>• Several small meals daily</li> <li>• Relatively high fat and protein content</li> <li>• Low roughage</li> <li>• Relatively low carbohydrate content</li> <li>• No milk, sweets, or sugars</li> <li>• Liquid between meals <i>only</i></li> </ul>			

**Alkaline reflux gastropathy**, also known as *bile reflux gastropathy*, is a complication of gastric surgery in which the pylorus is bypassed or removed. Endoscopic examination reveals regurgitated bile in the stomach and mucosal hyperemia. Symptoms include early satiety (satisfied quickly with little food), abdominal discomfort, and vomiting.

*Delayed gastric emptying* is often present after gastric surgery and usually resolves within 1 week. Edema at the anastomosis (surgical connection areas) or adhesions (scar tissue) obstructing the

distal loop may cause mechanical blockage. Metabolic causes (e.g., hypokalemia, hypoproteinemia, or hyponatremia) should be considered. The edema is resolved with nasogastric suction, maintenance of fluid and electrolyte balance, and proper nutrition.

Several problems related to NUTRITION develop as a result of partial removal of the stomach, including deficiencies of vitamin B<sub>12</sub>, folic acid, and iron; impaired calcium metabolism; and reduced absorption of calcium and vitamin D. These problems are caused by a reduction of intrinsic factor. The decrease results from the resection and from inadequate absorption because of rapid entry of food into the bowel. In the absence of intrinsic factor, signs and symptoms of pernicious anemia may occur. Assess for the development of atrophic glossitis secondary to vitamin B<sub>12</sub> deficiency. In atrophic glossitis, the tongue takes on a shiny, smooth, and “beefy” appearance. The patient may also have signs of anemia secondary to folic acid and iron deficiency. Monitor the complete blood count (CBC) for signs of megaloblastic anemia (low red blood cell [RBC] level) and leukopenia (low white blood cell [WBC] level). These manifestations are corrected by the administration of vitamin B<sub>12</sub>. The health care provider may also prescribe folic acid or iron preparations.

## NCLEX Examination Challenge 55-4

### Psychosocial Integrity

Which client statement regarding treatment for gastric cancer requires the nurse to intervene **immediately**?

- A. “I understand my treatment regimen.”
- B. “My prognosis is frightening to me and my partner.”
- C. “Life just doesn't seem to be worth living anymore.”
- D. “There is a list of community resources stored in my computer for when I need them.”

### Care Coordination and Transition Management

Patients who have undergone total gastrectomy and those who are debilitated with advanced gastric cancer are discharged to home with maximal assistance and support or to a transitional care unit or skilled nursing facility. Patients who have undergone subtotal gastrectomy and are not debilitated may be discharged to home with partial assistance for ADLs. Recurrence of cancer is common, and patients need regular follow-up examinations and imaging assessments. Collaborate with the case manager (CM) to ensure continuity of care and thorough follow-up with diagnostic testing.

### Home Care Management.

Gastric cancer is a life-threatening illness. Therefore the patient and family members require physical and emotional care. Assess their ability to cope with the disease and the possible need for end-of-life care. The adverse effects of gastric cancer treatment can be debilitating, and patients need to learn symptom-management strategies. Hospice programs can help both the patient and the family cope with these physical and emotional needs.

Patients may fear returning home because of their inability for self-management. Enlisting family and health care resources for the patient may ease some of this anxiety. Provide the family with adequate information about community support systems to make the transition to home care easier. If the prognosis is poor, they need continued professional support from case managers, social workers, and/or nurses to cope with death and dying. (See [Chapter 7](#) for a discussion of end-of-life care.)

### Self-Management Education.

Educate the patient and family about any continuing needs, drug therapy, and nutrition therapy. If patients are discharged to home with surgical dressings, teach the patient and family how to change

them. Review the manifestations of incisional infection (e.g., fever, redness, and drainage) that they should report to their surgeon.

Patients who will be receiving radiation therapy or chemotherapy require instructions related to the side effects of these treatments. Nausea and vomiting are common side effects of chemotherapy, and instruction in the use of prescribed antiemetics may be needed. (See [Chapter 22](#) for health teaching for patients receiving chemotherapy or radiation therapy.)

In collaboration with the dietitian, teach the patient and family about the type and quantity of foods that will provide optimal nutritional value. Interventions to minimize dumping syndrome and decrease gastric stimulants are also emphasized (see [Table 55-3](#)). Remind the patient to:

- Eat small, frequent meals
- Avoid drinking liquids with meals
- Avoid foods that cause discomfort
- Eliminate caffeine and alcohol consumption
- Begin a smoking-cessation program, if needed
- Receive B<sub>12</sub> injections, as prescribed
- Lie flat after eating for a short time

### **Health Care Resources.**

A home care referral provides continued assessment, assistance, and encouragement to the patient and family. A home care nurse can help with care procedures and provide valuable psychological support. Additional referrals to a dietitian, professional counselor, or clergy/spiritual leader may be necessary. Referral to a hospice agency can be of great assistance for the patient with advanced disease. Hospice care may be delivered in the home or in an institutional setting. Appropriate support groups (e.g., I Can Cope, provided by the American Cancer Society [<http://www.cancer.org/treatment/index>]) can be a major resource.

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- When caring for patients with gastric health problems, collaborate with the members of the interprofessional team, including the pharmacist, dietitian, health care provider, and/or case manager. **QSEN: Teamwork and Collaboration**

### Health Promotion and Maintenance

- Refer the patient with gastric cancer to the American Cancer Society.
- Identify patients at risk for gastritis and PUD, especially those with *H. pylori* and older adults who take large amounts of NSAIDs. **QSEN: Safety**
- Teach adults to prevent PUD by avoiding excess consumption of caffeine, alcohol, coffee, aspirin, NSAIDs, and contaminated food and water and by avoiding smoking (see [Chart 55-1](#)). **QSEN: Evidence-Based Practice**
- Teach patients the importance of adhering to *H. pylori* treatment to prevent development of gastric cancer. **QSEN: Evidence-Based Practice**

### Psychosocial Integrity

- Allow patients with gastric cancer to express feelings of grief, fear, and anxiety. **QSEN: Patient-Centered Care**
- For patients with advanced gastric cancer, identify end-of-life care needs, including referral to hospice care. **Ethics**

### Physiological Integrity

- Recall that *acute* gastritis causes a rapid onset of epigastric pain and dyspepsia; *chronic* gastritis causes vague epigastric pain (usually relieved with food) and intolerance to fatty and spicy foods (see [Chart 55-2](#)).
- Remember that patients with gastric ulcers may be malnourished and have pain that is worsened by ingestion of food; patients with duodenal ulcers are usually well nourished, have pain that is relieved by ingestion of food, and awakened with pain during the night (see [Table 55-2](#)).
- For patients who have undergone a gastrectomy, collaborate with the dietitian and instruct the patient regarding diet changes to avoid abdominal distention and dumping syndrome. **QSEN: Teamwork and Collaboration**
- Teach patients with abnormal abdominal symptoms to consult with their health care provider immediately. **QSEN: Safety**
- Teach that hematemesis is a medical emergency and refer to the emergency department for prompt treatment. **QSEN: Safety**
- Teach the proper administration of antacids (one or two after meals), reminding patients that antacids can interfere with the effectiveness of certain drugs, such as phenytoin (Dilantin). **QSEN: Evidence-Based Practice**
- Teach the proper administration of H<sub>2</sub> antagonists and explain that they should be taken at bedtime (see [Chart 55-3](#)). **QSEN: Evidence-Based Practice**
- Teach the proper administration of antisecretory agents, noting that most cannot be crushed because they are sustained-release or enteric-coated tablets. **QSEN: Evidence-Based Practice**
- Monitor patients with ulcers for signs and symptoms of upper GI bleeding that are listed in [Chart](#)

55-4. Report any of these symptoms to the health care provider immediately. **QSEN: Safety**

- After an EGD, monitor vital signs, heart rhythm, and oxygen saturation frequently until they return to baseline. To prevent aspiration, assess the gag reflex and ensure that it is intact before giving the patient food or fluids. **QSEN: Safety**
- Observe for signs and symptoms of dumping syndrome after gastric surgery; teach characteristics and management of this syndrome. **QSEN: Evidence-Based Practice**

## CHAPTER 56

# Care of Patients With Noninflammatory Intestinal Disorders

Keelin Cromar

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concepts for this chapter are:**

- ELIMINATION
- CELLULAR REGULATION

✚ The ELIMINATION concept exemplar for this chapter is Intestinal Obstruction, below.

✚ The CELLULAR REGULATION concept exemplar for this chapter is Colorectal Cancer, p. 1126.

**The interrelated concepts for this chapter are:**

- NUTRITION
- COMFORT
- FLUID AND ELECTROLYTE BALANCE

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to protect the patient with a noninflammatory intestinal disorder from injury and infection.
2. Identify community resources to ensure appropriate transition management for patients with a noninflammatory intestinal disorder.

### Health Promotion and Maintenance

3. Teach adults health promotion practices to prevent noninflammatory intestinal disorders.
4. Teach patients with a colostomy about self-management.

### Psychosocial Integrity

5. Implement nursing interventions to minimize stressors for the patient with a noninflammatory intestinal disorder.

### Physiological Integrity

6. Apply knowledge of anatomy, physiology, pathophysiology, genetic risk, age-related changes, and psychomotor skills to perform a focused assessment of the gastrointestinal system.
  7. Prioritize care for patients with colorectal cancer (CRC).
  8. Describe interprofessional care and educational needs to promote NUTRITION and COMFORT for the patient with a noninflammatory intestinal disorder.
  9. Differentiate between assessment findings associated with small-bowel and large-bowel obstructions.
0. Develop an evidence-based plan of care for the patient undergoing an intestinal surgical procedure.

If not diagnosed and managed early, certain intestinal problems can lead to inadequate absorption

of vital nutrients and affect the need for NUTRITION and ELIMINATION. If these disorders become severe or progress, COMFORT and/or CELLULAR REGULATION alterations and problems with FLUID AND ELECTROLYTE BALANCE may occur. Intestinal health problems are classified as inflammatory or noninflammatory; this chapter focuses on disorders that are noninflammatory in origin.

## Elimination Concept Exemplar Intestinal Obstruction

### Pathophysiology

Intestinal obstructions can be partial or complete and are classified as mechanical or nonmechanical. With either condition, ELIMINATION is compromised by this common and serious disorder.

### Types of Intestinal Obstructions

In **mechanical obstruction**, the bowel is physically blocked by problems outside the intestine (e.g., adhesions), in the bowel wall (e.g., Crohn's disease), or in the intestinal lumen (e.g., tumors).

**Nonmechanical obstruction** (also known as **paralytic ileus** or *adynamic ileus*) does not involve a physical obstruction in or outside the intestine. Instead, peristalsis is decreased or absent as a result of neuromuscular disturbance, resulting in a slowing of the movement or a backup of intestinal contents (McCance et al., 2014).

Intestinal contents are composed of ingested fluid, food, and saliva; gastric, pancreatic, and biliary secretions; and swallowed air. In both mechanical and nonmechanical obstructions, the intestinal contents accumulate at and above the area of obstruction. Distention results from the intestine's inability to absorb the contents and move them down the intestinal tract. To compensate for the lag, peristalsis increases in an effort to move the intestinal contents forward. This increase stimulates more secretions, which then leads to additional distention. The bowel then becomes edematous, and increased capillary permeability results. Plasma leaking into the peritoneal cavity and fluid trapped in the intestinal lumen decrease the absorption of fluid and electrolytes into the vascular space. Reduced circulatory blood volume (hypovolemia) and electrolyte imbalances typically occur. Hypovolemia ranges from mild to extreme (hypovolemic shock).

### Complications of Intestinal Obstruction

Specific problems related to FLUID AND ELECTROLYTE BALANCE and acid-base balance result, depending on the part of the intestine that is blocked. An obstruction high in the small intestine causes a loss of gastric hydrochloride, which can lead to *metabolic alkalosis*. Obstruction below the duodenum but above the large bowel results in a loss of both acids and bases so that acid-base balance is usually not compromised. Obstruction at the end of the small intestine and lower in the intestinal tract causes loss of alkaline fluids, which can lead to *metabolic acidosis* (McCance et al., 2014).

If hypovolemia is severe, acute kidney injury or even death can occur. Bacterial peritonitis with or without actual perforation can also result. Bacteria in the intestinal contents lie stagnant in the obstructed intestine. This is not a problem unless the blood flow to the intestine is compromised. However, with *closed-loop obstruction* (blockage in two different areas) or a **strangulated obstruction** (obstruction with compromised blood flow), the risk for peritonitis is greatly increased. Bacteria without blood supply can form and release an endotoxin into the peritoneal or systemic circulation and cause septic shock. With a strangulated obstruction, major blood loss into the intestine and the peritoneum can occur. Sepsis and bleeding can result in an increased intra-abdominal pressure (IAP) or acute compartment syndrome.

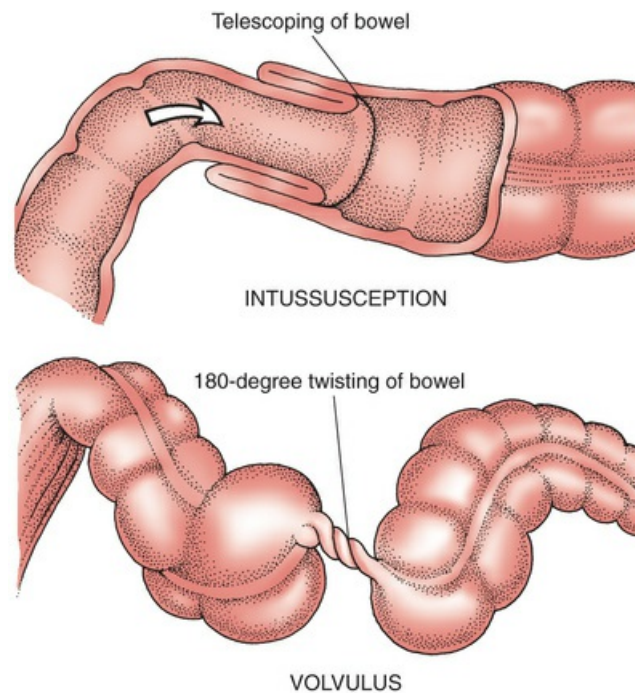

### Etiology

Intestinal obstruction is caused by a variety of conditions and associated with significant morbidity. It can occur anywhere in the intestinal tract, although the ileum in the small intestine (the narrowest part of the intestinal tract) is the most common site.

*Mechanical* obstruction can result from:

- Adhesions (scar tissue from surgeries or pathology)
- Benign or malignant tumor
- Complications of appendicitis
- Hernias
- Fecal impactions (especially in older adults)
- Strictures due to Crohn's disease (an inflammatory condition) or previous radiation therapy

- **Intussusception** (telescoping of a segment of the intestine within itself) (Fig. 56-1)

**FIG. 56-1** Two major types of mechanical obstruction.

- **Volvulus** (twisting of the intestine) (see Fig. 56-1)
- Fibrosis due to disorders such as endometriosis
- Vascular disorders (e.g., emboli and arteriosclerotic narrowing of mesenteric vessels)

In people ages 65 years or older, diverticulitis, tumors, and fecal impaction are the most common causes of obstruction (McCance et al., 2014).

Postoperative ileus (POI) (paralytic ileus), or *nonmechanical* obstruction, is most commonly caused by handling of the intestines during abdominal surgery. In patients with POI, intestinal function is lost for a few hours to several days. Electrolyte disturbances, especially hypokalemia, predispose the patient to this problem. The ileus can also be a consequence of **peritonitis** because leakage of colonic contents causes severe irritation and triggers an inflammatory response and infection (see discussion of the Concept Exemplar of peritonitis in Chapter 57). Vascular insufficiency to the bowel, also referred to as *intestinal ischemia*, is another potential cause of an ileus. It results when arterial or venous thrombosis or an embolus decreases blood flow to the mesenteric blood vessels surrounding the intestines, as in heart failure or severe shock. Severe insufficiency of blood supply can result in infarction of surrounding organs (e.g., bowel infarction).

## ❖ Interprofessional Collaborative Care

Care for the patient with an intestinal obstruction takes place in the hospital setting. The interprofessional team that collaborates to care for this patient generally includes the surgeon, nurse, and dietitian.

### ◆ Assessment: Noticing

#### History.

Collect information about a history of GI disorders, surgeries, and treatments. Question the patient about recent nausea and vomiting and the color of emesis, noting if vomitus is described as green, bilious, or hematemesis. Perform a thorough pain assessment with particular attention to the onset, aggravating factors, alleviating factors, and patterns or rhythms of the pain. Severe pain that then stops and changes to tenderness on palpation may indicate perforation and should be reported

promptly to the physician. Ask about the passage of flatus and the time, character, and consistency of the last bowel movement. Singultus (hiccups) is common with all types of intestinal obstruction. When an obstruction is suspected, keep the patient NPO and contact the physician promptly for further direction.

Assess for a family history of colorectal cancer (CRC) and ask about blood in the stool or a change in bowel pattern. Body temperature with uncomplicated obstruction is rarely higher than 100° F (37.8° C). A temperature higher than this, with or without guarding and tenderness, and a sustained elevation in pulse could indicate a strangulated obstruction or peritonitis. A fever, tachycardia, hypotension, increasing abdominal pain, abdominal rigidity, or change in color of skin overlying the abdomen should be reported to the health care provider immediately.

### Physical Assessment/Signs and Symptoms.

The patient with *mechanical* obstruction in the *small intestine* often has mid-abdominal pain or cramping. The pain can be sporadic, and the patient may feel comfortable between episodes. If strangulation is present, the pain becomes more localized and steady. Vomiting often accompanies obstruction and is more profuse with obstructions in the proximal small intestine. The vomitus may contain bile and mucus or be orange-brown and foul smelling as a result of bacterial overgrowth with low ileal obstruction. Prolonged vomiting can result in a disruption in FLUID AND ELECTROLYTE BALANCE. **Obstipation** (no passage of stool) and failure to pass flatus are signs of ELIMINATION concerns associated with complete obstruction; diarrhea may be present in partial obstruction.

*Mechanical colonic obstruction* causes a milder, more intermittent colicky abdominal pain than is seen with small-bowel obstruction. Lower abdominal distention and obstipation may be present, or the patient may have ribbonlike stools if obstruction is partial. ELIMINATION alterations in bowel patterns and blood in the stools may accompany the obstruction if colorectal cancer or diverticulitis is the cause.

On examination of the abdomen, observe for abdominal distention, which is common in all forms of intestinal obstruction. Peristaltic waves may also be visible. Auscultate for proximal high-pitched bowel sounds (**borborygmi**), which are associated with cramping early in the obstructive process as the intestine tries to push the mechanical obstruction forward. In later stages of mechanical obstruction, bowel sounds are absent, especially distal to the obstruction. Abdominal tenderness and rigidity are usually minimal. The presence of a tense, fluid-filled bowel loop mimicking a palpable abdominal mass may signal a closed-loop, strangulating small-bowel obstruction.

In most types of *nonmechanical* obstruction, the pain is described as a constant, diffuse discomfort. Colicky cramping is not characteristic of this type of obstruction. Pain associated with obstruction caused by vascular insufficiency or infarction is usually severe and constant. On inspection, abdominal distention is typically present. On auscultation of the abdomen, note and document decreased bowel sounds in early obstruction and absent bowel sounds in later stages. Vomiting of gastric contents and bile is frequent, but the vomitus rarely has a foul odor and is rarely profuse. Obstipation may or may not be present. [Chart 56-1](#) compares small- and large-bowel obstructions.

#### Chart 56-1

### Key Features

#### Small-Bowel and Large-Bowel Obstructions

SMALL-BOWEL OBSTRUCTIONS	LARGE-BOWEL OBSTRUCTIONS
Abdominal discomfort or pain possibly accompanied by visible peristaltic waves in upper and middle abdomen	Intermittent lower abdominal cramping
Upper or epigastric abdominal distention	Lower abdominal distention
Nausea and early, profuse vomiting (may contain fecal material)	Minimal or no vomiting
Obstipation	Obstipation or ribbonlike stools
Severe fluid and electrolyte imbalances	No major fluid and electrolyte imbalances
Metabolic alkalosis	Metabolic acidosis (not always present)

### Diagnostic Assessment.

There is no definitive laboratory test to confirm a diagnosis of mechanical or nonmechanical obstruction. *White blood cell (WBC) counts* are normal unless there is a strangulated obstruction, in which case there may be leukocytosis (increased WBCs). *Hemoglobin, hematocrit, creatinine, and blood urea nitrogen (BUN)* values are often elevated, indicating dehydration. Serum sodium, chloride, and

potassium are decreased. Elevations in serum amylase levels may be found with strangulating obstructions, which can damage the pancreas.

The health care provider obtains imaging information in the form of an *abdominal CT scan* or MRI as soon as an obstruction is suspected. Distention with fluid and gas in the small intestine with the absence of gas in the colon indicates an obstruction in the small intestine.

The diagnostic examination chosen depends on the suspected location of the obstruction. As an initial assessment, the health care provider may order an *abdominal ultrasound* to evaluate the potential cause of the obstruction. The health care provider may perform endoscopy (sigmoidoscopy or colonoscopy) to determine the cause of the obstruction, except when perforation or complete obstruction is suspected.

### ◆**Analysis: Interpreting**

The priority collaborative problems for patients with intestinal obstruction include:

1. Potential for injury (e.g., peritonitis, acute kidney injury) due to obstruction
2. Acute pain due to obstruction

### ◆**Planning and Implementation: Responding**

Interventions are aimed at uncovering the cause and relieving the obstruction. Relieving the obstruction simultaneously decreases the potential for injury and reduces pain. Intestinal obstructions can be relieved by nonsurgical or surgical means. If the obstruction is partial and there is no evidence of strangulation, nonsurgical management may be the treatment of choice ([Chart 56-2](#)). Once the obstruction has been addressed effectively, expected ELIMINATION patterns should resume.

## 📊**Chart 56-2**

### **Best Practice for Patient Safety & Quality Care** QSEN

#### **Nursing Care of Patients Who Have an Intestinal Obstruction**

- Monitor vital signs, especially blood pressure, for indications of fluid balance.
- Assess the patient's abdomen at least twice a day for bowel sounds, distention, and passage of flatus.
- Monitor fluid and electrolyte status, including laboratory values.
- Manage the patient who has a nasogastric tube (NGT):
  - Monitor drainage.
  - Ensure tube patency.
  - Check tube placement.
  - Irrigate tube as prescribed.
- Maintain the patient on NPO status.
- Provide frequent mouth and nares care.

- Maintain the patient in a semi-Fowler's position.
- Give analgesics for pain as prescribed.
- Give alvimopan (Entereg) as prescribed for patients with a postoperative ileus.
- Maintain parenteral NUTRITION if prescribed.

## Reducing Potential for Injury and Reducing Pain

### Nonsurgical Management.

Paralytic ileus responds well to nonsurgical methods of relieving obstruction. Nonsurgical approaches are also preferred in the treatment of patients with terminal disease associated with bowel obstruction. In addition to being NPO, patients typically have a nasogastric tube (NGT) inserted to decompress the bowel by draining fluid and air. The tube is attached to suction.

### Nasogastric Tubes.

Most patients with an obstruction have an NGT unless the obstruction is mild. A **Salem sump tube** is inserted through the nose and placed into the stomach. It is attached to low continuous suction. This tube has a vent (“pigtail”) that prevents the stomach mucosa from being pulled away during suctioning. Levin tubes do not have a vent and therefore should only be connected to low intermittent suction. They are used much less often than the Salem sump tubes.

## Nursing Safety Priority QSEN

### Action Alert

At least every 4 hours, assess the patient with an NGT for proper placement of the tube, tube patency, and output (quality and quantity). Monitor the nasal skin around the tube for irritation. Use a device that secures the tube to the nose to prevent accidental removal. Assess for peristalsis by auscultating for bowel sounds with the suction disconnected (suction masks peristaltic sounds).

Ask the patient about the passage of flatus and record flatus and the character of bowel movements daily. Flatus or stool means that peristalsis has returned. Assess for nausea and ask the patient to report this symptom if he or she begins to experience it.

Monitor any NGT for proper functioning. Occasionally NGTs move out of optimal drainage position or become plugged. In this case, note a decrease in gastric output or stasis of the tube's contents. Assess the patient for nausea, vomiting, increased abdominal distention, and placement of the tube. If the NGT is repositioned or replaced, confirmation of proper placement may be obtained by x-ray before use. After appropriate placement is established, aspirate the contents and irrigate the tube with 30 mL of normal saline every 4 hours or as requested by the health care provider.

### Other Nonsurgical Interventions.

Most types of nonmechanical obstruction respond to nasogastric decompression with medical treatment of the primary disorder. Incomplete mechanical obstruction can sometimes be treated successfully without surgery. Obstruction caused by lower fecal impaction usually resolves after disimpaction and enema administration. Intussusception may respond to hydrostatic pressure changes during a barium enema.

For patients with a postoperative ileus (POI), alvimopan (Entereg) may be given for short-term use. This drug is an oral, peripherally acting mu opioid receptor antagonist that increases GI motility (Bragg et al., 2015).

*IV fluid replacement and maintenance* are indicated for all patients with intestinal obstruction because the patient is NPO and FLUID AND ELECTROLYTE BALANCE is lost (particularly potassium) through vomiting and nasogastric suction. On the basis of serum electrolytes and blood urea nitrogen (BUN) levels, the health care provider prescribes aggressive fluid replacement with 2 to 4 L of an isotonic solution (normal saline or lactated Ringer's solution) with potassium added. Use

care with patients who are susceptible to fluid overload (e.g., older adults with a history of heart or kidney failure). Monitor lung sounds, weight, and intake and output daily. Weight is the most reliable indicator of fluid balance. Blood replacement may be indicated in strangulated obstruction because of blood loss into the bowel or peritoneal cavity.

Monitor vital signs and other measures of fluid status (e.g., urine output, skin turgor, mucous membranes) every 2 to 4 hours, depending on the severity of the patient's symptoms. In collaboration with the dietitian, the health care provider may prescribe parenteral NUTRITION (PN), especially if the patient has had chronic nutritional problems and has been NPO for an extended period. [Chapter 60](#) discusses the nursing care of patients receiving PN.

The patient with intestinal obstruction is usually thirsty, although some older adults have a decreased thirst response. Delegate frequent mouth care to unlicensed assistive personnel (UAP) to help maintain moist mucous membranes. Be sure to supervise this activity. A few ice chips may be allowed if the patient is not having surgery. Follow agency protocol or the health care provider's request regarding ice chips.

Abdominal distention can cause a great deal of pain, especially when it is severe. The colicky, crampy pain that comes and goes with mechanical obstruction, as well as the nausea, vomiting, dry mucous membranes, and thirst contribute to the patient's alteration in COMFORT. Continually assess the character and location of the pain and immediately report any pain that significantly increases or changes from colicky and intermittent to a constant discomfort. These changes can indicate perforation of the intestine or peritonitis.

Opioid analgesics may be temporarily withheld in the diagnostic workup period so signs and symptoms of perforation or peritonitis are not masked. Explain to the patient and family the rationale for not giving analgesics. In addition, if analgesics such as morphine are given, they may slow intestinal motility and can cause vomiting. Be alert to this side effect because nausea and vomiting are also signs of NGT obstruction or worsening bowel obstruction. Consider the importance of nonpharmacologic pain control measures when withdrawing this type of medication.

Help the patient obtain a position of COMFORT with frequent position changes to promote increased peristalsis. A semi-Fowler's position helps alleviate the pressure of abdominal distention on the chest and promotes thoracic excursion to facilitate breathing.

Discomfort is generally lesser with nonmechanical obstruction than with mechanical obstruction. With both types of obstruction, COMFORT alterations are aggravated by taking in food or fluids.

If strangulation is thought to be likely, the health care provider prescribes IV broad-spectrum antibiotics. In addition, in cases of partial obstruction or paralytic ileus, drugs that enhance gastric motility such as octreotide acetate (Sandostatin) may be used.

### **Surgical Management.**

In patients with complete mechanical obstruction and in some cases of incomplete mechanical obstruction, surgical intervention is necessary to relieve the obstruction. A strangulated obstruction is complete, and surgical intervention is always required. An **exploratory laparotomy** (a surgical opening of the abdominal cavity to investigate the cause of the obstruction) is initially performed for many patients with obstruction. More specific surgical procedures depend on the cause of the obstruction.

### **Preoperative Care.**

Provide general preoperative teaching for both the patient and family as discussed in [Chapter 14](#). In cases of complete obstruction, the patient may feel too ill to absorb and understand the information. In this case, reinforce the information with the family or other caregiver. Depending on the cause and severity of the obstruction and the expertise of the surgeon, patients have either minimally invasive surgery (MIS) via laparoscopy or a conventional open approach.

### **Operative Procedures.**

In the *conventional open surgical approach*, the surgeon makes a large incision, enters the abdominal cavity, and explores for obstruction and its cause, if possible (exploratory laparotomy). If adhesions are found, they are lysed (cut and released). Obstruction caused by a tumor or diverticulitis requires a colon resection with primary anastomosis or a temporary or permanent colostomy. If obstruction is caused by intestinal infarction, an embolectomy, thrombectomy, or resection of the gangrenous small or large bowel may be necessary. In severe cases a colectomy (removal of the entire colon)

may be needed.

For the *MIS* approach, the specially trained surgeon makes several small incisions in the abdomen and places a video camera to view the abdominal contents to determine the extent of the obstruction. A laparoscope (type of endoscope) with a lighted end is inserted along with various surgical instruments to address and remove the problem. This procedure takes longer than the open approach, but blood loss is less, and healing is faster. Robotic assistance may be used, depending on the experience of the surgeon and available equipment.

### Postoperative Care.

General postoperative care for the patient undergoing an *exploratory laparotomy* with lysis of adhesions, colon resection, thrombectomy, or embolectomy is similar to that described in [Chapter 16](#). In addition, patients who had an open surgical approach have an NGT in place until peristalsis resumes. A clear liquid diet may be prescribed to encourage peristalsis return. As liquids are started, the NGT can be disconnected from suction and capped for 1 to 2 hours after the patient has taken clear liquids to determine if he or she is able to tolerate them. If the patient vomits after liquids, the suction is resumed. When the patient has return of peristalsis, the NGT suction is discontinued, and the tube is clamped for a scheduled amount of time. If the patient does not experience nausea while the NGT is clamped, the tube is removed.

Most patients today have laparoscopic surgery (*MIS*) for mechanical intestinal obstructions. They usually do *not* have an NGT and can recover more quickly than those with the open surgical approach. The hospital stay for a patient having *MIS* to remove tumors, adhesions, and other obstructions may be as short as 1 to 2 days compared with 3 days or longer for the conventional surgical patients. Recovery is much quicker because there is less pain and there are fewer postoperative complications among those who had laparoscopic surgery.

## Clinical Judgment Challenge 56-1

### Patient-Centered Care; Teamwork and Collaboration; Informatics USEN

You receive a 40-year-old woman on your medical-surgical unit after being admitted from the emergency department for a bowel obstruction. When the patient arrives, she has a Salem sump nasogastric tube (NGT) in place that is currently clamped. She also has IV normal saline running at 125 mL/hr. The patient's vital signs are stable, except for her blood pressure, which remains low at 90/45. She reports a pain score of 8/10 in her lower abdomen. The patient currently does not have orders related to her NGT.

1. After the patient arrives, what are your primary assessments?
2. What nursing intervention is appropriate related to the patient's incomplete NGT orders?
3. Using SBAR, how will you communicate the information about this patient to the health care provider?
4. What immediate evidence-based collaborative interventions are appropriate for this patient?
5. What information will you document in the electronic health record?

### Care Coordination and Transition Management

All patients with intestinal obstruction are hospitalized for monitoring and treatment. The length of stay varies according to the type of obstruction, the treatment, and the presence of complications. Patients who have complicated obstruction, such as strangulation or incarceration, are at greater risk for peritonitis, sepsis, and shock.

Patients with nonmechanical (adynamic) intestinal obstruction are less likely to require a lengthy hospitalization because of the obstruction alone. Nonmechanical obstruction generally responds to nasogastric suction and possible drug therapy within a few days. However, if the ileus occurs as a complication of an abdominal surgery, the hospital stay could be lengthy.

## Home Care Management.

Preparation for home care depends on the cause of the obstruction and the treatment required. Those who have resolution of obstruction without surgical intervention are assessed for their knowledge of strategies to avoid recurrent obstruction. For example, if fecal impaction was the cause of the obstruction, assess the patient's ability to carry out a bowel regimen independently (Chart 56-3). For those who have had surgery, evaluate their ability to function at home with the added tasks of incision care and possibly colostomy care.

### Chart 56-3

## Nursing Focus on the Older Adult

### Preventing Fecal Impaction

- Teach the patient to eat high-fiber foods, including plenty of raw fruits and vegetables and whole-grain products.
- Encourage the patient to drink adequate amounts of fluids, especially water.
- Do not routinely administer a laxative; teach the patient that laxative abuse decreases abdominal muscle tone and contributes to an atonic colon.
- Encourage the patient to exercise regularly, if possible. Walking every day is an excellent exercise for promoting intestinal motility.
- Use natural foods to stimulate peristalsis, such as warm beverages and prune juice.
- Take bulk-forming products, such as Metamucil, to provide fiber.
- Check the patient's stool for amount and frequency; oozing of soft or diarrheal stool often indicates a fecal impaction.
- Have the patient sit on a toilet or bedside commode rather than on a bedpan for ELIMINATION.

### Self-Management Education.

Instruct the patient to report any abdominal pain or distention, nausea, or vomiting, with or without constipation, because these symptoms might indicate recurrent obstruction. However, the patient should be reassured that recurrent paralytic ileus is not common.

Teach the patient who has had surgery about incision care, drug therapy, and activity limitations. Drug therapy consists of an oral opioid analgesic, such as oxycodone hydrochloride with acetaminophen (Percocet), to be taken as needed for incisional discomfort. As with any opioid therapy, an over-the-counter laxative with a softener (e.g., docusate with senna) or polyethylene glycol (MiraLax) may be added to prevent constipation and possible recurrent obstruction.

The patient who had curative treatment of the underlying cause most likely requires less support than one who had treatment of obstruction related to a serious disease that will require further management. Encourage the patient to express fears and concerns about the future. Assess the patient's understanding and needs with regard to treatment plans.

### Health Care Resources.

The need for follow-up appointments depends on the cause of the obstruction and the treatment required. In collaboration with the case manager, make arrangements for a home care nurse if the patient needs help with incision or colostomy care.

### ◆Evaluation: Reflecting

Evaluate the care of the patient with intestinal obstruction based on the identified priority patient problems. The expected outcomes are that the patient will have relief of the obstruction and no evidence of injury (e.g., development of peritonitis or acute kidney injury) and report that pain is

controlled.

## Polyps

### ❖ Pathophysiology

**Polyps** in the intestinal tract are small growths covered with mucosa and attached to the surface of the intestine. Although most are benign, they are significant because some have the potential to become malignant.

Polyps can be classified as an adenomatous, malignant, or hyperplastic. Hyperplastic polyps have little chance of becoming cancerous; whereas adenomas have the potential to become malignant. A very small number of adenomas progress to cancer; almost all colorectal cancers develop from an adenoma. Adenomas are further classified as villous or tubular. Of these, villous adenomas pose a greater cancer risk. Malignant polyps are those that contain cancerous cells when they are discovered.

Familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC) are inherited syndromes characterized by progressive development of colorectal adenomas. Unless these syndromes are treated, colorectal cancer (CRC) inevitably occurs by the fourth to fifth decade of life. These conditions are discussed in the Genetic/Genomic Considerations feature in the Colorectal Cancer section.

### ❖ Interprofessional Collaborative Care

Polyps are usually asymptomatic and are discovered during routine colonoscopy screening. However, they can cause gross rectal bleeding, intestinal obstruction, or intussusception (telescoping of the bowel). Biopsy specimens of polyps can be obtained, and the entire polyp can be removed (polypectomy) during this procedure with the use of a snare that fits through the sigmoidoscope or colonoscope. This often eliminates the need for abdominal surgery to remove a suspicious or definitely malignant polyp. The patient with FAP often requires a total colectomy (colon removal) to prevent the development of cancer (see the [Genetic/Genomic Considerations](#) box).

## ❖ NCLEX Examination Challenge 56-1

### Psychosocial Integrity

A client with rectal bleeding who is preparing to undergo a colonoscopy tells the nurse, "I'm very afraid of having polyps and cancer." What is the appropriate nursing response?

- A. "Let's worry about that after the procedure."
- B. "Polyps are never cancerous, so you don't need to worry."
- C. "Unfortunately all polyps are malignant, so you may already have cancer."
- D. "It's understandable that you are fearful. Tell me what frightens you most."

Nursing care focuses on patient education. Instruct the patient about:

- The nature of the polyp
- Signs and symptoms to report to the health care provider
- The need for regular, routine monitoring or screening

If the patient has had a polypectomy, follow-up sigmoidoscopic or colonoscopic examinations are needed because of an increased risk for developing multiple polyps.

Nursing care of the patient after a polypectomy of the colorectal area includes monitoring for abdominal distention and pain, rectal bleeding, mucopurulent drainage from the rectum, and fever. A small amount of blood might appear in the stool after a polypectomy, but this should be temporary.

## Cellular Regulation Concept Exemplar Colorectal Cancer

### Pathophysiology

*Colorectal* refers to the colon and rectum, which together make up the large intestine, also known as the *large bowel*. Colorectal cancer (CRC) is cancer of the colon or rectum. This CELLULAR REGULATION concern (see Chapter 2) is a major health problem worldwide. In the United States, it is one of the most common malignancies. Patients often consider a diagnosis of cancer as a “death sentence,” but colon cancer is highly curable for many patients, especially if caught early.

Tumors occur in different areas of the colon, with about two thirds occurring within the rectosigmoid region as shown in Fig. 56-2. Most CRCs are **adenocarcinomas**, which are tumors that arise from the glandular epithelial tissue of the colon. Abnormal CELLULAR REGULATION develops as a multi-step process affecting immunity, resulting in a number of molecular changes. These changes include loss of key tumor suppressor genes and activation of certain oncogenes that alter colonic mucosa cell division. The increased proliferation of the colonic mucosa forms polyps that can transform into malignant tumors. Most CRCs are believed to arise from adenomatous polyps that present as visible protrusions from the mucosal surface of the bowel (McCance et al., 2014).

FIG. 56-2 Incidence of cancer in relation to colorectal anatomy.

CRC can metastasize by direct extension or by spreading through the blood or lymph. The tumor may spread locally into the four layers of the bowel wall and into neighboring organs. It may enlarge into the lumen of the bowel or spread through the lymphatics or the circulatory system. CRC enters the circulatory system directly from the primary tumor through blood vessels in the bowel or via the lymphatic system. The liver is the most common site of metastasis from circulatory spread. Metastasis to the lungs, brain, bones, and adrenal glands may also occur. Colon tumors can also spread by peritoneal seeding during surgical resection of the tumor. Seeding may occur when a tumor is excised and cancer cells break off from the tumor into the peritoneal cavity. For this reason, special techniques are used during surgery to decrease this possibility.

Complications related to the abnormal CELLULAR REGULATION in the increasing growth of the tumor locally or through metastatic spread include bowel obstruction or perforation with resultant peritonitis, abscess formation, and fistula formation to the urinary bladder or the vagina. The tumor may invade neighboring blood vessels and cause frank bleeding. Gradual obstruction of the intestine can occur when tumors grow; these tumors can eventually block it completely. Tumors

extending beyond the bowel wall may place pressure on neighboring organs (uterus, urinary bladder, and ureters) and cause symptoms that mask those of the cancer. [Chapter 21](#) discusses cancer pathophysiology in more detail.

### Etiology and Genetic Risk

The major risk factors for the development of colorectal cancer (CRC) include being older than 50 years, genetic predisposition, personal or family history of cancer, and/or diseases that predispose the patient to cancer such as familial adenomatous polyposis (FAP), Crohn's disease, and ulcerative colitis ([McCance et al., 2014](#)). Only a small percentage of colorectal cancers are familial and transmitted genetically.

## NCLEX Examination Challenge 56-2

### Health Promotion and Maintenance

The community nurse is talking with a group of individuals about colorectal cancer (CRC) risk factors. Which community participant is at the **highest risk** for development of CRC?

- A. 23-year-old vegetarian
- B. 30-year-old with Crohn's disease
- C. 39-year-old with no family history of cancer
- D. 46-year-old with genetic predisposition to cancer

## Genetic/Genomic Considerations

### Patient-Centered Care QSEN

People with a first-degree relative (parent, sibling, or child) diagnosed with colorectal cancer (CRC) have three to four times the risk for developing the disease. An autosomal-dominant inherited genetic disorder known as *familial adenomatous polyposis (FAP)* accounts for 1% of CRCs. FAP is the result of one or more mutations in the adenomatous polyposis coli (APC) gene. In very young patients, thousands of adenomatous polyps develop over the course of 10 to 15 years and have nearly a 100% chance of becoming malignant. By 20 years of age, most patients require surgical intervention, usually a colectomy with ileostomy or ileoanal pull-through, to prevent cancer. Chemotherapy may also be used for cancer prevention (Roncucci & Mariani, 2015).

Lynch Syndrome, also known as hereditary nonpolyposis colorectal cancer (HNPCC), is another autosomal-dominant disorder and accounts for approximately 3% of all CRCs. Lynch Syndrome is also caused by gene mutations, including *MLH1* and *MLH2*. People with these mutations have an 80% chance of developing CRC at an average of 45 years of age. They also tend to have a higher incidence of endometrial, ovarian, stomach, small bowel, brain, and ureteral cancers (Lynch et al., 2009). Genetic testing is available for both of these familial CRC syndromes. Refer patients for genetic counseling and testing if the patient prefers.

The role of infectious agents in the development of colorectal and anal cancer continues to be investigated. Some lower GI cancers are related to *Helicobacter pylori*, *Streptococcus bovis*, John Cunningham (JC) virus, and human papilloma virus (HPV) infections.

There is also strong evidence that long-term smoking, obesity, physical inactivity, and heavy alcohol consumption are risk factors for CRC ([American Cancer Society \[ACS\], 2016a](#)). A high-fat diet, particularly animal fat from red meats, increases bile acid secretion and anaerobic bacteria, which are thought to be carcinogenic for the bowel. Diets with large amounts of refined carbohydrates that lack fiber decrease bowel transit time.

### Incidence and Prevalence

Colorectal cancer (CRC) is the third most common cause of cancer death in the United States (ACS, 2016). The overall incidence of CRC has decreased over the past 20 years, probably as a result of increased cancer screenings (Wilkes, 2013). The disease is most common in African Americans, and their survival rate is lower than that of Euro-Americans (Caucasians). The possible reasons for this difference include less use of diagnostic testing (especially colonoscopy), increased biological susceptibilities, decreased access to health care, lack of health insurance, cultural or spiritual beliefs, and lack of education about the need for early cancer detection (Haddad & You, 2016; Tammana & Laiyemo, 2014).

## Health Promotion and Maintenance

People at risk can take action to decrease their chance of getting CRC and/or increase their chance of surviving it. For example, those whose family members have had hereditary CRC should be genetically tested for FAP and Lynch Syndrome. If gene mutations are present, the individual at risk can collaborate with the health care team to decide which prevention or treatment plan to implement.

Teach adults about the need for diagnostic screening. When an adult turns 40 years of age, he or she should discuss with the primary health care provider the need for colon cancer screening. The interval depends on level of risk. Adults of average risk who are 50 years of age and older and without a family history should undergo regular CRC screening. The screening includes fecal occult blood testing (FOBT) every year, colonoscopy every 10 years, or double-contrast barium enema every 5 years. Adults who have a personal or family history of the disease should begin screening earlier and more frequently. Teach all patients to follow the American Cancer Society (ACS, 2016b) recommendations for CRC screening listed in Chart 56-4.

### Chart 56-4

## Best Practice for Patient Safety & Quality Care QSEN

### Screening Recommendations for Men and Women Ages 50 Years and Older at Average Risk for Colorectal Cancer

PROCEDURE	FREQUENCY	NOTES
Fecal occult blood test (FOBT) <i>and</i> (choose one of the following)	Yearly	FOBT procedure: two or three samples from three consecutive bowel movements obtained at home; tested by physician or nurse
Sigmoidoscopy	Every 5 years	
Double-contrast barium enema	Every 5 years	
Colonoscopy	Every 10 years	

Teach adults, regardless of risk, to modify their diets as needed to decrease fat, refined carbohydrates, and low-fiber foods. Encourage baked or broiled foods, especially those high in fiber and low in animal fat. Remind adults to eat increased amounts of brassica vegetables, including broccoli, cabbage, cauliflower, and sprouts.

Educate about the hazards of smoking, excessive alcohol, and physical inactivity. Refer patients as needed for smoking- or alcohol-cessation programs and recommend ways to increase regular physical exercise.

## ❖ Interprofessional Collaborative Care

Care for the patient with CRC usually takes place in the hospital setting. The interprofessional team that collaborates to care for this patient generally includes the surgeon, oncologist, and nurse and may include the dietitian, psychologist, social worker, and spiritual leader of the patient's choice.

## ◆ Assessment: Noticing

### History.

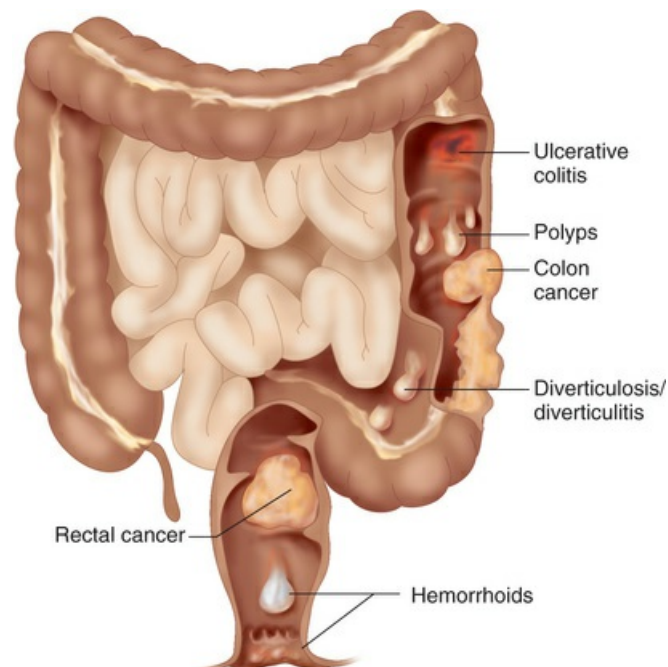

When taking a history, ask the patient about major risk factors, such as a personal history of breast, ovarian, or endometrial cancer (which can spread to the colon); ulcerative colitis; Crohn's disease; familial polyposis or adenomas; polyps; or a family history of CRC. In addition, assess the patient's

participation in age-specific cancer screening guidelines. Ask about whether the patient uses tobacco and/or alcohol. Assess his or her usual physical activity level. Explore cultural preferences because food choices may contribute to development of colon cancer.

Ask whether vomiting and changes in bowel ELIMINATION habits, such as constipation or change in shape of stool with or without blood, have been noted. The patient may also report fatigue (related to anemias), abdominal fullness, vague abdominal pain, or unintentional weight loss. These symptoms suggest advanced disease.

### Physical Assessment/Signs and Symptoms.

The signs and symptoms of CRC depend on the location of the tumor. *However, the most common signs are rectal bleeding, anemia, and a change in stool consistency or shape.* Stools may contain microscopic amounts of blood that are occult (hidden), or the patient may have mahogany (dark)-colored or bright red stools (Fig. 56-3). Gross blood is not usually detected with tumors of the right side of the colon, but it is common (but not massive) with tumors of the left side of the colon and the rectum.

**FIG. 56-3** Common causes of lower gastrointestinal bleeding.

Tumors in the transverse and descending colon result in symptoms of obstruction as growth of the tumor blocks the passage of stool. The patient may report “gas pains,” cramping, or incomplete evacuation. Tumors in the rectosigmoid colon are associated with **hematochezia** (the passage of red blood via the rectum), straining to pass stools, and narrowing of stools. Patients may report dull pain. Right-sided tumors can grow quite large without disrupting bowel patterns or appearance because the stool consistency is more liquid in this part of the colon. These tumors ulcerate and bleed intermittently; thus stools can contain mahogany (dark)-colored blood. A mass may be palpated in the lower right quadrant, and the patient often has anemia secondary to blood loss.

Examination of the abdomen begins with assessment for obvious distention or masses. Visible peristaltic waves accompanied by high-pitched or “tinkling” bowel sounds may indicate a partial bowel obstruction from the tumor. With auscultation, total absence of bowel sounds indicates a complete bowel obstruction. Palpation and percussion are performed by the advanced practice nurse or other health care provider to determine whether the spleen or liver is enlarged or whether masses are present along the colon. The examiner may also perform a digital rectal examination to palpate the rectum and lower sigmoid colon for masses. Fecal occult blood testing (FOBT) should not be done with a specimen from a rectal examination because it is not reliable. A positive result could occur as a consequence of tissue trauma during the examination.

### Psychosocial Assessment.

The psychological consequences associated with a diagnosis of colorectal cancer (CRC) are numerous. Patients must cope with a diagnosis that instills fear and anxiety about treatment, feelings that life has been disrupted, a need to search for ways to deal with the diagnosis, and concern about family. They also have questions about why colon cancer affected them, as well as concerns about pain, possible body changes, and possible death. In addition, if the cancer is believed to have a genetic origin, there is anxiety concerning implications for immediate family members.

### Laboratory Assessment.

Hemoglobin and hematocrit values are often decreased as a result of the intermittent bleeding associated with the tumor. For some patients, that may be the first indication that a tumor is present. CRC that has metastasized to the liver causes liver enzymes to be elevated.

A positive test result for occult blood in the stool (**fecal occult blood test [FOBT]**) indicates bleeding in the GI tract. These tests can yield false-positive results if certain vitamins or drugs are taken before the test. Depending on the age of the test being used, the patient may need to avoid aspirin, vitamin C, iron, and red meat for 48 hours before giving a stool specimen. Also assess whether the patient is taking anti-inflammatory drugs (e.g., ibuprofen, corticosteroids, or salicylates). These drugs should be discontinued for a designated period before the test. Two or three separate stool samples should be tested on 3 consecutive days. Negative results do not completely rule out the possibility of CRC; for this reason additional testing may be suggested (see [Chart 56-4](#)).

**Carcinoembryonic antigen (CEA)**, an oncofetal antigen, is elevated in many people with CRC. The normal value is less than 5 ng/mL ([Pagana et al., 2017](#)). This protein is not specifically associated with the CRC, and it may be elevated in the presence of other benign or malignant diseases and in smokers. CEA is often used to monitor the effectiveness of treatment and to identify disease recurrence.

### Imaging Assessment.

A *double-contrast barium enema* (air and barium are instilled into the colon) or colonoscopy provides better visualization of polyps and small lesions than does a barium enema alone. These tests may show an occlusion in the bowel where the tumor is decreasing the size of the lumen.

*CT* or *MRI* of the chest, abdomen, pelvis, lungs, or liver helps confirm the existence of a mass, the extent of disease, and the location of distant metastases. CT-guided virtual colonoscopy is growing in popularity and may be more thorough than traditional colonoscopy. However, treatments, biopsies, or surgeries cannot be performed when a virtual colonoscopy is used.

### Other Diagnostic Assessment.

A *sigmoidoscopy* provides visualization of the lower colon using a fiberoptic scope. Polyps can be visualized, and tissue samples can be taken for biopsy. Polyps are usually removed during the procedure. A *colonoscopy* provides views of the entire large bowel from the rectum to the ileocecal valve. As with sigmoidoscopy, polyps can be seen and removed, and tissue samples can be taken for biopsy. Colonoscopy is the definitive test for the diagnosis of colorectal cancer. These procedures and associated nursing care are discussed in [Chapter 52](#).

#### ◆Analysis: Interpreting

The priority collaborative problems for patients with colorectal cancer (CRC) include:

1. Potential for metastasis due to colorectal cancer
2. Potential for grieving due to cancer diagnosis

#### ◆Planning and Implementation: Responding

The primary approach to treating CRC is to remove the entire tumor or as much of the tumor as possible to prevent or slow metastatic spread of the disease. A patient-centered collaborative care approach is essential to meet the desired outcomes.

## Preventing or Controlling Metastasis

### Planning: Expected Outcomes.

The patient with colorectal cancer (CRC) is expected to not have the cancer spread to vital organs. Thus the patient's life expectancy will be increased, and the quality of life will be improved. However, if metastasis is present, the desired outcome is to limit further metastasis and to ensure that the patient is as comfortable as possible and pain is well managed.

### Interventions.

Although surgical resection is the primary method used to control the disease, several adjuvant (additional) therapies are used. Adjuvant therapies are administered before or after surgery to achieve a cure and prevent recurrence, if possible.

### Nonsurgical Management.

The type of therapy used is based on the pathologic staging of the disease. The staging system used most often in colorectal cancer is the TNM (tumor, nodes, metastasis) classification; more information on the use of this system can be found in [Chapter 21](#).

The administration of preoperative *radiation therapy* has not improved overall survival rates for colon cancer, but it has been effective in providing local or regional control of the disease. Postoperative radiation has not demonstrated any consistent improvement in survival or recurrence. However, as a palliative measure, radiation therapy may be used to control pain, hemorrhage, bowel obstruction, or metastasis to the lung in advanced disease. For rectal cancer, unlike colon cancer, radiation therapy is almost always a part of the treatment plan. Reinforce information about the radiation therapy procedure to the patient and family and monitor for possible side effects (e.g., diarrhea, fatigue). [Chapter 22](#) describes the general nursing care of patients undergoing radiation therapy.

Adjuvant *chemotherapy* after primary surgery is recommended for patients with stage II or stage III disease to interrupt the DNA production of cells and destroy them. The drugs of choice are IV 5-fluorouracil (5-FU) with leucovorin (LV) (folinic acid) (5-FU/LV), capecitabine (Xeloda), or a combination of drugs referred to as *FOLFOX4*. The most frequently used FOLFOX4 combination for metastatic CRC is fluorouracil (5-FU), leucovorin (LV), and oxaliplatin (Eloxatin), a platinum analog. These drugs cannot discriminate between cancer and healthy cells. Therefore common side effects are diarrhea, mucositis, leukopenia, mouth ulcers, and peripheral neuropathy ([Cutsem et al., 2014](#)).

Bevacizumab (Avastin) and panitumumab (Vectibix) are antiangiogenesis drugs, also known as *vascular endothelial growth factor (VEGF) inhibitors*, approved for advanced CRC. These drugs reduce blood flow to the growing tumor cells, thereby depriving them of necessary nutrients needed to grow ([Cutsem et al., 2014](#)). A VEGF inhibitor is usually given in combination with other chemotherapeutic agents.

Cetuximab (Erbix), a monoclonal antibody known as an *epidermal growth factor receptor (EGFR) inhibitor (EGFRI)*, may also be given in combination with other drugs for advanced disease ([Cutsem et al., 2014](#)). This drug works by blocking factors that promote cancer cell growth.

Intrahepatic arterial chemotherapy, often with 5-FU, may be administered to patients with liver metastasis. Patients with CRC also receive drugs for relief of symptoms, such as opioid analgesics and antiemetics. [Chapter 22](#) describes care of patients receiving chemotherapy in detail.

### Surgical Management.

Surgical removal of the tumor with margins free of disease is the best method of ensuring removal of CRC. The size of the tumor, its location, the extent of metastasis, the integrity of the bowel, and the condition of the patient determine which surgical procedure is performed for colorectal cancer ([Table 56-1](#)). Many regional lymph nodes are removed and examined for presence of cancer. The number of lymph nodes that contain cancer is a strong predictor of prognosis. The most common surgeries performed are **colon resection** (removal of the tumor and regional lymph nodes) with reanastomosis, **colectomy** (colon removal) with *colostomy (temporary or permanent) or ileostomy/ileoanal pull-through*, and **abdominoperineal (AP) resection**. A **colostomy** is the surgical creation of an opening of the colon onto the surface of the abdomen. An AP resection is performed when rectal tumors are present. The surgeon removes the sigmoid colon, rectum, and anus through

combined abdominal and perineal incisions.

**TABLE 56-1**  
**Surgical Procedures for Colorectal Cancers in Various Locations**

<b>Right-Sided Colon Tumors</b>
<ul style="list-style-type: none"> <li>• Right hemicolectomy for smaller lesions</li> <li>• Right ascending colostomy or ileostomy for large, widespread lesions</li> <li>• Cecostomy (opening into the cecum with intubation to decompress the bowel)</li> </ul>
<b>Left-Sided Colon Tumors</b>
<ul style="list-style-type: none"> <li>• Left hemicolectomy for smaller lesions</li> <li>• Left descending colostomy for larger lesions</li> </ul>
<b>Sigmoid Colon Tumors</b>
<ul style="list-style-type: none"> <li>• Sigmoid colectomy for smaller lesions</li> <li>• Sigmoid colostomy for larger lesions</li> <li>• Abdominoperineal resection for large, low sigmoid tumors (near the anus) with colostomy (the rectum and the anus are completely removed, leaving a perineal wound)</li> </ul>
<b>Rectal Tumors</b>
<ul style="list-style-type: none"> <li>• Resection with anastomosis or pull-through procedure (preserves anal sphincter and normal ELIMINATION pattern)</li> <li>• Colon resection with permanent colostomy</li> <li>• Abdominoperineal resection with colostomy</li> </ul>

For patients having a colon resection, minimally invasive surgery (MIS) via laparoscopy is commonly performed today. This procedure results in shorter hospital stays, less pain, fewer complications, and quicker recovery compared with the conventional open surgical approach (Kapritsou et al., 2013).

### Preoperative Care.

Reinforce the physician's explanation of the planned surgical procedure. The patient is told as accurately as possible what anatomic and physiologic changes will occur with surgery. The location and number of incision sites and drains are also discussed.

Before evaluating the tumor and colon during surgery, the surgeon may not be able to determine whether a colostomy (or less commonly, an ileostomy) will be necessary. The patient is told that a colostomy is a possibility. If a colostomy is planned, the surgeon consults a certified wound, ostomy, continence nurse (CWOCN) to recommend optimal placement of the ostomy. The CWOCN teaches the patient about the rationale and general principles of ostomy care. In many settings, the CWOCN marks the patient's abdomen to indicate a potential ostomy site that will decrease the risk for complications such as interference of the undergarments or a prosthesis with the ostomy appliance. Table 56-2 describes the role of the CWOCN.

**TABLE 56-2**  
**Preoperative Assessment by the CWOCN Before Ostomy Surgery**

<b>Key Points of Psychosocial Assessment</b>
<ul style="list-style-type: none"> <li>• Patient's and family's level of knowledge of disease and ostomy care</li> <li>• Patient's educational level</li> <li>• Patient's physical limitations (particularly sensory)</li> <li>• Support available to patient</li> <li>• Patient's type of employment</li> <li>• Patient's involvement in activities such as hobbies</li> <li>• Financial concerns regarding purchase of ostomy supplies</li> </ul>
<b>Key Points of Physical Assessment</b>
<ul style="list-style-type: none"> <li>• Before marking the placement for the ostomy, the nurse specialist considers:</li> <li>• Contour of the abdomen in lying, sitting, and standing positions</li> <li>• Presence of skinfolds, creases, bony prominences, and scars</li> <li>• Location of belt line</li> <li>• Location that is easily visible to the patient</li> <li>• Possible location in the rectus muscle</li> </ul>

CWOCN, Certified wound, ostomy, continence nurse.

The patient who requires low rectal surgery (e.g., AP resection) is faced with the risk for postoperative sexual dysfunction and urinary incontinence after surgery as a result of nerve damage during surgery. The surgeon discusses the risk for these problems with the patient before surgery and allows him or her to verbalize concerns and questions related to this risk before he or she gives informed consent. Reinforce teaching about abdominal surgery performed for the patient under general anesthesia and review the routines for turning and deep breathing (see Chapter 14). Teach the patient about the method of pain management to be used after surgery such as IV patient-controlled analgesia (PCA), epidural analgesia, or other method.

If the bowel is not obstructed or perforated, elective surgery is planned. The patient may be instructed to thoroughly clean the bowel, or "bowel prep," to minimize bacterial growth and prevent complications. Mechanical cleaning is accomplished with laxatives and enemas or with "whole-gut lavage." The use of bowel preps is controversial, and some surgeons do not recommend it because alterations in COMFORT may arise. Older adults may become dehydrated from this

process.

To reduce the risk for infection, the surgeon may prescribe one dose of oral or IV antibiotics to be given before the surgical incision is made. Teach patients that a nasogastric tube (NGT) may be placed for decompression of the stomach after surgery. A peripheral IV or central venous catheter is also placed for fluid and electrolyte replacement while the patient is NPO after surgery. Patients having minimally invasive surgeries do not need an NGT.

The patient with colorectal cancer faces a serious illness with long-term consequences of the disease and treatment. A case manager or social worker can be very helpful in identifying patient and family needs and ensuring continuity of care and support.

### Operative Procedures.

For the conventional open surgical approach, the surgeon makes a large incision in the abdomen and explores the abdominal cavity to determine whether the tumor can be removed. For a colon resection, the portion of the colon with the tumor is excised, and the two open ends of the bowel are irrigated before **anastomosis** (reattachment) of the colon. If an anastomosis is not feasible because of the location of the tumor or inflammation of the bowel, a colostomy is created.

A temporary or permanent colostomy may be created in the ascending, transverse, descending, or sigmoid colon (Fig. 56-4). One of several techniques is used to construct a colostomy. A loop **stoma** (surgical opening) is made by bringing a loop of colon to the skin surface, severing and everting the anterior wall, and suturing it to the abdominal wall. Loop colostomies are usually performed in the transverse colon and are usually temporary. An external rod may be used to support the loop until the intestinal tissue adheres to the abdominal wall. Care must be taken to avoid displacing the rod, especially during appliance changes.

The **ascending colostomy** is done for right-sided tumors.

The **transverse (double-barrel) colostomy** is often used in such emergencies as intestinal obstruction or perforation because it can be created quickly. There are two stomas. The proximal one, closest to the small intestine, drains feces. The distal stoma drains mucus.

The **descending colostomy** is done for left-sided tumors.

The **sigmoid colostomy** is done for rectal tumors.

**FIG. 56-4** Different locations of colostomies in the colon.

An end stoma is often constructed, usually in the descending or sigmoid colon, when a colostomy

is intended to be permanent. It may also be done when the surgeon oversees the distal stump of the colon and places it in the abdominal cavity, preserving it for future reattachment. An end stoma is constructed by severing the end of the proximal portion of the bowel and bringing it out through the abdominal wall.

The least common colostomy is the **double-barrel stoma**, which is created by dividing the bowel and bringing both the proximal and distal portions to the abdominal surface to create two stomas. The proximal stoma (closest to the patient's head) is the functioning stoma and eliminates stool. The distal stoma (farthest from the head) is considered nonfunctioning, although it may secrete some mucus. The distal stoma is sometimes referred to as a *mucous fistula*.

*Laparoscopic (MIS) colon resection or total colectomy* allows complete tumor removal with an adequate surgical margin and removal of associated lymph nodes. Several small incisions are made, and a miniature video camera is placed within the abdomen to help see the area that is involved. This technique takes longer than the conventional procedure and requires specialized training. However, blood loss is reduced.

### Postoperative Care.

Patients who have an *open colon resection* without a colostomy receive care similar to that of those having any abdominal surgery (see [Chapter 16](#)). Other patients have surgeries that also require colostomy management. They typically have a nasogastric tube (NGT) after open surgery and receive IV PCA for the first 24 to 36 hours. After NGT removal, the diet is slowly progressed from liquids to solid foods as tolerated. The care of patients with an NGT is found in the Interventions discussion in the Intestinal Obstruction section.

By contrast, patients who have *laparoscopic (MIS) surgery* can eat solid foods very soon after the procedure. Because they usually have less pain, they are able to ambulate earlier than those who have the conventional approach. The hospital stay is usually shorter for the patient with MIS—typically 1 to 2 days, depending on the patient's age and general condition.

### Colostomy Management.

The patient who has a colostomy may return from surgery with a clear ostomy pouch system in place. A clear pouch allows the health care team to observe the stoma. If no pouch system is in place, a petrolatum gauze dressing is usually placed over the stoma to keep it moist. This is covered with a dry, sterile dressing. In collaboration with the CWOCN, place a pouch system as soon as possible. The colostomy pouch system, also called an *appliance*, allows more convenient and suitable collection of stool than a dressing does.

Assess the color and integrity of the stoma frequently. A healthy stoma should be reddish pink and moist and protrude about  $\frac{3}{4}$  inch (2 cm) from the abdominal wall ([Fig. 56-5](#)). During the initial postoperative period, the stoma may be slightly edematous. A small amount of bleeding at the stoma is common.

**FIG. 56-5** Mature colostomy. (From Evans, S. [2009]. *Surgical pitfalls*. Philadelphia: Saunders.)

## Nursing Safety Priority QSEN

### Action Alert

Report any of these problems related to the colostomy to the surgeon:

- Signs of ischemia and necrosis (dark red, purplish, or black color; dry)
- Unusual bleeding
- Mucocutaneous separation (breakdown of the suture line securing the stoma to the abdominal wall)

Also assess the condition of the peristomal skin (skin around the stoma) and frequently check the pouch system for proper fit and signs of leakage. The skin should be intact, smooth, and without redness or excoriation.

The colostomy should start functioning in 2 to 3 days after surgery. When it begins to function, the pouch may need to be emptied frequently because of excess gas collection. It should be emptied when it is one-third to one-half full of stool. Stool is liquid immediately after surgery but becomes more solid, depending on where in the colon the stoma was placed. For example, the stool from a colostomy in the ascending colon is liquid, the stool from a colostomy in the transverse colon is pasty, and the stool from a colostomy in the descending colon is more solid (similar to stool expelled from the rectum).

### Wound Management.

For an AP resection, the perineal wound is generally surgically closed, and two bulb suction drains such as Jackson-Pratt drains are placed in the wound or through stab wounds near the wound. The drains help prevent drainage from collecting within the wound and are usually left in place for several days, depending on the character and amount of drainage. These drains are described in more detail in [Chapter 16](#).

Monitoring drainage from the perineal wound and cavity is important because of the possibility of infection and abscess formation. Serosanguineous drainage from the perineal wound may be observed for 1 to 2 months after surgery. Complete healing of the perineal wound may take 6 to 8 months. This wound can be a greater source of COMFORT alteration than the abdominal incision and ostomy, and more care may be required. The patient may experience phantom rectal sensations because sympathetic innervation for rectal control has not been interrupted. Rectal pain and itching may occasionally occur after healing. Interventions may include use of antipruritic drugs, such as benzocaine, and warm compresses. Continually assess for signs of infection, abscess, or other complications and implement methods for promoting wound drainage and comfort ([Chart 56-5](#)).

### Chart 56-5

## Best Practice for Patient Safety & Quality Care QSEN

### Perineal Wound Care

#### Wound Care

- Place an absorbent dressing (e.g., abdominal pad) over the wound.
- Instruct the patient that he or she may:
  - Use a feminine napkin as a dressing
  - Wear jockey-type shorts rather than boxers

### Comfort Measures

- If prescribed, soak the wound area in a sitz bath for 10 to 20 minutes three or four times per day or use warm/hot compresses or packs.
- Administer pain medication as prescribed and assess its effectiveness.
- Instruct the patient about permissible activities. The patient should:
  - Assume a side-lying position in bed; avoid sitting for long periods
  - Use foam pads or a soft pillow on which to sit whenever in a sitting position
  - Avoid the use of air rings or rubber donut devices

### Prevention of Complications

- Maintain FLUID AND ELECTROLYTE BALANCE by monitoring intake and output and output from the perineal wound.
- Observe incision integrity and monitor wound drains; watch for erythema, edema, bleeding, drainage, unusual odor, and excessive or constant pain.

## NCLEX Examination Challenge 56-3

### Physiological Integrity

A client had an open partial colectomy and ascending colostomy 3 days ago. Which assessment findings does the nurse expect? **Select all that apply.**

- A. Black, moist stoma
- B. Gas inside the pouch
- C. Pain controlled with analgesics
- D. Small amount of formed stool from the colostomy
- E. Serosanguineous fluid draining from two Jackson-Pratt drains

### Assisting With the Grieving Process

#### Planning: Expected Outcomes.

The expected outcomes are that the patient will verbalize feelings about the diagnosis and treatment and progress through the normal stages of grief.

#### Interventions.

The patient and family are faced with a possible loss of or alteration in body functions. Medical and surgical interventions for the treatment of colorectal cancer may result in cure, disease control, or palliation. Nursing interventions are designed to help the patient and family plan effective strategies for expressing feelings of grief and developing coping skills.

Observe and identify:

- The patient's and family's current methods of coping
- Effective sources of support used in past crises

- The patient's and family's present perceptions of the health problem
- Signs of anticipatory grief, such as denial, crying, anger, and withdrawal from usual relationships

Encourage the patient and family to verbalize feelings about the diagnosis, treatment, and anticipated alteration in body functions if a colostomy is planned. (See the Operative Procedures discussion in the Surgical Management section.) Denial, sadness, anger, feelings of loss, and depression are common responses to this change in body function. The patient will need to learn new methods for toileting and how to cope with these changes.

If a colostomy is planned, instruct the patient on what to expect about the appearance and care of the colostomy. After surgery, encourage him or her to look at and touch the stoma. When the patient is physically able, ask him or her to participate in colostomy care. Participation helps restore the patient's sense of control over his or her lifestyle and thus facilitates improved self-esteem. If culturally appropriate, encourage participation of family or other caregivers in colostomy care.

Help the patient identify the nature of and reaction to the loss. Encourage the patient and family to verbalize feelings and identify fears to help move them through the appropriate phases of the grief process. Establish a trusting, ongoing relationship with the patient and family and provide support through the personal grieving stages.

In collaboration with the social worker or chaplain, help the patient identify personal coping strategies. Encourage him or her to implement cultural, spiritual, and social customs associated with the loss and identify sources of community support. Modifications in lifestyle are needed for patients with CRC. Help the patient and family identify these changes and how best to make them. The spiritual leader of the patient's choice, social worker, or case manager assists in discussions and decisions with them concerning treatment, the prognosis, and end-of-life decisions as appropriate.

## Genetics/Genomics Considerations

### Patient-Centered Care OSEN

Refer patients who are at risk for or have familial CRC for genetic counseling. Specially trained nurses can discuss the purposes and goals of genetic testing. Ensure privacy and confidentiality. A review of the family history may provide important information concerning the pattern of CRC inheritance. To make an informed decision, the patient and family need information about the advantages, risks, and costs of appropriate genetic tests. Monitor the patient's response regarding genetic risk factors.

### Care Coordination and Transition Management

Patients undergoing a colon resection by open approach are typically hospitalized for 2 to 3 days or longer, depending on the age of the patient and any complications or concurrent health problems. Collaborate with the case manager to help patients and their families cope with the immediate postoperative phase of recovery. After hospitalization for surgery, the patient is usually managed at home. Radiation therapy or chemotherapy is typically administered on an ambulatory care basis. For the patient with advanced cancer, hospice care may be an option (see [Chapter 7](#)).

### Home Care Management.

Assess all patients for their ability for self-management within limitations. For those requiring assistance with care, home care visits by nurses or assistive nursing personnel can be provided.

For the patient who has undergone a colostomy, review the home situation to help the patient arrange for care. Ostomy products should be kept in an area (preferably the bathroom) where the temperature is neither hot nor cold (skin barriers may become stiff or melt in extreme temperatures) to ensure proper functioning.

No changes are needed in sleeping accommodations. A moisture-proof covering may initially be placed over the bed mattress if patients feel insecure about the pouch system. They may consume their usual diet on discharge.

### Self-Management Education.

Before discharge, teach the patient to avoid lifting heavy objects or straining on defecation to prevent tension on the anastomosis site. If he or she had the open surgical approach, the patient

should avoid driving and vigorous physical activity for 4 to 6 weeks while the incision heals. Patients who have had laparoscopy can usually return to all usual activities in 1 to 2 weeks.

## Nursing Safety Priority QSEN

### Action Alert

A stool softener may be prescribed to keep stools soft in consistency for ease of passage. Teach patients to note the frequency, amount, and character of the stools. In addition to this information, teach those with colon resections to watch for and report signs and symptoms of intestinal obstruction and perforation (e.g., cramping, abdominal pain, nausea, vomiting). Advise the patient to avoid gas-producing foods and carbonated beverages. The patient may require 4 to 6 weeks to establish the effects of certain foods on bowel patterns.

### Colostomy Care.

Rehabilitation after surgery requires that patients and family members learn how to perform colostomy care. Provide adequate opportunity before discharge for patients to learn the psychomotor skills involved in this care. Plan sufficient practice time for learning how to handle, assemble, and apply all ostomy equipment. Teach patients and families or other caregivers about:

- Appearance of a normal stoma
- Signs and symptoms of complications
- Measurement of the stoma
- Choice, use, care, and application of the appropriate appliance to cover the stoma
- Measures to protect the skin adjacent to the stoma
- NUTRITION changes to control gas and odor
- What to expect in terms of stool consistency
- Resumption of normal activities, including work, travel, and sexual intercourse

The appropriate pouch system must be selected and fitted to the stoma. Patients with flat, firm abdomens may use either flexible (bordered with paper tape) or nonflexible (full skin barrier wafer) pouch systems. A firm abdomen with lateral creases or folds requires a flexible system. Patients with deep creases, flabby abdomens, a retracted stoma, or a stoma that is flush or concave to the abdominal surface can benefit from a convex appliance with a stoma belt. This type of system presses into the skin around the stoma, causing the stoma to protrude. This protrusion helps tighten the skin and prevents leaks around the stoma opening onto the peristomal skin.

Measurement of the stoma is necessary to determine the correct size of the stomal opening on the appliance. The opening should be large enough not only to cover the peristomal skin but also to avoid stomal trauma. The stoma will shrink within 6 to 8 weeks after surgery. Therefore it needs to be measured at least once weekly during this time to gauge appliance fit and COMFORT. Measurements are also necessary if the patient gains or loses weight. Teach the patient and family caregiver to trace the pattern of the stomal area on the wafer portion of the appliance and to cut an opening about  $\frac{1}{8}$ - to  $\frac{1}{16}$ -inch larger than the stomal pattern to ensure that stomal tissue will not be constricted.

Skin preparation may include clipping peristomal hair or shaving the area (moving from the stoma outward) to achieve a smooth surface, prevent unnecessary discomfort when the wafer is removed, and minimize the risk for infected hair follicles. Advise the patient to clean around the stoma with mild soap and water before putting on an appliance. He or she should avoid using moisturizing soaps to clean the area because the lubricants can interfere with adhesion of the appliance.

## Nursing Safety Priority QSEN

### Action Alert

Teach the patient and family to apply a skin sealant (preferably without alcohol) and allow it to dry

before application of the appliance (colostomy bag) to facilitate less painful removal of the tape or adhesive. If peristomal skin becomes raw, stoma powder or paste or a combination may also be applied. The paste or other filler cream is also used to fill in crevices and creases to create a flat surface for the flange of the colostomy bag. If the patient develops a fungal rash, an antifungal cream or powder should be used.

Control of gas and odor from the colostomy is often an important outcome for patients with new ostomies. Although a leaking or inadequately closed pouch is the usual cause of odor, flatus can also contribute to it. Remind the patient with an ostomy that, although generally no foods are forbidden, certain foods (such as vegetables) can cause flatus or contribute to odor when the pouch is open. Charcoal filters, pouch deodorizers, or placement of a breath mint in the pouch helps eliminate odors. The patient should be cautioned to not put aspirin tablets in the pouch because they may cause ulceration of the stoma. Vents that allow release of gas from the ostomy bag through a deodorizing filter are available and may decrease the patient's level of self-consciousness about odor.

The patient with a sigmoid colostomy may benefit from colostomy irrigation to regulate ELIMINATION. However, most patients with a sigmoid colostomy can become regulated through diet. An irrigation is similar to an enema but is administered through the stoma rather than the rectum.

In addition to teaching the patient about the signs and symptoms of obstruction and perforation, ask him or her to report any fever or sudden onset of pain or swelling around the stoma. Other home care assessment is listed in [Chart 56-6](#).

## Chart 56-6

### Home Care Assessment

#### The Patient With a Colostomy

Assess gastrointestinal status, including:

- Dietary and fluid intake and habits
- Presence or absence of nausea and vomiting
- Weight gain or loss
- Bowel elimination pattern and characteristics and amount of effluent (stool)
- Bowel sounds

Assess condition of stoma, including:

- Location, size, protrusion, color, and integrity
- Signs of ischemia, such as dull coloring or dark or purplish bruising

Assess peristomal skin for:

- Presence or absence of excoriated skin, leakage underneath drainage system

- Fit of appliance and effectiveness of skin barrier and appliance

Assess the patient's and family's coping skills, including:

- Self-care abilities in the home
- Acknowledgment of changes in body image and function
- Sense of loss

### Psychosocial Concerns.

The diagnosis of cancer can be emotionally immobilizing for the patient and family or significant others, but treatment may be welcomed because it may provide hope for control of the disease. Explore reactions to the illness and perceptions of planned interventions.

The patient's reaction to ostomy surgery may include:

- Fear of not being accepted by others
- Feelings of grief related to disturbance in body image
- Concerns about sexuality

Encourage the patient and family to verbalize their feelings. Education about how to physically manage the ostomy will empower both the family and patient to begin restoration of self-esteem and improvement of body image. Inclusion of family and significant others in the rehabilitation process may help preserve relationships and raise self-esteem. Anticipatory instruction includes information on leakage accidents, odor control measures, and adjustments to resuming sexual relationships.

### Health Care Resources.

Several resources are available to maintain continuity of care in the home environment and provide for patient needs that the nurse is not able to meet. Make referrals to community-based case managers or social workers who can provide further emotional counseling, aid in managing financial concerns, or arrange for services in the home or long-term care facility as needed.

Provide information about the United Ostomy Associations of America, Inc. ([www.uoaa.org](http://www.uoaa.org)), a self-help group of people with ostomies. This group has literature such as the organization's publication (*Ostomy Quarterly*) and information about local chapters. The organization conducts a visitor program that sends specially trained visitors (who have an ostomy [ostomate]) to talk with patients. After obtaining consent, make a referral to the visitor program so the volunteer ostomate can see the patient both before and after surgery. A health care provider's consent for visitation may be necessary.

The local division or unit of the American Cancer Society (ACS) ([www.cancer.org](http://www.cancer.org)) can help provide necessary medical equipment and supplies, home care services, travel accommodations, and other resources for the patient who is having cancer treatment or surgery. Inform the patient and family of the programs available through the local division or unit. Other excellent Internet resources include Cancer Care ([www.cancercare.org](http://www.cancercare.org)), Colon Cancer Alliance ([www.ccalliance.org](http://www.ccalliance.org)), and the National Cancer Institute ([www.nci.gov](http://www.nci.gov)).

Because of short hospital stays, patients with new ostomies receive much health teaching from nurses working for home health care agencies. This resource also helps provide physical care needs, medication management, and emotional support. If the patient has advanced colorectal cancer, a referral for hospice services in the home, nursing home, or other long-term care setting may be appropriate. The home health care nurse informs the patient and family about which ostomy supplies are needed and where they can be purchased. Price and location are considered before recommendations are made.

## Clinical Judgment Challenge 56-2

## Safety; Patient-Centered Care QSEN

After an open colon resection and colostomy for ascending colon cancer, you begin caring for a 60-year-old patient who has IV fluids running at 150 mL/hr and is receiving morphine via patient-controlled anesthesia (PCA). He has an NGT in place connected to low-intermittent suction, and he is NPO. His abdominal dressing is dry and intact, and his oxygen saturation is 96% on 2 L/min of oxygen via nasal cannula. The surgeon has placed an activity order to get the patient out of bed to the bathroom and chair today.

1. The patient is admitted to your care at noon. Will you delegate taking vital signs to an unlicensed assistive personnel (UAP)? Why or why not?
2. When the patient states that he needs to go to the bathroom, will you delegate this activity to the unlicensed assistive personnel (UAP)? Why or why not?
3. The patient's oxygen saturation level decreases to 88% after using the bathroom. What is the appropriate nursing intervention?
4. The patient asks about treatment and survival rates for patients with colorectal cancer. How will you respond to him?

### ◆ **Evaluation: Reflecting**

Evaluate the care of the patient with colorectal cancer based on the identified priority patient problems. The expected outcomes are that the patient:

- Adjusts to actual or impending loss
- Is free of complications or metastasis associated with CRC
- States that he or she has well-controlled pain and is as comfortable as possible (if metastasis is present)

# Irritable Bowel Syndrome

## ❖Pathophysiology

**Irritable bowel syndrome (IBS)** is a functional GI disorder that causes chronic or recurrent diarrhea, constipation, and/or abdominal pain and bloating. It is sometimes referred to as *spastic colon*, *mucous colon*, or *nervous colon* (Fig. 56-6). IBS is the most common digestive disorder seen in clinical practice and may affect as many as one in five people in the United States (McCance et al., 2014).

**FIG. 56-6** Spastic contractions of the colon as they occur with irritable bowel syndrome.

In patients with IBS, bowel motility changes, and increased or decreased bowel transit times result in changes in the normal *bowel* ELIMINATION pattern to one of these classifications: diarrhea (IBS-D), constipation (IBS-C), alternating diarrhea and constipation (IBS-A), or a mix of diarrhea and constipation (IBS-M). Symptoms of the disease typically begin to appear in young adulthood and continue throughout the patient's life.

The etiology of IBS remains unclear. Research suggests that a combination of environmental, immunologic, genetic, hormonal, and stress factors play a role in the development and course of the disorder. Examples of environmental factors include foods and fluids such as caffeinated or carbonated beverages and dairy products. Infectious agents have also been identified. Several studies have found that patients with IBS often have small-bowel bacterial overgrowth, which causes bloating and abdominal distention. Multiple normal flora and pathogenic agents have been identified, including *Pseudomonas aeruginosa* (Kerckhoffs et al., 2011). Other researchers believe that these agents are less causative and serve as measurable biomarkers for the disease (Berry & Reinisch, 2013).

Immunologic and genetic factors have also been associated with IBS, especially cytokine genes, including pro-inflammatory interleukins (IL), such as IL-6, IL-8, and tumor necrosis factor (TNF)-alpha. These findings may provide the basis of targeted drug therapy for the disease.

In the United States, women are two times more likely to have IBS than are men. This difference may be the result of hormonal differences. However, in other areas of the world, this distribution pattern may not occur.

Considerable evidence relates the role of stress and mental or behavioral illness, especially anxiety and depression, to IBS. Many patients diagnosed with IBS meet the criteria for at least one primary mental health disorder. However, the pain and other chronic symptoms of the disease may

lead to secondary mental health disorders. For example, when diarrhea is predominant, patients fear that there will be no bathroom facilities available and can become very anxious. As a result, they may not want to leave their homes or travel on trips where bathrooms are not available at all times. The long-term nature of dealing with a chronic disease for which there is no cure can lead to secondary depression in some patients.

## ❖ Interprofessional Collaborative Care

Care for the patient with IBS usually takes place in the outpatient setting, although patients with severe cases of IBS may be hospitalized for a period of time. The interprofessional team that collaborates to care for this patient generally includes the health care provider, nurse, and possibly the dietitian if NUTRITION modification is indicated.

### ◆ Assessment: Noticing

Ask the patient about a history of weight change, fatigue, malaise, abdominal pain, changes in the bowel pattern (constipation, diarrhea, or an alternating pattern of both) or consistency of stools, and the passage of mucus. Patients with IBS do not usually lose weight. Ask whether the patient has had any GI infections. Collect information on all drugs that the patient is taking because some can cause symptoms similar to those of IBS. Ask about the NUTRITION history, including the use of caffeinated drinks or beverages sweetened with sorbitol or fructose, which can cause bloating or diarrhea.

The course of the illness is specific to each patient. Most patients can identify factors that cause exacerbations, such as diet, stress, or anxiety. Food intolerance may be associated with IBS. Dairy products (e.g., for those with lactose intolerance), raw fruits, and grains can contribute to bloating, **flatulence** (gas), and abdominal distention. Patients may keep a food diary to record possible triggers for IBS symptoms.

A flare-up of worsening cramps, abdominal pain, and diarrhea and/or constipation may bring the patient to the health care provider. One of the *most common concerns of patients with IBS is pain in the left lower quadrant of the abdomen*. Assess the location, intensity, and quality of the pain. Some patients have internal visceral (organ) hypersensitivity that can cause or contribute to it. Nausea may be associated with mealtime and defecation. The constipated stools are small and hard and are generally followed by several softer stools. The diarrheal stools are soft and watery, and mucus is often present. Patients with IBS often report belching, gas, anorexia, and bloating.

The patient generally appears well, with a stable weight, and nutritional and fluid status is within normal ranges. Inspect and auscultate the abdomen. Bowel sounds vary but are generally within normal range. With constipation, bowel sounds may be hypoactive; with severe diarrhea, they may be hyperactive.

Routine laboratory values (including a complete blood count [CBC], serum albumin, erythrocyte sedimentation rate [ESR], and stools for occult blood) remain normal in IBS. Some health care providers request a *hydrogen breath test* (Rana & Malik, 2014) or small-bowel bacterial overgrowth breath test. When small-intestinal bacterial overgrowth or malabsorption of nutrients is present, an excess of hydrogen is produced. Some of this hydrogen is absorbed into the bloodstream and travels to the lungs where it is exhaled. Patients with IBS often exhale an increased amount of hydrogen.

Teach the patient that he or she will need to be NPO (may have water) for at least 12 hours before the hydrogen breath test. At the beginning of the test, the patient blows into a hydrogen analyzer. Then, small amounts of test sugar are ingested, depending on the purpose of the test, and additional breath samples are taken every 15 minutes for 1 to 5 hours (Pagana et al., 2017).

### ◆ Interventions: Responding

The patient with IBS is usually managed on an ambulatory care basis and learns self-management strategies. Interventions include health teaching, drug therapy, and stress reduction. Some patients also use complementary and integrative therapies. A holistic approach to patient care is essential for positive outcomes (Chey et al., 2015).

Dietary fiber and bulk help produce bulky, soft stools and establish regular bowel ELIMINATION habits. The patient should ingest about 30 to 40 g of fiber each day. Eating regular meals, drinking 8 to 10 glasses of water each day, and chewing food slowly help promote normal bowel function.

Drug therapy depends on the main symptom of IBS. The health care provider may prescribe bulk-forming or antidiarrheal agents and/or newer drugs to control symptoms.

For the treatment of *constipation-predominant IBS (IBS-C)*, bulk-forming laxatives, such as *psyllium hydrophilic mucilloid (Metamucil)*, are generally taken at mealtimes with a glass of water. The hydrophilic properties of these drugs help prevent dry, hard, or liquid stools. *Lubiprostone (Amitiza)* is an oral laxative approved for women with IBS-C, which increases fluid in the intestines to promote bowel ELIMINATION. Teach the patient to take the drug with food and water. *Linaclotide (Linzess)* is the newest drug for IBS-C, which works by simulating receptors in the intestines to increase fluid and promote bowel transit time. The drug also helps relieve pain and cramping that are associated with IBS. Teach patients to take this drug once a day about 30 minutes before breakfast.

*Diarrhea-predominant IBS (IBS-D)* may be treated with antidiarrheal agents, such as loperamide (Imodium), and psyllium (a bulk-forming agent). *Alosetron (Lotronex)*, a selective serotonin (5-HT<sub>3</sub>) receptor antagonist, may be used with caution in women with IBS-D as a last resort when they have not responded to conventional therapy (Nee et al., 2015). Patients taking this drug must agree to report symptoms of colitis or constipation early because it is associated with potentially life-threatening bowel complications, including ischemic colitis (lack of blood flow to the colon).

## Nursing Safety Priority QSEN

### Drug Alert

Before the patient begins alosetron (Lotronex), take a thorough drug history (including alternative treatments), both prescribed and over the counter, because it interacts with many drugs in a variety of classes. Remind patients that they should not take psychoactive drugs and antihistamines while taking alosetron. Teach patients to report severe constipation, fever, increasing abdominal pain, increasing fatigue, darkened urine, bloody diarrhea, or rectal bleeding as soon as it occurs and to stop the drug immediately (Lilley et al., 2017).

Many patients with IBS who have bloating and abdominal distention without constipation have success with *rifaximin (Xifaxan)*, an antibiotic that works locally with little systemic absorption. The U.S. Food and Drug Administration (FDA) originally approved this drug for “traveler's diarrhea,” and only recently has it been approved for use in IBS-D (Nee et al., 2015).

A newer group of drugs called *muscarinic-receptor antagonists* also inhibit intestinal motility. Some of these agents have been approved for people with overactive bladder but have not yet received FDA approval for IBS. Examples in this group currently undergoing clinical trials for IBS are darifenacin (Enablex) and fesoterodine (Toviaz).

For IBS in which pain is the predominant symptom, tricyclic antidepressants such as amitriptyline (Elavil) have also been used successfully. It is unclear whether their effectiveness is the result of the antidepressant or anticholinergic effects of the drugs. If patients have postprandial (after eating) alterations in COMFORT, they should take these drugs 30 to 45 minutes before mealtime.

### Complementary and Integrative Health.

For patients with increased intestinal bacterial overgrowth, recommend daily probiotic supplements. *Probiotics* have been shown to be effective for reducing bacteria and successfully alleviating GI symptoms of IBS (Quigley, 2015). There is also evidence that peppermint oil capsules may be effective in reducing symptoms for patients with IBS (Grundmann & Yoon, 2014).

Stress management is also an important part of holistic care. Suggest relaxation techniques, meditation, and/or yoga to help the patient decrease GI symptoms. If the patient has a stressful work or family situation, personal counseling may be helpful. Based on patient preference, make appropriate referrals or assist in making appointments if needed. The opportunity to discuss problems and attempt creative problem solving is often helpful. Teach the patient that regular exercise is important for managing stress and promoting regular bowel ELIMINATION.

# Herniation

## ❖Pathophysiology

A **hernia** is a weakness in the abdominal muscle wall through which a segment of the bowel or other abdominal structure protrudes. Hernias can also penetrate through any other defect in the abdominal wall, through the diaphragm, or through other structures in the abdominal cavity.

The most important elements in the development of a hernia are congenital or acquired muscle weakness and increased intra-abdominal pressure. The most significant factors contributing to increased intra-abdominal pressure are obesity, pregnancy, and lifting heavy objects.

The most common types of abdominal hernias (Fig. 56-7) are indirect, direct, femoral, umbilical, and incisional (McCance et al., 2014).

FIG. 56-7 Types of abdominal hernias.

- An **indirect inguinal hernia** is a sac formed from the peritoneum that contains a portion of the intestine or omentum. The hernia pushes downward at an angle into the inguinal canal. In males, indirect inguinal hernias can become large and often descend into the scrotum.
- **Direct inguinal hernias**, in contrast, pass through a weak point in the abdominal wall.
- **Femoral hernias** protrude through the femoral ring. A plug of fat in the femoral canal enlarges and eventually pulls the peritoneum and often the urinary bladder into the sac.
- **Umbilical hernias** are congenital or acquired. Congenital umbilical hernias appear in infancy. Acquired umbilical hernias directly result from increased intra-abdominal pressure. They are most commonly seen in people who are obese.
- **Incisional**, or **ventral, hernias** occur at the site of a previous surgical incision. These hernias result from inadequate healing of the incision, which is usually caused by postoperative wound infections, inadequate NUTRITION, and obesity.

Hernias may also be classified as reducible, irreducible (incarcerated), or strangulated. A hernia is **reducible** when the contents of the hernial sac can be placed back into the abdominal cavity by application of gentle pressure. An **irreducible** (incarcerated) hernia cannot be reduced or placed back into the abdominal cavity. *Any hernia that is not reducible requires immediate surgical evaluation.*

A hernia is **strangulated** when the blood supply to the herniated segment of the bowel is cut off by pressure from the hernial ring (the band of muscle around the hernia). If a hernia is strangulated, there is ischemia and obstruction of the bowel loop. *This can lead to necrosis of the bowel, sepsis, and possibly bowel perforation. Signs of strangulation are abdominal distention, nausea, vomiting, pain, fever, and tachycardia.*

Indirect inguinal hernias, the most common type, occur mostly in men because they follow the tract that develops when the testes descend into the scrotum before birth. Direct hernias occur more often in older adults. Femoral and adult umbilical hernias are most common in pregnant women or those with obesity. Incisional hernias can occur in people who have undergone abdominal surgery.

## ❖Interprofessional Collaborative Care

Care for the patient with a hernia usually takes place in the outpatient setting while the hernia is monitored. Patients with inguinal hernias often need surgery and will be hospitalized following this procedure. The interprofessional team that collaborates to care for this patient generally includes the health care provider (or surgeon, if the hernia requires surgical repair) and nurse.

### ◆ **Assessment: Noticing**

The patient with a hernia typically comes to the health care provider's office, clinic, or the emergency department with a report of a "lump" or protrusion felt at the involved site. The development of the hernia may be associated with straining or lifting.

Perform an abdominal assessment inspecting the abdomen when the patient is lying and again when he or she is standing. If the hernia is reducible, it may disappear when the patient is lying flat. The advanced practice nurse or other health care provider asks the patient to strain or perform the Valsalva maneuver and observes for bulging. Auscultate for active bowel sounds. *Absent bowel sounds may indicate obstruction and strangulation, which are considered medical emergencies.*

To palpate an inguinal hernia, the health care provider gently examines the ring and its contents by inserting a finger in the ring and noting any changes when the patient coughs. *The hernia is never forcibly reduced; this maneuver could cause strangulated intestine to rupture.*

If a male patient suspects a hernia in his groin, the health care provider has him stand for the examination. Using the right hand for the patient's right side and the left hand for the patient's left side, the examiner pushes in the loose scrotal skin with the index finger, following the spermatic cord upward to the external inguinal cord. At this point, the patient is asked to cough, and any palpable herniation is noted.

### ◆ **Interventions: Responding**

The type of treatment selected depends on patient factors such as age and the type and severity of the hernia.

#### **Nonsurgical Management.**

If the patient is not a surgical candidate (often an older man with multiple health problems), the health care provider may prescribe a truss for an inguinal hernia, usually for men. A **truss** is a pad made with firm material. It is held in place over the hernia with a belt to help keep the abdominal contents from protruding into the hernial sac. If a truss is used, it is applied only after the physician has reduced the hernia if it is not incarcerated. The patient usually applies the truss on awakening. Teach him to assess the skin under the truss daily and to protect it with a light layer of powder.

#### **Surgical Management.**

Most hernias are inguinal, and surgical repair is the treatment of choice. Surgery is usually performed on an ambulatory care basis for patients who have no pre-existing health conditions that would complicate the operative course. In same-day surgery centers, anesthesia may be regional or general, and the procedure is typically laparoscopic. If bowel strangulation and tissue death occur, more extensive surgery, such as a bowel resection or temporary colostomy, may be necessary. Patients undergoing this extensive surgery are hospitalized for a longer period.

Surgical repair of a hernia is called **herniorrhaphy**. A **minimally invasive inguinal hernia repair (MIIHR)** through a laparoscope is the surgery of choice. A conventional open herniorrhaphy may be performed when laparoscopy is not appropriate. Patients having minimally invasive surgery (MIS) recover more quickly, have less pain, and develop fewer postoperative complications compared with those having a conventional open surgery.

In addition to patient education about the procedure, the most important preoperative preparation is to teach the patient to remain NPO for the number of hours before surgery that the surgeon specifies. If same-day surgery is planned, remind the patient to arrange for someone to take him or her home and for that adult to be available for the rest of the day at home. For patients having a conventional open approach, provide general preoperative care as described in [Chapter 14](#).

During an MIIHR, the surgeon makes several small incisions, identifies the defect, and places the intestinal contents back into the abdomen. During a conventional open herniorrhaphy, the surgeon makes an abdominal incision to perform this procedure. When a **hernioplasty** is also performed,

the surgeon reinforces the weakened outside abdominal muscle wall with a mesh patch.

The patient who has had MIIHR is discharged from the surgical center in 3 to 5 hours, depending on recovery from anesthesia. Teach him or her to avoid strenuous activity for several days before returning to work and a normal routine. A stool softener may be needed to prevent constipation. Caution patients who are taking oral opioids for pain management to not drive or operate heavy machinery. Teach them to observe incisions for redness, swelling, heat, drainage, and increased pain and promptly report their occurrence to the surgeon. Remind patients that soreness and alterations in COMFORT (rather than severe, acute pain) are common after MIIHR. Be sure to make a follow-up telephone call on the day after surgery to check on the patient's status.

General postoperative care of patients having a hernia repair is the same as that described in [Chapter 16](#) *except that they should avoid coughing*. To promote lung expansion, encourage deep breathing and ambulation. With repair of an indirect inguinal hernia, the physician may suggest a scrotal support and ice bags applied to the scrotum to prevent swelling, which often contributes to pain. Elevation of the scrotum with a soft pillow helps prevent and control swelling.

In the immediate postoperative period, male patients who have had an inguinal hernia repair may experience difficulty voiding. Encourage them to stand to allow a more natural position for gravity to facilitate voiding and bladder emptying. Urine output of less than 30 mL per hour should be reported to the surgeon. Techniques to stimulate voiding such as allowing water to run may also be used. A fluid intake of at least 1500 to 2500 mL daily prevents dehydration, maintains urinary function, and minimizes constipation. A “straight” or intermittent (“in and out”) catheterization is required if the patient cannot void. [Chart 56-7](#) summarizes best nursing practices for postoperative care after an MIIHR.

#### **Chart 56-7**

### **Best Practice for Patient Safety & Quality Care**

#### **Nursing Care of the Postoperative Patient Having a Minimally Invasive Inguinal Hernia Repair (MIIHR)**

- Monitor vital signs, especially blood pressure, for indications of internal bleeding.
- Assess and manage incisional pain with oral analgesics; report and document severe pain that does not respond to drug therapy immediately.
- Encourage deep breathing after surgery; avoid excessive coughing.
- Encourage ambulation with assistance as soon as possible after surgery (within the first few hours).
- Apply ice packs as prescribed to the surgical area.
- Assist the patient to void by standing the first time after surgery.
- Teach patients at discharge to:
  - Rest for several days after surgery.
  - Observe the incision sites for redness or drainage and report these findings to the surgeon.
  - Shower after 24 to 36 hours after removing any bandage (do not remove Steri-Strips); be aware that the Steri-Strips will fall off in about a week.

- Monitor temperature for the first few days and report the occurrence of a fever.
- Do not lift more than 10 lb until allowed by the surgeon.
- Avoid constipation by eating high-fiber foods and drinking extra fluids.
- Return to work when allowed by the surgeon, usually in 1 to 2 weeks, depending on the patient's work responsibilities.

PROCEDURE: CHOICE OF ONE OF THE FOLLOWING	INTERVAL AFTER SCREENING INITIATED AT AGE 50 YEARS	COMMENTS
FOBT and sigmoidoscopy	Every 5 years	FOBT procedure: two or three samples from three consecutive bowel movements obtained at home; tested by physician or nurse
<i>or</i>		
Double-contrast barium enema	Every 5 years	
<i>or</i>		
Colonoscopy	Every 10 years	

FOBT, Fecal occult blood testing.

Most patients have uneventful recoveries after a hernia repair. Surgeons generally allow them to return to their usual activities after surgery, with avoidance of straining and lifting for several weeks while subcutaneous tissues heal and strengthen.

On discharge, provide oral instructions and a written list of symptoms to be reported, including fever, chills, wound drainage, redness or separation of the incision, and increasing incisional pain. Teach the patient to keep the wound dry and clean with antibacterial soap and water. Showering is usually permitted in a few days (see [Chart 56-7](#)).

## NCLEX Examination Challenge 56-4

### Physiological Integrity

The emergency department nurse is assessing a client with a known inguinal hernia. Which assessment findings indicate that the hernia may have strangulated? **Select all that apply.**

- A. Fever
- B. Tachycardia
- C. Abdominal distention
- D. Mild abdominal pain
- E. Nausea and vomiting

## Hemorrhoids

### ❖Pathophysiology

**Hemorrhoids** are unnaturally swollen or distended veins in the anorectal region. The veins involved in the development of hemorrhoids are part of the normal structure in the anal region. With limited distention, the veins function as a valve overlying the anal sphincter that assists in continence. Increased intra-abdominal pressure causes elevated systemic and portal venous pressure, which is transmitted to the anorectal veins. Arterioles in the anorectal region shunt blood directly to the distended anorectal veins, which increases the pressure. With repeated elevations in pressure from increased intra-abdominal pressure and engorgement from arteriolar shunting of blood, the distended veins eventually separate from the smooth muscle surrounding them. The result is prolapse of the hemorrhoidal vessels.

Hemorrhoids can be internal or external (Fig. 56-8). **Internal hemorrhoids**, which cannot be seen on inspection of the perineal area, lie above the anal sphincter. **External hemorrhoids** lie below the anal sphincter and can be seen on inspection of the anal region. Prolapsed hemorrhoids can become thrombosed or inflamed, or they can bleed (McCance et al., 2014).

**FIG. 56-8** Internal, external, and prolapsed hemorrhoids. *Internal hemorrhoids* lie above the anal sphincter and cannot be seen on inspection of the anal area. *External hemorrhoids* lie below the anal sphincter and can be seen on inspection of the anal region. Hemorrhoids that enlarge, fall down, and protrude through the anus are called *prolapsed hemorrhoids*.

Hemorrhoids are common and not significant unless they cause pain or bleeding. Because of the increase in abdominal pressure, the condition worsens during pregnancy, or with constipation with straining, obesity, heart failure, prolonged sitting or standing, and strenuous exercise and weight lifting. Decreased fluid intake can also cause hemorrhoids because of the development of hard stool and subsequent constipation. Straining while evacuating stool causes hemorrhoids to enlarge.

### Health Promotion and Maintenance

Prevention of constipation is the most essential measure to address hemorrhoids. It can be prevented by increasing fiber in the diet, such as eating more whole grains and raw vegetables and fruits. Encourage patients to drink plenty of water unless otherwise contraindicated (e.g., kidney disease, heart disease). Remind the patient to avoid straining at stool. Remind him or her to exercise regularly with a gradual buildup in intensity. Maintaining a healthy weight also helps prevent hemorrhoids.

### ❖Interprofessional Collaborative Care

Care of the patient with hemorrhoids usually takes place in the outpatient setting and is delivered by the health care provider and nurse. If surgery is required, the patient will be admitted to an

inpatient facility, and care is provided by the surgeon and nurse. The dietitian may be consulted to recommend nutrition sources that normalize bowel patterns and minimize constipation.

### ◆ **Assessment: Noticing**

The most common symptoms of hemorrhoids are bleeding, swelling, and prolapse (bulging). Blood is characteristically bright red and is present on toilet tissue or streaked in the stool. Pain is a common symptom and is often associated with thrombosis, especially if thrombosis occurs suddenly. Other symptoms include itching and a mucous discharge. Diagnosis is usually made by inspection and digital examination.

### ◆ **Interventions: Responding**

Interventions are typically conservative and are aimed at reducing symptoms with minimal discomfort, cost, and time lost from usual activities. Local treatment and NUTRITION therapy are used when symptoms begin. Cold packs applied to the anorectal region for a few minutes at a time beginning with the onset of pain and tepid sitz baths three or four times per day are often enough to relieve discomfort, even if the hemorrhoids are thrombosed.

Topical anesthetics, such as lidocaine (Xylocaine), are useful for severe pain. Dibucaine (Nupercainal) ointment and similar products are available over the counter and may be applied for mild-to-moderate pain and itching. However, this ointment should be used only temporarily, because it can mask worsening symptoms and delay diagnosis of a severe disorder. If itching or inflammation is present, the primary health care provider prescribes a steroid preparation, such as hydrocortisone. Cleansing the anal area with moistened cleansing tissues rather than standard toilet tissue helps avoid irritation. The anal area should be cleansed gently by dabbing rather than wiping.

Diets high in fiber and fluids are recommended to promote regular bowel movements without straining. Stool softeners, such as docusate sodium (Colace) or polyethylene glycol (Miralax), can be used temporarily. Irritating laxatives are avoided, as are foods and beverages that can make hemorrhoids worse. Spicy foods, nuts, coffee, and alcohol can be irritating. Remind patients to avoid sitting for long periods. The primary health care provider may prescribe mild oral analgesics for pain if the hemorrhoids are thrombosed.

Conservative treatment should alleviate symptoms in 3 to 5 days. If symptoms continue or recur frequently, the patient may require surgical intervention.

The surgeon can perform several procedures in an ambulatory care setting to remove symptomatic hemorrhoids (**hemorrhoidectomy**). The type of surgery (e.g., ultrasound or laser removal) depends on the degree of prolapse, whether there is thrombosis, and the overall condition of the patient. Complications of these procedures include pain, thrombosis of other hemorrhoids, infection, bleeding, and abscess formation. If the hemorrhoid is prolapsed, a circular stapling device may be used to excise a band of mucosa above the prolapse and restore the hemorrhoidal tissue back into the anal canal.

Teach patients with hemorrhoids about the need to eat high-fiber, high-fluid diets to promote regular bowel patterns before and after surgery. Advise them to avoid stimulant laxatives, which can be habit forming.

For patients who undergo any type of surgical intervention, monitor for bleeding and pain after surgery and teach them to report these problems to their health care provider. Using moist heat (e.g., sitz baths or warm compresses) three or four times per day can help promote COMFORT.

## ■ **Nursing Safety Priority** QSEN

### **Action Alert**

*Tell the patient who has had surgical intervention for hemorrhoids that the first postoperative bowel movement may be very painful. Be sure that someone is with or near the patient when this happens. Some patients become light-headed and diaphoretic and may have syncope related to a vasovagal response (Moss & Bordeianou, 2013).*

The health care provider usually prescribes stool softeners such as docusate sodium (Colace) to

begin before surgery and continue after surgery. Analgesics and anti-inflammatory drugs are prescribed. A mild laxative should be administered if the patient has not had a bowel movement by the third postoperative day.

# Malabsorption Syndrome

## ❖ Pathophysiology

**Malabsorption** is a syndrome associated with a variety of disorders and intestinal surgical procedures. This syndrome can be caused by inflammation, intrinsic disease, or injury to the lining of the intestine. With various disorders, physiologic mechanisms limit absorption of nutrients because of one or more of these abnormalities:

- Bile salt deficiencies
- Enzyme deficiencies
- Presence of bacteria
- Disruption of the mucosal lining of the small intestine
- Altered lymphatic and vascular circulation
- Decrease in the gastric or intestinal surface area

The nutrient involved in malabsorption depends on the type and location of the abnormality in the intestinal tract.

Deficiencies of bile salts can lead to malabsorption of fats and fat-soluble vitamins. Bile salt deficiencies can result from decreased synthesis of bile in the liver, bile obstruction, or alteration of bile salt absorption in the small intestine.

Enzymes normally found in the intestine split disaccharides (complex sugars) to monosaccharides (simple sugars). Examples of these enzymes are lactase, sucrase, maltase, and isomaltase. Lactase deficiency is the most common disaccharide enzyme deficiency. Without sufficient amounts of this enzyme, the body is not able to break down lactose. Lactase deficiency can be the result of genetic inheritance, injury to intestinal mucosa from viral hepatitis, or excessive bacteria in the intestine. Deficiencies of the other disaccharide enzymes are rare.

Pancreatic enzymes are also necessary for absorption of vitamin B<sub>12</sub>. With destruction or obstruction of the pancreas or insufficient pancreatic stimulation, this nutrient is not well absorbed. Chronic pancreatitis, pancreatic carcinoma, resection of the pancreas, and cystic fibrosis can cause these malabsorption problems.

Loops of bowel can accumulate intestinal contents, resulting in bacterial overgrowth, when peristalsis is decreased. Bacteria at these sites break down bile salts, and fewer salts are available for fat absorption. These bacteria can also ingest vitamin B<sub>12</sub>, which contributes to vitamin B<sub>12</sub> deficiency. This process can occur after a gastrectomy.

Obstruction to lymphatic flow in the intestine can lead to loss of plasma proteins along with loss of minerals (e.g., iron, copper, calcium), vitamin B<sub>12</sub>, folic acid, and lipids. Lymphatic obstruction can be caused by many conditions. Certain cancers such as lymphoma, inflammatory states, radiation enteritis, Crohn's disease, heart failure, and constrictive pericarditis are causes of lymphatic obstruction.

Interference with blood flow to the intestinal mucosa results in malabsorption. With intestinal surgery, there is loss of the surface area needed to facilitate absorption. Resection of the ileum results in vitamin B<sub>12</sub>, bile salt, and other nutrient deficiencies. Gastric surgery is one of the most common causes of malabsorption and maldigestion. Other conditions associated with poor digestion and malabsorption include small-bowel ischemia and radiation enteritis.

## ❖ Interprofessional Collaborative Care

Care of the patient with malabsorption syndrome may take place in the inpatient or outpatient setting depending on severity, and it is usually delivered by the health care provider and nurse.

### ◆ **Assessment: Noticing**

*Chronic diarrhea is a classic symptom of malabsorption.* It occurs as a result of unabsorbed nutrients, which add to the bulk of the stool, and unabsorbed fat. **Steatorrhea** (greater than normal amounts of fat in the feces) is a common sign. It is a result of bile salt deconjugation, nonabsorbed fats, or bacteria in the intestine. Not all patients with malabsorption have diarrhea. Instead some have an

increased stool mass. Other symptoms include:

- Unintentional weight loss
- Bloating and flatus (carbohydrate malabsorption)
- Decreased libido
- Easy bruising (purpura)
- Anemia (with iron and folic acid or vitamin B<sub>12</sub> deficiencies)
- Bone pain (with calcium and vitamin D deficiencies)
- Edema (caused by hypoproteinemia)

*Serum laboratory studies* reveal a decrease in mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC). These decreases indicate hypochromic microcytic anemia resulting from iron deficiency. Increased MCV and variable MCH and MCHC values indicate macrocytic anemia (pernicious anemia) resulting from vitamin B<sub>12</sub> and folic acid deficiencies. Serum iron levels are low in protein malabsorption because of insufficient gastric acid for use of iron. Serum cholesterol levels may be low from decreased absorption and digestion of fat. Low serum calcium levels may indicate malabsorption of vitamin D and amino acids. Low levels of serum vitamin A (retinol) and carotene, its precursor, indicate a bile salt deficiency and malabsorption of fat. Serum albumin and total protein levels are low if protein is lost.

A quantitative *fecal fat analysis* is often elevated in either malabsorption or maldigestive disorders (Pagana et al., 2017).

A *lactose tolerance test* is a type of disaccharidase analysis that may show an inability to digest foods and beverages that contain lactose. A hydrogen breath test can also be performed to detect this problem. The D-xylose absorption test can reveal low urine and serum D-xylose levels if malabsorption in the small intestine is present (Pagana et al., 2017).

The *Schilling test* measures urinary excretion of vitamin B<sub>12</sub> for diagnosis of pernicious anemia and a variety of other malabsorption syndromes. The *bile acid breath test* assesses the absorption of bile salt. If the patient has bacterial overgrowth, the bile salts will become deconjugated, and the carbon dioxide level in the breath will peak earlier than expected.

*Ultrasonography* is used to diagnose pancreatic tumors and tumors in the small intestine that are causing malabsorption. X-rays of the GI tract reveal pancreatic calcifications, tumors, or other abnormalities that cause malabsorption. A CT scan may also be done.

### ◆Interventions: Responding

Interventions for most malabsorption syndromes focus on (1) avoidance of substances that aggravate malabsorption, and (2) supplementation of nutrients. Surgical management of the primary disease may be indicated. Drug therapy may also improve or resolve malabsorption.

NUTRITION management includes a low-fat diet for patients who have gallbladder disease, severe steatorrhea, or cystic fibrosis. A low-fat diet may or may not be indicated for pancreatic insufficiency because this disorder improves with enzyme replacement. Some clinicians believe that limitation of fat intake is not necessary with enzyme replacement. Dietary intake of fat is actually beneficial to the patient because it has a high number of calories. After a total gastrectomy, a high-protein, high-calorie diet and small, frequent meals are recommended. Lactose-free or lactose-restricted diets are available for patients with lactase deficiency, and gluten-free diets are available for those with celiac disease, discussed in Chapter 57.

The health care provider prescribes NUTRITION supplements according to the specific deficiency. Common supplements include:

- Water-soluble vitamins, such as folic acid and vitamin B complex
- Fat-soluble vitamins, such as vitamins A, D, and K
- Minerals, such as calcium, iron, and magnesium
- Pancreatic enzymes, such as pancrelipase (Pancrease, Viokase)

Antibiotics are used to treat disorders involving bacterial overgrowth. Bacterial overgrowth can be caused by a variety of disorders but is often treated with tetracycline and metronidazole (Flagyl, Novonidazol).

Drug therapy is used to control the signs and symptoms of malabsorption. Antidiarrheal agents,

such as diphenoxylate hydrochloride and atropine sulfate (Lomotil, N-Lomotil), are often used to control diarrhea and steatorrhea. Anticholinergics, such as dicyclomine hydrochloride (Bentyl, Bentylol), may be given before meals to inhibit gastric motility. IV fluids may be necessary to replenish fluid losses associated with diarrhea.

Provide special measures to protect the skin when chronic diarrhea occurs (Chart 56-8). Conduct an ongoing assessment for signs and symptoms of malabsorption and relate these to activities and dietary intake. For example, patients with steatorrhea are monitored for FLUID AND ELECTROLYTE BALANCE and are encouraged to drink electrolyte-rich liquids liberally. Teach them the rationale for dietary, drug, and surgical management of nutritional deficiencies and evaluate interventions on the basis of changes in or resolution of signs and symptoms.

### Chart 56-8

## Best Practice for Patient Safety & Quality Care

### Special Skin Care for Patients With Chronic Diarrhea

- Use medicated wipes or premoistened disposable wipes rather than toilet tissue to clean the perineal area.
- Clean the perineal area well with mild soap and warm water after each stool; rinse soap from the area well.
- If the physician allows, provide a sitz bath several times per day.
- Apply a thin coat of A+D ointment or other medicated protective barrier, such as aloe products, after each stool.
- Keep the patient off the affected buttock area.
- Cover open areas with thin DuoDerm or Tegaderm occlusive dressing to promote rapid healing.
- Observe for fungal or yeast infections, which appear as dark red rashes with “satellite” lesions. Obtain prescription for medication if this problem occurs.

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Collaborate with the certified wound, ostomy, continence nurse (CWOCN) or enterostomal therapist (ET) when a patient is scheduled for or has a new colostomy. **QSEN: Teamwork and Collaboration**
- Collaborate with the case manager/discharge planner, health care provider, and CWOCN to plan care for the patient with colorectal cancer (CRC). **QSEN: Teamwork and Collaboration**

### Health Promotion and Maintenance

- Refer patients with familial CRC syndromes for genetic counseling and testing. **QSEN: Evidence-Based Practice**
- Refer ostomy patients to the United Ostomy Associations of America, Inc. and the American Cancer Society for additional information and support groups. **QSEN: Patient-Centered Care**
- Teach patients with irritable bowel syndrome (IBS) to avoid GI stimulants, such as caffeine, alcohol, and milk and milk products, and to manage stress. **QSEN: Evidence-Based Practice**
- Instruct patients on dietary modifications to decrease the occurrence of CRC, such as eating a diet high in fiber and avoiding red meat. **QSEN: Evidence-Based Practice**
- Teach adults 50 years and older to have routine screening for CRC as listed in [Chart 56-4](#); people with genetic predispositions should have earlier and more frequent screening. **QSEN: Evidence-Based Practice**
- Teach people to prevent or manage constipation to help avoid hemorrhoids; teach patients the importance of maintaining a healthy weight to decrease the risk for hemorrhoids. **QSEN: Evidence-Based Practice**
- Teach patients and caregivers how to provide colostomy care, including dietary measures, skin care, and ostomy products. **QSEN: Patient-Centered Care**

### Psychosocial Integrity

- Assist the patient with CRC with the grieving process. **QSEN: Patient-Centered Care**
- Be aware that having a colostomy is a life-altering event that can severely impact one's body image; issues related to sexuality and fear of acceptance should be discussed. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Be aware that minimally invasive inguinal hernia repair is an ambulatory care procedure done via laparoscopy; postoperative management requires health teaching regarding rest for a few days and inspection of incisions for signs of infection (see [Chart 56-7](#)). **QSEN: Evidence-Based Practice**
- Be aware that a strangulated hernia can cause ischemia and bowel obstruction, requiring immediate intervention. **QSEN: Safety**
- Monitor patients who have conventional open herniorrhaphy for ability to void. **QSEN: Safety**
- Recall that changes in bowel habits or stool characteristics and/or rectal bleeding are often associated with a diagnosis of CRC. **QSEN: Safety**
- Keep the peristomal skin clean and dry; observe for leakage around the pouch seal. **QSEN: Evidence-Based Practice**
- Provide meticulous perineal wound care for patients having an abdominoperineal (AP) resection,

as described in [Chart 56-5](#). **QSEN: Safety**

- Recognize characteristics of the colostomy stoma, which should be reddish pink and moist; report abnormalities such as ischemia and necrosis (purplish or black) or unusual bleeding to the surgeon. **Clinical Judgment**
- Recall that bowel sounds are altered in patients with obstruction; absent bowel sounds imply total obstruction. **QSEN: Safety**
- Assess the patient's nasogastric tube for proper placement, patency, and output at least every 4 hours. **QSEN: Safety**
- Monitor patients with bowel obstruction for signs and symptoms of fluid, electrolyte, and acid-base imbalances; patients with small bowel obstruction are at greater risk for problems with FLUID AND ELECTROLYTE BALANCE. **QSEN: Safety**
- Teach patients having hemorrhoid surgery to take stool softeners before and after surgery to decrease discomfort during ELIMINATION. **QSEN: Evidence-Based Practice**
- Provide COMFORT measures for the patient who has chronic diarrhea associated with malabsorption as described in [Chart 56-8](#). **QSEN: Patient-Centered Care**
- Reinforce teaching regarding supplements or dietary restrictions needed for malabsorption management. **QSEN: Evidence-Based Practice**

## CHAPTER 57

# Care of Patients With Inflammatory Intestinal Disorders

Keelin Cromar

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concepts for this chapter are:**

- IMMUNITY
- ELIMINATION

✚ The IMMUNITY concept exemplar for this chapter is Peritonitis, below.

✚ The ELIMINATION concept exemplar for this chapter is Ulcerative Colitis, p. 1150.

**The interrelated concepts for this chapter are:**

- NUTRITION
- COMFORT
- FLUID AND ELECTROLYTE BALANCE

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to protect and provide care for the patient with an inflammatory bowel disorder (IBD).
2. Identify community resources to ensure appropriate transition management for patients with an inflammatory bowel disorder (IBD).

### Health Promotion and Maintenance

3. Teach patients how to self-care for an ileostomy or other surgical diversion.
4. Discuss ways to prevent gastroenteritis.

### Psychosocial Integrity

5. Implement nursing interventions to minimize stressors for the patient with an inflammatory bowel disorder (IBD) who has ileostomy or other surgical diversion.

### Physiological Integrity

6. Differentiate pathophysiology and presentation of common types of acute inflammatory bowel disorders (IBDs).
7. Prioritize care for patients with inflammatory bowel disorders (IBDs).
8. Discuss the purpose of, and nursing implications related to, drug therapy for patients with an inflammatory bowel disorder (IBD).
9. Create an evidence-based plan of care for the patient undergoing surgery for an inflammatory bowel disorder (IBD).
0. Explain the role of NUTRITION therapy in caring for a patient with diverticular disease.
1. Describe nursing interventions that promote IMMUNITY, COMFORT, and ELIMINATION and maintain FLUID AND ELECTROLYTE BALANCE for patients with an inflammatory bowel disorder (IBD).

The *intestinal tract* is made up of the small intestine and large intestine (colon). Continued digestion of food and absorption of nutrients occurs primarily in the small intestine to meet the body's needs for energy. Water is reabsorbed in the large intestine to help maintain a fluid balance and promote the passage of waste products. When the intestinal tract and its nearby structures become inflamed, NUTRITION may be inadequate to meet a patient's needs. Bowel ELIMINATION changes, COMFORT is altered, and IMMUNITY concerns and/or problems with FLUID AND ELECTROLYTE BALANCE can arise.

# Acute Inflammatory Bowel Disorders

Appendicitis, gastroenteritis, and peritonitis are the most common acute inflammatory bowel problems. These disorders are potentially life threatening and can have major systemic complications if not treated promptly.

## Immunity Concept Exemplar Peritonitis

**Peritonitis** is a life-threatening, acute inflammation and infection of the visceral/parietal peritoneum and endothelial lining of the abdominal cavity. This type of acute inflammation and infection alters the body's process of IMMUNITY (see [Chapter 2](#)). Primary peritonitis is rare (and thus not discussed here) and indicates that the peritoneum is infected via the bloodstream.

### Pathophysiology

Normally the peritoneal cavity contains about 50 mL of sterile fluid (transudate), which prevents friction in the abdominal cavity during peristalsis. When the peritoneal cavity is contaminated by bacteria, the body first begins an inflammatory reaction, walling off a localized area to fight the infection. The body's IMMUNITY is immediately affected by this local reaction, which involves vascular dilation and increased capillary permeability, allowing transport of leukocytes and subsequent phagocytosis of the offending organisms. If the process of walling-off fails, the inflammation spreads, and contamination becomes massive, resulting in diffuse (widespread) peritonitis.

Peritonitis is most often caused by contamination of the peritoneal cavity by bacteria or chemicals. Bacteria gain entry into the peritoneum by perforation (from appendicitis, diverticulitis, peptic ulcer disease) or from an external penetrating wound, a gangrenous gallbladder, bowel obstruction, or ascending infection through the genital tract. Less common causes include perforating tumors, leakage or contamination during surgery, and infection by skin pathogens in patients undergoing continuous ambulatory peritoneal dialysis (CAPD).

When diagnosis and treatment of peritonitis are delayed, blood vessel dilation continues. The body responds to the continuing infectious process by shunting extra blood to the area of inflammation (hyperemia). Fluid is shifted from the extracellular fluid compartment into the peritoneal cavity, connective tissues, and GI tract ("*third spacing*"). This shift of fluid can result in a significant decrease in circulatory volume and *hypovolemic shock*. Severely decreased circulatory volume can result in insufficient perfusion of the kidneys, leading to acute kidney injury with impaired FLUID AND ELECTROLYTE BALANCE ([McCance et al., 2014](#)). Assess for signs and symptoms of these life-threatening problems.

*Peristalsis slows or stops* in response to severe peritoneal inflammation, and the lumen of the bowel becomes distended with gas and fluid. Fluid that normally flows to the small bowel and the colon for reabsorption accumulates in the intestine in volumes of 7 to 8 L daily. The toxins or bacteria responsible for the peritonitis can also enter the bloodstream from the peritoneal area and lead to bacteremia or **septicemia** (bacterial invasion of the blood), a life-threatening condition when the body's IMMUNITY is compromised.

*Respiratory problems* can occur as a result of increased abdominal pressure against the diaphragm from intestinal distention and fluid shifts to the peritoneal cavity. Pain can interfere with respirations at a time when the patient has an increased oxygen demand because of the infectious process.

### Etiology

Common bacteria responsible for peritonitis include *Escherichia coli*, *Streptococcus*, *Staphylococcus*, *Pneumococcus*, and *Gonococcus*. Chemical peritonitis results from leakage of bile, pancreatic enzymes, and gastric acid ([McCance et al., 2014](#)), all of which can greatly alter the patient's IMMUNITY.

### Incidence and Prevalence

Peritonitis is the dominant cause of death from surgical infections, with a mortality rate of up to

20% (Doklešćić et al., 2014).

### ❖ **Interprofessional Collaborative Care**

Patients with peritonitis are hospitalized because of the severe nature of the illness. If complications are extensive, the patients are often admitted to a critical care unit. The interprofessional team that collaborates to care for this patient generally includes the health care provider (and/or surgeon), nurse, respiratory therapist, and social worker to facilitate transition.

### ◆ **Assessment: Noticing**

#### **History.**

Ask the patient about abdominal pain and determine the character of the pain (e.g., cramping, sharp, aching), location of the pain, and whether the pain is localized or generalized. Ask about a history of a low-grade fever or recent spikes in temperature.

#### **Physical Assessment/Signs and Symptoms.**

Physical findings of peritonitis (Chart 57-1) depend on several factors: the stage of the disease, the ability of the body to localize the process by walling off the infection, and whether the inflammation has progressed to generalized peritonitis. The patient most often appears acutely ill, lying still, possibly with the knees flexed. Movement is guarded, and he or she may report and show signs of pain (e.g., facial grimacing) with coughing or movement of any type. During inspection, observe for progressive abdominal distention, often seen when the inflammation markedly reduces intestinal motility. Auscultate for bowel sounds, which usually disappear with progression of the inflammation.

#### ▶ **Chart 57-1**

### **Key Features**

#### **Peritonitis**

- Rigid, boardlike abdomen (classic)
- Abdominal pain (localized, poorly localized, or referred to the shoulder or chest)
- Distended abdomen
- Nausea, anorexia, vomiting
- Diminishing bowel sounds
- Inability to pass flatus or feces
- Rebound tenderness in the abdomen
- High fever
- Tachycardia
- Dehydration from high fever (poor skin turgor)
- Decreased urine output
- Hiccups
- Possible compromise in respiratory status

*The cardinal signs of peritonitis are abdominal pain, tenderness, and distention. In the patient with*

*localized* peritonitis, the abdomen is tender on palpation in a well-defined area with rebound tenderness in this area. With *generalized* peritonitis, tenderness is widespread.

### Psychosocial Assessment.

The patient with peritonitis may be very fearful and anxious about the implications of a diagnosis of peritonitis and may be distressed regarding the physical pain that he or she feels. Provide a calm, nonanxious presence and reassure the patient that you will stay with him or her during this time. Allow the patient to express feelings of fear and anxiety, and provide nonjudgmental listening and presence.

## Nursing Safety Priority QSEN

### Action Alert

For patients with peritonitis, assess for abdominal wall rigidity, which is a classic finding that is sometimes referred to as a “boardlike” abdomen. Monitor the patient for a high fever because of the infectious process. Assess for tachycardia occurring in response to the fever and decreased circulating blood volume. Observe whether he or she has dry mucous membranes and a low urine output seen with third spacing. Nausea and vomiting may also be present. Hiccups may occur as a result of diaphragmatic irritation. Be sure to document all assessment findings.

### Laboratory Assessment.

*White blood cell (WBC) counts* are often elevated to 20,000/mm<sup>3</sup> with a high neutrophil count. *Blood culture* studies may be done to determine whether septicemia has occurred and to identify the causative organism to enable appropriate antibiotic therapy. The health care provider may request laboratory tests to assess FLUID AND ELECTROLYTE BALANCE and renal status, including blood urea nitrogen (BUN), creatinine, hemoglobin, and hematocrit. Oxygen saturation and end-carbon dioxide monitoring may be obtained to assess respiratory function and acid-base balance.

### Imaging Assessment.

*Abdominal x-rays* can assess for free air or fluid in the abdominal cavity, indicating perforation. The x-rays may also show dilation, edema, and inflammation of the small and large intestines. An *abdominal ultrasound* may also be performed.

### ◆ Analysis: Interpreting

The priority collaborative problems for patients with peritonitis include:

1. Potential for infection due to peritonitis
2. Potential for fluid volume shift due to fluid moving into interstitial or peritoneal space
3. Acute pain due to peritonitis

### ◆ Planning and Implementation: Responding

#### Decreasing Potential for Infection

#### Planning: Expected Outcomes.

The patient will be free from infection.

#### Interventions

#### Nonsurgical Management.

Assess vital signs frequently, noting any change that may indicate septic shock, such as unresolved or progressive hypotension, decreased pulse pressure, tachycardia, fever, skin changes, and/or tachypnea. Monitor mental changes for any sign of confusion or altered level of consciousness. Practice proper handwashing and maintain strict asepsis when caring for wounds, drains, and

dressings to decrease chance of infection. If the patient has or requires a urinary catheter, maintain strict sterile technique and provide appropriate catheter care. Observe and document wound drainage; report any changes immediately to the health care provider. Administer broad-spectrum antibiotics as prescribed to treat known or potential pathogens. Apply oxygen as ordered and according to the patient's respiratory status and oxygen saturation via pulse oximetry (e.g., SpO<sub>2</sub> less than 93%).

### **Surgical Management.**

Abdominal surgery may be needed to identify and repair the cause of the peritonitis to decrease further chance for infection. If the patient is critically ill and surgery would be life threatening, it may be delayed. Surgery focuses on controlling the contamination, removing foreign material from the peritoneal cavity, and draining collected fluid.

Exploratory laparotomy (surgical opening into the abdomen) or laparoscopy is used to remove or repair the inflamed or perforated organ (e.g., appendectomy for an inflamed appendix; a colon resection, with or without a colostomy, for a perforated diverticulum). Before the incision(s) is closed, the surgeon irrigates the peritoneum with antibiotic solutions. Several catheters may be inserted to drain the cavity and provide a route for irrigation after surgery.

If an open surgical procedure is needed, the infection may slow healing of an incision, or the incision may be partially open to heal by second or third intention. These wounds require special care involving manual irrigation or packing as prescribed by the surgeon. If the surgeon requests peritoneal irrigation through a drain, *maintain sterile technique during manual irrigation* to prevent further risk for infection. The preoperative care is similar to that described in [Chapter 14](#) for patients having general anesthesia. [Chapter 16](#) describes general postoperative care.

## **Nursing Safety Priority** QSEN

### **Action Alert**

Monitor the patient's level of consciousness, vital signs, respiratory status (respiratory rate and breath sounds), and intake and output at least hourly immediately after abdominal surgery. Maintain the patient in a semi-Fowler's position to promote drainage of peritoneal contents into the lower region of the abdominal cavity. This position also helps increase lung expansion.

### **Restoring Fluid Volume Balance**

#### **Planning: Expected Outcomes.**

The patient will experience restoration of fluid volume balance.

#### **Interventions.**

The health care provider prescribes hypertonic IV fluids and broad-spectrum antibiotics immediately after establishing the diagnosis of peritonitis. IV fluids are used to replace fluids collected in the peritoneum and bowel. Monitor daily weight and intake and output carefully. A nasogastric tube (NGT) decompresses the stomach and the intestine, and the patient is NPO.

Multi-system complications can occur with peritonitis. Loss of fluids and electrolytes from the extracellular space to the peritoneal cavity, NGT suctioning, and NPO status require that the patient receives IV fluid replacement. Be sure that unlicensed assistive personnel (UAP) carefully measure intake and output. Fluid rates may be changed frequently based on laboratory values, assessment findings, and patient condition.

Assess whether the patient retains fluid used for irrigation by comparing and recording the amount of fluid returned with the amount of fluid instilled. Fluid retention could cause abdominal distention or pain.

### **Managing Acute Pain**

#### **Planning: Expected Outcomes.**

The patient with peritonitis is expected to report pain control as evidenced by no more than a 3 on a 0-to-10 pain intensity scale.

## Interventions.

Peritonitis causes significant alteration in COMFORT. Interventions to manage pain focus on drug therapy. Administer analgesics and monitor for pain control. Document all pain assessments and interventions implemented to promote comfort thoroughly.

## Care Coordination and Transition Management

### Home Care Management.

The length of hospitalization for a patient with peritonitis depends on the extent and severity of the infectious process. Patients who have a localized abscess drained and who respond to antibiotics and IV fluids without multi-system complications are discharged in several days. Others may require mechanical ventilation or hemodialysis with longer hospital stays. Some patients may be transferred to a transitional care unit to complete their antibiotic therapy and recovery. Convalescence is often longer than for other surgeries because of multi-system involvement.

### Self-Management Education.

When discharged home, assess the patient's ability for self-management at home with the added task of incision care and a reduced activity tolerance. Provide the patient and family with written and oral instructions to report the following problems to the health care provider immediately:

- Unusual or foul-smelling drainage
- Swelling, redness, or warmth or bleeding from the incision site
- A temperature higher than 101° F (38.3° C)
- Abdominal pain
- Signs of wound dehiscence or ileus

Patients with large incisions heal by second or third intention and may require dressings, solution, and catheter-tipped syringes to irrigate the wound. A home care nurse may be needed to assess, irrigate, or pack the wound and change the dressing as needed until the patient and family feel comfortable with the procedure. If the patient needs assistance with ADLs, a home care aide or temporary placement in a skilled care facility may be indicated.

Review information about antibiotics and analgesics. For patients taking oral opioid analgesics such as oxycodone with acetaminophen (Percocet, Endocet) for any length of time, a stool softener such as docusate sodium (Colace) may be prescribed with a laxative such as Senna. Older adults are especially at risk for constipation from codeine-based drugs. Remind patients to avoid taking additional acetaminophen (Tylenol) to prevent liver toxicity.

Teach patients to refrain from any lifting for *at least* 6 weeks after an open surgical procedure. Other activity limitations are made on an individual basis with the health care provider's recommendation. Patients who have laparoscopic surgery can resume activities within a week or two and may not have any major restrictions.

## NCLEX Examination Challenge 57-1

### Safe and Effective Care Environment

A client who recently had laparoscopic surgery to treat a ruptured appendix has developed subsequent peritonitis. The client currently has two Jackson Pratt drains placed in the abdomen. Which finding(s) would the nurse report **immediately** to the surgeon? **Select all that apply.**

- A. Serosanguineous drainage
- B. Fever
- C. Cloudy drainage
- D. Painful abdominal distention
- E. Pain level 3 on a scale of 1 to 10

## Health Care Resources.

Patients with peritonitis may benefit from a social services consultation. Social workers can help patients locate the most appropriate and affordable supplies that will be needed for ongoing care. Collaborate with the case manager (CM) to determine the appropriate setting for seamless continuing care in the community.

### ◆Evaluation: Reflecting

Evaluate the care of the patient with peritonitis based on the identified priority patient problems. The expected outcomes are that the patient:

- Does not develop further infection
- Experiences restoration of fluid balance
- Verbalizes relief or control of pain and alterations in COMFORT

## Appendicitis

### ❖Pathophysiology

Appendicitis is an acute inflammation of the vermiform appendix that occurs most often among young adults. It is the most common cause of right lower quadrant (RLQ) pain. The appendix usually extends off the proximal cecum of the colon just below the ileocecal valve. Inflammation occurs when the lumen (opening) of the appendix is obstructed (blocked), leading to infection as bacteria invade the wall of the appendix. The initial obstruction is usually a result of fecaliths (very hard pieces of feces) composed of calcium phosphate-rich mucus and inorganic salts. Less common causes are malignant tumors, helminthes (worms), or other infections (McCance et al., 2014).

When the lumen is blocked, the mucosa secretes fluid, increasing the internal pressure and restricting blood flow, which results in pain. If the process occurs slowly, an abscess may develop, but a rapid process may result in peritonitis (inflammation and infection of the peritoneum). *All complications of peritonitis are serious. Gangrene and sepsis can occur within 24 to 36 hours, are life threatening, and are some of the most common indications for emergency surgery. Perforation may develop within 24 hours, but the risk rises rapidly after 48 hours.* Perforation of the appendix also results in peritonitis with a temperature of greater than 101° F (38.3° C) and a rise in pulse rate.

## Considerations for Older Adults

### Patient-Centered Care QSEN

Appendicitis is relatively rare at extremes in age. However, perforation is more common in older adults, causing a higher mortality rate. The diagnosis of appendicitis is difficult to establish in older adults because symptoms of pain and tenderness may not be as pronounced in this age-group. This difference results in treatment delay and an increased risk for perforation, peritonitis, and death.

### ❖Interprofessional Collaborative Care

Patients with appendicitis are hospitalized because of the severe nature of the illness. The interprofessional team that collaborates most closely to care for this patient generally includes the health care provider, surgeon, and nurse.

### ◆Assessment: Noticing

History taking and tracking the sequence of symptoms are important because nausea or vomiting before abdominal pain can indicate gastroenteritis. Abdominal pain followed by nausea and vomiting can indicate appendicitis. Ask about risk factors such as age, familial tendency, and intra-abdominal tumors. Classically, patients with appendicitis have cramping pain in the epigastric or periumbilical area. Anorexia is a frequent symptom, with nausea and vomiting occurring in many cases.

Perform a complete pain assessment. Initially pain can present anywhere in the abdomen or flank area. As the inflammation and infection progress, the pain becomes more severe and steady and

shifts to the RLQ between the anterior iliac crest and the umbilicus. This area is referred to as *McBurney's point* (Fig. 57-1). *Abdominal pain that increases with cough or movement and is relieved by bending the right hip or the knees suggests perforation and peritonitis.* An advanced practice nurse or other health care provider will assess for muscle rigidity and guarding on palpation of the abdomen. The patient may report pain after release of pressure. This is referred to as *rebound tenderness*.

**FIG. 57-1** McBurney's point is located midway between the anterior iliac crest and the umbilicus in the right lower quadrant. This is the classic area for localized tenderness during the later stages of appendicitis.

Laboratory findings do not establish the diagnosis, but often there is a moderate elevation of the *white blood cell (WBC) count* (leukocytosis) to 10,000 to 18,000/mm<sup>3</sup> with a “shift to the left” (an increased number of immature WBCs). A WBC elevation to greater than 20,000/mm<sup>3</sup> may indicate a perforated appendix. An *ultrasound* study may show the presence of an enlarged appendix. If symptoms are recurrent or prolonged, a CT scan can be used for diagnosis and may reveal the presence of a fecaloma (a small “stone” of feces).

#### ◆ **Interventions: Responding**

All patients with suspected or confirmed appendicitis are hospitalized, and most have surgery to remove the inflamed appendix.

#### **Nonsurgical Management.**

Keep the patient with suspected or known appendicitis NPO to prepare for the possibility of surgery and to avoid making the inflammation worse. Before surgical intervention be sure that the patient's pain is adequately managed.

### **Nursing Safety Priority** QSEN

#### **Action Alert**

For the patient with suspected appendicitis, administer IV fluids as prescribed to maintain FLUID AND ELECTROLYTE BALANCE and replace fluid volume. If tolerated, advise the patient to maintain a semi-Fowler's position so abdominal drainage can be contained in the lower abdomen. Once the diagnosis of appendicitis is confirmed and surgery is scheduled, administer opioid analgesics and antibiotics as prescribed. *The patient with suspected or confirmed appendicitis should not receive laxatives or enemas, which can cause perforation of the appendix. Do not apply heat to the abdomen because this may increase circulation to the appendix and result in increased inflammation and perforation!*

#### **Surgical Management.**

Surgery is required as soon as possible. An **appendectomy** is the removal of the inflamed appendix by one of several surgical approaches. Uncomplicated appendectomy procedures are done via laparoscopy. A **laparoscopy** is a minimally invasive surgery (MIS) with one or more small incisions

near the umbilicus through which a small endoscope is placed. Patients having this type of surgery for appendix removal have few postoperative complications (see [Chapter 15](#)). A procedure known as natural orifice transluminal endoscopic surgery (NOTES) (e.g., transvaginal endoscopic appendectomy) does not require an external skin incision. In this procedure the surgeon places the endoscope into the vagina or other orifice and makes a small incision to enter the peritoneal space. Patients having any type of laparoscopic procedure are typically discharged the same day of surgery with less pain and few complications after discharge. Most patients can return to usual activities in 1 to 2 weeks.

If the diagnosis is not definitive but the patient is at high risk for complications from suspected appendicitis, the surgeon may perform an exploratory laparotomy to rule out appendicitis. A **laparotomy** is an open surgical approach with a large abdominal incision for complicated or atypical appendicitis or peritonitis.

Preoperative teaching is often limited because the patient is in pain or may be admitted quickly for emergency surgery. The patient is prepared for general anesthesia and surgery as described in [Chapter 14](#). After surgery, care of the patient who has undergone an appendectomy is the same as that required for anyone who has received general anesthesia (see [Chapter 16](#)).

If complications such as peritonitis or abscesses are found during *open* traditional surgery, wound drains are inserted, and a nasogastric tube may be placed to decompress the stomach and prevent abdominal distention. Administer IV antibiotics and opioid analgesics as prescribed. Help the patient out of bed on the evening of surgery to help prevent respiratory complications, such as atelectasis. He or she may be hospitalized for as long as 3 to 5 days and return to normal activity in 4 to 6 weeks.

## Gastroenteritis

### ❖ Pathophysiology

**Gastroenteritis** is a very common health problem worldwide that causes diarrhea and/or vomiting as a result of inflammation of the mucous membranes of the stomach and intestinal tract. It affects mainly the small bowel and can be caused by either viral (more common) or bacterial infection. [Table 57-1](#) lists common types of gastroenteritis and their primary characteristics.

**TABLE 57-1**

**Common Types of Gastroenteritis and Their Characteristics**

TYPE	CHARACTERISTICS
<b>Viral Gastroenteritis</b>	
Epidemic viral	Caused by many parvovirus-type organisms Transmitted by the fecal-oral route in food and water Incubation period 10-51 hr Communicable during acute illness
Norovirus (Norwalk viruses)	Transmitted by the fecal-oral route and possibly the respiratory route (vomitus) Incubation in 48 hr Affects adults of all ages Older adults can become hypovolemic and experience electrolyte imbalances
<b>Bacterial Gastroenteritis</b>	
<i>Campylobacter</i> enteritis	Transmitted by the fecal-oral route or by contact with infected animals or infants Incubation period 1-10 days Communicable for 2-7 weeks
<i>Escherichia coli</i> diarrhea	Transmitted by fecal contamination of food, water, or fomites
Shigellosis	Transmitted by direct and indirect fecal-oral routes Incubation period 1-7 days Communicable during the acute illness to 4 weeks after the illness Humans possibly carriers for months

Norovirus (also known as a *Norwalk-like virus*) is the leading foodborne disease that causes gastroenteritis. It occurs most often between November and April because it is resistant to low temperatures and has a long viral shedding before and after the illness. Norovirus is transmitted (spread) through the fecal-oral route from person to person and from contaminated food and water. Infected individuals can also contaminate surfaces and objects in the environment. Vomiting may cause the virus to become airborne. The incubation time is 1 to 2 days.

In most cases of gastroenteritis, the illness is self-limiting and lasts about 3 days. However, in those who are immunosuppressed or in older adults, dehydration and hypovolemia can occur as complications requiring medical attention and possibly hospitalization.

### Health Promotion and Maintenance

Outbreaks of norovirus have occurred in prisons, on cruise ships, and in nursing homes, college

dormitories, and other places where large groups of people are in close proximity. Handwashing and sanitizing surfaces and other environmental items help prevent the spread of the illness. Hand sanitizers are often placed in public areas so hands can be cleaned when washing with soap and water is inconvenient. Proper food and beverage preparation is also important to prevent contamination.

### ❖ **Interprofessional Collaborative Care**

Patients with gastroenteritis are generally cared for in the community setting and self-manage at home. Those who develop the more severe types of this condition, or become extremely dehydrated during its course, may be hospitalized. The interprofessional team that collaborates to care for this patient generally includes the health care provider and nurse.

### ◆ **Assessment: Noticing**

The patient history can provide information related to the potential cause of the illness. Ask about recent travel, especially to tropical regions of Asia, Africa, Mexico, or Central or South America, because these areas historically have been a source of gastroenteritis. Inquire if the patient has eaten at any restaurant in the past 24 to 36 hours. Some have acquired gastroenteritis from eating in “fast-food” restaurants or from food items purchased at a farmer's market or grocery store. Bacterial infections have caused large outbreaks that resulted from contaminated spinach and lettuce in the United States.

The patient who has gastroenteritis usually looks ill. Nausea and vomiting typically occur first, followed by abdominal cramping and diarrhea.

For patients who are older or for those who have inadequate immune systems, weakness and cardiac dysrhythmias may occur from loss of potassium (hypokalemia) from diarrhea. Monitor for and document manifestations of hypokalemia and hypovolemia (dehydration).

## ■ **Nursing Safety Priority** QSEN

### Action Alert

For patients with gastroenteritis, note any abdominal distention and listen for hyperactive bowel sounds. Depending on the amount of fluids and electrolytes lost through diarrhea and vomiting, patients may have varying degrees of dehydration manifested by:

- Poor skin turgor
- Fever (not common in older adults)
- Dry mucous membranes
- Orthostatic blood pressure changes (which can cause a fall, especially for older adults)
- Hypotension
- Oliguria (decreased or absent urinary output)

In some cases, dehydration may be severe. It occurs rapidly in older adults. Monitor mental status changes, such as acute confusion, that result from hypoxia in the older adult. These changes may be the only signs and symptoms of dehydration in older adults.

### ◆ **Interventions: Responding**

For any type of gastroenteritis, encourage fluid replacement. The amount and route of fluid administration are determined by the patient's hydration status and overall health condition. Teach patients to drink extra fluids to replace fluid lost through vomiting and diarrhea. Oral rehydration therapy (ORT) may be needed for some patients to replace fluids and electrolytes. Examples of ORT solutions include Gatorade, Pedialyte, and Powerade. Depending on the patient's age and severity of dehydration, he or she may be treated in the hospital with IV fluids to restore hydration.

Drugs that suppress intestinal motility may not be given for bacterial or viral gastroenteritis. *Use of these drugs can prevent the infecting organisms from being eliminated from the body.* If the health care provider determines that antiperistaltic agents are necessary, loperamide (Imodium) may be recommended.

## Nursing Safety Priority QSEN

### Drug Alert

Diphenoxylate hydrochloride with atropine sulfate (Lomotil, Lomanate) reduces GI motility but is used sparingly because of its habit-forming ability. *The drug should not be used for older adults because it also causes drowsiness and could contribute to falls.*

Treatment with antibiotics may be needed if the gastroenteritis is caused by bacterial infection with fever and severe diarrhea. Depending on the type and severity of the illness, examples of drugs that may be prescribed include ciprofloxacin (Cipro) or azithromycin (Zithromax). If the gastroenteritis is caused by shigellosis, anti-infective agents such as trimethoprim/sulfamethoxazole (Septra DS, Bactrim DS) or ciprofloxacin (Cipro) are prescribed (Fhogartaigh & Dance, 2013).

Frequent stools that are rich in electrolytes and enzymes and frequent wiping and washing of the anal region can irritate the skin. Teach the patient to avoid toilet paper and harsh soaps. Ideally, he or she can gently clean the area with warm water or an absorbent material, followed by thorough but gentle drying. Cream, oil, or gel can be applied to a damp, warm washcloth to remove stool that sticks to open skin. Special prepared skin wipes can also be used. Protective barrier cream can be applied to the skin between stools. Sitz baths for 10 minutes two or three times daily can also relieve discomfort.

If leakage of stool is a problem, the patient can use an absorbent cotton or panty liner and keep it in place with snug underwear. For patients who are incontinent, the use of incontinent pads at night instead of briefs allows air to circulate to the skin and prevents irritation. Remind unlicensed assistive personnel (UAP) to keep the perineal and buttock areas clean and dry and that frequent changes will be necessary.

During the acute phase of the illness, teach the patient and family about the importance of fluid replacement. Patient and family education regarding risk for transmission of gastroenteritis is also important (Chart 57-2).

### Chart 57-2

## Patient and Family Education: Preparing for Self-Management

### Preventing Transmission of Gastroenteritis

Advise the patient to:

- Wash hands well for at least 30 seconds with an antibacterial soap, especially after a bowel movement, and maintain good personal hygiene.
- Restrict the use of glasses, dishes, eating utensils, and tubes of toothpaste for his or her own use. In severe cases, disposable utensils may be wise.
- Maintain clean bathroom facilities to avoid exposure to stool.
- Inform the health care provider if symptoms persist beyond 3 days.
- Do not prepare or handle food that will be consumed by others. If you (the patient) are employed as a food handler, the public health department should be consulted for recommendations about the return to work.

## Chronic Inflammatory Bowel Disease

Ulcerative colitis and Crohn's disease are the two most common inflammatory bowel diseases (IBDs) that affect adults. Comparisons and differences are listed in [Table 57-2](#). Many other infectious mechanisms can cause symptoms similar to those of IBD, and other problems must be ruled out before a definitive diagnosis is made. The approach to each patient is individualized. Encourage patients to self-manage their disease by learning about the illness, treatment, drugs, and complications.

**TABLE 57-2**  
**Differential Features of Ulcerative Colitis and Crohn's Disease**

FEATURE	ULCERATIVE COLITIS	CROHN'S DISEASE
Location	Begins in the rectum and proceeds in a continuous manner toward the cecum	Most often in the terminal ileum, with patchy involvement through all layers of the bowel
Etiology	Unknown	Unknown
Peak incidence at age	15-25 yr and 55-65 yr	15-40 yr
Number of stools	10-20 liquid, bloody stools per day	5-6 soft, loose stools per day, nonbloody
Complications	Hemorrhage Nutritional deficiencies	Fistulas (common) Nutritional deficiencies
Need for surgery	Infrequent	Frequent

### Elimination Concept Exemplar Ulcerative Colitis

#### ❖ Pathophysiology

**Ulcerative colitis (UC)** creates widespread inflammation of mainly the rectum and rectosigmoid colon but can extend to the entire colon when the disease is extensive. Distribution of the disease can remain constant for years. UC is a disease that is associated with periodic remissions and exacerbations (flare-ups). Many factors can cause exacerbations, including intestinal infections. Most patients who are affected have mild-to-moderate disease, but 10% to 15% of patients present with severe symptoms ([Macken & Blaker, 2015](#)). Older adults with UC are at high risk for impaired FLUID AND ELECTROLYTE BALANCE as a result of diarrhea, including dehydration and hypokalemia.

The intestinal mucosa becomes hyperemic (has increased blood flow), edematous, and reddened. In more severe inflammation, the lining can bleed, and small erosions, or ulcers, occur. Abscesses can form in these ulcerative areas and result in tissue necrosis (cell death). Continued edema and mucosal thickening can lead to a narrowed colon and possibly a partial bowel obstruction. [Table 57-3](#) lists the categories of the severity of UC.

**TABLE 57-3**  
**American College of Gastroenterologists Classification of UC Severity**

SEVERITY	STOOL FREQUENCY	SIGNS/SYMPOMS
Mild	<4 stools/day with/without blood	Asymptomatic Laboratory values usually normal
Moderate	>4 stools/day with/without blood	Minimal symptoms Mild abdominal pain Mild intermittent nausea Possible increased C-reactive protein* or ESR†
Severe	>6 bloody stools/day	Fever Tachycardia Anemia Abdominal pain Elevated C-reactive protein* and/or ESR†
Fulminant	>10 bloody stools/day	Increasing symptoms Anemia may require transfusion Colonic distention on x-ray

\*C-reactive protein is a sensitive acute-phase serum marker that is evident in the first 6 hours of an inflammatory process.

†ESR, erythrocyte sedimentation rate; may be helpful but is less sensitive than C-reactive protein.

UC, Ulcerative colitis.

The patient's stool typically contains blood and mucus. Patients report **tenesmus** (an unpleasant and urgent sensation to defecate) and lower abdominal colicky pain relieved with defecation. Malaise, anorexia, anemia, dehydration, fever, and weight loss are common. Extraintestinal manifestations such as migratory polyarthritis, ankylosing spondylitis, and erythema nodosum are present in a large number of patients. The common and extraintestinal complications of UC are

listed in [Table 57-4](#).

**TABLE 57-4**  
**Complications of Ulcerative Colitis and Crohn's Disease**

COMPLICATION	DESCRIPTION
Hemorrhage/perforation	Lower GI bleeding results from erosion of the bowel wall.
Abscess formation	Localized pockets of infection develop in the ulcerated bowel lining.
Toxic megacolon	Paralysis of the colon causes dilation and subsequent colonic ileus, possibly perforation.
Malabsorption	Essential nutrients cannot be absorbed through the diseased intestinal wall, causing anemia and malnutrition (most common in Crohn's disease).
Nonmechanical bowel obstruction	Obstruction results from toxic megacolon or cancer.
Fistulas	In Crohn's disease in which the inflammation is transmural, fistulas can occur anywhere but usually track between the bowel and bladder, resulting in pyuria and fecaluria.
Colorectal cancer	Patients with ulcerative colitis with a history longer than 10 years have a high risk for colorectal cancer. This complication accounts for about one third of all deaths related to ulcerative colitis.
Extraintestinal complications	Complications include arthritis, hepatic and biliary disease (especially cholelithiasis), oral and skin lesions, and ocular disorders, such as iritis. The cause is unknown.
Osteoporosis	Osteoporosis occurs especially in patients with Crohn's disease.

### Etiology and Genetic Risk

The exact cause of UC is unknown; but a combination of genetic, immunologic, and environmental factors likely contributes to disease development. A genetic basis of the disease has been supported because it is often found in families and twins. Immunologic causes, including autoimmune dysfunction, are likely the etiology of extraintestinal manifestations of the disease. Epithelial antibodies in the immunoglobulin G (IgG) class have been identified in the blood of some patients with UC ([McCance et al., 2014](#)).

With long-term disease, cellular changes can occur that increase the risk for colon cancer. Damage from pro-inflammatory cytokines, such as specific interleukins (ILs) (e.g., IL-1, IL-6, IL-8) and tumor necrosis factor (TNF)-alpha, have cytotoxic effects on the colonic mucosa ([McCance et al., 2014](#)).

### Incidence and Prevalence

Chronic inflammatory bowel disease (IBD) affects about 1.4 million individuals in the United States and is split about equally between ulcerative colitis (UC) and Crohn's disease (discussed later). Although diagnosis can occur at any age, most people are diagnosed between 15 and 35 years of age ([Crohn's and Colitis Foundation, 2017](#)). Women are more often affected than men in their younger years, but men have the disease more often as middle-age and older adults ([McCance et al., 2014](#)).

## Cultural/Spiritual Considerations

### Patient-Centered Care QSEN

Ulcerative colitis is more common among Askenazki Jewish individuals than among those who are not Jewish and among whites more than nonwhites ([McCance et al., 2014](#)). The reasons for these cultural differences are not known.

### ❖ Interprofessional Collaborative Care

Patients with UC may be self-managed at home, cared for in the community setting, or hospitalized, depending on their immediate condition related to this chronic bowel disease. The interprofessional team that collaborates to care for this patient generally includes the health care provider (and/or surgeon), nurse, psychologist, social worker, and spiritual leader of the patient's choice.

### ◆ Assessment: Noticing

#### History.

Collect data on family history of IBD, previous and current therapy for the illness, and dates and types of surgery. Obtain a NUTRITION history, including intolerance of milk and milk products and fried, spicy, or hot foods. Ask about usual bowel ELIMINATION pattern (color, number, consistency, and character of stools), abdominal pain, tenesmus, anorexia, and fatigue. Note any relationship between diarrhea, timing of meals, emotional distress, and activity. Inquire about recent (past 2 to 3

month) exposure to antibiotics to rule out a *Clostridium difficile* infection. Has the patient traveled to or emigrated from tropical areas? Ask about recent use of NSAIDs because these can cause a flare-up of the disease. Inquire about any extraintestinal symptoms such as arthritis, mouth sores, vision problems, and skin disorders.

### Physical Assessment/Signs and Symptoms.

Symptoms vary with an acuteness of onset. Vital signs are usually within normal limits in mild disease. In more severe cases, the patient may have a low-grade fever (99° to 100° F [37.2° to 37.8° C]). The physical assessment findings are usually nonspecific, and in milder cases the physical examination may be normal. Viral and bacterial infections can cause symptoms similar to those of UC.

Note any abdominal distention along the colon. Fever associated with tachycardia may indicate dehydration, peritonitis, and bowel perforation. Assess for signs and symptoms associated with extraintestinal complications, such as inflamed joints and lesions inside the mouth.

### Psychosocial Assessment.

Many patients are very concerned about the frequency of stools and the presence of blood. *The inability to control the disease symptoms, particularly diarrhea, can be disruptive and anxiety producing.* Severe illness may limit the patient's activities outside the home with fear of fecal incontinence resulting in feeling "tied to the toilet." Severe anxiety and depression may result. Eating may be associated with pain and cramping and an increased frequency of stools. This can make mealtimes an unpleasant experience. Frequent visits to health care providers and close monitoring of the colon mucosa for abnormal cell changes can be anxiety provoking.

Assess the patient's understanding of the illness and its impact on his or her lifestyle. Encourage and support the patient while exploring:

- The relationship of life events to disease exacerbations
- Stress factors that produce symptoms
- Family and social support systems
- Concerns regarding the possible genetic basis and associated cancer risks of the disease
- Internet access for reliable education information

### Laboratory Assessment.

As a result of chronic blood loss, hematocrit and hemoglobin levels may be low, which indicates anemia and a chronic disease state. *An increased WBC count, C-reactive protein, or erythrocyte sedimentation rate (ESR) is consistent with inflammatory disease.* Blood levels of sodium, potassium, and chloride may be low as a result of frequent diarrheal stools and malabsorption through the diseased bowel (Pagana et al., 2017). Hypoalbuminemia (decreased serum albumin) is found in patients with extensive disease from losing protein in the stool.

### Other Diagnostic Assessment.

*Magnetic resonance enterography (MRE)* is the main examination used to study the bowel in patients who have IBD. An MRE allows the primary provider to visualize the bowel lumen and wall, mesentery, and surrounding abdominal organs. Teach the patient that he or she will need to fast for 4 to 6 hours before the test. As part of the test the patient drinks a large amount of contrast medium; this can cause abdominal discomfort and diarrhea. Be sure that the patient has the opportunity to go to the restroom before positioning on the MRI table. The patient then lies prone while the first of two doses of glucagon are given subcutaneously. This substance helps to slow the bowel's activity and motility (Sinha, 2015).

An upper endoscopy and/or *colonoscopy* may be done to aid in diagnosis, but the bowel prep can be especially uncomfortable for patients with inflammatory bowel disease (IBD). Frequent colonoscopies are recommended when patients have longer than a 10-year history of UC involving the entire colon because they are at high risk for colorectal cancer. In some cases, a *CT scan* may be done to confirm the disease or its complications. *Barium enemas* with air contrast can show differences between UC and Crohn's disease and identify complications, mucosal patterns, and the distribution and depth of disease involvement. In early disease, the barium enema may show incomplete filling as a result of inflammation and fine ulcerations along the bowel contour, which

appear deeper in more advanced disease.

### ◆Analysis: Interpreting

The priority collaborative problems for patients with UC include:

1. Diarrhea due to inflammation of the bowel mucosa
2. Acute pain or chronic noncancer pain due to inflammation and ulceration of the bowel mucosa and skin irritation
3. Potential for lower GI bleeding and resulting anemia due to UC

### ◆Planning and Implementation: Responding

#### Decreasing Diarrhea

#### Planning: Expected Outcomes.

The major concern for a patient with ulcerative colitis is the occurrence of frequent, bloody diarrhea and fecal incontinence from tenesmus. Therefore the goal of treatment is for the patient to have decreased diarrhea, formed stools, and control of bowel movements, which allow for mucosal healing.

#### Interventions.

Many measures are used to relieve symptoms and reduce intestinal motility, decrease inflammation, and promote intestinal healing. Nonsurgical and/or surgical management may be needed.

#### Nonsurgical Management.

Nonsurgical management includes drug and NUTRITION therapy. The use of physical and emotional rest is also an important consideration. Teach the patient to record color, volume, frequency, and consistency of stools, either on paper or via an electronic app, to determine severity of the problem.

Monitor the skin in the perianal area for irritation and ulceration resulting from loose, frequent stools. Stool cultures may be sent for analysis if diarrhea continues. Have the patient weigh himself or herself one or two times per week. If the patient is hospitalized, remind unlicensed assistive personnel to weigh him or her on admission and daily in the morning before breakfast and document all weights.

## NCLEX Examination Challenge 57-2

### Physiological Integrity

The nurse is caring for an older adult client who experiences an exacerbation of ulcerative colitis with severe diarrhea that have lasted a week. For which complications will the nurse assess? **Select all that apply.**

- A. Dehydration
- B. Hypokalemia
- C. Skin breakdown
- D. Deep vein thrombus
- E. Hyperkalemia

#### Drug Therapy.

Common drug therapy for UC includes aminosalicylates, glucocorticoids, antidiarrheal drugs, and

immunomodulators. Teach patients about side effects and adverse drug events (ADEs) and when to call their health care provider.

The *aminosalicylates* are drugs commonly used to treat mild-to-moderate UC and/or maintain remission. Several aminosalicylic acid compounds are available. These drugs, also called 5-ASAs, are thought to have an anti-inflammatory effect on the lining of the intestine by inhibiting prostaglandins and are usually effective in 2 to 4 weeks.

Sulfasalazine (Azulfidine, Azulfidine EN-tabs), the first aminosalicylate approved for UC, is metabolized by the intestinal bacteria into 5-ASA, which delivers the beneficial effects of the drug, and sulfapyridine, which is responsible for unwanted side effects. Teach patients to take a folic acid supplement, because sulfa decreases its absorption.

## Nursing Safety Priority QSEN

### Drug Alert

Teach patients taking sulfasalazine to report nausea, vomiting, anorexia, rash, and headache to the health care provider. With higher doses, hemolytic anemia, hepatitis, male infertility, or agranulocytosis can occur. This drug is in the same family as sulfonamide antibiotics. Therefore assess the patient for an allergy to sulfonamide or other drugs that contain sulfa *before* the patient takes the drug. The use of a thiazide diuretic may be a contraindication for sulfasalazine (Pfizer, 2016).

Mesalamine (Apriso, Asacol HD, Asacol 800 , Canasa, Lialda, Pentasa, Rowasa) is better tolerated than sulfasalazine because none of its preparations contain sulfapyridine. Asacol is a delayed-release drug and is released in the terminal ileum and beyond within the colon. Pentasa is an extended-release drug that works throughout the colon and rectum. Rowasa can be given as an enema, and Canasa can be given as a suppository. These preparations have minimal systemic absorption and therefore have fewer side effects. Table 57-5 lists these commonly used 5-ASA drugs.

**TABLE 57-5**

**5-ASA Medications Used to Treat Mild to Moderate Ulcerative Colitis**

GENERIC NAME	TRADE NAME
Sulfasalazine	Azulfidine Azulfidine EN-tabs
Mesalamine	Apriso Asacol HD Asacol 800  Lialda Pentasa Rowasa

5-ASA, 5-aminosalicylic acid.

*Glucocorticoids*, such as prednisone and prednisolone, are corticosteroid therapies prescribed during exacerbations of the disease. Prednisone is typically prescribed, and the dose may be increased as acute flare-ups occur. Once clinical improvement occurs, the corticosteroids are tapered because of the adverse effects that commonly occur with long-term steroid therapy (e.g., hyperglycemia, osteoporosis, peptic ulcer disease, increased potential for infection, adrenal insufficiency). For patients with rectal inflammation, topical steroids in the form of small retention enemas or suppositories may be prescribed. Medications such as budesonide (Uceris or Entocort EC), steroids that are thought to work mostly in the bowel, produce less systemic side effects.

To provide symptomatic management of diarrhea, *antidiarrheal drugs* may be prescribed. However, these drugs are given very cautiously because they can cause colon dilation and toxic megacolon. Common antidiarrheal drugs include diphenoxylate hydrochloride and atropine sulfate (Lomotil) and loperamide (Imodium).

*Immunomodulators* are drugs that alter an individual's immune response. Alone, they are often not effective in the treatment of ulcerative colitis. However, in combination with steroids, they may offer a synergistic effect to a quicker response, thereby decreasing the amount of steroids needed. Biologic response modifiers (BRMs) used for UC (and Crohn's disease, discussed later in this chapter) include infliximab (Inflectra , Remicade, Remsima ) and adalimumab (Humira).

Although not approved as a first-line therapy for UC, infliximab may be used for refractory disease or for severe complications, such as **toxic megacolon** (massive dilation of the colon that can lead to gangrene and peritonitis) and extraintestinal manifestations. Remicade (Inflectra 🌿, Remsima 🌿) is an immunoglobulin G (IgG) monoclonal antibody that reduces the activity of tumor necrosis factor (TNF) to decrease inflammation. Adalimumab (Humira) is another monoclonal antibody approved for refractory (not responsive to other therapies) cases. BRMs are used more commonly in management of Crohn's disease. These drugs cause immunosuppression and should be used with caution. Teach the patient to report any signs of a beginning infection, including a cold, and to avoid large crowds or others who are sick.

Several newer monoclonal antibodies have recently been approved by the U.S. Food and Drug Administration (FDA) for use in patients with IBD. One of these drugs, vedolizumab (Entyvio), is an intestinal-specific leukocyte traffic inhibitor in that it prevents white blood cells from migrating to inflamed bowel tissue (Randall et al., 2015).

### **Nutrition Therapy and Rest.**

Patients with severe symptoms who are hospitalized are kept NPO to ensure bowel rest. The physician may prescribe total parenteral NUTRITION (TPN) for severely ill and malnourished patients during severe exacerbations. Chapter 60 describes this therapy in detail. Patients with less severe symptoms may drink elemental formulas such as Vivonex Plus or Vivonex T.E.N., which have components that are absorbed in the small bowel and reduce bowel stimulation.

Diet is not a major factor in the inflammatory process, but some patients with ulcerative colitis (UC) find that caffeine and alcohol increase diarrhea and cramping. For some patients, raw vegetables and other high-fiber foods can cause GI symptoms. Lactose-containing foods may be poorly tolerated and should be reduced or eliminated. Teach patients that carbonated beverages, pepper, nuts and corn, dried fruits, and smoking are common GI stimulants that could cause discomfort. Each patient differs in his or her food and fluid tolerances.

During an exacerbation of the disease, patient activity is generally restricted because rest can reduce intestinal activity, provide COMFORT, and promote healing. Ensure that the patient has easy access to a bedpan, bedside commode, or bathroom in case of urgency or tenesmus.

### **Complementary and Integrative Health.**

In addition to dietary changes, complementary and integrative therapies may be used to supplement traditional management of UC. Examples include herbs (e.g., flaxseed), selenium, and vitamin C. Biofeedback, hypnosis, yoga, acupuncture, and ayurveda (a combination of diet, yoga, herbs, and breathing exercises) may also be helpful. These therapies need further study to validate their effectiveness, but some patients find them helpful.

### **Surgical Management.**

Some patients with UC require surgery to help manage their disease when medical therapies alone are not effective. In some cases, surgery is performed for complications of UC such as toxic megacolon, hemorrhage, bowel perforation, dysplastic biopsy results, and colon cancer.

### **Preoperative Care.**

General preoperative teaching related to abdominal surgery is described in Chapter 14. If a temporary or permanent ileostomy is planned, provide an in-depth explanation to the patient and family. An **ileostomy** is a procedure in which a loop of the ileum is placed through an opening in the abdominal wall (**stoma**) for drainage of fecal material into a pouching system worn on the abdomen. The external pouching system consists of a solid skin barrier (wafer) to protect the skin and a fecal collection device (pouch), similar to the system used for patients with colostomies (discussed in Chapter 56).

If an ileostomy is planned, the surgeon consults with a certified wound, ostomy, continence nurse (CWOCN) before surgery for recommendations on the best location of the stoma. A visit before surgery from an **ostomate** (a patient with an ostomy) may be helpful. **Parenteral antibiotics are given within 1 hour of surgical opening based on current best evidence and per The Joint Commission's National Patient Safety Goals.**

### **Operative Procedures.**

Any one of several surgical approaches may be used for the patient with UC. Minimally invasive procedures, such as laparoscopic, laparoscopic-assisted, hand-assisted, and robotic-assisted surgery, are common for patients with UC in large tertiary care centers (Seifarth et al., 2015). Laparoscopic surgery usually involves one or several small incisions but often takes longer to perform than the open surgical approach. The natural orifice transluminal endoscopic surgery (NOTES) procedure can be performed via the anus or vagina for certain patients. The availability of this type of procedure depends greatly on the training of the surgeon. Patients may have moderate sedation or general anesthesia for minimally invasive surgical procedures and because of this are not typically admitted to critical care units for continuing postoperative care.

Patients who are obese, have had previous abdominal surgeries, or have dense scar tissue (adhesions) may not be candidates for laparoscopic procedures. The conventional open surgical approach involves an abdominal incision and is completed under general anesthesia. Patients with open procedures are typically admitted to critical care units for short-term stabilization.

### Restorative Proctocolectomy With Ileo Pouch–Anal Anastomosis (RPC-IPAA).

This procedure has become the gold standard for patients with UC. In some centers, the surgery is performed via laparoscopy (laparoscopic RPC-IPAA). It is usually a two-stage procedure that includes the removal of the colon and most of the rectum (Fig. 57-2). The anus and anal sphincter remain intact. The surgeon then surgically creates an internal pouch (reservoir) using the last  $1\frac{1}{2}$  feet of the small intestine. The pouch, sometimes called a *J-pouch*, *S-pouch*, or *pelvic pouch*, is then connected to the anus. A temporary ileostomy through the abdominal skin is created to allow healing of the internal pouch and all anastomosis sites. It also allows for an increase in the capacity of the internal pouch. In the *second* surgical stage, the loop ileostomy is closed. The time interval between the first and second stages varies, but many patients have the second surgical stage to close the ileostomy within 1 to 2 months of the first surgery.

**FIG. 57-2** Creation of an ileo-anal reservoir.

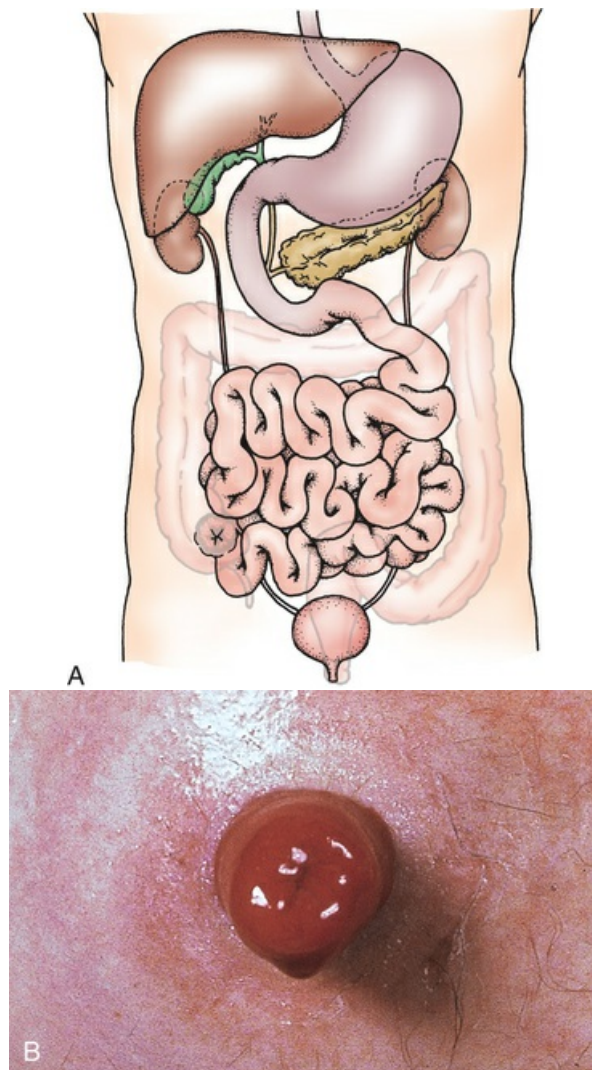

Usually bowel continence is excellent after this procedure, but some patients report leakage of stool during sleep. They may take antidiarrheal drugs to help control this problem. Reassure the patient that it is not unusual to have frequent stools and urgency after this procedure.

### Total Proctocolectomy With a Permanent Ileostomy.

Total proctocolectomy with a permanent ileostomy is done for patients who are not candidates for or do not want the ileo-anal pouch. The procedure involves the removal of the colon, rectum, and anus with surgical closure of the anus (Fig. 57-3A). The surgeon brings the end of the ileum out

through the abdominal wall and forms a stoma, or **ostomy**.

**FIG. 57-3** A, Total proctocolectomy with a permanent ileostomy. This involved removal of the colon, the rectum, and the anus with closure of the anus. Note the missing colon, rectum, and anus with the resultant stoma (B) in the right lower quadrant. (B from Perry, A.G., & Potter, P.A. (2006). *Clinical nursing skills & techniques* [6th ed.]. St. Louis: Mosby. Courtesy ConvaTec, a Bristol-Myers Squibb Company, Princeton, NJ.)

## **Nursing Safety Priority** QSEN

### **Critical Rescue**

The ileostomy stoma (Fig. 57-3B) is usually placed in the right lower quadrant of the abdomen below the belt line. It should not be prolapsed or retract into the abdominal wall. *Assess the stoma frequently after stoma placement. Recognize that it should be pinkish to cherry red to ensure an adequate blood supply. If the stoma looks pale, bluish, or dark, respond by reporting these findings to the health care provider immediately!*

Initially after surgery the output from an ileostomy is a loose, dark green liquid that may contain some blood. Over time, a process called *ileostomy adaptation* occurs. The small intestine begins to perform some of the functions that had previously been done by the colon, including the absorption of increased amounts of sodium and water. Stool volume decreases, becomes thicker (pastelike), and turns yellow-green or yellow-brown. The effluent (fluid material) usually has little odor or a

sweet odor. Any foul or unpleasant odor may be a symptom of a problem such as blockage or infection.

The ostomy drains frequently, and the stool is irritating. *The patient with an ostomy must wear a pouch system at all times.* The stool from the small intestine contains many enzymes and bile salts, which can quickly irritate and excoriate the skin. *Skin care around the stoma is a priority!* A pouch system with a skin barrier (gelatin or pectin) provides sufficient protection for most patients. Other products are also available.

### Postoperative Care.

Provide general postoperative care after surgery, as described in [Chapter 16](#). The few patients requiring open-approach surgery for UC will have a large abdominal incision. At first they are NPO, and a nasogastric tube (NGT) is used for suction. The tube is removed in 1 to 2 days as the drainage decreases, and fluids and food are slowly introduced. The patient having minimally invasive surgery (MIS) usually does not have an NGT.

In collaboration with the CWOCN, help the patient adjust and learn the required care. The ileostomy usually begins to drain stool within 24 hours after surgery at more than 1 liter per day. Be sure that fluids are replaced by adding an additional 500 mL or more each day to prevent dehydration. After about a week of high-volume output, the stool drainage slows and becomes thicker. During this period, some patients need antidiarrheal drugs.

The hospital stay is usually from 1 to 4 days, depending on whether the patient has laparoscopic or conventional open surgery. Patients having MIS have less pain from surgery and faster restoration of bowel function when compared with other surgical patients ([Hata et al., 2015](#)).

For those who have the RPC-IPAA procedure, remind them that the internal pouch can become inflamed. This problem is usually effectively treated with metronidazole (Flagyl) for 7 to 10 days. VSL#3, a probiotic, has also been shown in some studies to reduce incidence of pouchitis ([Singh et al., 2015](#)). Teach patients that, after the second stage of surgery, they might have burning during bowel ELIMINATION because gastric acid cannot be absorbed well by the ileum. Also instruct them to omit foods that can cause odors or gas, such as cabbage, asparagus, Brussels sprouts, and beans. Teach patients to eliminate foods that cannot be digested well, such as nuts and corn. Each patient differs in which foods he or she can tolerate.

Surgery for UC may result in altered body image. However, it may be viewed as positive because the patient will have fewer symptoms and feel more comfortable than before the procedure. Patients have to adjust to having an ostomy before they can resume their presurgery activities.

## NCLEX Examination Challenge 57-3

### Physiological Integrity

The nurse is caring for a client who has just been prescribed a glucocorticoid to treat an exacerbation of ulcerative colitis. What teaching will the nurse provide?

- A. Decrease the drug dose during the next exacerbation.
- B. Report fever to health care provider immediately.
- C. Determine if the client's insurance covers payment for this medication.
- D. This drug will act as an antidiarrheal.

### Minimizing Pain

#### Planning: Expected Outcomes.

The desired outcome for the patient is that he or she will verbalize decreased pain and an improvement in COMFORT as a result of collaborative, evidence-based pain management interventions. Take into consideration the effects of opioid-based pain medications on intestinal function.

#### Interventions.

Pain control requires pharmacologic and nonpharmacologic measures. Physical discomfort can contribute to emotional distress. A variety of symptom-reducing interventions and supportive measures are used. Surgery also reduces pain for many patients.

The purpose of pain management is alleviation of pain or a reduction in pain to a level of comfort that is acceptable to the patient. Increases in pain may indicate the development of complications such as peritonitis (see earlier discussion in this chapter). Assist the patient in reducing or eliminating factors that can cause or increase the pain experience. For example, he or she may benefit from NUTRITION changes to decrease abdominal discomfort such as cramping and bloating.

Antidiarrheal drugs may be needed to control diarrhea, thus reducing the discomfort. However, they must be used with caution and for a short time because toxic megacolon can develop.

Perineal skin can be irritated by contact with loose stools and frequent cleaning. Explain special measures for skin care. Use of medicated wipes is soothing if the rectal area is tender or sensitive from the use of toilet tissue (Chart 57-3). A number of ostomy manufacturers (e.g., Hollister, ConvaTec) produce a system for skin care that may help prevent and heal perineal skin irritation. These systems usually include a skin-cleaning solution, a moisturizing and healing cream, and a petroleum jelly–like barrier that prevents contact of moisture and stool with the skin.

### Chart 57-3

## Best Practice for Patient Safety & Quality Care QSEN

### Pain Control and Skin Care for Patients With Inflammatory Bowel Disease

PATIENT PROBLEM	INTERVENTIONS
Abdominal pain (particularly with exacerbations of the disease)	Administer analgesics. Assist with frequent positioning. Identify foods that increase pain. Perform a comprehensive pain assessment. Observe for signs and symptoms of peritonitis. Evaluate effectiveness of pain management. Teach music therapy, guided imagery.
Skin excoriation and/or irritation from frequent bowel movements	Encourage good skin care with a mild soap and water after each bowel movement. Gently pat the area dry. Identify foods that increase diarrhea. Sitz baths may be of benefit. Apply a thin coat of A+D Ointment or aloe cream. Use medicated wipes instead of tissue. Ensure appropriate ostomy supplies that fit well. Antidiarrheal medications may help, but use with caution. Observe for symptoms related to megacolon (fever, leukocytosis, tachycardia, distended abdomen with three-view abdominal x-ray noting an enlarged colon).

### Monitoring for Lower GI Bleeding

#### Planning: Expected Outcomes.

The patient with UC is expected to have a reduction in or cessation of bleeding with prompt collaborative care. If possible, patients are expected to remain free of complications that can cause bleeding, such as perforation or anemia.

#### Interventions.

The nursing priority is to monitor the patient closely for signs and symptoms of GI bleeding resulting from the disease or its complications.

## Nursing Safety Priority QSEN

### Critical Rescue

Recognize that it is important to monitor stools for blood loss for the patient with ulcerative colitis. The blood may be bright red (frank bleeding) or black and tarry (melena). Monitor hematocrit, hemoglobin, and electrolyte values and assess vital signs. Prolonged slow bleeding can lead to anemia. Observe for fever, tachycardia, and signs of fluid volume depletion. Changes in mental status may occur, especially among older adults, and may be the first indication of dehydration or anemia.

*If symptoms of GI bleeding begin, respond by notifying the health care provider immediately.* Blood products are often prescribed for patients with severe anemia. Prepare for the blood transfusion by

inserting a large-bore IV catheter if it is not already in place. Chapter 40 outlines nursing actions during blood transfusion.

If the patient has lower GI bleeding of more than 0.5 mL per minute, a *GI bleeding scan* may be useful to localize the site of the bleeding (Pagana et al., 2017). However, this test cannot indicate the cause of the bleeding and may take several hours to administer. Patients in the critical care unit are not candidates for the test because they must leave the unit for it. Keep in mind that a GI bleeding is considered a medical emergency; therefore the patient should be monitored closely to prevent complications.

## Care Coordination and Transition Management

### Home Care Management.

The patient with ulcerative colitis provides self-management at home but may require hospitalization during severe exacerbations or after surgical intervention. In addition, those who have extraintestinal problems often need ongoing collaborative care for joint and/or skin problems.

Home care management focuses on controlling signs and symptoms and monitoring for complications. For patients returning home or transferring to nursing home or transitional care after surgery, ongoing respiratory care, incision care (if applicable), ostomy care, and pain management should be continued.

### Self-Management Education.

Teach the patient about the nature of ulcerative colitis, including its acute episodes, remissions, and symptom management. Also stress that, even though the cause is unknown, relapses can be prevented with proper health care. Teach patients taking immunosuppressive drugs, such as corticosteroids and biologic response modifiers—more commonly known as *biologics* (monoclonal antibodies), to report signs of possible infection, such as sore throat, to the health care provider. Remind them to avoid crowds and anyone who has an infection. Review the purpose of drug therapy, when drugs should be taken, side effects, and adverse drug events.

Instruct the patient about measures to reduce or control abdominal pain, cramping, and diarrhea. Also teach the patient and family about symptoms associated with disease exacerbation that should be reported to the health care provider, such as fever higher than 101° F (38.3° C), tachycardia, palpitations, and an increase in diarrhea, abdominal pain, or nausea/vomiting. Provide written information and contact numbers for the health care provider.

There is no special diet for a patient with an ileostomy. However, teach the patient to avoid any foods that cause gas. Examples include high-fiber foods such as nuts, raw cabbage, corn, celery, apples with peels, and popcorn. The patient needs to learn which foods he or she tolerates best and adjust the diet accordingly.

If the patient has undergone a temporary or permanent surgical diversion, collaborate with the CWOCN to explain and demonstrate required care so he or she can self-manage or the family/caregiver can assist. Also teach the importance of including adequate amounts of salt and water in the diet because the ileostomy increases the loss of these substances. Urge the patient to be cautious in situations that lead to heavy sweating or fluid loss, such as strenuous physical activity, high environmental heat, and episodes of diarrhea and vomiting.

Finding the best ostomy pouching system is a major issue for many patients. An effective system is one that:

- Protects the skin
- Contains the effluent (drainage) and reduces odor, if any
- Remains securely attached to the skin for a dependable period of time

Most patients desire an adhesive barrier that will last for 3 to 7 days. The barrier must create a solid seal to prevent the enzymes in the drainage from irritating the skin. Solid barriers are classified as “regular wear” or “extended wear.” An adult with a high output may want an extended-wear barrier. A special cream can be used to help fill any uneven skin surfaces and provide a consistent seal. Pouches can also be individualized by the patient. Large pouches can hold more but are heavy when full. Patients also have to consider the costs of the various systems and if or how much their insurance will pay for them. [Chart 57-4](#) describes the main aspects of ileostomy

care, including skin care.

#### **Chart 57-4**

## **Patient and Family Education: Preparing for Self-Management**

### **Ileostomy Care**

#### **Skin Protection**

- Use a skin barrier to protect your skin from contact with contents from the ostomy.
- Use skin-care products, such as skin sealants and ostomy skin creams. If your skin continues to come into contact with ostomy contents, select a product to fill in problem areas and provide an even skin surface.
- Watch your skin for any irritation or redness.

#### **Pouch Care**

- Empty your pouch when it is one-third to one-half full.
- Change the pouch during inactive times, such as before meals, before retiring at night, on waking in the morning, and 2 to 4 hours after eating.
- Change the entire pouch system every 3 to 7 days.

#### **Nutrition**

- Chew food thoroughly.
- Be cautious of high-fiber and high-cellulose foods. You may need to eliminate these from the diet if they cause severe problems (diarrhea, constipation, or blockage). Examples include corn, peanuts, coconut, Chinese vegetables, string beans, tough-fiber meats, shrimp and lobster, rice, bran, and vegetables with skins (tomatoes, corn, and peas).

#### **Drug Therapy**

- Avoid taking enteric-coated and capsule medications.
- Inform any health care provider who is prescribing medications for you that you have an ostomy. Before having prescriptions filled, inform your pharmacist that you have an ostomy.
- Do not take any laxative or enemas. You should usually have loose stool and should contact a physician if no stool has passed in 6 to 12 hours.

#### **Symptoms to Watch**

- Report any drastic increase or decrease in drainage to your health care provider.
- If stomal swelling, abdominal cramping, or distention occurs or if ileostomy contents stop draining:
- Remove the pouch with faceplate.
- Lie down, assuming a knee-chest position.

- Begin abdominal massage.
- Apply moist towels to the abdomen.
- Drink hot tea.
- If none of these maneuvers is effective in resuming ileostomy flow or if abdominal pain is severe, call your health care provider right away.

A patient with an ileostomy may have many concerns about management at home and about sexual and social adjustments. Considering possible sexual issues helps the patient identify and discuss these concerns with the sex partner. For example, a change in positioning during intercourse may alleviate apprehension. Social situations may cause anxiety related to decreased self-esteem and a disturbance in body image. Encourage the patient to discuss possible concerns in addressing and resolving these potentially stressful events. Clinical depression is common among patients with ulcerative colitis. Refer patients to appropriate mental health resources if depression is suspected.

Some hospitals provide community support groups for their patients with inflammatory bowel disease (IBD). These groups help patients and their families cope with the psychological impact of IBD and educate them about NUTRITION and complementary and integrative therapies.

#### Health Care Resources.

If the patient needs assistance with self-management at home, collaborate with the case manager or social worker to arrange the services of a home care aide or nurse. A home care nurse can provide assessment and guidance in integrating ostomy care into the patient's lifestyle. The nurse may also teach about wound care, including monitoring wound healing, if needed ([Chart 57-5](#)). The patient and family need to know where to purchase ostomy supplies, along with the name, size, and manufacturer's order number.

### Chart 57-5

## Home Care Assessment

### The Patient With Inflammatory Bowel Disease

Assess gastrointestinal function and nutritional status, including:

- Abdominal cramping or pain
- Bowel elimination pattern, specifically frequency, characteristics, and amount of stools and presence or absence of blood in stools
- Food and fluid intake (include relationship of specific foods to cramping and stools)
- Weight gain or loss
- Signs and symptoms of dehydration

- Presence or absence of fever, rectal tenesmus, or urgency
- Bowel sounds
- Condition of perianal skin, including presence or absence of perianal fistula or abscess

Assess patient's and family's coping skills, including:

- Current and ongoing stress level and coping style
- Availability of support system

Assess home environment, including:

- Adequacy and availability of bathroom facilities
- Opportunity for rest and relaxation

Assess ability to self-manage therapeutic regimen, including:

- Drug therapy
- Signs and symptoms to report
- Nutrition therapy
- Availability of community resources
- Importance of follow-up care

For patients with a permanent ileostomy, locate a community ostomy support group by contacting the United Ostomy Associations of America ([www.uoaa.org](http://www.uoaa.org)). The United Ostomy Association of Canada serves the needs of Canadian patients ([www.ostomycanada.ca](http://www.ostomycanada.ca)). A local support group or the Crohn's and Colitis Foundation of America ([www.ccfa.org](http://www.ccfa.org)) may be helpful in obtaining supplies and providing education for ostomates. Inform the patient and family members of available ostomy ambulatory care clinics and ostomy specialists. If the patient agrees, a visit from an ostomate can be continued after discharge to home.

#### ◆ **Evaluation: Reflecting**

Evaluate the care of the patient with ulcerative colitis based on the identified priority patient problems. Expected outcomes may include that the patient will:

- Experience no diarrhea or a decrease in diarrheal episodes
- Verbalize decreased pain
- Gain control over bowel ELIMINATION
- Have absence of lower GI bleeding
- Self-manage the ileostomy (temporary or permanent)
- Maintain peristomal skin integrity

- Demonstrate behaviors that integrate ostomy care into his or her lifestyle if a permanent ileostomy is performed

## Crohn's Disease

### ❖ Pathophysiology

Crohn's disease (CD) is a chronic inflammatory disease of the small intestine (most often), the colon, or both. It can affect the GI tract from the mouth to the anus but most commonly affects the terminal ileum. CD is a slowly progressive and unpredictable disease with involvement of multiple regions of the intestine with normal sections in between (called *skip lesions* on x-rays). Like ulcerative colitis (UC), this disease is recurrent, with remissions and exacerbations.

CD presents as inflammation that causes a thickened bowel wall. Strictures and deep ulcerations (cobblestone appearance) also occur, which put the patient at risk for developing bowel **fistulas** (abnormal openings between two organs or structures). The result is severe diarrhea and malabsorption of vital nutrients. Anemia is common, usually from iron deficiency or malabsorption issues (McCance et al., 2014).

The complications associated with CD are similar to those of UC (see Table 57-4). Hemorrhage is more common in UC, but it can occur in CD as well. Severe malabsorption by the small intestine is more common in patients with CD versus UC that may not involve the small bowel to any significant extent. Therefore patients with CD can become very malnourished and debilitated.

Rarely, cancer of the small bowel and colon develop but can occur after the disease has been present for 15 to 20 years. Fistula formation is a common complication of CD but is rare in UC. Fistulas can occur between segments of the intestine or manifest as cutaneous fistulas (opening to the skin) or perirectal abscesses. They can also extend from the bowel to other organs and body cavities, such as the bladder or vagina (Fig. 57-4). Some patients develop intestinal obstruction, which at first is secondary to inflammation and edema. Over time, fibrosis and scar tissue develop, and obstruction results from a narrowing of the bowel. Most patients with CD require surgery at some point.

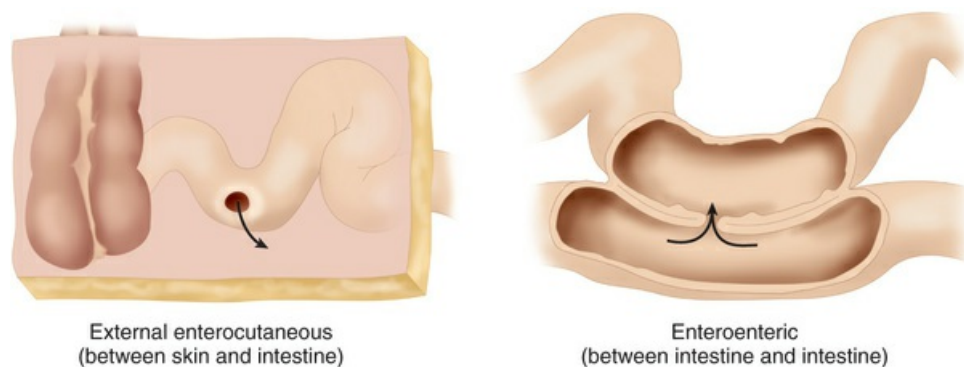

FIG. 57-4 Types of fistulas that are complications of Crohn's disease.

## Genetic/Genomic Considerations

### Patient-Centered Care QSEN

The exact cause of CD is unknown. A combination of genetic, immune, and environmental factors may contribute to its development. About 20% of patients have a positive family history for the disease (Cleynen et al., 2016). The discovery of a mutation in the *NOD2/CARD15* gene on chromosome 16 seems to be associated with some patients who have CD. This gene is found in monocytes that normally recognize and destroy bacteria.

Pro-inflammatory cytokines, such as tumor necrosis factor–alpha (TNF-alpha) and interleukins (ILs) (e.g., IL-6 and IL-8), are immunologic factors that contribute to the etiology of CD (McCance et al., 2014). Many of the drugs used for the disease inhibit or block one or more of these factors.

Other risk factors include tobacco use, Jewish ethnicity, and living in urban areas (McCance et al., 2014). CD is more common in individuals of Ashkenazi Jewish background than in any other group. Current research has found genetic markers in this population that contribute to higher rates of CD (Zhang et al., 2013). It was once thought that stress and nutrition play a role in the development of CD, but these factors have not been proven. However, inadequate NUTRITION can exacerbate the patient's symptoms.

Almost a million individuals in the United States have Crohn's disease, and Canada has one of the highest incidences of Crohn's and colitis worldwide (Crohn's and Colitis Canada, 2016). Most have symptoms and are diagnosed as adolescents or young adults between 15 and 35 years of age (Crohn's and Colitis Foundation, 2017).

### ❖ **Interprofessional Collaborative Care**

Similar to patients with ulcerative colitis, patients with Crohn's disease may be self-managed at home, cared for in the community setting, or hospitalized depending on their immediate condition related to this chronic bowel disease. The interprofessional team that collaborates to care for this patient generally includes the health care provider (and/or surgeon), nurse, psychologist, social worker, dietitian, and spiritual leader of the patient's choice.

### ◆ **Assessment: Noticing**

Crohn's disease can be exacerbated by bacterial infection. A detailed history is needed to identify manifestations specific to the disease. Ask about recent unintentional weight loss, the frequency and consistency of stools, the presence of blood in the stool, fever, and abdominal pain.

Perform a thorough abdominal assessment. Assess for manifestations of the disease, and evaluate the patient's NUTRITION and hydration status.

When inspecting the abdomen, assess for distention, masses, or visible peristalsis. Inspection of the perianal area may reveal ulcerations, fissures, or fistulas. During auscultation, bowel sounds may be decreased or absent with severe inflammation or obstruction. An increase in high-pitched or rushing sounds may be present over areas of narrowed bowel loops. Muscle guarding, masses, rigidity, or tenderness may be noted on palpation by the advanced practice nurse or health care provider.

The signs and symptoms associated with Crohn's disease vary greatly from person to person. Most patients report diarrhea, abdominal pain, and low-grade fever. Fever is common with fistulas, abscesses, and severe inflammation. If the disease occurs in only the ileum, diarrhea occurs five or six times per day, often with a soft, loose stool. **Steatorrhea** (fatty diarrheal stools) is common. Stools may contain bright red blood.

*Abdominal pain* from the inflammatory process is usually constant and often located in the right lower quadrant. The patient also may have pain around the umbilicus before and after bowel movements. If the lower colon is diseased, pain is common in both lower abdominal quadrants.

Most patients with Crohn's disease have *weight loss*. Nutritional problems are the result of increased catabolism from chronic inflammation, anorexia, malabsorption, or self-imposed dietary restrictions. These problems result in impaired FLUID AND ELECTROLYTE BALANCE and vital nutrient deficiencies.

The inflammatory bowel changes decrease the small bowel's ability to absorb nutrients, which may be made worse by surgery and fistulas.

## 📌 **Nursing Safety Priority** QSEN

### **Action Alert**

For the patient with Crohn's disease, be especially alert for signs and symptoms of peritonitis (discussed earlier in this chapter), small-bowel obstruction, and nutritional and fluid imbalances. Early detection of a change in the patient's status helps reduce these life-threatening complications.

The patient who has Crohn's disease (CD) needs a complete psychosocial assessment. The chronic nature of the problem and the associated complications can greatly affect patients and their

families. Lifestyle changes are necessary to cope with such a disruptive and painful chronic illness. Assess the patient's coping skill and help identify support systems. Similar to problems associated with other chronic diseases, clinical depression and severe anxiety disorders are common among patients with CD.

The health care provider requests many laboratory studies for patients with CD. The results of laboratory tests often indicate the extent and severity of inflammation or complications that occur with the disease.

*Anemia* is common as a result of slow bleeding and poor nutrition. Serum levels of folic acid and vitamin B<sub>12</sub> are generally low because of malabsorption, further contributing to anemia. Amino acid malabsorption and protein-losing enteropathy may result in *decreased albumin* levels. C-reactive protein and ESR may be elevated to indicate inflammation. White blood cells (WBCs) in the urine may show infection (pyuria), which is caused by ureteral obstruction or an enterovesical (bowel to bladder) fistula. If severe diarrhea or fistula is present, the patient may have fluid and electrolyte losses, particularly potassium and magnesium. Assess the patient for signs and symptoms that can occur as a result of electrolyte losses (see [Chapter 11](#)).

X-rays show the narrowing, ulcerations, strictures, and fistulas common with Crohn's disease. *Magnetic resonance enterography (MRE)* is performed to determine bowel activity and motility as discussed under Other Diagnostic Assessment in the Ulcerative Colitis concept exemplar. An *abdominal ultrasound* or CT scan may also be performed. In acute illness, these tests may be deferred until the risk for perforation lessens. If the patient has lower GI bleeding of more than 0.5 mL per minute, a *GI bleeding scan* may be useful to localize the site of the bleeding ([Pagana et al., 2017](#)).

### ◆Interventions: Responding

Collaborative care for patients with Crohn's disease is similar to that described in the Nonsurgical Management discussion in the Ulcerative Colitis section. Specific interventions vary with the severity of disease and the complications that are present.

## Nonsurgical Management

### Drug Therapy.

Drugs used to manage Crohn's disease (CD) are similar to those used in the treatment of ulcerative colitis (UC). For mild-to-moderate disease, 5-ASA drugs may be effective, although research shows that their usage for CD has produced mixed results (see the [Drug Therapy discussion in the Ulcerative Colitis](#) section).

Most patients have moderate-to-severe disease and need stronger drug therapy to control their symptoms. Two agents that may be prescribed for CD are azathioprine (Azasan, Imuran) and mercaptopurine (Purinethol). These drugs suppress the immune system and can lead to serious infections. Methotrexate may also be given to suppress immune activity of the disease.

A group of biologic response modifiers (BRMs), also known as *monoclonal antibody drugs*, have been approved for use in CD when other drugs have been ineffective. These drugs inhibit tumor necrosis factor (TNF)-alpha, which decreases the inflammatory response. Examples of commonly used drugs for patients with CD include infliximab (Inflixtra ♣, Remicade, Remsima ♣), adalimumab (Humira), natalizumab (Tysabri), certolizumab pegol, (Cimzia), and vedolizumab (Entyvio) ([Randall et al., 2015](#)). These agents are not given to patients with a history of cancer, heart disease, or multiple sclerosis.

## 📌Nursing Safety Priority QSEN

### Drug Alert

Both infliximab and certolizumab pegol must be given in a health care setting, such as a physician's office, via parenteral routes. Adalimumab (Humira) is self-administered by subcutaneous injection every other week. Teach patients how to give themselves a subcutaneous injection. Teach them to report injection site reactions, including redness and swelling. Remind them that headache, abdominal pain, and nausea and vomiting are common side effects. Teach them to avoid crowds and people with infection. Reinforce the need to report any infection, including a cold or sore throat, to the health care provider immediately.

Natalizumab is given IV under medical supervision every 4 weeks for moderate-to-severe CD and when other drugs are not effective. Natalizumab can cause **progressive multifocal leukoencephalopathy** (PML), a deadly infection that affects the brain. Before giving the drug, be sure that the patient is free of all infections. Teach patients the importance of reporting any cognitive, motor, or sensory changes immediately to the health care provider.

Vedolizumab (Entyvio) is used for treatment of moderate-to-severe CD. This drug is administered IV at weeks 0, 2, 6, and then 8 weeks afterward. Clinical trials verify that it does not increase risk for PML; but, because of its mechanism action, the FDA strongly encourages education regarding this possible complication (Randall et al., 2015).

Although glucocorticoids can be effective for patients with CD, sepsis can result from abscesses or fistulas that may be present. These drugs mask the symptoms of infection. Therefore they must be used with caution and only on a short-term basis. Monitor the patient closely for signs of infection. Teach the patient not to stop the steroids abruptly because of the potential for adrenal insufficiency. Ciprofloxacin (Cipro) and metronidazole (Flagyl, Novo-Nidazol ) have been helpful in patients with fistulas and infections related to CD.

### Nutrition Therapy.

Long-standing nutritional deficits can have severe consequences for the patient with Crohn's disease. Poor NUTRITION can lead to inadequate fistula and wound healing, loss of lean muscle mass, decreased immune responses, and increased morbidity and mortality. During severe exacerbations of the disease, the patient may be hospitalized to provide bowel rest and nutritional support with total parenteral nutrition (TPN). Nutritional supplements such as Ensure or Sustacal can be given to provide nutrients and more calories. Teach the patient to avoid GI stimulants, such as caffeinated beverages and alcohol.

### Fistula Management.

Fistulas (abnormal tracts between two or more body areas) are common with acute exacerbations of Crohn's disease. They can be between the bowel and bladder (enterovesical), between two segments of bowel (enteroenteric), between the skin and bowel (enterocutaneous), or between the bowel and vagina (enterovaginal) (see Fig. 57-4). The patient with one or more fistulas often has complications such as systemic infections, skin problems, malnutrition, and impaired FLUID AND ELECTROLYTE BALANCE. Treatment of the patient with a fistula is complicated and includes nutrition and electrolyte therapy, skin care, and prevention of infection.

## Nursing Safety Priority QSEN

### Action Alert

Adequate NUTRITION and FLUID AND ELECTROLYTE BALANCE are priorities in the care of the patient with a fistula. GI secretions are high in volume and rich in electrolytes and enzymes. The patient is at high risk for malnutrition, dehydration, and hypokalemia (decreased serum potassium). Assess for these complications and collaborate with the health care team to manage them. Monitor urinary output and daily weights. A decrease indicates possible dehydration, which should be treated immediately by providing additional fluids.

The patient requires at least 3000 calories daily to promote healing of the fistula. If he or she cannot take adequate oral fluids and nutrients, total enteral nutrition (TEN) or TPN may be prescribed. For patients who do not require TEN or TPN, collaborate with the dietitian to:

- Carefully monitor the patient's tolerance of the prescribed diet
- Help the patient select high-calorie, high-protein, high-vitamin, low-fiber meals
- Offer enteral supplements, such as Ensure and Vivonex PLUS
- Record food intake for accurate calorie counts

Providing enteral supplements, recording intake and output, and taking daily weights may be delegated to unlicensed assistive personnel (UAP) under the supervision of the registered nurse

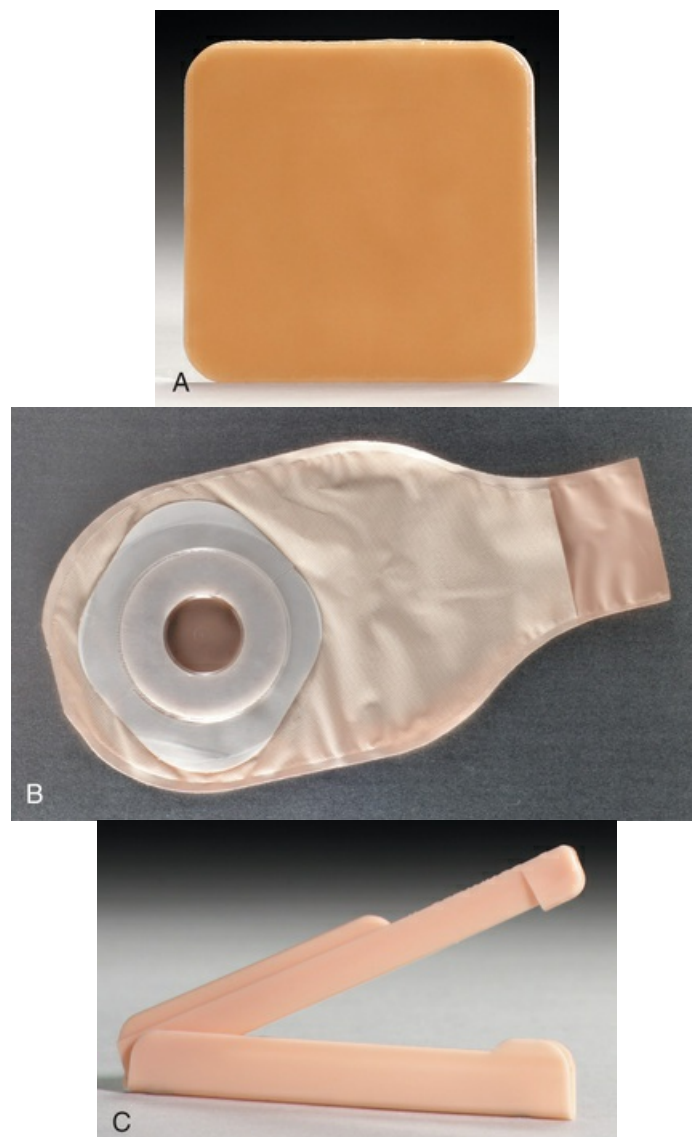

(RN). Collaborate with the certified wound, ostomy, and continence nurse (CWOCN) to select the most appropriate wound management for each patient.

## Nursing Safety Priority QSEN

### Action Alert

For patients with fistulas, preserving and protecting the skin are the nursing priorities. Be sure that wound drainage is not in direct contact with skin because intestinal fluid enzymes are caustic! Clean the skin promptly to prevent skin breakdown or fungal infection, which can cause major discomfort for the patient.

Enzymes and bile in the stool contribute to the problem of skin irritation and excoriation. Skin irritation needs to be prevented. This may be accomplished through the use of skin barriers, pouching systems, and insertion of drains (Fig. 57-5). Skin barriers or dressings are used when the fistula drainage is less than 100 mL in 24 hours. A pouch is used for heavily draining fistulas to reduce the risk for skin breakdown and measure the **effluent** (drainage). However, they are very challenging because of location and drainage amount. Treatment with an antifungal powder applied to the skin around the fistula is often very helpful to prevent or treat *Candida* infection.

**FIG. 57-5** Skin barriers, such as wafers (A) are cut to fit  $\frac{1}{8}$  inch around the fistula. A drainable pouch (B) is applied over the wafer and clamped (C) until the pouch is to be emptied. Effluent should drain into the bag and not contact the skin. (Courtesy ConvaTec, a Bristol-Myers Squibb Company, Princeton, NJ.)

For some fistulas, pouching may not be possible because of their location. Drainage may need to be managed using regulated wall suction or a negative-pressure wound therapy device. Continuous low wall suction is attached to a suction catheter in the wound bed of the fistula, not into the fistula tract. These systems are not meant for long-term management.

Negative-pressure wound therapy (e.g., vacuum-assisted closure, or wound VAC therapy) promotes wound healing by secondary intention as it prepares the wound bed for closure, reduces edema, promotes granulation and perfusion, and removes exudate and infectious material. It should not be used for patients who are at risk for bleeding or only for the purpose of drainage containment.

Patients with fistulas are also at high risk for intra-abdominal abscesses and sepsis. Antibiotic therapy is commonly prescribed. Observe for signs of sepsis (systemic infection), such as fever, abdominal pain, or a change in mental status. Monitor for increased WBC levels that could indicate a systemic infection.

Other helpful interventions for the patient with CD are those that relax the patient and soothe the GI tract. Such therapies may include naturopathy, herbs (e.g., ginger), acupuncture, hypnotherapy, and ayurveda (a combination of diet, herbs, yoga, and breathing exercises). The evidence supporting the use of these substances for CD is lacking, but many patients find them helpful for overall physical and emotional health. Teach patients about the availability of these therapies and recommend that they include them in their collaborative plan of care.

## Clinical Judgment Challenge 57-1

### Patient-Centered Care; Evidence-Based Practice; Teamwork and Collaboration **QSEN**

A 19-year-old man has a new diagnosis of Crohn's disease. This patient reports that he recently started college and that his stress levels have been higher than ever. He has been prescribed and is taking prednisone to control his flare-up but currently has not made any other modifications. The patient is concerned because he has very little knowledge about his new diagnosis and how it might impact his current lifestyle.

1. What is your therapeutic response to the patient at this time?
2. Based on the patient data provided, what priority problems do you identify?
3. What lifestyle modifications might be helpful for this patient?
4. What complementary and/or integrative therapies would be available?
5. Using best current evidence, how will you plan care with other members of the health care team? What members of the health care team will be involved in this patient's care?

### Surgical Management.

Surgery for Crohn's disease may be performed for patients who have not improved with medical management or for those who have complications from the disease. Surgery to manage Crohn's disease is not as successful as that for ulcerative colitis because of the extent of the disease. The patient with a fistula may undergo resection of the diseased area. Other indications for surgical treatment include perforation, massive hemorrhage, intestinal obstruction or strictures, abscesses, or cancer.

In some cases, a resection (removal of part of the small bowel) can be performed as minimally invasive surgery (MIS) via laparoscopy. This surgery involves one or more small incisions, less pain, and a quicker surgical recovery when compared with traditional open surgery. Both small-bowel resection (usually the ileum) and ileocecal resection can be done using this procedure. For other patients, an open surgical approach is used to allow for better visual access to the bowel.

Strictureplasty may be performed for bowel strictures related to Crohn's disease. This procedure

increases the bowel diameter. Care before and after each of these surgical procedures is similar to care for patients undergoing other types of abdominal surgery (see [Chapters 14 and 16](#)).

## Care Coordination and Transition Management

### Home Care Management.

The discharge care plan for the patient with Crohn's disease is similar to that for the patient with ulcerative colitis (see the [Care Coordination and Transition Management discussion in the Ulcerative Colitis](#) section). Collaborate with the case manager and CWOCN or wound nurse to help the patient plan self-management.

### Self-Management Education.

Reinforce measures to control the disease and related symptoms and manage NUTRITION. Teach the patient and family to make arrangements for the patient to have easy access to the bathroom and privacy to perform fistula care, if needed.

The health teaching plan for Crohn's disease is similar to that for the patient with ulcerative colitis. Teach the patient about the usual course of the disease, symptoms of complications, and when to notify the health care provider. Provide health teaching for drug therapy, including purpose, dose, and side effects. In addition to other drugs, vitamin supplements, including monthly vitamin B<sub>12</sub> injections, may be needed because of the inability of the ileum to absorb these nutrients. In collaboration with the dietitian, instruct the patient to follow a low-residue, high-calorie diet and to avoid foods that cause discomfort, such as milk, gluten (wheat products), and other GI stimulants like caffeine.

Remind the patient to take rest periods, especially during exacerbations of the disease. If stress appears to increase symptoms of the disease, recommend stress-management techniques, counseling, and/or physical activity to improve quality of life. For long-term follow-up, teach the patient about the increased risk for bowel cancer and the importance of frequent colorectal cancer screening (see [Chapter 56](#)).

If a patient has a fistula, explain and demonstrate wound care. Provide the opportunity for the patient to practice this care in the hospital. Ideally, he or she should be independent in fistula care before leaving the hospital. However, because of location of the fistula (perirectal or vaginal) or a large abdomen, assistance may be needed. If this is the case, teach a family member or other caregiver how to manage the wound. Patients may be transferred to a transitional or skilled nursing unit for collaborative care.

### Health Care Resources.

Patients who are discharged to home after undergoing resection and anastomosis may require visits from a home care nurse to assess the surgical wound and monitor for complications (see [Chart 57-5](#)). Assess the patient's and family's ability to monitor the progress of fistula healing and to watch for indications of infection and sepsis. A home care aide or other service might be helpful for the patient who cannot meet nutritional needs or who needs help with grocery shopping and meal preparation.

In collaboration with the case manager, assist with obtaining the equipment and supplies for fistula care, such as skin barriers and wound drainage bags. A support group sponsored by the United Ostomy Associations of America ([www.uoaa.org](http://www.uoaa.org)) or a local hospital in the community may also be available to help with meeting physical and psychosocial needs.

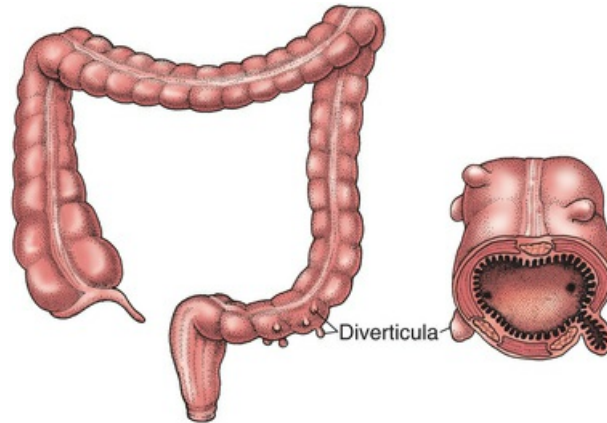

## Diverticular Disease

Diverticula are pouchlike herniations of the mucosa through the muscular wall of any part of the gut but most commonly the colon. **Diverticulosis** is the presence of many abnormal pouchlike herniations (diverticula) in the wall of the intestine. Acute **diverticulitis** is the inflammation or infection of diverticula.

### ❖Pathophysiology

Diverticula can occur in any part of the small or large intestine, but usually occur in the sigmoid colon ([Fig. 57-6](#)). The muscle of the colon hypertrophies, thickens, and becomes rigid, and

herniation of the mucosa and submucosa through the colon wall is seen. Diverticula seem to occur at points of weakness in the intestinal wall, often at areas where blood vessels interrupt the muscle layer. Muscle weakness develops as part of the aging process or as a result of a lack of fiber in the diet.

**FIG. 57-6** Several abnormal outpouchings, or herniations, in the wall of the intestine, which are diverticula. These can occur anywhere in the small or large intestine but are found most often in the colon. Diverticulitis is the inflammation of a diverticulum that occurs when undigested food or bacteria become trapped in the diverticulum.

Diverticula without inflammation cause few problems. However, if undigested food or bacteria become trapped in a diverticulum, blood supply to that area is reduced. Bacteria invade the diverticulum, resulting in diverticulitis, which then can perforate and develop a local abscess. A perforated diverticulum can progress to an intra-abdominal perforation with peritonitis (inflammation of the peritoneum). Lower GI bleeding may also occur.

High intraluminal pressure forces the formation of a pouch in the weakened area of the mucosa. Diets low in fiber that cause less bulky stool and constipation have been implicated in the formation of diverticula. Retained undigested food in diverticula is suggested to be one cause of diverticulitis. The retained food reduces blood flow to that area and makes bacterial invasion of the sac easier (McCance et al., 2014).

The exact incidence of diverticulosis is unknown, but millions are affected by the problem. It is found in two thirds of adults older than 80 years, with more men than women affected.

### ❖ **Interprofessional Collaborative Care**

Patients with diverticular disease are self-managed at home, cared for in the community setting, or hospitalized if surgery is needed to correct the concern. The interprofessional team that collaborates to care for this patient generally includes the health care provider (and/or surgeon) and nurse.

### ◆ **Assessment: Noticing**

The patient with *diverticulosis* usually has no symptoms. Unless pain or bleeding develops, the condition may go undiagnosed. Diverticula are most often diagnosed during routine colonoscopy. Occasionally diverticulosis will cause symptoms. For the patient with uncomplicated diverticulosis, ask about intermittent pain in the left lower quadrant and a history of constipation. If diverticulitis is suspected, ask about a history of low-grade fever, nausea, and abdominal pain. Inquire about recent bowel ELIMINATION patterns because constipation may develop as a result of intestinal inflammation. Also ask about any bleeding from the rectum.

The patient with *diverticulitis* may have abdominal pain, most often localized to the left lower quadrant. It is intermittent at first but becomes progressively steady. Occasionally pain may be just above the pubic bone or may occur on one side. Abdominal pain is generalized if peritonitis has occurred. Nausea and vomiting are common. The patient's temperature is elevated, ranging from a low-grade fever to 101° F (38.3° C). Chills may be present. Often an increased heart rate (tachycardia) occurs with fever (Almerie & Simpson, 2015).

## Considerations for Older Adults

### Patient-Centered Care QSEN

The first sign of peritonitis in older adults may be a sudden change in mental status (e.g., acute confusion). For those who have dementia, the confusion worsens. Fever and chills may not be present because of normal physiologic changes associated with aging.

On examination of the abdomen, observe for distention. The patient may report tenderness over the involved area. Localized muscle spasm, guarded movement, and rebound tenderness may be present with peritoneal irritation. If generalized peritonitis is present, profound guarding occurs; rebound tenderness is more widespread; and sepsis, hypotension, or hypovolemic shock can occur. If the perforated diverticulum is close to the rectum, the health care provider may palpate a tender mass during the rectal examination. Blood pressure checks may show orthostatic changes. *If bleeding is massive, the patient may have hypovolemia and hypotension that result in shock.*

For the patient with uncomplicated diverticulosis, laboratory studies are not indicated. However, the patient with diverticulitis has an *elevated white blood cell (WBC) count*. *Decreased hematocrit and hemoglobin* values are common if chronic or severe bleeding occurs. Stool tests for occult blood, if requested, are sometimes positive. Abdominal x-rays may be done to evaluate for free air and fluid indicating perforation. A CT scan may be performed to diagnose an abscess or thickening of the bowel related to diverticulitis.

*Abdominal ultrasonography*, a noninvasive test, may also reveal bowel thickening or an abscess. The health care provider may recommend a colonoscopy 4 to 8 weeks *after the acute phase* of the illness to rule out a tumor in the large intestine, particularly if the patient has rectal bleeding.

### Interventions: Responding

Patients are managed on an ambulatory care basis if the symptoms are mild. Monitor the patient for any prolonged or increased fever, abdominal pain, or blood in the stool. The patient with moderate-to-severe diverticulitis may be hospitalized, especially if he or she is older or has complications. Manifestations suggesting the need for admission are a temperature higher than 101° F (38.3° C), persistent and severe abdominal pain for more than 3 days, and/or lower GI bleeding.

### Nonsurgical Management.

A combination of drug and NUTRITION therapy with rest is used to decrease the inflammation associated with diverticular disease. Broad-spectrum antimicrobial drugs, such as metronidazole (Flagyl) in conjunction with trimethoprim/sulfamethoxazole (TMZ) (Bactrim or Bactrim DS, Septra) or ciprofloxacin (Cipro), are often prescribed. A mild analgesic may be given for pain. [Chart 57-6](#) lists nursing interventions needed for care of older adults with diverticulitis.

### Chart 57-6

## Nursing Focus on the Older Adult

### Diverticulitis

- Provide antibiotics, analgesics, and anticholinergics as prescribed. Observe older patients carefully for side effects of these drugs, especially confusion (or increased confusion), urinary retention or failure, and orthostatic hypotension.
- Do not give laxatives or enemas. Teach the patient and family about the importance of avoiding these measures.
- Encourage the patient to rest and to avoid activities that may increase intra-abdominal pressure, such as straining and bending.
- While diverticulitis is active, provide a *low-fiber* diet. When the inflammation resolves, provide a *high-fiber* diet. Teach the patient and family about these diets and when they are appropriate.

- Because older patients do not always experience the typical pain or fever expected, observe carefully for other signs of active disease, such as a sudden change in mental status.
- Perform frequent abdominal assessments to determine distention and tenderness on palpation.
- Check stools for occult or frank bleeding.

The patient with more severe pain may be admitted to the hospital for IV fluids to correct dehydration and IV drug therapy. For patients with moderate-to-severe diverticulitis, an opioid analgesic may alleviate pain.

Laxatives and enemas are avoided because they increase intestinal motility. Assess the patient on an ongoing basis for manifestations of impaired FLUID AND ELECTROLYTE BALANCE.

Teach the patient to rest during the acute phase of illness. Remind him or her to refrain from lifting, straining, coughing, or bending to avoid an increase in intra-abdominal pressure, which can result in perforation of the diverticulum. NUTRITION therapy should be restricted to low fiber or clear liquids based on symptoms. The patient with more severe symptoms is NPO. A nasogastric tube (NGT) is inserted if nausea, vomiting, or abdominal distention is severe. Infuse IV fluids as prescribed for hydration. In collaboration with a dietitian, the patient increases dietary intake slowly as symptoms subside. When inflammation has resolved and bowel function returns to normal, a fiber-containing diet is introduced gradually.

### Surgical Management.

Diverticulitis can result in rupture of the diverticulum with peritonitis, pelvic abscess, bowel obstruction, fistula, persistent fever or pain, or uncontrolled bleeding. The surgeon performs emergency surgery if peritonitis, bowel obstruction, or pelvic abscess is present. Colon resection, with or without a colostomy, is the most common surgical procedure for patients with diverticular disease. [Chapter 56](#) discusses the nursing care for patients with this procedure.

### Care Coordination and Transition Management

Discharge plans vary according to the treatment. The patient who has surgical intervention has the added responsibilities of incision care and possibly colostomy care with temporary limitations placed on activities.

Patients with diverticular disease need education regarding a high-fiber diet. Encourage the patient with *diverticulosis* to eat a diet high in cellulose and hemicellulose types of fiber. These substances can be found in wheat bran, whole-grain breads, and cereals. Teach the patient to eat at least 25 to 35 grams of fiber per day. Fresh fruits and vegetables with high fiber content are added to provide bulk to stools.

If not accustomed to eating high-fiber foods, teach the patient to add them to the diet gradually to avoid flatulence and abdominal cramping. If he or she cannot tolerate the recommended fiber requirement, a bulk-forming laxative, such as psyllium hydrophilic mucilloid (Metamucil), can be taken to increase fecal size and consistency. Teach the patient to drink plenty of fluids to help prevent bloating that may occur with a high-fiber diet. Alcohol should be avoided because it irritates the bowel. Foods containing seeds or indigestible material that may block a diverticulum, such as nuts, corn, popcorn, cucumbers, tomatoes, figs, and strawberries, may need to be eliminated. Teach the patient that dietary fat intake should not exceed 30% of the total daily caloric intake.

The patient should be instructed to avoid all fiber when symptoms of *diverticulitis* are present, because high-fiber foods can be irritating. As inflammation resolves, fiber can gradually be added until progression to a high-fiber diet is established. The patient who has undergone surgery is usually taking solid food by the time of discharge from the hospital.

Provide oral and written instructions on incision care and the signs and symptoms to report to the health care provider for the patient who had abdominal surgery. If a colostomy was created, reinforce ostomy care as needed. Encourage the patient to express concerns about body image. Allow time and address sexual concerns regarding the changed body image.

Instruct the patient with any type of diverticular disease about the manifestations of acute diverticulitis, including fever, abdominal pain, and bloody, mahogany, or tarry stools. Advise patients to avoid the use of laxatives (other than bulk-forming types) and enemas. Reassure them

that this disorder should not cause problems if a proper diet is followed.

In collaboration with the case manager, arrange for a home care nurse, if needed, to assess wound healing and proper functioning of the ostomy and the appliance. If the patient is interested, arrange for a visit from an ostomy volunteer (ostomate) or an ostomy nurse. For information about other community resources, remind the patient to contact the United Ostomy Associations of America ([www.uoaa.org](http://www.uoaa.org)).

## NCLEX Examination Challenge 57-4

### Physiological Integrity

The nurse is teaching a client about nutrition and diverticulosis. Which food will the nurse teach the client to avoid?

- A. Popcorn
- B. Oatmeal
- C. Bran
- D. Lettuce

## Celiac Disease

Celiac disease (CD) was once thought to be a rare disease but, as a result of improved diagnostic testing, many cases have been diagnosed in the past 10 to 15 years. CD is a multi-system autoimmune disease with an estimated incidence as high as 1 in 250 of the world's population (Mavrinac et al., 2014). Patients who have other autoimmune diseases, such as rheumatoid arthritis and diabetes mellitus type 1, are at the highest risk for the disease.

CD is a chronic inflammation of the small intestinal mucosa that can cause bowel wall atrophy, malabsorption, and diarrhea. Like many inflammatory disorders, it is thought to be caused by a combination of genetic, immunologic, and environmental factors. The primary complication of CD is cancer, specifically non-Hodgkin's lymphoma or GI cancers and NUTRITION deficiencies.

Patients with CD have varying signs and symptoms with cycles of remission and exacerbation (flare-up), usually related to how well they monitor their diet. Classic symptoms include anorexia, diarrhea and/or constipation, steatorrhea (fatty stools), abdominal pain, abdominal bloating and distention, and weight loss. Some patients have no symptoms. Still others have atypical symptoms that affect every body system (Chart 57-7). Diagnosis is usually made by obtaining a screening blood test and endoscopy.

### Chart 57-7

## Key Features

### Celiac Disease

#### Classic Symptoms

- Weight loss
- Anorexia
- Diarrhea and/or constipation
- Steatorrhea
- Abdominal pain and distention
- Vomiting

## Atypical Symptoms

- Osteoporosis
- Joint pain and inflammation
- Lactose intolerance
- Iron deficiency anemia
- Depression
- Migraines
- Epilepsy
- Autoimmune disorders
- Stomatitis
- Early menopause
- Protein-calorie malnutrition
- Infertility

## NCLEX Examination Challenge 57-5

### Physiological Integrity

The nurse is caring for a client who has celiac disease. Which food will the nurse remove from the client's dietary tray? **Select all that apply.**

- A. Rice
- B. Graham crackers
- C. Croissant
- D. Fresh peaches
- E. Chicken breast

Dietary management is the only available treatment for achieving disease remission. In most cases, a gluten-free diet (GFD) results in healing the intestinal mucosa after about 2 years (Mavrinac et al., 2014). Gluten is the primary substance in wheat and wheat-based products. Teach patients to carefully check for hidden sources of gluten that are in foods, food additives, drugs, and cosmetics. Patients often take vitamin and mineral supplements to replace those lost in avoiding gluten foods. A registered dietitian should be included in the patient's long-term planning and overall treatment.

## Anal Disorders

### Anorectal Abscess

**Anorectal abscess** is a localized area of induration and pus caused by inflammation of the soft tissue near the rectum or anus. It is most often the result of obstruction of the ducts of glands in the anorectal region. Feces, foreign bodies, or trauma can be the cause of the obstruction and stasis, leading to infection that spreads into nearby tissue.

Rectal pain is often the first symptom. There may be no other signs or symptoms at first, but local swelling, redness, and tenderness are present within a few days after the onset of pain. If the abscess becomes chronic, discharge, bleeding, and pruritus (itching) may exist. Fever occurs if larger abscesses are present.

Anorectal abscesses are managed by surgical incision and drainage (I&D). The physician can often excise (surgically remove) simple perianal and ischioanal abscesses using a local anesthetic. For patients with a more extensive abscess, a regional or general anesthetic may be needed. Systemic antibiotics are given only for patients who are immunocompromised, have diabetes, have valvular disease or a prosthetic valve, or are obese.

### Nursing Safety Priority QSEN

#### Action Alert

For patients with an anorectal abscess, nursing interventions are focused on COMFORT and helping the patient maintain optimal perineal hygiene. Encourage the use of warm sitz baths, analgesics, bulk-producing agents, and stool softeners after the surgery to promote healing. *Stress the importance of good perineal hygiene after all bowel movements and the maintenance of a regular bowel pattern with a high-fiber diet.*

Patients are often embarrassed about having anal problems. Provide privacy and maintain the patient's dignity during the examination and treatment.

### Anal Fissure

An **anal fissure** is a tear in the anal lining, which can be very painful. Smaller fissures occur with straining to have a stool, such as with diarrhea or constipation. Larger, deeper fissures may occur as a result of another disorder (e.g., Crohn's disease, tuberculosis, leukemia, neoplasm) or from trauma (e.g., from a foreign body, anal intercourse, perirectal surgery).

An *acute* anal fissure is superficial and usually resolves on its own or heals with conservative treatment. It can take up to 6 weeks for a fissure to heal. *Chronic* fissures recur, and surgical treatment may be needed. Pain during and after defecation and bright red blood in the stool are the most common symptoms. Other manifestations include pruritus, urinary frequency or retention, dysuria, and **dyspareunia** (painful intercourse).

The diagnosis is made by stretching and inspecting the perianal skin. If the patient is having pain at the time of the examination, diagnostic testing is usually limited to inspection. If he or she is not in severe pain, a digital examination and possibly a sigmoidoscopy are performed. When painless or multiple fissures are present, a colonoscopy may be performed to rule out any inflammatory bowel disorder.

Management of an acute fissure is usually aimed at local pain relief and softening of stools to reduce trauma to the area. Teach the patient to use warm sitz baths, analgesics, and bulk-producing agents (e.g., psyllium hydrophilic mucilloid [Metamucil]) to help minimize the pain from defecation. Topical anti-inflammatory agents (hydrocortisone creams and suppositories) may be helpful for some patients.

Explain pain control measures to the patient. Remind him or her to notify the health care provider if pain is not relieved within a few days. If fissures do not respond to management within several days to weeks, surgical repair under a local anesthetic may be needed. Teach the patient to report any drainage or bleeding from the rectum to the health care provider.

## Anal Fistula

An anal fistula, or *fistula in ano*, is an abnormal tract leading from the anal canal to the perianal skin. Most anal fistulas result from anorectal abscesses, which are caused by obstruction of anal glands (see the [Anorectal Abscess](#) section). Fistulas can also occur with tuberculosis, Crohn's disease, or cancer. Intermittent discharge is usually noted over the perianal area.

The patient with an anal fistula has pruritus (itching), purulent discharge, and tenderness or pain that worsens with bowel movements. A proctoscope may be used to identify the source of symptoms and to locate the fistula. Because fistulas do not heal spontaneously, surgery is necessary. To perform a fistulotomy, the surgeon opens the tissue over the tract and scrapes the base. The incision site then heals by secondary intention. For a fistula higher in the anus, a special surgical technique is used to preserve important sphincters. After surgery, instruct the patient about sitz baths, analgesics, and the use of bulk-producing agents or stool softeners to reduce pain.

## Parasitic Infection

### ❖ Pathophysiology

Parasites can enter and invade the GI tract and cause infection. They commonly enter through the mouth (oral-fecal transmission) from contaminated food or water, oral-anal sexual practices, or contact with feces from a contaminated person. Common parasites that cause infection in humans are *Giardia lamblia*, which causes giardiasis; *Entamoeba histolytica*, which causes amebiasis (amoebic dysentery); and *Cryptosporidium*. *Handwashing is the best way to prevent the spread of parasitic infections.*

*Giardia lamblia* is a protozoal parasite that causes superficial invasion, destruction, and inflammation of the mucosa in the small intestine. This organism occurs in cysts and trophozoites (sporozoan parasites). Trophozoites die rapidly after they leave the body in stool; but cysts can remain alive in the right type of environment for weeks or months. Humans who eliminate cysts are infectious. Flies can spread the cysts, and the problem is more common in areas that use human excrement for fertilizer. Humans are hosts to this organism, but beavers and dogs may be reservoirs for infection.

Giardiasis is a well-recognized problem in international travelers, campers, and immunosuppressed patients. In the United States, it is prevalent and is the most common parasitic infection. This disorder affects only the intestinal system, causing acute diarrhea, chronic diarrhea, or malabsorption syndrome. The acute phase usually is self-limiting, lasting days or weeks. The chronic phase can last for years. Diarrhea is usually mild in both forms, but it can be severe. As stools increase in frequency, they become more watery, greasy, frothy, and malodorous with mucus. Weight loss and weakness are also common. Malabsorption can occur with diarrhea that continues for longer than 3 weeks. Manifestations result from malabsorption of fat, protein, and vitamin B<sub>12</sub> and lactase deficiency.

Humans are the only known hosts for *E. histolytica* (also known as *amebiasis*). This organism also occurs in cysts and trophozoites. Amebiasis occurs worldwide, but it is most common in tropical areas. Prevalence rates are high in areas with poor sanitation, crowding, and poor NUTRITION. Amebiasis causes tens of thousands of deaths annually worldwide. The disease causes less severe symptoms and often goes undiagnosed in temperate climates. *E. histolytica* either feeds on bacteria in the intestine or invades and ulcerates the mucosa of the large intestine. The parasite can be limited to the GI tract (intestinal amebiasis), or it can extend outside the intestines (extraintestinal amebiasis). Individuals can have intestinal amebiasis without having any symptoms, or symptoms can range from mild to severe.

*Cryptosporidium* is manifested by diarrhea. This infection occurs most commonly in immunosuppressed patients, particularly those with human immune deficiency virus (HIV). It can also occur in children and older adults from contaminated swimming pools. (See [Chapter 19](#) for a discussion of HIV infection.)

Chagas disease is caused by the *Trypanosoma cruzi* parasite, which is most commonly transmitted in impoverished areas of Latin America by the triatomine (kissing) bug. Patients first develop an acute infection, followed by an intermediate asymptomatic period and a chronic infection. Patients with chronic Chagas disease often develop cardiac dysrhythmias or heart failure and colon or esophagus dilation, causing impaired digestion and bowel ELIMINATION. An estimated 300,000 individuals in the United States have the disease (most in the southern areas of the United States), which can be transmitted through blood transfusions and organ transplantations. The Centers for Disease Control and Prevention (CDC) has targeted Chagas disease as one of five neglected parasitic infections that require public health action as the number of cases is expected to increase (CDC, 2016).

### ❖ Interprofessional Collaborative Care

#### ◆ Assessment: Noticing

A thorough history can help determine potential sources of exposure to parasitic infection. A history of travel to parts of the world where such infections are prevalent increases suspicion for infection with parasites. GI symptoms related to travel may be delayed as long as 1 to 2 weeks for the return home. Immigrants (newcomers) may have the infection on entering a new country. A

NUTRITION history is especially helpful if several people in a group become ill. Common water supplies or bodies of water may be infected with *Giardia* or *Cryptosporidium*. Trichinosis should be considered if the patient has eaten pork products.

Mild-to-moderate *E. histolytica* infestation causes the daily passage of several strongly foul-smelling stools, possibly with mucus but without blood, accompanied by abdominal cramping, flatulence (gas), fatigue, and weight loss.

The infected patient usually experiences remissions and recurrences. Severe amoebic dysentery is manifested by frequent, more liquid, and foul-smelling stools with mucus *and* blood. Fever up to 104° F (40° C), **tenesmus** (feeling the urge to defecate), generalized abdominal tenderness, and vomiting can also occur. The ulcerations of invading amebiasis that occur in the colon can cause pain, bleeding, and obstruction. Ulcerations can also occur in the rectum, resulting in formed stool with blood. Complications are rare but include appendicitis and bowel perforation.

Extraintestinal amebiasis can occur without symptoms of intestinal infection. The most common form is amoebic liver abscess, which causes symptoms of fever, pain, and an enlarged liver. The abscess can rupture, and death can result if the infection and complications are not treated.

The diagnosis of *amebiasis* is made by examining the stool for parasites. Because *E. histolytica* is difficult to detect, serial stool examinations are needed if the disease is suspected. The use of sigmoidoscopy may detect ulcerations in the rectum or colon. Exudate obtained during sigmoidoscopic examination is studied for the parasite. The white blood cell (WBC) count can be very high when severe dysentery is present.

The diagnosis of *giardiasis* is also confirmed by the presence of parasites in the stool. Because organisms may not be detected for at least 1 week after symptoms appear, multiple stool samples should be examined.

### ◆Interventions: Responding

Treatment for all types of *amebiasis* involves the use of amebicide drugs. Metronidazole (Flagyl, Novo-Nidazol 🍀), followed by a luminal agent such as paromomycin, is commonly prescribed (Leder & Weller, 2016). The patient with severe amoebic dysentery requires IV fluid replacement and possibly an opiate-like drug, such as diphenoxylate hydrochloride and atropine sulfate (Lomotil), to control bowel motility. The patient with extraintestinal amebiasis or severe dehydration, especially the older adult, is hospitalized. The patient with asymptomatic, mild, or moderate disease is treated with drug therapy on an ambulatory care basis. Therapy effectiveness is based on the examination of at least three stools at 2- to 3-day intervals, starting 2 to 4 weeks after drug therapy has been completed. *Teach patients the importance of keeping their follow-up appointments and taking all drugs as prescribed.*

Treatment for *giardiasis* is drug therapy. Metronidazole (Flagyl, Novo-Nidazol 🍀) is the drug of choice. Tinidazole can be used as an alternative. Stools are examined 2 weeks after treatment to assess for drug effectiveness.

## 📌Nursing Safety Priority QSEN

### Action Alert

Explain modes of transmission of parasitic infections and means to avoid the spread of infection and recurrent contact with parasitic organisms. *Inform the patient that the infection can be transmitted to others until amebicides effectively kill the parasites. Teach the patient to:*

- Avoid contact with stool
- Keep toilet areas clean
- Wash hands meticulously with an antimicrobial soap after bowel movements
- Maintain good personal hygiene by bathing or showering daily
- Avoid stool from dogs and beavers

Advise the patient to avoid sexual practices that allow rectal contact until drug therapy is

completed. *All household and sexual partners should have stool examinations for parasites.* If the water supply is suspected as the source, a sample is obtained and sent for analysis. Multiple infections are common in households, often as a result of contaminated water supplies. Well water and water from areas with inadequate or no filtration equipment can be sources of contamination.

Infection with *Cryptosporidium* is usually self-limiting in adults who have normal immune function. Drug therapy for patients who are immunosuppressed may include paromomycin, an aminoglycoside antibiotic. Teach patients that this drug can cause dizziness.

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Collaborate with a CWOCN, health care provider, and case manager to plan care for patients with IBD. **QSEN: Teamwork and Collaboration**
- When transitioning care, remind patients and families about community resources for IBD, including the United Ostomy Associations of America and the Crohn's and Colitis Foundation of America. **QSEN: Teamwork and Collaboration**

### Health Promotion and Maintenance

- Teach patients to use infection control measures to prevent transmission of gastroenteritis as stated in [Chart 57-2](#). **QSEN: Safety**
- Teach patients how to self-manage an ileostomy or other surgical diversion, including skin care, pouch management, and stoma assessment (see [Chart 57-4](#)).

### Psychosocial Integrity

- Be aware that all IBDs (acute and chronic) are very disruptive to one's daily routine; living with IBD requires a lifetime of modifications. **QSEN: Patient-Centered Care**
- Recognize that having a chronic bowel disease or an ileostomy impacts the patient's body image and self-esteem; assess for coping strategies that the patient has previously used, and identify personal support systems, such as family members, to assist in coping. **Clinical Judgment**

### Physiological Integrity

- Assess for the classic signs and symptoms of appendicitis, which include abdominal pain, nausea and vomiting, and abdominal tenderness on palpation (McBurney's point); some patients also have leukocytosis. **QSEN: Safety**
- Recognize that perforation (rupture) of the appendix requires prompt intervention and can result in peritonitis. **QSEN: Safety**
- Assess for the key features of peritonitis as listed in [Chart 57-1](#).
- Assess for signs and symptoms of dehydration in patients who have acute and chronic inflammatory bowel disorders.
- Administer antidiarrheal medications as prescribed to decrease stools and therefore prevent dehydration in patients with acute and chronic inflammatory bowel disorders. **QSEN: Evidence-Based Practice**
- Differentiate between two major types of chronic inflammatory bowel disease (IBD): ulcerative colitis (UC) and Crohn's disease (see [Table 57-2](#)). **Clinical Judgment**
- Be alert for GI bleeding in the patient with chronic IBD. **QSEN: Safety**
- Be aware that patients with Crohn's disease are at high risk for malnutrition as a result of an inability to absorb nutrients via the small intestine. **Clinical Judgment**
- Priority problems for patients with UC include diarrhea, pain, and potential for lower GI bleeding.
- Monitor for complications of UC as listed in [Table 57-4](#).
- Provide nursing interventions for patients with IBD as listed in [Chart 57-3](#).
- Teach patients with IBD to avoid GI stimulants, such as alcohol and caffeine. **QSEN: Evidence-Based Practice**

- Administer 5-aminosalicylic acid (5-ASA) drugs as prescribed to decrease inflammation in patients with UC.
- Administer infliximab (Inflectra ✱, Remicade, Remsima ✱) or other monoclonal antibody agent as prescribed for patients with Crohn's disease; these drugs may also be useful for those with UC in selected cases.
- Observe for signs and symptoms of lower GI bleeding in patients with chronic inflammatory and diverticular disease. **QSEN: Safety**
- Teach patients with diverticulosis to eat a high-fiber diet; diverticulitis requires a low-fiber diet. **QSEN: Evidence-Based Practice**
- Teach older patients how to self-manage diverticulitis as outlined in [Chart 57-6](#).
- Instruct patients with diverticulosis about NUTRITION modifications, such as avoiding nuts, foods with seeds, and GI stimulants. **QSEN: Evidence-Based Practice**
- Be aware that patients with celiac disease (CD) have various signs and symptoms; some have no symptoms, some have classic symptoms, and some have atypical symptoms (see [Chart 57-7](#)). Teach patients with CD about the need to consume a strict gluten-free diet, which avoids wheat and wheat-based products. **QSEN: Evidence-Based Practice**
- Be aware that GI problems, including diarrhea, may be caused by parasites and food poisoning.
- Instruct patients with anorectal disorders to use sitz baths, bulk-forming agents (e.g., Metamucil), and stool softeners to decrease pain.

## CHAPTER 58

# Care of Patients With Liver Problems

Lara Carver, Jennifer Powers

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concepts for this chapter are:**

- CELLULAR REGULATION
- IMMUNITY

✚ The CELLULAR REGULATION concept exemplar for this chapter is Cirrhosis, below.

✚ The IMMUNITY concept exemplar for this chapter is Hepatitis, p. 1180.

**The interrelated concepts for this chapter are:**

- COMFORT
- FLUID AND ELECTROLYTE BALANCE
- NUTRITION

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to provide care for the patient with liver inflammation and necrosis.
2. Identify community resources to ensure appropriate transition management for patient with chronic liver disease.

### Health Promotion and Maintenance

3. Teach adults how to prevent hepatitis and its spread to others.
4. Teach patients how to prevent or slow the progress of alcohol-induced cirrhosis.

### Psychosocial Integrity

5. Implement nursing interventions to minimize stressors for the patient with liver problems.

### Physiological Integrity

6. Differentiate among assessment findings associated with cirrhosis, hepatitis, and other liver problems.
7. Prioritize care for patients with liver problems.
8. Create an evidence-based plan of care for the patient with late-stage cirrhosis.
9. Describe nursing interventions to address life-threatening complications associated with liver problems.
0. Explain the role of the nurse in assisting with paracentesis.
1. Describe nursing interventions that promote IMMUNITY, CELLULAR REGULATION, COMFORT, and FLUID AND ELECTROLYTE BALANCE for patients with liver problems.

As the largest and one of the most vital internal organs, the liver performs more than 400 functions and affects every bodily system. When the liver is diseased or damaged, IMMUNITY, CELLULAR REGULATION, *digestion*, NUTRITION, and *metabolism* can be severely affected. Liver diseases range in severity from mild hepatic inflammation to chronic end-stage cirrhosis.

## Cellular Regulation Concept Exemplar Cirrhosis

**Cirrhosis** is extensive, irreversible scarring of the liver, usually caused by a chronic reaction to hepatic inflammation and necrosis. This scarring process directly impairs CELLULAR REGULATION. The disease typically develops slowly and has a progressive, prolonged, destructive course resulting in end-stage liver disease. The most common causes for cirrhosis in the United States are chronic alcoholism, chronic viral hepatitis, nonalcoholic steatohepatitis (NASH), bile duct disease, and genetic diseases (Table 58-1).

**TABLE 58-1**

### Common Causes of Cirrhosis

- |   |
|---|
| <ul style="list-style-type: none"><li>• Alcoholic liver disease</li><li>• Viral hepatitis</li><li>• Autoimmune hepatitis</li><li>• Steatohepatitis (from fatty liver)</li><li>• Drugs and chemical toxins</li><li>• Gallbladder disease</li><li>• Metabolic/genetic causes</li><li>• Cardiovascular disease</li></ul> |
|---|

### Pathophysiology

Cirrhosis is characterized by widespread fibrotic (scarred) bands of connective tissue that change the liver's normal makeup and its associated CELLULAR REGULATION. Inflammation caused by either toxins or disease results in extensive degeneration and destruction of **hepatocytes** (liver cells). As cirrhosis develops, the tissue becomes nodular. These nodules can block bile ducts and normal blood flow throughout the liver. Impairments in blood and lymph flow result from compression caused by excessive fibrous tissue. In early disease, the liver is usually enlarged, firm, and hard. As the pathologic process continues, the liver shrinks in size, resulting in decreased liver function, which can occur in weeks to years. Some patients with cirrhosis have no symptoms until serious complications occur. The impaired liver function results in elevated serum liver enzymes (Pagana et al., 2017).

Cirrhosis of the liver can be divided into several common types, depending on the cause of the disease (McCance et al., 2014):

- Postnecrotic cirrhosis (caused by viral hepatitis [especially hepatitis C] and certain drugs or other toxins)
- Laennec's or alcoholic cirrhosis (caused by chronic alcoholism)
- Biliary cirrhosis (also called *cholestatic*; caused by chronic biliary obstruction or autoimmune disease)

### Complications of Cirrhosis

Common problems and complications associated with hepatic cirrhosis depend on the amount of damage sustained by the liver. In **compensated cirrhosis**, the liver is scarred and CELLULAR REGULATION is impaired, but the organ can still perform essential functions without causing major symptoms. In **decompensated cirrhosis**, liver function is impaired with obvious signs and symptoms of liver failure.

The loss of hepatic function contributes to the development of metabolic abnormalities. Hepatic cell damage may lead to these common complications:

- Portal hypertension
- Ascites and esophageal varices
- Coagulation defects
- Jaundice
- Portal-systemic encephalopathy (PSE) with hepatic coma
- Hepatorenal syndrome
- Spontaneous bacterial peritonitis

## Portal Hypertension.

**Portal hypertension**, a persistent increase in pressure within the portal vein greater than 5 mm Hg, is a major complication of cirrhosis. It results from increased resistance to or obstruction (blockage) of the flow of blood through the portal vein and its branches. The blood meets resistance to flow and seeks collateral (alternative) venous channels around the high-pressure area.

Blood flow backs into the spleen, causing **splenomegaly** (spleen enlargement). Veins in the esophagus, stomach, intestines, abdomen, and rectum become dilated. Portal hypertension can result in ascites (excessive abdominal [peritoneal] fluid), esophageal varices (distended veins), prominent abdominal veins (caput medusae), and hemorrhoids.

## Ascites and Gastroesophageal Varices.

**Ascites** is the collection of free fluid within the peritoneal cavity caused by increased hydrostatic pressure from portal hypertension (McCance et al., 2014). The collection of plasma protein in the peritoneal fluid reduces the amount of circulating plasma protein in the blood. When this decrease is combined with the inability of the liver to produce albumin because of impaired liver cell functioning, the serum colloid osmotic pressure is decreased in the circulatory system. The result is a fluid shift from the vascular system into the abdomen, a form of “third spacing.” As a result, the patient may have hypovolemia and edema at the same time.

*Massive* ascites may cause renal vasoconstriction, triggering the renin-angiotensin system. This results in sodium and water retention, which increases hydrostatic pressure and the vascular volume and leads to more ascites.

As a result of portal hypertension, the blood backs up from the liver and enters the esophageal and gastric veins. **Esophageal varices** occur when fragile, thin-walled esophageal veins become distended and tortuous from increased pressure. The potential for varices to bleed depends on their size; size is determined by direct endoscopic observation. Varices occur most often in the distal esophagus but can be present also in the stomach and rectum.

*Bleeding esophageal varices are a life-threatening medical emergency. Severe blood loss may occur, resulting in shock from hypovolemia.* The bleeding may be either **hematemesis** (vomiting blood) or **melena** (black, tarry stools). Loss of consciousness may occur before any observed bleeding. Variceal bleeding can occur spontaneously with no precipitating factors. However, any activity that increases abdominal pressure may increase the likelihood of a variceal bleed, including heavy lifting or vigorous physical exercise. In addition, chest trauma or dry, hard food in the esophagus can cause bleeding.

Patients with portal hypertension may also have **portal hypertensive gastropathy**. This complication can occur with or without esophageal varices. Slow gastric mucosal bleeding occurs, which may result in chronic slow blood loss, occult-positive stools, and anemia.

**Splenomegaly** (enlarged spleen) results from the backup of blood into the spleen. The enlarged spleen destroys platelets, causing thrombocytopenia (low serum platelet count) and increased risk for bleeding. Thrombocytopenia is often the first clinical sign that a patient has liver dysfunction.

## Biliary Obstruction.

In patients with cirrhosis, the production of bile in the liver is decreased. This prevents the absorption of fat-soluble vitamins (e.g., vitamin K). Without vitamin K, clotting factors II, VII, IX, and X are not produced in sufficient quantities, and the patient is susceptible to bleeding and easy bruising. These abnormalities are confirmed by coagulation studies. Some patients have a genetic predisposition to obstruction of the bile duct that leads to biliary cirrhosis—usually from gallbladder disease or an autoimmune form of the disease called *primary biliary cirrhosis (PBC)*.

**Jaundice** (yellowish coloration of the skin) in patients with cirrhosis is caused by one of two mechanisms: hepatocellular disease or intrahepatic obstruction (Fig. 58-1). *Hepatocellular* jaundice develops because the liver cells cannot effectively excrete bilirubin. This decreased excretion results in excessive circulating bilirubin levels. *Intrahepatic obstructive* jaundice results from edema, fibrosis, or scarring of the hepatic bile channels and bile ducts, which interferes with normal bile and bilirubin excretion. Patients with jaundice often report pruritus (itching).

**FIG. 58-1** Jaundice as a result of liver dysfunction such as cirrhosis and hepatitis. (From Leonard, P. [2011]. *Quick & easy medical terminology* (6th ed.). St. Louis: Saunders.)

### Hepatic Encephalopathy.

**Hepatic encephalopathy** (also called **portal-systemic encephalopathy [PSE]**) is a complex cognitive syndrome that results from liver failure and cirrhosis. Patients report sleep disturbance, mood disturbance, mental status changes, and speech problems early as this complication begins. Hepatic encephalopathy may be reversible with early intervention. Later neurologic symptoms include an altered level of consciousness, impaired thinking processes, and neuromuscular problems.

Hepatic encephalopathy may develop slowly in patients with chronic liver disease and go undetected until the late stages. Symptoms develop rapidly in acute liver dysfunction. Four stages of development have been identified (Table 58-2). The patient's symptoms may gradually progress to coma or fluctuate among the four stages.

**TABLE 58-2**  
**Stages of Hepatic Encephalopathy**

<p><b>Stage I</b></p> <ul style="list-style-type: none"> <li>• Subtle manifestations that may not be recognized immediately</li> <li>• Personality changes</li> <li>• Behavior changes (agitation, belligerence)</li> <li>• Emotional lability (euphoria, depression)</li> <li>• Impaired thinking</li> <li>• Inability to concentrate</li> <li>• Fatigue, drowsiness</li> <li>• Slurred or slowed speech</li> <li>• Sleep pattern disturbances</li> </ul>
<p><b>Stage II</b></p> <ul style="list-style-type: none"> <li>• Continuing mental changes</li> <li>• Mental confusion</li> <li>• Disorientation to time, place, or person</li> <li>• Asterixis (hand flapping)</li> </ul>
<p><b>Stage III</b></p> <ul style="list-style-type: none"> <li>• Progressive deterioration</li> <li>• Marked mental confusion</li> <li>• Stuporous, drowsy but arousable</li> <li>• Abnormal electroencephalogram tracing</li> <li>• Muscle twitching</li> <li>• Hyperreflexia</li> <li>• Asterixis (hand flapping)</li> </ul>
<p><b>Stage IV</b></p> <ul style="list-style-type: none"> <li>• Unresponsiveness, leading to death in most patients progressing to this stage</li> <li>• Unarousable, obtunded</li> <li>• Usually no response to painful stimulus</li> <li>• No asterixis</li> <li>• Positive Babinski's sign</li> <li>• Muscle rigidity</li> <li>• Feter hepaticus (characteristic liver breath—musty, sweet odor)</li> <li>• Seizures</li> </ul>

The exact mechanisms causing hepatic encephalopathy are not clearly understood but probably are the result of the shunting of portal venous blood into the central circulation so the liver is bypassed. As a result, substances absorbed by the intestine are not broken down or detoxified and

may lead to metabolic abnormalities, such as elevated serum ammonia and gamma-aminobutyric acid (GABA). Elevated serum ammonia results from the inability of the liver to detoxify protein by-products and is common in patients with hepatic encephalopathy. However, it is not a clear indicator of the presence of encephalopathy. Some patients may have major impairment without high elevations of serum ammonia, and elevations of ammonia can occur without evidence of encephalopathy.

Factors that may lead to hepatic encephalopathy in patients with cirrhosis include:

- High-protein diet
- Infection
- Hypovolemia (decreased fluid volume)
- Hypokalemia (decreased serum potassium)
- Constipation
- GI bleeding (causes a large protein load in the intestines)
- Drugs (e.g., hypnotics, opioids, sedatives, analgesics, diuretics, illicit drugs)

The prognosis depends on the severity of the underlying cause, the precipitating factors, and the degree of liver dysfunction.

### Other Complications.

The development of **hepatorenal syndrome (HRS)** indicates a poor prognosis for the patient with liver failure. It is often the cause of death in these patients. This syndrome is manifested by:

- A sudden decrease in urinary flow (<500 mL/24 hr) (oliguria)
- Elevated blood urea nitrogen (BUN) and creatinine levels with abnormally decreased urine sodium excretion
- Increased urine osmolality

HRS often occurs after clinical deterioration from GI bleeding or the onset of hepatic encephalopathy. It may also complicate other liver diseases, including acute hepatitis and fulminant liver failure.

Patients with cirrhosis and ascites may develop acute *spontaneous bacterial peritonitis (SBP)*. Those who are particularly susceptible are patients with very advanced liver disease. This may be the result of low concentrations of proteins; proteins normally provide some protection against bacteria.

The bacteria responsible for SBP are typically from the bowel and reach the ascitic fluid after migrating through the bowel wall and transversing the lymphatics. Symptoms vary but may include fever, chills, alterations in COMFORT (especially in the abdomen), and tenderness. However, indications can also be minimal with only mild symptoms in the absence of fever. Worsening encephalopathy and increased jaundice may also be present without abdominal symptoms.

The diagnosis of SBP is made when a sample of ascitic fluid is obtained by paracentesis for cell counts and culture. An ascitic fluid leukocyte count of more than 250 polymorphonuclear (PMN) leukocytes may indicate the need for treatment.

### Etiology and Genetic Risk

Hepatitis C is a leading cause of cirrhosis and liver failure in the United States ([Centers for Disease Control and Prevention, 2017](#)). It is an infectious bloodborne illness that usually causes chronic disease and compromises the body's IMMUNITY. Inflammation caused by infection over time leads to progressive scarring of the liver, which impedes CELLULAR REGULATION. It usually takes decades for cirrhosis to develop, although alcohol use in combination with hepatitis C may speed the process.

Hepatitis B and hepatitis D are the most common causes of cirrhosis worldwide. Hepatitis B also causes inflammation and low-grade damage over decades that can ultimately lead to cirrhosis. Hepatitis D virus can infect the liver but only in people who already have hepatitis B (see discussion in [Immunity Concept Exemplar: Hepatitis](#)).

Cirrhosis may also occur as a result of nonalcoholic fatty liver disease (NAFLD), a rapidly growing health care concern. NAFLD is associated with obesity, diabetes mellitus type 2, and metabolic syndrome. It is the most common cause of liver disease in the world ([World Gastroenterology Organisation, 2012](#)). This disease can progress to liver cancer, cirrhosis, or failure, causing premature death. Up to 30% of Americans may have NAFLD ([American Liver Foundation](#),

2017a). The Patatin-like phospholipase domain-containing 3 gene (*PNPLA3*) has been identified as a risk gene for the disease. Hispanics have this gene more often than other ethnic groups and therefore are at the highest risk for NAFLD (Houghton-Rahrig et al., 2014).

Another common cause of cirrhosis is excessive and prolonged alcohol use. Alcohol has a direct toxic effect on the hepatocytes and causes liver inflammation (**alcoholic hepatitis**). The liver becomes enlarged, with cellular degeneration and infiltration by fat, leukocytes, and lymphocytes. Over time, the inflammatory process decreases, and the destructive phase increases, as the ability to maintain appropriate CELLULAR REGULATION decreases. Early scar formation is caused by fibroblast infiltration and collagen formation. Damage to the liver tissue progresses as malnutrition and repeated exposure to the alcohol continue. If alcohol is withheld, the fatty infiltration and inflammation are reversible. If alcohol use continues, widespread scar tissue formation and fibrosis infiltrate the liver as a result of cellular necrosis. The long-term use of illicit drugs, such as cocaine, has similar effects on the liver.

## Gender Health Considerations

### Patient-Centered Care OSEN

The amount of alcohol necessary to cause cirrhosis varies widely from individual to individual, and there are gender differences. In women, it may take as few as two or three drinks per day over a minimum of 10 years. In men, perhaps six drinks per day over the same time period may be needed to cause disease. However, a smaller amount of alcohol over a long period of time can increase memory loss from alcohol toxicity of the cerebral cortex. Binge drinking can increase risk for hepatitis and fatty liver.

### Incidence and Prevalence

Approximately 3.2 million Americans have hepatitis C (American Liver Foundation, 2017b), and 1 in 7 Americans have hepatitis B, which can particularly affect Asian American and Pacific Islander-born individuals (Immunization Action Coalition, 2016).

Combined, the incidence of chronic liver disease and cirrhosis are a major common cause of death in the United States. The national prevalence of hepatitis B in Canada is 270,000 individuals (Canadian Digestive Health Association, 2017). It is more challenging to quantify the exact number of Canadians with liver disease, since these statistics are grouped with other digestive disorders; however, it is known that approximately 7000 Canadians die annually after being affected with a liver disorder (Canadian Digestive Health Association, 2017.)

## Interprofessional Collaborative Care

Care for the patient with cirrhosis can take place in various settings. These patients may, at different times, self-manage at home, be hospitalized for immediate concerns, need rehabilitative care, or be cared for in the community setting. Members of the interprofessional team that collaborate most closely to care for the patient with cirrhosis include the primary and specialty health care providers, nurse, dietitian, social worker, pharmacist, and spiritual leader of the patient's choice.

### Assessment: Noticing

#### History.

Obtain data from patients with suspected cirrhosis, including age, gender, and employment history, especially history of exposure to alcohol, drugs (prescribed and illicit), use of herbal preparations, and chemical toxins. Keep in mind that all exposures are important, regardless of how long ago they occurred. Determine whether there has ever been a needlestick injury. Sexual history and orientation may be important in determining an infectious cause for liver disease, because men having sex with men (MSM) are at high risk for hepatitis A, hepatitis B, and hepatitis C. People with hepatitis can develop cirrhosis.

Inquire about whether there is a family history of alcoholism and/or liver disease. Ask the patient to describe his or her alcohol intake, including the amount consumed during a given period. Is

there a history of illicit drug use, including oral, IV, and intranasal forms? Is there a history of obtaining tattoos? If so, when and where were they done? Has the patient been in the military or in prison? Is the patient a health care worker, firefighter, or police officer? For patients previously or currently in an alcohol or drug recovery program, how long have they been sober? This information is sensitive and often difficult for the patient to answer. Be sure to establish why you are asking these questions and accept answers in a nonjudgmental manner. Provide privacy during the interview. For many people, the behaviors causing the liver disease occurred years before the onset of their current illness, and they are regretful and often embarrassed.

Ask the patient about previous medical conditions, such as an episode of jaundice or acute viral hepatitis, biliary tract disorders (such as cholecystitis), viral infections, surgery, blood transfusions, autoimmune disorders, obesity, altered lipid profile, heart failure, respiratory disorders, or liver injury.

### Physical Assessment/Signs and Symptoms.

Because cirrhosis has a slow onset, many of the *early* signs and symptoms are vague and nonspecific. Assess for:

- Fatigue
- Significant change in weight
- GI symptoms, such as anorexia and vomiting
- COMFORT alterations in the abdominal area and liver tenderness (both of which may be ignored by the patient)

Liver function problems are often found during a routine physical examination or when laboratory tests are completed for an unrelated illness or problem. The patient with *compensated cirrhosis* may be completely unaware that there is a liver problem. The first sign may present before the onset of symptoms when routine laboratory tests, presurgical evaluations, or life and health insurance assessments show abnormalities. These tests could indicate abnormal liver function or thrombocytopenia, requiring a more thorough diagnostic workup.

The development of late signs of *advanced cirrhosis* (also called *end-stage liver failure*) usually causes the patient to seek medical treatment. GI bleeding, jaundice, ascites, and spontaneous bruising indicate poor liver function and complications of cirrhosis.

Thoroughly assess the patient with liver dysfunction or failure because it affects every body system. The clinical picture and course vary from patient to patient, depending on the severity of the disease. Assess for:

- Obvious yellowing of the skin (jaundice) and sclerae (icterus)
- Dry skin
- Rashes
- Purpuric lesions, such as **petechiae** (round, pinpoint, red-purple lesions) or **ecchymoses** (large purple, blue, or yellow bruises)
- Warm and bright red palms of the hands (palmar erythema)
- Vascular lesions with a red center and radiating branches, known as **spider angiomas** (telangiectases, spider nevi, or vascular spiders), on the nose, cheeks, upper thorax, and shoulders
- Ascites (abdominal fluid)
- Peripheral dependent edema of the extremities and sacrum
- Vitamin deficiency (especially fat-soluble vitamins A, D, E, and K)

### Abdominal Assessment.

*Massive* ascites can be detected as a distended abdomen with bulging flanks (Fig. 58-2). The umbilicus may protrude, and dilated abdominal veins (caput medusae) may radiate from the umbilicus. Ascites can cause physical problems. For example, orthopnea and dyspnea from increased abdominal distention can interfere with lung expansion. The patient may have difficulty maintaining an erect body posture, and problems with balance may affect walking. Inspect and palpate for the presence of inguinal or umbilical hernias, which are likely to develop because of increased intra-abdominal pressure. *Minimal* ascites is often more difficult to detect, especially in the obese patient.

**FIG. 58-2** Patient with abdominal ascites in late-stage cirrhosis. (From Talley, N., & O'Connor, S. [2010]. *Clinical examination: A systematic guide to physical diagnosis* (6th ed.). Sydney: Churchill Livingstone Australia.)

When performing an assessment of the abdomen, keep in mind that **hepatomegaly** (liver enlargement) occurs in many cases of early cirrhosis. Splenomegaly is common in nonalcoholic causes of cirrhosis. As the liver deteriorates, it may become hard and small.

Measure the patient's abdominal girth to evaluate the progression of ascites (see Fig. 58-2). To measure abdominal girth, the patient lies flat while the nurse or other examiner pulls a tape measure around the largest diameter (usually over the umbilicus) of the abdomen. The girth is measured at the end of exhalation. Mark the abdominal skin and flanks to ensure the same tape measure placement on subsequent readings. *However, taking daily weights is the most reliable indicator of fluid retention.*

#### Other Physical Assessment.

Observe vomitus and stool for blood. This may be indicated by frank blood in the excrement or by a positive fecal occult blood test (FOBT) (Hema-Check, Hematest). Gastritis, stomach ulceration, or oozing esophageal varices may be responsible for the blood in the stool. Note the presence of **fetor hepaticus**, which is the distinctive breath odor of chronic liver disease and hepatic encephalopathy and is characterized by a fruity or musty odor.

Amenorrhea (no menstrual period) may occur in women; and men may exhibit testicular atrophy, **gynecomastia** (enlarged breasts), and impotence as a result of inactive hormones. Patients with problems of the hematologic system caused by hepatic failure may have bruising and petechiae (small, purplish hemorrhagic spots on the skin).

Continually assess the patient's neurologic function; it may also be helpful to include family members in conversations about the patient's baseline mental status if the patient is unable to effectively communicate. Subtle changes in mental status and personality often progress to coma—a late complication of encephalopathy. Monitor for **asterixis**—a coarse tremor characterized by rapid, nonrhythmic extensions and flexions in the wrists and fingers (hand-flapping).

#### Psychosocial Assessment.

The patient with hepatic cirrhosis may undergo subtle or obvious personality, cognitive, and behavior changes, such as agitation. He or she may experience sleep pattern disturbances or exhibit signs of emotional lability (fluctuations in emotions), euphoria (a very elevated mood), or depression. A psychosocial assessment identifies needs and helps guide care.

Repeated hospitalizations are common for patients with cirrhosis. It is a life-altering chronic disease, impacting not only the patient but also the immediate and extended family members and significant others. There are significant emotional, physical, and financial changes. Substance use may continue even as health worsens. It is important, whenever possible, to use resources available to these patients and their families. Collaborate with social workers, substance use counselors, and mental health/behavioral health care professionals as needed for patient assessment and management.

Part of the psychosocial assessment is determining if the patient is alcohol dependent. If this is the case, observe and prepare for alcohol withdrawal. Care of the patient experiencing withdrawal can be a medical emergency. Consult mental health textbooks or references for this chapter for more

information about caring for the alcohol-dependent patient.

## NCLEX Examination Challenge 58-1

### Physiological Integrity

The nurse is caring for a client who is jaundiced and reports pruritus. Which intervention will the nurse include in the plan of care?

- A. Monitor the client's vital signs and intake and output
- B. Instruct the client to scratch with knuckles instead of nails
- C. Assist the client with a hot bath and apply moisturizer
- D. Encourage the client to eat a high-protein, high-cholesterol diet

### Laboratory Assessment.

Laboratory study abnormalities are common in patients with liver disease (Table 58-3). Serum levels of *aspartate aminotransferase* (AST), *alanine aminotransferase* (ALT), and *lactate dehydrogenase* (LDH) typically are elevated because these enzymes are released into the blood during hepatic inflammation. However, as the liver deteriorates, the hepatocytes may be unable to create an inflammatory response, and the AST and ALT may be normal. ALT levels are more specific to the liver, whereas AST can be found in muscle, kidney, brain, and heart. An AST/ALT ratio greater than 1.0 is usually found in alcoholic liver disease (Pagana et al., 2017).

**TABLE 58-3**  
**Assessment of Abnormal Laboratory Findings in Liver Disease**

ABNORMAL FINDING	SIGNIFICANCE
<b>Serum Enzymes</b>	
Elevated serum aspartate aminotransferase (AST)	Hepatic cell destruction, hepatitis
Elevated serum alanine aminotransferase (ALT)	Hepatic cell destruction, hepatitis (most specific indicator)
Elevated lactate dehydrogenase (LDH)	Hepatic cell destruction
Elevated serum alkaline phosphatase	Obstructive jaundice, hepatic metastasis
Elevated gamma-glutamyl transpeptidase (GGT)	Biliary obstruction, cirrhosis
<b>Bilirubin</b>	
Elevated serum total bilirubin	Hepatic cell disease
Elevated serum direct conjugated bilirubin	Hepatitis, liver metastasis
Elevated serum indirect unconjugated bilirubin	Cirrhosis
Elevated urine bilirubin	Hepatocellular obstruction, viral or toxic liver disease
Elevated urine urobilinogen	Hepatic dysfunction
Decreased fecal urobilinogen	Obstructive liver disease
<b>Serum Proteins</b>	
Increased serum total protein	Acute liver disease
Decreased serum total protein	Chronic liver disease
Decreased serum albumin	Severe liver disease
Elevated serum globulin	Immune response to liver disease
<b>Other Tests</b>	
Elevated serum ammonia	Advanced liver disease or portal-systemic encephalopathy (PSE)
Prolonged prothrombin time (PT) or international normalized ratio (INR)	Hepatic cell damage and decreased synthesis of prothrombin

Increased *alkaline phosphatase* and gamma-glutamyl transpeptidase (GGT) levels are caused by biliary obstruction and therefore may increase in patients with cirrhosis. Alkaline phosphatase is a nonspecific bone, intestinal, and liver enzyme. However, alkaline phosphatase also increases when bone disease, such as osteoporosis, is present. Total serum *bilirubin* levels also rise. Indirect bilirubin levels increase in patients with cirrhosis because of the inability of the failing liver to excrete bilirubin. Therefore bilirubin is present in the urine (urobilinogen) in increased amounts. Fecal urobilinogen concentration is decreased in patients with biliary tract obstruction. These patients have light- or clay-colored stools.

Total serum *albumin* levels are decreased in patients with severe or chronic liver disease as a result of decreased synthesis by the liver (Pagana et al., 2017). Loss of osmotic “pull” proteins such as albumin promotes the movement of intravascular fluid into the interstitial tissues (e.g., ascites). Prothrombin time/*international normalized ratio* (PT/INR) is prolonged because the liver decreases the production of prothrombin. The platelet count is low, resulting in a characteristic thrombocytopenia of cirrhosis. Anemia may be reflected by decreased red blood cell (RBC), hemoglobin, and hematocrit values. The white blood cell (WBC) count may also be decreased.

*Ammonia* levels are usually elevated in patients with advanced liver disease. Serum creatinine may be elevated in patients with deteriorating kidney function. Dilutional hyponatremia (low serum sodium) may occur in patients with ascites.

### Imaging Assessment.

Plain x-rays of the abdomen may show hepatomegaly, splenomegaly, or massive ascites. A CT scan may be requested.

*MRI* is another test used to diagnose the patient with liver disease. It can reveal mass lesions, giving additional specific information. This information is helpful in determining whether the condition is malignant or benign. *MR elastography* is a type of MRI that provides a way to assess liver elasticity, which helps the health care provider determine the amount of liver disease present.

### Other Diagnostic Assessment.

Ultrasound (US) of the liver is often the first assessment for an adult with suspected liver disease to detect ascites, hepatomegaly, and splenomegaly. It can also determine the presence of biliary stones or biliary duct obstruction. Liver US with Doppler is useful in detecting portal vein thrombosis and evaluating whether the direction of portal blood flow is normal.

Some patients being assessed for liver disease require biopsies to determine the exact pathology and the extent of disease progression. This procedure can be problematic because a large number of patients are at risk for bleeding. Even a **percutaneous** (through the skin) biopsy can pose a significant risk to the patient. To minimize this risk, an interventional radiologist can perform a liver biopsy using a long sheath through a jugular vein that then is threaded into the hepatic vein and liver. A tissue sample is obtained for microscopic evaluation. If a biopsy procedure is not possible, a radioisotope liver scan may be used to identify cirrhosis or other diffuse disease.

The health care provider may request *arteriography* if US is not conclusive in finding portal vein thrombosis. To evaluate the portal vein and its branches, a portal venogram may be performed instead, by passing a catheter into the liver and into the portal vein. This procedure is described in the **Transjugular Intrahepatic Portal-Systemic Shunt (TIPS)** section.

The health care provider may perform an **esophagogastroduodenoscopy (EGD)** to directly visualize the upper GI tract to detect complications of liver failure. These complications may include bleeding or oozing esophageal varices, stomach irritation and ulceration, or duodenal ulceration and bleeding. EGD is performed by introducing a flexible fiberoptic endoscope into the mouth, esophagus, and stomach while the patient is under moderate sedation. A camera attached to the scope permits direct visualization of the mucosal lining of the upper GI tract. An **endoscopic retrograde cholangiopancreatography (ERCP)** uses the endoscope to inject contrast material via the sphincter of Oddi to view the biliary tract and allow for stone removals, sphincterotomies, biopsies, and stent placements if required. These procedures are described in more detail in **Chapter 52**.

### ◆Analysis: Interpreting

The priority collaborative problems for patients with cirrhosis include:

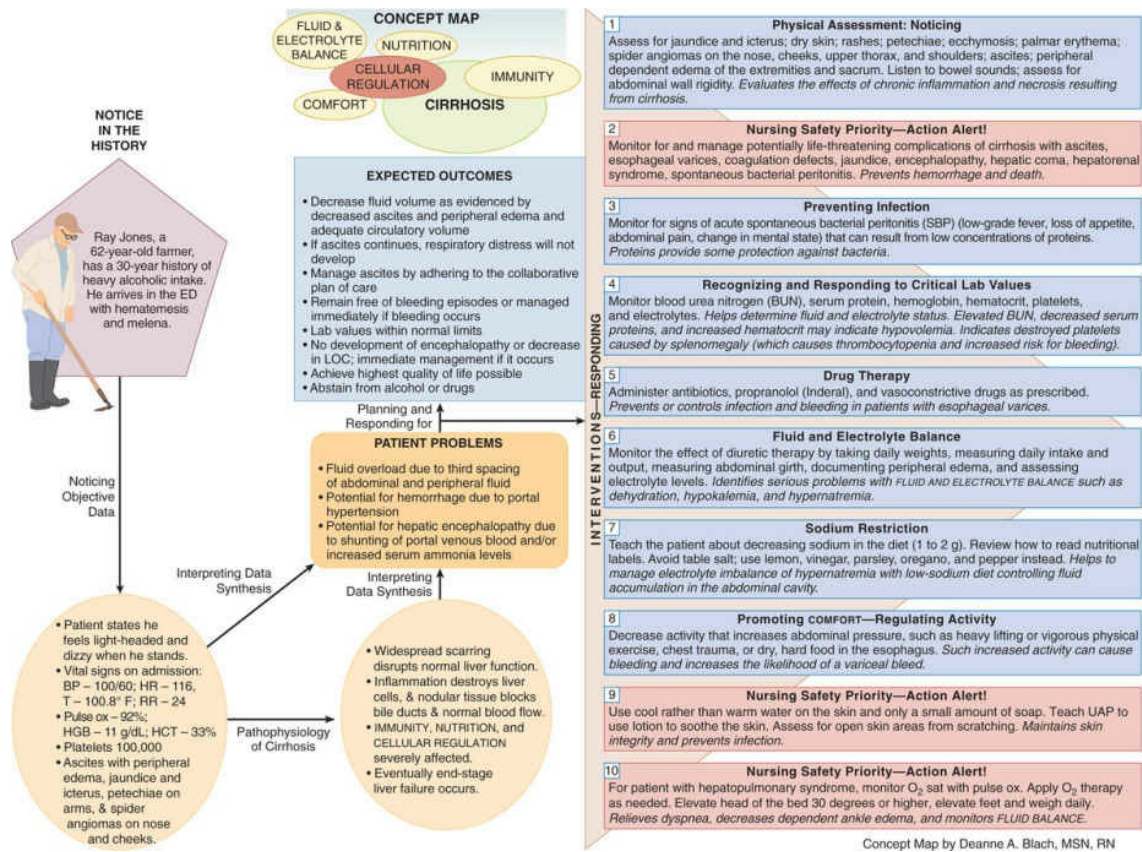

1. Fluid overload due to third spacing of abdominal and peripheral fluid
2. Potential for hemorrhage due to portal hypertension
3. Potential for hepatic encephalopathy due to shunting of portal venous blood and/or increased serum ammonia levels

### ◆Planning and Implementation: Responding

#### Managing Fluid Volume

##### Planning: Expected Outcomes.

The patient with cirrhosis is expected to have less excess fluid volume as evidenced by decreased ascites and peripheral edema and adequate circulatory volume. If ascites continues, the patient will not have respiratory distress and will manage ascites by adhering to the collaborative plan of care (see the Concept Map for liver failure caused by cirrhosis).

Concept Map by Deanne A. Blach, MSN, RN

## Interventions.

Fluid accumulations are minimal during the early stages of ascites. Therefore interventions are aimed at preventing the accumulation of additional fluid and moving the existing fluid collection. Nonsurgical treatment measures are used to treat ascites in most cases.

Supportive measures to control abdominal ascites include NUTRITION therapy, drug therapy, paracentesis, and respiratory support. The patient's FLUID AND ELECTROLYTE BALANCE is also carefully monitored. If the patient is jaundiced, he or she will likely scratch the skin because the excess bilirubin products cause irritation and pruritus (itching).

## Nursing Safety Priority QSEN

### Action Alert

For skin irritation and pruritus associated with jaundice, teach the patient to use cool rather than warm water on the skin and to use a small amount of soap. Teach unlicensed assistive personnel to use lotion to soothe the skin. Assess for open skin areas from scratching, which could become infected.

### Nutrition Therapy.

The health care provider usually places the patient with abdominal ascites on a low-sodium diet as an initial means of controlling fluid accumulation in the abdominal cavity. The amount of daily sodium (Na<sup>+</sup>) intake restriction varies, but a 1- to 2-g (2000 mg) Na<sup>+</sup> restriction may be tried first. In collaboration with the dietitian, explain the purpose of the restriction and advise the patient and family to read the sodium content labels on all food and beverages. Table salt should be completely excluded. Low-sodium diets may be distasteful, so suggest alternative flavoring additives such as lemon, vinegar, parsley, oregano, and pepper. Remind the patient that seasoned and salty food is an acquired taste; in time, he or she will become used to the decrease in dietary sodium.

In general, patients with late-stage cirrhosis are malnourished and have multiple dietary

deficiencies. Vitamin supplements such as thiamine, folate, and multivitamin preparations are typically added to the IV fluids because the liver cannot store vitamins. For patients with biliary cirrhosis, bile may not be available for fat-soluble vitamin transport and absorption. Oral vitamins are prescribed when IV fluid administration is discontinued.

### Drug Therapy.

The health care provider usually prescribes a *diuretic* to reduce fluid accumulation and prevent cardiac and respiratory problems. Monitor the effect of diuretic therapy by weighing the patient daily, measuring daily intake and output, measuring abdominal girth, documenting peripheral edema, and assessing electrolyte levels. Serious fluid and electrolyte imbalances, such as dehydration, hypokalemia (decreased potassium), and hyponatremia (decreased sodium), may occur with loop diuretic therapy. Depending on the diuretic selected, the provider may prescribe an oral or IV potassium supplement. Some clinicians prescribe furosemide (Lasix) and spironolactone (Aldactone) as a combination diuretic therapy for the treatment of ascites. Because these drugs work differently, they are used for maintenance of sodium and potassium balance. For example, furosemide causes potassium loss, whereas spironolactone conserves it in the body.

All patients with ascites have the potential to develop **spontaneous bacterial peritonitis (SBP)** from bacteria in the collected ascitic fluid. In some patients, mild symptoms such as low-grade fever and loss of appetite occur. In others, there may be abdominal pain, fever, and change in mental status. When performing an abdominal assessment, listen for bowel sounds and assess for abdominal wall rigidity. Treatment involves IV cefotaxime or other third-generation cephalosporins or fluoroquinolones (Runyon, 2016).

### Paracentesis.

For some patients, abdominal **paracentesis** may be needed. Nursing implications associated with this procedure are described in [Chart 58-1](#). The procedure is performed at the bedside, in an interventional radiology department, or in an ambulatory care setting. The health care provider inserts a trocar catheter or drain into the abdomen to remove the ascitic fluid from the peritoneal cavity. This procedure is done using ultrasound for added safety. In some situations, a short-term ascites drain catheter may be placed while the patient is awaiting surgical intervention, or tunneled ascites drains (e.g., PleurX drains) can allow a patient or family caregiver to drain ascitic fluid at home.

#### Chart 58-1

### Best Practice for Patient Safety & Quality Care

#### The Patient With Paracentesis

- Explain the procedure and answer patient questions.
- Obtain vital signs, including weight.
- *Ask the patient to void before the procedure to prevent injury to the bladder!*
- Position the patient in bed with the head of the bed elevated.
- Monitor vital signs per protocol or physician's request.
- Measure the drainage and record accurately.
- Describe the collected fluid.
- Label and send the fluid for laboratory analysis; document in the patient record that specimens were sent.
- After the physician removes the catheter, apply a dressing to the site; assess for leakage.
- Maintain bedrest per protocol.

- Weigh the patient after the paracentesis; document in the patient record weight both before and after paracentesis.

If SBP is suspected, a sample of fluid is withdrawn and sent for cell count and culture. If the patient has symptoms of infection, the health care provider may prescribe antibiotics while awaiting the culture results.

### Respiratory Support.

Excessive ascitic fluid volume may cause the patient to have respiratory problems. He or she may develop *hepatopulmonary syndrome*. Dyspnea develops as a result of increased intra-abdominal pressure, which limits thoracic expansion and diaphragmatic excursion. Auscultate lungs every 4 to 8 hours for crackles that could indicate pulmonary complications, depending on the patient's overall condition.

## Nursing Safety Priority QSEN

### Action Alert

For the patient with hepatopulmonary syndrome, monitor his or her oxygen saturation with pulse oximetry. If needed, apply oxygen therapy to ease breathing. Elevate the head of the bed to at least 30 degrees or as high as the patient wants to improve breathing. This position, with his or her feet elevated to decrease dependent ankle edema, often relieves dyspnea. Weigh the patient daily or delegate and supervise this activity.

FLUID AND ELECTROLYTE BALANCE problems are common as a result of the disease or treatment. Laboratory tests, such as blood urea nitrogen (BUN), serum protein, hematocrit, and electrolytes, help determine fluid and electrolyte status. An elevated BUN, decreased serum proteins, and increased hematocrit may indicate hypovolemia.

If medical management fails to control ascites, the health care provider may choose to divert ascites into the venous system by creating a shunt. Patients with ascites are poor surgical risks. The transjugular intrahepatic portal-systemic shunt (TIPS) is a nonsurgical procedure that is used to control long-term ascites and reduce variceal bleeding. This procedure is described in the discussion of Interventions in the [Preventing or Managing Hemorrhage](#) section that follows.

## NCLEX Examination Challenge 58-2

### Physiological Integrity

The nurse is caring for a client who has had paracentesis performed. Which nursing intervention is appropriate? **Select all that apply.**

- A. Keep head of bed flat
- B. Measure, describe, and record drainage
- C. Ambulate 30 minutes postprocedure
- D. Weigh client
- E. Label fluid container and send for laboratory analysis

### Preventing or Managing Hemorrhage

#### Planning: Expected Outcomes.

The patient is expected to be free of bleeding episodes. However, if he or she has a hemorrhage, it is expected to be controlled by prompt, evidence-based interdisciplinary interventions. Esophageal

variceal bleeds are the most common type of upper GI bleeding.

### Interventions.

All patients with cirrhosis should be screened for esophageal varices by endoscopy to detect them early *before they bleed*. If patients have varices, they are placed on preventive therapy. If acute bleeding occurs, early interventions are used to manage it. *Because massive esophageal bleeding can cause rapid blood loss, emergency interventions are needed.*

### Drug Therapy.

The role of early drug therapy is to *prevent* bleeding and infection in patients who have varices. A nonselective *beta-blocking agent* such as propranolol (Inderal) is usually prescribed to prevent bleeding. By decreasing heart rate and the hepatic venous pressure gradient, the chance of bleeding may be reduced ([World Gastroenterology Organisation, 2012](#)).

Up to 20% of cirrhotic patients who are admitted to the hospital as a result of upper GI bleeding have bacterial infections, and even more patients develop health care–associated infections, usually urinary tract infections or pneumonia ([McCance et al., 2014](#)). Infection is one of the most common indicators that patients will have an acute variceal bleed (AVB). Therefore cirrhotic patients with GI bleeding should receive *antibiotics* when admitted to the hospital.

If bleeding occurs, the health care team intervenes quickly to control it by combining vasoactive drugs with endoscopic therapies. *Vasoactive* drugs, such as vasopressin and octreotide acetate (Sandostatin), reduce blood flow through vasoconstriction to decrease portal pressure. Octreotide also suppresses secretion of gastrin, serotonin, and intestinal peptides, which decreases GI blood flow to help with pressure reduction within the varices ([World Gastroenterology Organisation, 2012](#)).

### Endoscopic Therapies.

Endoscopic therapies include ligation of the bleeding veins or sclerotherapy. Both procedures have been very effective in controlling bleeding and improving patient survival rates. Esophageal varices may be managed with **endoscopic variceal ligation (EVL) (banding)**. This procedure involves the application of small “O” bands around the base of the varices to decrease the blood supply to the varices. The patient is unaware of the bands, and they cause no discomfort.

*Endoscopic sclerotherapy (EST)*, also called **injection sclerotherapy**, may be done to stop bleeding. The varices are injected with a sclerosing agent via a catheter. This procedure is associated with complications such as mucosal ulceration, which could result in further bleeding.

### Rescue Therapies.

If rebleeding occurs, rescue therapies are used. These procedures include a second endoscopic procedure, balloon tamponade and esophageal stents, and shunting procedures. Short-term esophagogastric balloon tamponade with esophageal stents is a very effective way to control bleeding. However, the procedure can cause potentially life-threatening complications, such as aspiration, asphyxia, and esophageal perforation ([World Gastroenterology Organisation, 2012](#)). Similar to a nasogastric tube, the tube is placed through the nose and into the stomach. An attached balloon is inflated to apply pressure to the bleeding variceal area. Before this tamponade, the patient is usually intubated and placed on a mechanical ventilator to protect the airway. This therapy is used if the patient is not able to have a second endoscopy or TIPS procedure.

### Transjugular Intrahepatic Portal-Systemic Shunt.

The transjugular intrahepatic portal-systemic shunt (TIPS) is a nonsurgical procedure performed in interventional radiology departments. This procedure is used for patients who have not responded to other modalities for hemorrhage or long-term ascites. If time permits, patients have a Doppler ultrasound to assess jugular vein anatomy and patency. The patient receives heavy IV sedation or general anesthesia for this procedure. The radiologist places a large sheath through the jugular vein. A needle is guided through the sheath and pushed through the liver into the portal vein. A balloon enlarges this tract, and a stent keeps it open. Most patients also have a Doppler ultrasound study of the liver after the TIPS procedure to record the blood flow through the shunt. Treating patients with TIPS who have esophageal/gastric varix hemorrhage problems may also require esophageal/gastric vein embolization as a part of the procedure. Patients with a highly cirrhotic liver usually have little

flow through the liver parenchyma. These patients develop large portal-esophageal (or portal-gastric) veins diverting blood away from the diseased liver. Even after a successful TIPS, the diverting veins may persist and must be embolized (intentionally blocked) so they will not rebleed.

Serious complications of TIPS are not common. Patients are usually discharged in 1 or 2 days and are followed up with ultrasounds for the first year after the shunt is placed to ensure continued patency. Patients must also be monitored for hepatic encephalopathy, which can be caused by a TIPS. After creation of the TIPS, blood now bypasses most of the liver's filtration processes, allowing toxins to circulate throughout the body. For some patients, this can cause disturbances in consciousness and behavior. Lactulose or other medications may be given to counteract this effect, and dietary modification may also be helpful. In some cases, a TIPS shunt may have to have the flow reduced or closed completely to reverse the encephalopathy. This is done by deploying a smaller stent or occluding device inside the original TIPS shunt. This is a delicate decision for the health care provider to make, because reduction of flow through the shunt will likely cause the initial esophageal hemorrhaging to recur.

Patients receiving TIPS can also have significant elevation of their pulmonary artery pressure. This is a result of the sudden increase of blood flow to the right heart. Diuretics may help to treat this problem. For this reason, patients must be carefully evaluated for right heart failure before TIPS placement.

### Other Interventions.

Depending on the procedure done to control esophageal bleeding, patients usually have a nasogastric tube (NGT) inserted to detect any new bleeding episodes. They often receive packed red blood cells, fresh frozen plasma, dextran, albumin, and platelets through large-bore IV catheters.

Monitor vital signs every hour and check coagulation studies, including prothrombin time (PT), partial thromboplastin time (PTT), platelet count, and international normalized ratio (INR). Additional interventions for upper GI bleeding are discussed in [Chapter 55](#).

## Preventing or Managing Hepatic Encephalopathy

### Planning: Expected Outcomes.

The patient is expected to be free of encephalopathy. However, if it occurs, it is expected that the interdisciplinary team will intervene early to prevent further health problems or death.

### Interventions.

The poorly functioning liver cannot convert ammonia and other by-products of protein metabolism to a less toxic form. They are carried by the circulatory system to the brain, where they affect cerebral function. Interventions are planned around the management of slowing or stopping the accumulation of ammonia in the body.

Because ammonia is formed in the GI tract by the action of bacteria on protein, nonsurgical treatment measures to decrease ammonia production include dietary limitations and drug therapy to reduce bacterial breakdown.

### Nutrition Therapy.

Patients with cirrhosis have increased nutritional requirements—high-carbohydrate, moderate-fat, and high-protein foods. However, the diet may be changed for those who have elevated serum ammonia levels with signs of encephalopathy. Patients should have a moderate amount of protein and fat foods and simple carbohydrates. Strict protein restrictions are not required because patients need protein for healing. In collaboration with the dietitian, be sure to include family members or significant others in NUTRITION counseling. The patient is often weak and unable to remember complicated guidelines. Brief, simple directions regarding dietary dos and don'ts are recommended. Keep in mind any financial, cultural, or personal implications and the patient's food allergies when discussing food choices.

### Drug Therapy.

Drugs are used sparingly because they are difficult for the failing liver to metabolize. In particular, opioid analgesics, sedatives, and barbiturates should be restricted, especially for the patient with a history of encephalopathy.

However, several types of drugs may eliminate or reduce ammonia levels in the body. These include lactulose (e.g., Evalose, Heptalac) or lactitol and nonabsorbable antibiotics ([AASLD practice guideline, 2014](#)). The health care provider may prescribe *lactulose* (or lactitol) to promote the excretion of ammonia in the stool. This drug is a viscous, sticky, sweet-tasting liquid that is given either orally or by NG tube. The purpose is to obtain a laxative effect. Cleansing the bowels may rid the intestinal tract of the toxins that contribute to encephalopathy. It works by increasing osmotic pressure to draw fluid into the colon and prevents absorption of ammonia in the colon. The drug may be prescribed to the patient who has manifested signs of encephalopathy, regardless of the stage. The desired effect of the drug is production of two or three soft stools per day and a decrease in patient confusion caused by this complication.

Observe for response to lactulose. The patient may report intestinal bloating and cramping. Serum ammonia levels may be monitored but do not always correlate with symptoms. Hypokalemia and dehydration may result from excessive stools. Remind unlicensed nursing personnel to help the patient with skin care if needed to prevent breakdown caused by excessive stools.

Several *nonabsorbable antibiotics* may be given if lactulose does not help the patient meet the desired outcome or if he or she cannot tolerate the drug. These drugs should not be given together. Older adults can become weak and dehydrated from having multiple stools. Neomycin sulfate or rifaximin (Xifaxan), both broad-spectrum antibiotics, may be given to act as an intestinal antiseptic. These drugs destroy the normal flora in the bowel, diminishing protein breakdown and decreasing the rate of ammonia production. Maintenance doses of neomycin are given orally but may also be administered as a retention enema. Long-term use has the potential for kidney toxicity and therefore is not commonly used. It cannot be used for patients with existing kidney disease.

Metronidazole (Flagyl, Nidagel 🍀, Novo-Nidazol 🍀) is another broad-spectrum antibiotic with similar action to neomycin, but it can cause peripheral neuropathy. Vancomycin (Vancocin) may also be given, but its long-term use can lead to resistance ([AASLD practice guideline, 2014](#)).

Frequently assess for changes in level of consciousness and orientation. Check for asterixis (liver flap) and fetor hepaticus (liver breath). These signs suggest worsening encephalopathy. Thiamine supplements and benzodiazepines may be needed if the patient is at risk for alcohol withdrawal.

## Clinical Judgment Challenge 58-1

### Safety; Evidence-Based Practice QSEN

You are caring for a 45-year-old man who arrived at the emergency department. He reports having abdominal pain for 3 weeks and states that he drinks three to five mixed alcoholic drinks daily. He has no known history of liver disease. He denies fever, chills, nausea and vomiting, or discolored stools. His last drink was last night. Assessment reveals yellowed skin, blood pressure of 100/58 mm Hg, and pulse rate of 102 beats/min. His abdomen is distended, and he is having some difficulty breathing; his respirations are 34 breaths/min, and room air pulse oximetry is 87%. The emergency department health care provider orders an ECG, chest x-ray, CT scan of abdomen/pelvis, oxygen at 2L/NC, and IV access.

1. For which complications is this patient at risk, and why?
2. Into what position will you place the patient, and why? What evidence supports your answer?
3. You anticipate that the patient has acute liver failure. What assessment findings support this suspicion?
4. What laboratory findings do you anticipate that would support the diagnosis of liver failure?

### Care Coordination and Transition Management

If the patient with late-stage cirrhosis survives life-threatening complications, he or she is usually discharged to home or to a long-term care facility after treatment measures have managed the acute medical problems. A home care referral may be needed if the patient is discharged to home. These chronically ill patients are often readmitted multiple times; and community-based care is aimed at

optimizing COMFORT, promoting independence, supporting caregivers, and preventing rehospitalization. Patients with end-stage disease may benefit from hospice care. Collaborate with the case manager (CM) or other discharge planner to coordinate interdisciplinary continuing care.

### Home Care Management.

In collaboration with the patient, family, and case manager, assess physical adaptations needed to prepare the patient's home for recovery. Referrals for physical therapy, nutrition therapy, and transportation for health care provider and laboratory follow-up may be needed. The patient's rest area needs to be close to a bathroom because diuretic and/or lactulose therapy increases the frequency of urination and stools. If the patient has difficulty reaching the toilet, additional equipment (e.g., bedside commode) is necessary. Special adult-size incontinence pads or briefs may be helpful if the patient has an altered mental status and incontinence. If the patient has shortness of breath from massive ascites, elevating the head of the bed and maintaining him or her in a semi-Fowler's to high-Fowler's position may help alleviate respiratory distress. Alternatively, a reclining chair with an elevated foot rest may be used.

### Self-Management Education.

The patient is discharged to the home setting with an individualized teaching plan (Chart 58-2) that includes NUTRITION therapy, drug therapy, and alcohol abstinence, if needed. The patient who has a tunneled ascites drain (e.g., PleurX drain) will need to be taught how to access the drain and remove excess fluid. *Review the home care instructions that are provided with the drainage system with both the patient and family/caregiver. Remind them not to remove more than 2000 mL from the abdomen at one time to prevent hypovolemic shock.*

#### Chart 58-2

## Patient and Family Education: Preparing for Self-Management

### Cirrhosis

#### Nutrition Therapy

- Consume a diet that adheres to the guidelines set by your physician, nurse, or dietitian.
- If you have excessive fluid in your abdomen, follow the low-sodium diet prescribed for you.
- Eat small, frequent meals that are nutritionally well balanced.
- Include in your diet daily supplemental liquids (e.g., Ensure or Ensure Plus) and a multivitamin.

#### Drug Therapy

- Take the diuretic or preventive beta blocker prescribed for you. If you experience muscle weakness, irregular heartbeat, or light-headedness, contact your health care provider right away.
- Take the medication prescribed for you that helps prevent GI bleeding.
- Take the lactulose syrup as prescribed to maintain two or three bowel movements every day.
- Do *not* take any other medication (prescribed or over the counter) unless specifically prescribed by your health care provider.

#### Alcohol Abstinence

- Do not consume any alcohol.
- Seek support services for help if needed.

The patient with encephalopathy often finds that small, frequent meals are best tolerated. If his or her nutritional intake or albumin/prealbumin is decreased after discharge, multivitamin supplements and supplemental liquid feedings (e.g., Ensure, Boost) are usually needed. Teach patients to avoid excessive vitamins and minerals that can be toxic to the liver, such as fat-soluble vitamins, excessive iron supplements, and niacin. Remind patients to check with their health care provider before taking any vitamin supplement.

The patient is often discharged while receiving diuretics. Provide instructions regarding the health care provider's prescription for the diuretic. Teach about side effects of therapy, such as hypokalemia. The patient may need to take a potassium supplement if he or she is taking a diuretic that is not potassium sparing.

If the patient has had problems with bleeding from gastric ulcers, the health care provider may prescribe an H<sub>2</sub>-receptor antagonist agent or proton pump inhibitor to reduce acid reflux (see [Chapter 55](#)). Patients who have had episodes of spontaneous bacterial peritonitis (SBP) may be on a daily maintenance antibiotic.

Teach family members how to recognize signs of encephalopathy and to contact the health care provider if these signs develop. Reinforce that constipation, bleeding, and infections can increase the risk for encephalopathy.

Advise the patient to avoid all over-the-counter drugs, especially NSAIDs and hepatic toxic herbs, vitamins, and minerals. Reinforce the need to keep appointments for follow-up medical care. Remind the patient and family to notify the health care provider immediately if any GI bleeding (overt bleeding or melena) is noted so re-evaluation can begin quickly.

## Nursing Safety Priority QSEN

### Action Alert

One of the most important aspects of ongoing care for the patient with cirrhosis is to stress the need to avoid acetaminophen (Tylenol), alcohol, smoking, and illicit drugs. By avoiding these substances, the patient may:

- Prevent further fibrosis of the liver from scarring
- Allow the liver to heal and regenerate
- Prevent gastric and esophageal irritation
- Reduce the incidence of bleeding
- Prevent other life-threatening complications

### Health Care Resources.

The patient with chronic cirrhosis may require a home care nurse for several visits after hospital discharge. The home care nurse can monitor the effectiveness of treatment in controlling ascites. The encephalopathic patient may need to be monitored for adherence to drug therapy and alcohol abstinence, if appropriate. Individual and group therapy sessions may be arranged to help patients deal with alcohol abstinence if they are too ill to attend a formal treatment program. Because some patients may have alienated relatives over the years because of substance use, it may be necessary to help them identify a friend, neighbor, or adult in their recovery group for support. If needed, refer the patient and family to self-help groups, such as Alcoholics Anonymous and Al-Anon.

The patient with cirrhosis may also desire spiritual or other psychosocial support. Finances are frequently a problem for the chronically ill patient and family; social support and community services need to be identified. The American Liver Foundation ([www.liverfoundation.org](http://www.liverfoundation.org)) and American Gastroenterological Association ([www.gastro.org](http://www.gastro.org)) are excellent sources for more information about liver disease.

For patients who are not candidates for liver transplantation, address end-of-life issues. Discuss options such as hospice care with patients and their families (see [Chapter 7](#)). Be aware that they will go through a grieving process and will perhaps be in denial or very angry.

### ◆ **Evaluation: Reflecting**

Evaluate the care of the patient with cirrhosis based on the identified priority patient problems. The expected outcomes include that the patient will:

- Have a decrease in or have no ascites
- Have electrolytes within normal limits (WNL)
- Not have hemorrhage or will be managed immediately if bleeding occurs
- Not develop encephalopathy or will be managed immediately if it occurs
- Successfully abstain from alcohol or drugs (if disease is caused by these substances)

## Immunity Concept Exemplar Hepatitis

### Pathophysiology

**Hepatitis** is the widespread inflammation of liver cells. *Viral* hepatitis, which can be acute or chronic, is the most common type. Less common types of hepatitis are caused by chemicals, drugs, and some herbs. This section discusses hepatitis caused by a virus. **Viral hepatitis** results from an infection caused by one of five major categories of viruses:

- Hepatitis A virus (HAV)
- Hepatitis B virus (HBV)
- Hepatitis C virus (HCV)
- Hepatitis D virus (HDV)
- Hepatitis E virus (HEV)

Some cases of viral hepatitis are not caused by any of these viruses. These patients have non-A-E hepatitis.

Liver injury with inflammation can develop after exposure to a number of drugs and chemicals by inhalation, ingestion, or parenteral (IV) administration. **Toxic and drug-induced hepatitis** can result from exposure to hepatotoxins (e.g., industrial toxins, alcohol, and drugs). Hepatitis may also occur as a secondary infection during the course of infections with other viruses, such as Epstein-Barr, herpes simplex, varicella-zoster, and cytomegalovirus. Occurrence of any type of hepatitis affects the body's IMMUNITY and ability to protect itself.

After the liver has been exposed to any causative agent (e.g., a virus), it becomes enlarged and congested with inflammatory cells, lymphocytes, and fluid, resulting in right upper quadrant pain and discomfort. As the disease progresses, the liver's normal lobular pattern becomes distorted as CELLULAR REGULATION is compromised as a result of widespread inflammation, necrosis, and hepatocellular regeneration. This distortion increases pressure within the portal circulation, interfering with the blood flow into the hepatic lobules. Edema of the liver's bile channels results in obstructive **jaundice** (yellowing of the skin).

### Classification of Hepatitis and Etiologies

The five major types of acute viral hepatitis vary by mode of transmission, manner of onset, and incubation periods. Hepatitis cases must be reported to the local public health department, which then notifies the Centers for Disease Control and Prevention (CDC).

#### Hepatitis A.

The causative agent of **hepatitis A**, hepatitis A virus (HAV), is a ribonucleic acid (RNA) virus of the enterovirus family. *It is a hardy virus and survives on human hands.* The virus is resistant to detergents and acids but is destroyed by chlorine (bleach) and extremely high temperatures.

Hepatitis A usually has a mild course similar to that of a typical flu-like infection and often goes unrecognized. It is spread most often by the fecal-oral route by fecal contamination either from person-to-person contact (e.g., oral-anal sexual activity) or by consuming contaminated food or water. Common sources of infection include shellfish caught in contaminated water and food contaminated by food handlers infected with HAV. The incubation period of hepatitis A is usually 15 to 50 days, with a peak of 25 to 30 days. The disease is usually not life threatening, but its course may be more severe in adults older than 40 years and those with pre-existing liver disease such as hepatitis C (McCance et al., 2014).

In a small percentage of hepatitis A cases, severe illness with extrahepatic signs and symptoms can occur. Advanced age and conditions such as chronic liver disease may cause widespread damage that requires a liver transplant. In some cases when the patient's IMMUNITY is irreparably affected, death may occur. The incidence of hepatitis A is particularly high in nonaffluent countries in which sanitation is poor; however, cases are diagnosed internationally across the globe (World Health Organization, 2016). Some adults have hepatitis A and do not know it. The course is similar to that of a GI illness, and the disease and recovery are usually uneventful.

#### Hepatitis B.

The **hepatitis B** virus (HBV) is not transmitted like HAV. It is a double-shelled particle containing DNA composed of a core antigen (HBcAg), a surface antigen (HBsAg), and another antigen found within the core (HBeAg) that circulates in the blood. HBV may be spread through these common modes of transmission (CDC, 2016):

- Unprotected sexual intercourse with an infected partner
- Sharing needles, syringes, or other drug-injection equipment
- Sharing razors or toothbrushes with an infected individual
- Accidental needlesticks or injuries from sharp instruments primarily in health care workers (low incidence)
- Blood transfusions (that have not been screened for the virus, before 1992)
- Hemodialysis
- Direct contact with the blood or open sores of an infected individual
- Birth (spread from an infected mother to baby during birth)

In addition, patients whose IMMUNITY is compromised either by disease or drug therapy are more likely to develop hepatitis B.

## NCLEX Examination Challenge 58-3

### Physiological Integrity

The nurse is caring for four clients. Which client is at the **highest** risk for hepatitis B infection?

- A. 24-year-old with abdominal pain who just returned from Central America
- B. 40-year-old who is 2 days postpartum and is breastfeeding
- C. 65-year-old who reports using street drugs 10 years ago when homeless
- D. 81-year-old who donated own blood before a surgical procedure

The clinical course of hepatitis B may be varied. Symptoms usually occur within 25 to 180 days of exposure and include (McCance et al., 2014):

- Anorexia, nausea, and vomiting
- Fever
- Fatigue
- Right upper quadrant pain
- Dark urine with light stool
- Joint pain
- Jaundice

Blood tests confirm the disease, although many individuals with hepatitis B have no symptoms.

Most adults who get hepatitis B recover, clear the virus from their body, and develop IMMUNITY. However, a small percentage of people do not develop immunity and become carriers. **Hepatitis carriers** can infect others even though they are not sick and have no obvious signs of hepatitis B. Chronic carriers are at high risk for cirrhosis and liver cancer. Because of the high number of newcomers from endemic areas, the incidence of hepatitis B has increased in the United States.

### Hepatitis C.

The causative virus of **hepatitis C** (HCV) is an enveloped, single-stranded RNA virus. Transmission is blood to blood. The rate of sexual transmission is very low in a single-couple relationship but increases with multiple sex partners. HCV is spread most commonly by:

- Illicit IV drug needle sharing (highest incidence)
- Blood, blood products, or organ transplants received before 1992
- Needlestick injury with HCV-contaminated blood (health care workers at high risk)

- Unsanitary tattoo equipment
- Sharing of intranasal cocaine paraphernalia

The disease is **not** transmitted by casual contact or intimate household contact. However, those infected are advised not to share razors, toothbrushes, or pierced earrings because microscopic blood may be on these items.

The average incubation period is 7 weeks. Acute infection and illness are not common. Most people are completely unaware that they have been infected. They are asymptomatic and not diagnosed until many months or years after the initial exposure when an abnormality is detected during a routine laboratory evaluation or when liver problems occur. Unlike with hepatitis B, most people infected with hepatitis C do not clear the virus, and a chronic infection develops.

HCV usually does its damage to the body's IMMUNITY over decades by causing a chronic inflammation in the liver that eventually causes the liver cells to scar. This scarring may progress to cirrhosis (McCance et al., 2014).

### Hepatitis D.

**Hepatitis D** (delta hepatitis) is caused by a defective RNA virus that needs the helper function of HBV. It occurs only with HBV to cause viral replication. This usually develops into chronic disease. The incubation period is about 14 to 56 days. As with hepatitis B, the disease is transmitted primarily by parenteral routes, especially in patients who are IV drug users. Having sexual contact with someone with HDV is also a high risk factor (McCance et al., 2014).

### Hepatitis E.

The **hepatitis E** virus (HEV) causes a waterborne infection associated with epidemics in the Indian subcontinent, Asia, Africa, the Middle East, Mexico, and Central and South America. Many large outbreaks have occurred after heavy rains and flooding. Like hepatitis A, hepatitis E is caused by fecal contamination of food and water.

In the United States, hepatitis E has been found only in international travelers. It is transmitted via the fecal-oral route, and the clinical course resembles that of hepatitis A. Hepatitis E has an incubation period of 15 to 64 days. There is no evidence at this time of a chronic form of the disease. The disease tends to be self-limiting and resolves on its own (McCance et al., 2014).

### Complications of Hepatitis

Failure of the liver cells to regenerate, with progression of the necrotic process, results in a severe acute and often fatal form of hepatitis known as **fulminant hepatitis**. Hepatitis is considered to be chronic when liver inflammation lasts longer than 6 months. **Chronic hepatitis** usually occurs as a result of hepatitis B or hepatitis C. Superimposed infection with hepatitis D virus (HDV) in patients with chronic hepatitis B may also result in chronic hepatitis. Chronic hepatitis can lead to cirrhosis and liver cancer. Many patients have multiple infections, especially a combination of HBV with HCV, HDV, or HIV infections (McCance et al., 2014).

### Incidence and Prevalence

The incidence of hepatitis A and hepatitis B is declining as a result of CDC recommendations for vaccination. However, hepatitis B and hepatitis C are a concern because of their association with cirrhosis and liver cancer. Although exact numbers are not known, it is estimated that about 71 million people worldwide have the hepatitis C virus (HCV) (World Health Organization, 2017). Currently there is no vaccine for HCV; however, patients may be treated with antiviral drug therapies. The goal of treatment of HCV-infected patients is to reduce mortality and liver-related health adverse consequences, including end-stage liver disease and liver cancer (AASLD, HCV Guidance, 2016). It is expected that the cases of HCV may rise over the next several decades as a result of increasing illicit drug use. Any increase will require a major increase in transplantations and lead to many more deaths.

### Health Promotion and Maintenance

Hepatitis vaccines for infants, children, and adolescents have helped to protect the population's IMMUNITY by decreasing the incidence of hepatitis A and hepatitis B. Some adults also are advised to

receive these immunizations.

Measures for preventing hepatitis A in adults include:

- Proper handwashing, especially after handling shellfish
- Avoiding contaminated food or water (including tap water in countries with high incidence)
- Receiving immunoglobulin within 14 days if exposed to the virus
- Receiving the HAV vaccine before traveling to areas where the disease is common (e.g., Mexico, Caribbean)
- Receiving the vaccine if living or working in enclosed areas with others, such as college dormitories, correctional institutions, day-care centers, and long-term care facilities

Several HAV vaccines are available (e.g., Havrix and Vaqta). Both of these vaccines are made of inactivated hepatitis A virus and are given in the deltoid muscle.

Several vaccines can also provide protection against hepatitis B (HBV) infection (e.g., Engerix-B and Recombivax-HB). Twinrix is a combination HAV and HBV vaccine that is also available for adults. Examples of groups for whom immunization against HBV should be used include:

- People who have sexual intercourse with more than one partner
- People with sexually transmitted infection (STI) or a history of STI
- Men having sex with men (MSM)
- People with any chronic liver disease (such as hepatitis C or cirrhosis)
- Patients with human immune deficiency virus (HIV) infection
- People who are exposed to blood or body fluids in the workplace, including health care workers, firefighters, and police
- People in correctional facilities
- Patients needing immunosuppressant drugs
- Family members, household members, and sexual contacts of people with HBV infection

Additional measures to prevent viral hepatitis for health care workers and others in contact with infected patients are listed in [Charts 58-3](#) and [58-4](#).

### **Chart 58-3**

## **Best Practice for Patient Safety & Quality Care** QSEN

### **Prevention of Viral Hepatitis in Health Care Workers**

- Use Standard Precautions to prevent the transmission of disease between patients or between patients and health care staff (see Chapter 23).
- Eliminate needles and other sharp instruments by substituting needleless systems. (Needlesticks are the major source of hepatitis B transmission in health care workers.)
- Take the hepatitis B vaccine (e.g., Recombivax HB), which is given in a series of three injections. This vaccine also prevents hepatitis D by preventing hepatitis B.
- For postexposure prevention of hepatitis A, seek medical attention immediately for immunoglobulin (Ig) administration.
- Report all cases of hepatitis to the local health department.

### **Chart 58-4**

## **Patient and Family Education: Preparing for Self-Management**

### **Health Practices to Prevent Viral Hepatitis**

- Maintain adequate sanitation and personal hygiene. Wash your hands before eating and after using the toilet.
- Drink water treated by a water purification system.
- If traveling in underdeveloped or nonindustrialized countries, drink only bottled water. Avoid food washed or prepared with tap water, such as raw vegetables, fruits, and soups. Avoid ice.
- Use adequate sanitation practices to prevent the spread of the disease among family members.
- Do not share bed linens, towels, eating utensils, or drinking glasses.
- Do not share needles for injection, body piercing, or tattooing.
- Do not share razors, nail clippers, toothbrushes, or Waterpiks®
- Use a condom during sexual intercourse or abstain from this activity.
- Cover cuts or sores with bandages.
- If ever infected with hepatitis, never donate blood, body organs, or other body tissue.

## ❖ Interprofessional Collaborative Care

Care for the patient with hepatitis can take place in various settings. These patients may, at different times, self-manage at home, be hospitalized for immediate concerns, or be cared for in the community setting. Members of the interprofessional team that collaborates most closely to care for the patient with hepatitis include the health care provider, nurse, and dietitian.

### ◆ Assessment: Noticing

#### History.

Begin by asking the patient whether or not he or she has had known exposure to a person with hepatitis. For the patient who presents with few or no symptoms of liver disease but has abnormal laboratory tests (e.g., elevated alanine aminotransferase [ALT] or aspartate aminotransferase [AST] level), the history may need to include additional questions regarding risk factors such as:

- Exposure to either inhaled or ingested chemical
- Use of herbal supplements
- Use of any new prescribed drug or over-the-counter (OTC) medication
- Recent ingestion of shellfish
- Exposure to a possibly contaminated water source
- Travel to another country
- Sexual activities with men, women, or both and whether it was protected or unprotected
- Illicit drug use, IV or intranasal
- For health care workers, recent needlestick exposure
- Body piercing or tattooing
- Close living accommodations (e.g., military barracks, correctional institutions, overcrowded dormitories, long-term care facilities, day-care centers) or employment in any such setting
- Blood or blood products or organ transplants received before 1992
- Military service
- Place of birth (United States or other country) and parents' place of birth
- Family history of liver disease
- History of alcohol use (how many drinks each day or week)
- Human immune deficiency virus (HIV)

## Physical Assessment/Signs and Symptoms.

Assess whether the patient has:

- Abdominal pain
- Changes in skin or sclera (icterus)
- **Arthralgia** (joint pain) or **myalgia** (muscle pain)
- Diarrhea/constipation
- Changes in color of urine or stool
- Fever
- Lethargy
- Malaise
- Nausea/vomiting
- Pruritus (itching)

Lightly palpate the right upper abdominal quadrant to assess for liver tenderness. The patient may report right upper quadrant pain with jarring movements. Inspect the skin, sclerae, and mucous membranes for jaundice. He or she may present for medical treatment only after jaundice appears, believing that other vague symptoms are related to a flu-like syndrome.

Jaundice in hepatitis results from intrahepatic obstruction and is caused by edema of the liver's bile channels. Dark urine and clay-colored stools are often reported by the patient. If possible, obtain a urine and stool specimen for visual inspection and laboratory analysis. The patient may also have skin abrasions from scratching because of pruritus (itching).

## Psychosocial Assessment.

Viral hepatitis has various presentations, but for most infected people the initial course is mild with few or no symptoms. The long-term complications of fibrosis and cirrhosis cause the more serious problem. This is especially true for patients who have chronic HBV and HCV infection.

Emotional problems for affected patients may center on their feeling sick and fatigued. General malaise, inactivity, and vague symptoms contribute to depression. Some patients often feel guilty and are remorseful about decisions made that caused the disease. These feelings are most likely to occur when the source of infection is from drug use.

Infectious diseases such as hepatitis continue to have a social stigma. (See the [Evidence-Based Practice](#) box on caring for military veterans with hepatitis C.) The patient may feel embarrassed by the precautions that are imposed in the hospital and continue to be necessary at home. This embarrassment may cause the patient to limit social interactions. Patients may be afraid that they will spread the virus to family and friends.

## Evidence-Based Practice QSEN

### Caring for Military Veterans With Hepatitis C

Phillips, F., & Barnes, D. (2016). Social support and adherence for military veterans with hepatitis C. *Clinical Nurse Specialist, 30*(1), 38–44.

This qualitative study's aim was to describe military veterans' experience of support after diagnosis of hepatitis C and how support impacted their adherence to treatment.

A convenience sample of 21 veterans was used for this phenomenological study. Inclusion criteria were comprised of veterans who were over 18 years of age; were receiving standard care for hepatitis C; and could read, write, and communicate in English. In keeping with a phenomenological design, researchers collected data during a one-time, in-depth interview with each participant. Follow-up phone calls were used to verify that the themes identified were congruent with the lived experience of subjects.

Results indicated that veterans selectively tell only certain individuals about their diagnosis due to fear of stigma. In turn, this limits the amount of people in their circle of support. Veterans found some level of support, yet some level of burden, when disclosing their status to family members, friends, and health care providers.

**Level of Evidence: 3**

This qualitative research was designed as a phenomenological study.

### Commentary: Implications for Practice and Research

Nurses must use empathy and concern while assessing availability of support systems for patients. In absence of a personal support network, or in addition to an existing support system, nurses should recommend support groups or counseling to help the patient adhere to treatment and management of hepatitis C.

Family members are sometimes afraid of getting the disease and may distance themselves from the patient. Allow them to verbalize these feelings and explore the reasons for these fears. Educate the patient and family members about modes of transmission, and clarify information as needed.

Patients may be unable to return to work for several weeks during the acute phases of illness. The loss of wages and the cost of hospitalization for a patient without insurance coverage may produce great anxiety and financial burden. This situation may last for months or years if hepatitis becomes chronic.

### Laboratory Assessment.

Hepatitis A, hepatitis B, and hepatitis C are usually confirmed by acute elevations in levels of liver enzymes, indicating liver cellular damage, and by specific serologic markers.

Levels of ALT and AST may possibly rise into the thousands in acute or fulminant cases of hepatitis. Alkaline phosphatase levels may be normal or elevated. Serum total bilirubin levels are elevated and are consistent with the clinical appearance of jaundice.

The presence of *hepatitis A* is established when hepatitis A virus (HAV) antibodies (anti-HAV) are found in the blood. Ongoing inflammation of the liver by HAV is indicated by the presence of immunoglobulin M (IgM) antibodies, which persist in the blood for 4 to 6 weeks. Previous infection is identified by the presence of immunoglobulin G (IgG) antibodies. These antibodies persist in the serum and provide permanent IMMUNITY to HAV.

The presence of the *hepatitis B* virus (HBV) is established when serologic testing confirms the presence of hepatitis B antigen-antibody systems in the blood and a detectable viral count (HBV polymerase chain reaction [PCR] DNA). Antigens located on the surface (shell) of the virus (HBsAg) and IgM antibodies to hepatitis B core antigen (anti-HBcAg IgM) are the most significant serologic markers. The presence of these markers establishes the diagnosis of hepatitis B. *The patient is infectious as long as hepatitis B surface antigen (HBsAg) is present in the blood.* Persistence of this serologic marker after 6 months or longer indicates a carrier state or chronic hepatitis. HBsAg levels normally decline and disappear after the acute hepatitis B episode. The presence of antibodies to HBsAg in the blood indicates recovery and immunity to hepatitis B. *People who have been vaccinated against HBV have a positive HBsAg because they also have immunity to the disease.*

To detect HCV infection, blood is tested for anti-HCV antibodies to HCV recombinant core antigen, NS3 gene, NS4 antigen, and NS5 antibody (Pagana et al., 2017). The antibodies can be detected within 4 weeks of the infection (Pagana et al., 2017). To identify the actual circulating virus, the HCV RNA test is used. This confirms active virus and can measure the viral load. A diagnostic tool called the *OraQuick HCV Rapid Antibody Test* has the advantage of providing a quick diagnosis of the disease as a point-of-care test.

The presence of *hepatitis D* virus (HDV) can be confirmed by the identification of intrahepatic delta antigen or, more often, by a rise in the hepatitis D virus antibodies (anti-HDV) titer. This increase can be seen within a few days of infection (Pagana et al., 2017).

*Hepatitis E* virus (HEV) testing is usually reserved for travelers in whom hepatitis is present but the virus cannot be detected. Hepatitis E antibodies (anti-HEV) are found in people infected with the virus.

### Other Diagnostic Assessment.

*Liver biopsy* may be used to confirm the diagnosis of hepatitis and establish the stage and grade of liver damage. Characteristic changes help the pathologist distinguish among a virus, drug, toxin, fatty liver, iron, and other disease. It is usually performed in an ambulatory care setting as a percutaneous procedure (through the skin) after a local anesthetic is given. However, if coagulation is abnormal, it may be done using either a CT-guided or transjugular route to reduce the risk for pneumothorax or hemothorax. *Ultrasound* also may be used.

### ◆**Analysis: Interpreting**

The priority collaborative problems for patients with hepatitis include:

1. Weight loss due to complications associated with inflammation of the liver
2. Fatigue due to decreased metabolic energy production
3. Potential for infection due to state of immunocompromise

### ◆**Planning and Implementation: Responding**

The patient with viral hepatitis can be mildly or acutely ill, depending on the severity of the inflammation. Most patients are not hospitalized, although older adults and those with dehydration may be admitted for a short-term stay. The plan of care for all patients with viral hepatitis is based on measures to rest the liver, promote CELLULAR REGULATION and regeneration, strengthen IMMUNITY, and prevent complications, if possible.

#### **Promoting Nutrition**

##### **Planning: Expected Outcomes.**

The patient will maintain appropriate weight and NUTRITION status as evidenced by laboratory reports free of signs of malnutrition.

##### **Interventions.**

The patient with hepatitis may decline food because of general malaise, anorexia, abdominal discomfort, or nausea. The patient's diet should be high in carbohydrates and calories with moderate amounts of fat and protein added after nausea and anorexia subside. Small, frequent meals are often preferable to three standard meals daily. Ask the patient about appealing food preferences because favorite foods are tolerated better than randomly selected foods. High-calorie snacks may be needed. Supplemental vitamins are often prescribed.

#### **Addressing Fatigue**

##### **Planning: Expected Outcomes.**

The patient will progressively exhibit increasing energy as evidenced by participation in ADLs and self-reported decrease in level of fatigue.

##### **Interventions**

##### **Rest.**

During the acute stage of viral hepatitis, interventions are aimed at resting the inflamed liver to promote hepatic cell regeneration. *Rest* is an essential intervention to reduce the liver's metabolic demands and increase its blood supply. Collaborative care is generally supportive. The patient is usually tired and expresses feelings of general malaise. Complete bedrest is usually not required, but rest periods alternating with periods of activity are indicated and are often enough to promote hepatic healing. Individualize the patient's plan of care and change it as needed to reflect the severity of symptoms, fatigue, and the results of liver function tests and enzyme determinations. Activities such as self-care and ambulating are gradually added to the activity schedule as tolerated.

##### **Drug Therapy.**

Drugs of any kind are used sparingly for patients with hepatitis to allow the liver to rest. An antiemetic to relieve nausea may be prescribed. However, because of the life-threatening nature of chronic hepatitis B and hepatitis C, a number of drugs are given, including antiviral and immunomodulating drugs (Table 58-4). Similar to patients with other chronic diseases, patients with hepatitis often use complementary and integrative therapies to promote general well-being and improve quality of life. Be sure to ask patients about their use of these therapies and incorporate them into the collaborative plan of care.

**TABLE 58-4**  
**Drug Therapy for Chronic Hepatitis B and Hepatitis C**

DRUG	NURSING INTERVENTIONS	RATIONALES
<b>Chronic Hepatitis B</b>		
Tenofovir (Viread)	Monitor kidney function.	Drug is excreted through kidneys; monitoring for renal impairment is important.
	Teach risk for falls to prevent fractures.	Can cause bone de-mineralization.
Adefovir (Hepsera)	Monitor kidney function.	Drug is excreted through kidneys; monitoring for renal impairment is important.
Lamivudine (Epivir-HBV, 3TC 🍀, Heptovir 🍀)	Monitor kidney function.	Drug is excreted through kidneys; monitoring for renal impairment is important.
	Remind patient to not discontinue drug without consulting with health care provider.	Discontinuation of drug can cause flareup of HBV.
Entecavir (Baraclude)	Monitor kidney function.	Drug is excreted through kidneys; monitoring for renal impairment is important.
<b>Chronic Hepatitis C</b>		
Telaprevir (Incivek)	Monitor complete blood count (CBC).	Anemia can be a side effect of this drug.
Boceprevir (Victrelis) in combination with HIV medications if co-infection present	Monitor chemistry panel.	Kidney and liver function may become impaired, and electrolyte imbalances may occur when taking this drug.
PEG-IFN/RBV (interferon/ribavirin)	Instruct patients that they cannot miss a dose.	Efficacy of treatment diminishes when doses are missed.

HBV, Hepatitis B virus; HIV, human immune deficiency virus.

## Reducing the Potential for Infection

### Planning: Expected Outcomes.

The patient will be free from infection as evidenced by remaining fever free with laboratory values that are free from indications of infection.

### Interventions.

Teach the patient and caregivers about proper handwashing and any implemented isolation precautions. Restrict visitors who have active infections or have recently been exposed to such. Monitor for development of fever; report increasing temperature and any changes in white blood cell laboratory values to the health care provider.

## Care Coordination and Transition Management

### Home Care Management.

Home care management varies according to the type of hepatitis and whether the disease is acute or chronic. A primary focus in any case is preventing the spread of the infection. For hepatitis transmitted by the fecal-oral route, careful handwashing and sanitary disposal of feces are important. Therefore education is very important.

## Nursing Safety Priority QSEN

### Action Alert

Teach the patient with viral hepatitis and the family to use measures to prevent infection transmission (see Chart 58-4). In addition, instruct the patient to avoid alcohol and to check with the health care provider before taking any medication or vitamin, supplement, or herbal preparation.

### Self-Management Education.

Encourage the patient to increase activity gradually to prevent fatigue. Suggest that the patient eats small, frequent meals of high-carbohydrate foods (Chart 58-5).

## Chart 58-5

# Patient and Family Education: Preparing for Self-Management

## Viral Hepatitis

- Avoid all medications, including over-the-counter drugs such as acetaminophen (Tylenol), unless prescribed by your physician.
- Avoid all alcohol.
- Rest frequently throughout the day, and get adequate sleep at night.
- Eat small, frequent meals with a high-carbohydrate, moderate-fat, and moderate-protein content.
- Avoid sexual intercourse until antibody testing results are negative.
- Follow the guidelines for preventing transmission of the disease (see Chart 58-4).

### Health Care Resources.

Collaborate with the certified infection control practitioner and infectious disease specialist if needed in caring for these patients. These experts can suggest appropriate resources for the patient and family.

### ◆Evaluation: Reflecting

Evaluate the care of the patient with hepatitis based on the identified priority patient problems. The expected outcomes include that the patient will:

- Maintain nutritional status adequate for body requirements
- Report increasing energy levels as the liver rests
- Remain infection-free

## Clinical Judgment Challenge 58-2

### Patient-Centered Care; Safety QSEN

You are caring for a 39-year-old woman who returned to the United States 3 weeks ago from a month-long humanitarian mission trip to South America. Since that time, she reports that she has been experiencing periodic fevers, abdominal pain, nausea, and fatigue. At first, she states that thought she had the flu, but she now thinks that something else “must be terribly wrong” because of how long her symptoms have persisted. She confirms that she is a nonsmoker and only drinks one to two alcoholic drinks monthly when out to dinner with friends. When asked about her dietary habits in South America, the patient reports that she and several of her friends often enjoyed fresh shrimp prepared by a street vendor.

1. Based on the patient's dietary intake in South America and current symptoms, what condition do you anticipate?
2. Other than fever, abdominal pain, nausea, and fatigue, what signs and symptoms do you anticipate you will find on physical assessment?
3. Which laboratory findings do you anticipate will be abnormal for this patient?
4. How do you respond to the patient's concern about something being “terribly wrong?”

## Fatty Liver (Steatosis)

**Fatty liver** is caused by the accumulation of fats in and around the hepatic cells. It may be caused by alcohol use or other factors. Nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH) are types of fatty liver disease. Causes include:

- Diabetes mellitus
- Obesity
- Elevated lipid profile
- Genetic contribution via the Patatin-like phospholipase domain-containing 3 gene (PNPLA3) ([Houghton-Rahrig et al., 2014](#)).

Fatty infiltration of the liver may result from faulty fat metabolism in the liver and the movement of fatty acids from adipose tissue (fat). Many patients are asymptomatic. The most common and typical finding is an elevated ALT and AST or normal ALT and elevated AST (part of a group of liver function tests [LFTs]).

MRI, ultrasound, and nuclear medicine examinations can be used to suggest excessive fat in the liver. A percutaneous biopsy can confirm the diagnosis. Interventions are aimed at removing the underlying cause of the infiltration. Weight loss, glucose control, and aggressive treatment using lipid-lowering agents are recommended. Monitoring liver function tests is essential in disease management.

## Liver Trauma

The liver is one of the most common organs to be injured in patients with abdominal trauma. Damage or injury should be suspected whenever any upper abdominal or lower chest trauma is sustained. The liver is often injured by steering wheels in vehicular crashes. Common injuries include simple lacerations, multiple lacerations, avulsions (tears), and crush injuries.

The liver is a highly vascular organ and receives almost a third of the body's cardiac output. When hepatic trauma occurs, blood loss can be massive. *Observe for early signs of hypovolemic shock (Chart 58-6).*

### Chart 58-6

#### Key Features

##### Liver Trauma

- Right upper quadrant pain with abdominal tenderness
- Abdominal distention and rigidity
- Guarding of the abdomen
- Increased abdominal pain exaggerated by deep breathing and referred to the right shoulder (Kehr's sign)
- Indicators of hemorrhage and hypovolemic shock:
  - Hypotension
  - Tachycardia
  - Tachypnea
  - Pallor
  - Diaphoresis
  - Cool, clammy skin
  - Confusion or other change in mental state

An ultrasound or CT scan of the abdomen is often done to determine the presence of a hematoma (blood clot). A decreased hematocrit may confirm suspected blood loss. Clinical signs and symptoms include right upper quadrant pain with abdominal tenderness, distention, guarding, and rigidity. COMFORT alterations exaggerated by deep breathing and referred to the right shoulder may indicate diaphragmatic irritation.

Liver trauma is managed in a conservative manner through new diagnostic and therapeutic modalities such as enhanced critical care monitoring and damage control surgery. The condition of the patient, grade of liver injury, and presence of other injuries will determine the management strategy (i.e., whether to operate or not). Patients with hepatic trauma may require multiple blood products such as packed red blood cells and fresh frozen plasma, as well as massive volume infusion to maintain adequate hydration. After surgery, the patient is admitted to a critical care

unit. Monitor the patient for persistent or new bleeding. Closely monitor complete blood count and coagulation studies for trends in changes.

# Cancer of the Liver

## ❖ Pathophysiology

Cancers may be *primary* tumors (hepatocellular carcinoma) starting in the liver, or they may be *metastatic* cancers that spread from another organ to the liver. Liver cancer is one of the most fatal types of cancer, and according to the [American Cancer Society \(2017\)](#), its incidence has more than tripled since 1980, likely because there continues to be an increase in cases of hepatitis C.

Chronic infection with HBV and HCV frequently lead to cirrhosis, which is a risk factor for developing liver cancer. It is important to remember that cirrhosis from any cause, including alcoholic liver disease, increases the risk for cancer.

## ❖ Interprofessional Collaborative Care

Care for the patient with cancer of the liver can take place in various settings. At different times, these patients may self-manage at home, be hospitalized for immediate concerns, need rehabilitative care, be cared for in the community setting, or be under the care of hospice. Members of the interprofessional team who collaborate most closely to care for the patient with liver cancer include the health care provider, surgeon, nurse, dietitian, psychologist, social worker, and spiritual leader of the patient's choice.

### ◆ Assessment: Noticing

In the early stage of cancer, most patients are without symptoms. Later in the disease, they report weight loss, anorexia, and weakness. Ask the patient if he or she has or has had recent alterations in abdominal COMFORT, the most common concern. It is most often felt in the right upper quadrant before jaundice, bleeding, ascites, and edema develop. Palpation may reveal an enlarged, nodular liver.

Elevated serum *alpha-fetoprotein* (AFP) (a tumor marker for cancers of the liver, testis, and ovary) and increased *alkaline phosphatase* are also common ([Pagana et al., 2017](#)). Ultrasound (US) and contrast-enhanced CT are both useful in detecting metastasis. If the primary tumor site is not known, a CT- or US-guided liver biopsy can confirm the diagnosis, although this procedure is risky because of possible bleeding and spread of the cancer cells.

### ◆ Interventions: Responding

Surgical resection and liver transplantation offer the only treatments for long-term survival from liver cancer. Unfortunately, most patients are not candidates for surgical removal because their tumors are unresectable. Tunneled abdominal drains, such as the PleurX drainage system, may be used at home by the patient and family to remove excess ascitic fluid. *Teach them how to empty the drain and maintain the system. Remind them not to remove more than 2000 mL of fluid at one time to prevent hypovolemic shock.*

The primary treatment for nonresectable liver cancer is a TACE (transarterial chemoembolization). In this procedure, an interventional radiologist injects microscopic-size embolic beads that have absorbed a chemotherapy drug directly. An angiographic catheter is advanced from the femoral artery and maneuvered into the liver and then directly into the blood vessel feeding the tumor. From there, the beads are injected. These beads clog up the tumor arteries, arresting blood flow as they release the chemotherapy. It is now becoming accepted practice to immediately follow the TACE with a microwave ablation (MWA) of the same tumor. This burns (ablates) the tumor to further slow any regrowth.

Selective internal radiation therapy (SIRT) is reserved for patients with nonresectable liver cancer and an occluded portal vein. Occluding some of the hepatic artery (TACE procedure) with an absence of portal flow reduces overall blood flow to the liver to an unacceptable level. SIRT therapy is quite expensive, and insurance companies limit its use to specific tumor types.

Other palliative approaches include hepatic artery embolization, ablation techniques, and drug therapy. *Hepatic artery embolization* causes cell death by blocking blood supply to the tumor in the liver. It is performed under moderate sedation by an interventional radiologist who threads a catheter through the femoral artery to inject small beads into the hepatic artery to block blood flow.

The patient usually stays overnight in the hospital for observation in case of bleeding. This procedure may be followed by infusing a chemotherapy agent directly into the hepatic artery (chemoembolization).

Common *ablation* procedures include radiofrequency ablation (RFA) and cryotherapy. RFA uses energy waves to heat cancer cells and kill them. It is most often performed as an ambulatory care procedure using a percutaneous laparoscopic approach. Cryotherapy uses liquid nitrogen to freeze and destroy liver tumors. The general nursing care for patients having cryotherapy is described in [Chapter 22](#).

Chemotherapy may be administered orally or IV. However, it is not effective in many cases. Examples of drugs used are doxorubicin (Adriamycin), 5-fluorouracil (5-FU), and cisplatin. Sorafenib (Nexavar) is a kinase inhibitor that is approved for inoperable liver cancer. Other drugs are targeted therapies that are being investigated and used with some success.

Another drug route is a catheter-directed method directly into the hepatic artery, a procedure called *hepatic arterial infusion (HAI)*. The interventional radiologist places a catheter into the artery that supplies the tumor and injects a mixture of chemotherapy and contrast agent into the tumor. This procedure has the unique effect of depositing chemotherapeutic drugs directly into the tumor without causing major systemic effects. [Chapter 22](#) describes the general nursing care for patients receiving chemotherapy.

Patients with advanced liver cancer usually need end-of-life care and hospice services. Collaborate with the case manager to help patients and their families find the best community resources that meet their needs. [Chapter 7](#) describes end-of-life care and hospice services in detail.

# Liver Transplantation

## ❖Pathophysiology

Liver transplantation has become a common procedure worldwide. The patient with end-stage liver disease or acute liver failure who has not responded to conventional medical or surgical intervention is a potential candidate for liver transplantation. Many diseases can cause liver failure. Cirrhosis (scarring of the liver) is the most common reason for liver transplants. Other common reasons are chronic hepatitis B and hepatitis C, bile duct diseases, autoimmune liver disease, primary liver cancer, alcoholic liver disease, and fatty liver disease.

## Transplantation Considerations

The patient for potential transplantation has extensive physiologic and psychological assessment and evaluation by health care providers and transplant coordinators. Alternative treatment should be extensively explored before committing a patient for a liver transplant. Patients who are *not* considered candidates for transplantation are those with:

- Severe cardiovascular instability with advanced cardiac disease
- Severe respiratory disease
- Metastatic tumors
- Inability to follow instructions regarding drug therapy and self-management

Liver transplantation has become the most effective treatment for an increasing number of patients with acute and chronic liver diseases. Inclusion and exclusion criteria vary among transplantation centers and are continually revised as treatment options change and surgical techniques improve.

Donor livers are obtained primarily from trauma victims who have not had liver damage. They are distributed through a nationwide program, the United Network of Organ Sharing (UNOS). This system distributes donor livers based on regional considerations and patient acuity. Candidates with the highest level of acuity receive highest priority.

The donor liver is transported to the surgery center in a solution that preserves the organ for up to 8 hours. The diseased liver is removed through an incision made in the upper abdomen. The new liver is carefully put in its place and attached to the patient's blood vessels and bile ducts. The procedure can take many hours to complete and requires a highly specialized team and large volumes of fluid and blood replacement.

Living donors have also been used and are usually close family members or spouse. This is done on a voluntary basis after careful psychological and physiologic preparation and testing. The donor's liver is resected (usually removal of one lobe) and implanted into the recipient after removal of the diseased liver. In both the donor and the recipient, the liver regenerates and grows in size to meet the demands of the body.

## Transplantation Complications

Although liver transplantations are commonly performed, complications can occur. Some problems can be managed medically, whereas others require removal of the transplant. The most common complications are acute graft rejection, infection, and bleeding (Lynn, 2016).

The success rate for transplantations has greatly improved since the introduction many years ago of cyclosporine (cyclosporin A), an immunosuppressant drug. Today many other anti-rejection drugs are used. (See Chapter 17 for a complete discussion of rejection and preventive drug therapy.)

## ❑Nursing Safety Priority QSEN

### Action Alert

For the patient who has undergone liver transplantation, monitor for clinical signs and symptoms of rejection, which may include tachycardia, fever, COMFORT alterations in the right upper quadrant or flank, decreased bile pigment and volume, and increasing jaundice. Laboratory findings include

elevated serum bilirubin, rising ALT and AST levels, elevated alkaline phosphatase levels, and increased prothrombin time/international normalized ratio (PT/INR).

Transplant rejection is treated aggressively with immunosuppressive drugs. As with all rejection treatments, the patient is at a greater risk for infection. If therapy is not effective, liver function rapidly deteriorates. Multi-system organ failure, including respiratory and renal involvement, develops along with diffuse coagulopathies and portal-systemic encephalopathy (PSE). The only alternative for treatment is emergency retransplantation.

Infection is another potential threat to the transplanted graft and the patient's survival. Vaccinations and prophylactic antibiotics are helpful in prevention. Immunosuppressant therapy, which must be used to prevent and treat organ rejection, significantly increases the patient's risk for infection. Other risk factors include the presence of multiple tubes and intravascular lines, immobility, and prolonged anesthesia.

In the early post-transplantation period, common infections include pneumonia, wound infections, and urinary tract infections. Opportunistic infections usually develop after the first postoperative month and include cytomegalovirus, mycobacterial infections, and parasitic infections. Latent infections such as tuberculosis and herpes simplex may be reactivated.

The health care provider prescribes broad-spectrum antibiotics for prophylaxis during and after surgery. Obtain culture specimens from all lines and tubes and collect specimens for culture at predetermined time intervals as dictated by the agency's policy. If an infection is detected, the health care provider prescribes organism-specific anti-infective agents. The patient should be taught to contact the health care provider at any time that signs of infection are present.

The biliary anastomosis is susceptible to breakdown, obstruction, and infection. If leakage occurs or if the site becomes necrotic or obstructed, an abscess can form; or peritonitis, bacteremia, and cirrhosis may develop. Observe for potential complications, which are listed in [Table 58-5](#).

**TABLE 58-5**

**Assessment and Prevention of Common Postoperative Complications Associated With Liver Transplantation**

ASSESSMENT	PREVENTION
<b>Acute Graft Rejection</b> Occurs from the 4th to 10th postoperative day Manifested by tachycardia, fever, right upper quadrant (RUQ) or flank pain, diminished bile drainage or change in bile color, or increased jaundice Laboratory changes: (1) increased levels of serum bilirubin, transaminases, and alkaline phosphatase; (2) prolonged prothrombin time	Prophylaxis with immunosuppressant agents, such as cyclosporine Early diagnosis to treat with more potent anti-rejection drugs
<b>Infection</b> Can occur at any time during recovery Manifested by fever or excessive, foul-smelling drainage (urine, wound, or bile); other indicators depend on location and type of infection	Antibiotic prophylaxis; vaccinations Frequent cultures of tubes, lines, and drainage Early removal of invasive lines Good handwashing Early diagnosis and treatment with organism-specific anti-infective agents
<b>Hepatic Complications (Bile Leakage, Abscess Formation, Hepatic Thrombosis)</b> Manifested by decreased bile drainage, increased RUQ abdominal pain with distention and guarding, nausea or vomiting, increased jaundice, and clay-colored stools Laboratory changes: increased levels of serum bilirubin and transaminases	If present, keep T-tube in dependent position and secure to patient; empty frequently, recording quality and quantity of drainage Report manifestations to physician immediately May necessitate surgical intervention
<b>Acute Renal Failure</b> Caused by hypotension, antibiotics, cyclosporine, acute liver failure, or hypothermia Indicators of hypothermia: shivering, hyperventilation, increased cardiac output, vasoconstriction, and alkalemia Early indicators of renal failure: changes in urine output, increased blood urea nitrogen (BUN) and creatinine levels, and electrolyte imbalance	Monitor all drug levels with nephrotoxic side effects Prevent hypotension Observe for early signs of renal failure and report them immediately to the physician

**❖ Interprofessional Collaborative Care**

Care of the patient undergoing liver transplantation requires an interprofessional team approach. Receiving a transplant has a major psychosocial impact. Transplant complications cause patients to be very anxious. In collaboration with the members of the health care team, assure them and their families that these problems are common and usually treated successfully.

After the patient is identified as a candidate and a donor organ is procured, the actual liver transplantation surgical procedure usually takes many hours. The length of the procedure can vary greatly.

In the immediate postoperative period, the patient is managed in the critical care unit and requires aggressive monitoring and care. Assess for signs and symptoms of complications of surgery and immediately report them to the surgeon (see [Table 58-5](#)).

## Nursing Safety Priority QSEN

### Action Alert

For the patient who has had a liver transplantation, monitor the temperature frequently per hospital protocol and report elevations, increased abdominal pain, distention, and rigidity, which are indicators of peritonitis. Nursing assessment also includes monitoring for a change in neurologic status that could indicate encephalopathy from a nonfunctioning liver. Report signs of clotting problems (e.g., bloody oozing from a catheter, petechiae, ecchymosis) to the surgeon immediately because they may indicate impaired function of the transplanted liver.

Post-liver transplant patients are living longer today than ever. Teach patients to be aware of side effects of immunosuppressive drugs, such as hypertension, nephrotoxicity, and gastrointestinal disturbances. Remind them that long-term management of care includes surveillance for malignancy, metabolic syndrome, and diabetes. Teaching the patient self-examination for skin, breast, and testicular malignancies and reminders for annual Papanicolaou (Pap) smears and other cancer screening tests are important. Post-transplant patients need to maintain lifestyle changes to increase their longevity after surgery.

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- When caring for patients with cirrhosis, collaborate with the health care provider, dietitian, pharmacist, social worker, and spiritual leader of the patient's choice to provide comprehensive interprofessional care. **QSEN: Teamwork and Collaboration**
- Refer patients with liver disorders to the American Liver Foundation; refer dying patients to hospice and other community resources as needed. **QSEN: Patient-Centered Care**

### Health Promotion and Maintenance

- Follow the guidelines listed in [Chart 58-3](#) to prevent viral hepatitis in the workplace. **QSEN: Evidence-Based Practice**
- Teach patients to take precautions to prevent viral hepatitis in the community as described in [Chart 58-4](#). **QSEN: Evidence-Based Practice**
- For patients with viral hepatitis, instruct them to follow the guidelines listed in [Chart 58-5](#). **QSEN: Safety**
- Teach patients to avoid alcohol and illicit drugs to prevent or slow the progression of alcohol-induced cirrhosis; remind them not to take any medication (including over-the-counter drugs) without checking with their health care provider. **QSEN: Safety**

### Psychosocial Integrity

- Recognize that patients with cirrhosis have mental and emotional changes due to hepatic encephalopathy. **QSEN: Patient-Centered Care**
- Be aware that patients with cirrhosis and/or chronic hepatitis may feel guilty about their disease because of past habits such as drug and alcohol use. Allow patients to express feelings openly. **Ethics**
- Be aware that family members and friends may fear getting hepatitis from the patient.
- Be aware that patients having liver transplantation have major concerns about the possibility of complications, such as organ rejection. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Be aware that cirrhosis has many causes other than alcohol use (see [Table 58-1](#)).
- Observe for clinical signs and symptoms of hepatic encephalopathy (PSE) as listed in [Table 58-2](#). **QSEN: Safety**
- Monitor laboratory values of patients suspected of or diagnosed with cirrhosis of the liver as listed in [Table 58-3](#). **Clinical Judgment**
- Monitor the patient with cirrhosis for bleeding and neurologic changes. **QSEN: Safety**
- Provide care for the patient having a paracentesis as described in [Chart 58-1](#). **QSEN: Safety**
- Administer drug therapy to decrease ammonia levels (that cause PSE) in patients with cirrhosis, such as lactulose and nonabsorbable antibiotics. **QSEN: Safety**
- Differentiate the five major types of hepatitis: A, B, C, D, and E. Hepatitis D occurs only with hepatitis B and is transmitted most commonly by blood and body fluid exposure. Hepatitis A is transmitted via the fecal-oral route. Hepatitis C is the most common type and is also transmitted via blood and body fluids. **QSEN: Evidence-Based Practice**
- Be aware that patients with chronic viral hepatitis often develop cirrhosis and cancer of the liver.

**QSEN: Evidence-Based Practice**

- Recognize that potent immunomodulators and antivirals are given to treat hepatitis B and hepatitis C; teach patients on immunomodulators to avoid large crowds and people who have infections. **QSEN: Safety**
- Monitor for bleeding in the patient with liver trauma; assume that any abdominal trauma has damaged the liver. **QSEN: Safety**
- Monitor the patient having a liver transplantation for complications, such as those described in [Table 58-5](#). **QSEN: Safety**
- Report and document elevated temperature, increased abdominal pain and rigidity, bleeding, and/or neurologic status changes as possible indicators of liver transplantation complications. **QSEN: Safety**

## CHAPTER 59

# Care of Patients With Problems of the Biliary System and Pancreas

Lara Carver, Jennifer Powers

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concepts for this chapter are:**

- NUTRITION
- IMMUNITY

✚ The NUTRITION concept exemplar for this chapter is Cholecystitis, below.

✚ The IMMUNITY concept exemplar for this chapter is Acute Pancreatitis, p. 1197.

**The interrelated concept for this chapter is COMFORT.**

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team members to provide care for the patient with a gallbladder or pancreatic disorder.
2. Identify community resources to ensure appropriate transition management for the patient with a gallbladder or pancreatic disorder.

### Health Promotion and Maintenance

3. Teach adults evidence-based health promotion practices to prevent gallbladder disease and pancreatitis.

### Psychosocial Integrity

4. Implement nursing interventions to minimize stressors for the patient with a gallbladder or pancreatic disorder.

### Physiological Integrity

5. Differentiate between assessment findings associated with various gallbladder and pancreatic disorders.
6. Prioritize care for patients with a gallbladder or pancreatic disorder.
7. Create an evidence-based plan of care for the patient with a gallbladder or pancreatic disorder.
8. Describe nursing interventions to address postoperative care of patients undergoing a cholecystectomy or Whipple procedure.
9. Describe nursing interventions that promote NUTRITION, IMMUNITY, and COMFORT for patients with a gallbladder or pancreatic disorder.

The liver, gallbladder, and pancreas make up the biliary system. This chapter focuses on problems of the gallbladder and pancreas. Liver disorders are described in [Chapter 58](#). The biliary system secretes enzymes and other substances that promote food digestion in the stomach and small intestine. When these organs do not work properly, IMMUNITY is impaired; and individuals experience impaired *digestion*, which may result in inadequate NUTRITION.

Disorders of the gallbladder and pancreas may extend to other organs because of the close anatomic location of these organs, if the primary health problem is not treated early. Inflammation, which impairs IMMUNITY, is caused by **obstruction** (blockage) in the biliary system from gallstones,

edema, stricture, or tumors. For example, gallstones in the cystic duct cause cholecystitis. Gallstones lodged in the ampulla of Vater block the flow of bile and pancreatic secretions, which can result in pancreatitis. These problems frequently cause the patient to have moderate-to-severe alterations in abdominal COMFORT.

## Nutrition Concept Exemplar Cholecystitis

### Pathophysiology

**Cholecystitis** is an inflammation of the gallbladder that affects many adults, very commonly in affluent countries. It may be either acute or chronic, although most patients have the acute type.

#### Acute Cholecystitis

Two types of acute cholecystitis can occur: calculous and acalculous cholecystitis. The most common type is **calculous cholecystitis**, in which chemical irritation and inflammation result from gallstones (**cholelithiasis**) that obstruct the cystic duct (most often), gallbladder neck, or common bile duct (choledocholithiasis) (Fig. 59-1). When the gallbladder is inflamed, trapped bile is reabsorbed and acts as a chemical irritant to the gallbladder wall. Reabsorbed bile, in combination with impaired circulation, edema, and distention of the gallbladder, causes ischemia and infection. The result is tissue sloughing with necrosis and gangrene within the gallbladder itself. The gallbladder wall may eventually perforate (rupture). If the perforation is small and localized, an abscess may form. **Peritonitis**, infection of the peritoneum, may result if the perforation is large.

**FIG. 59-1** Gallstones within the gallbladder and obstructing the common bile and cystic ducts.

The exact mechanism of gallstone formation is not clearly understood, but abnormal metabolism of cholesterol and bile salts plays an important role. The gallbladder provides an excellent environment for the production of stones because it only occasionally mixes its normally abundant mucus with its highly viscous, concentrated bile. Impaired gallbladder motility can lead to stone formation by delaying bile emptying and causing biliary stasis.

Gallstones are composed of substances normally found in bile, such as cholesterol, bilirubin, bile salts, calcium, and various proteins. They are classified as either cholesterol stones or pigment stones. Cholesterol calculi form as a result of metabolic imbalances of cholesterol and bile salts. They are the most common type found in adults in the United States (McCance et al., 2014).

Bacteria can collect around the stones in the biliary system. Severe bacterial invasion can lead to life-threatening *suppurative* cholangitis when symptoms are not recognized quickly and pus accumulates in the ductal system.

**Acalculous cholecystitis** (inflammation occurring without gallstones) is typically associated with biliary stasis caused by any condition that affects the regular filling or emptying of the gallbladder. For example, a decrease in blood flow to the gallbladder or anatomic problems such as twisting or kinking of the gallbladder neck or cystic duct can result in pancreatic enzyme reflux into the

gallbladder, causing inflammation. Sphincter of Oddi dysfunction (SOD) can also occur to cause reflux and inflammation. Most cases of this type of cholecystitis occur in patients with:

- Sepsis
- Severe trauma or burns
- Long-term total parenteral NUTRITION
- Multiple organ dysfunction syndrome (MODS)
- Major surgery
- Hypovolemia

### Chronic Cholecystitis

Chronic cholecystitis results when repeated episodes of cystic duct obstruction cause chronic inflammation. Calculi are almost always present. In chronic cholecystitis, the gallbladder becomes fibrotic and contracted, which results in decreased motility and deficient absorption.

Pancreatitis and cholangitis (bile duct inflammation) can occur as chronic complications of cholecystitis. These problems result from the backup of bile throughout the biliary tract. Bile obstruction leads to jaundice.

**Jaundice** (yellow discoloration of the skin and mucous membranes) and **icterus** (yellow discoloration of the sclera) can occur in patients with acute cholecystitis but are most commonly seen in those with the *chronic* form of the disease. Obstructed bile flow caused by edema of the ducts or gallstones contributes to *extrahepatic obstructive jaundice*. Jaundice in cholecystitis may also be caused by direct liver involvement. Inflammation of the liver's bile channels or bile ducts may cause *intrahepatic* obstructive jaundice, resulting in an increase in circulating levels of bilirubin, the major pigment of bile.

In an adult with obstructive jaundice, the normal flow of bile into the duodenum is blocked, and excessive bile salts accumulate in the skin. This accumulation of bile salts leads to **pruritus** (itching) or a burning sensation. The bile flow blockage also prevents bilirubin from reaching the large intestine, where it is converted to urobilinogen. Because urobilinogen accounts for the normal brown color of feces, clay-colored stools result. Water-soluble bilirubin is normally excreted by the kidneys in the urine. When an excess of circulating bilirubin occurs, the urine becomes dark and foamy because of the kidneys' effort to clear the bilirubin.

### Etiology and Genetic Risk

A familial or genetic tendency appears to contribute to the development of cholelithiasis, but this may be partially related to familial nutrition habits (excessive dietary cholesterol intake) and sedentary lifestyles. Gene-environment interactions may contribute to gallstone production. For example, some gene variations program some individuals to make and secrete more cholesterol into bile, leading to the increase in cholesterol-containing gallstones. The main risk factors for developing gallstones are obesity, type 2 diabetes, dyslipidemia, and insulin resistance. Independent risk factors for developing gallstones are increase in age, female gender, and family history (Agostino et al., 2013). Also, individuals who experience rapid weight loss and intestinal diseases affecting the normal absorption of nutrients, such as Crohn's disease, are at risk for gallstones. The highest frequency of gallstone production lies among the American-Indian and Mexican-American populations (McCance et al., 2014). Risk factors for cholecystitis are listed in Table 59-1.

**TABLE 59-1**  
**Risk Factors for Cholecystitis**

<ul style="list-style-type: none"> <li>• Women</li> <li>• Aging</li> <li>• American Indian, Mexican American, or Caucasian</li> <li>• Obesity</li> <li>• Rapid weight loss or prolonged fasting</li> <li>• Increased serum cholesterol</li> <li>• Women on hormone replacement therapy (HRT)</li> </ul>	<ul style="list-style-type: none"> <li>• Cholesterol-lowering drugs</li> <li>• Family history of gallstones</li> <li>• Prolonged total parenteral nutrition</li> <li>• Crohn's disease</li> <li>• Gastric bypass surgery</li> <li>• Sickle cell disease</li> <li>• Glucose intolerance/diabetes mellitus</li> <li>• Pregnancy</li> <li>• Genetic factors</li> </ul>
---	---

## NCLEX Examination Challenge 59-1

### Health Promotion and Maintenance

The community nurse is talking with four clients who have reported digestive concerns. Which client does the nurse recognize as **most** likely to experience gallstone production? **Select all that apply.**

- A. 23-year-old Caucasian vegetarian who is a dancer
- B. 35-year-old American Indian who works in construction
- C. 48-year-old Canadian who manages a fast-food restaurant
- D. 59-year-old Asian American who is an investment banker
- E. 64-year-old Mexican American who resides with grandchildren

## Gender Health Considerations

### Patient-Centered Care QSEN

Women between 20 and 60 years of age are twice as likely to develop gallstones as men. Obesity is a major risk factor for gallstone formation, especially in women. Pregnancy and drugs such as hormone replacements and birth control pills alter hormone levels and delay muscular contraction of the gallbladder, decreasing the rate of bile emptying. The incidence is higher in women who have had multiple pregnancies. Combinations of causative factors increase the incidence of stone formation, especially in women. Therefore some clinicians refer to the patient most at risk for acute cholecystitis and gallstones by the four **F**s:

- Female
- Forty
- Fat
- Fertile

### Incidence and Prevalence

The incidence of chronic cholecystitis is increased in young, thin women, especially those who are athletic (e.g., ballerinas and gymnasts). These women have chronic pain that is often misdiagnosed as gastritis.

### Interprofessional Collaborative Care

Care for the patient with cholecystitis primarily takes place by self-management at home, in the community, or within the hospital setting if surgery is required. Members of the interprofessional team who collaborate most closely to care for the patient with cholecystitis include the health care provider, surgeon if surgery is required, nurse, and dietitian.

### Assessment: Noticing

#### Physical Assessment/Signs and Symptoms.

Obtain the patient's height, weight, and vital signs; or delegate these activities to unlicensed assistive personnel (UAP) with appropriate supervision. Ask about food preferences and determine whether excessive fat and cholesterol are part of the diet, since **NUTRITION** intake often contributes to cholecystitis and may affect care that is provided for this disorder. Typically, diets high in fat, high

in calories, low in fiber, and high in refined white carbohydrates place patients at higher risk for developing gallstones. Inquire if intake of certain foods causes pain. Question whether any GI symptoms occur when fatty food is eaten: **flatulence** (gas), **dyspepsia** (indigestion), **eructation** (belching), anorexia, nausea, vomiting, and abdominal alterations in COMFORT.

Patients with cholecystitis have abdominal pain, although symptoms vary in intensity and frequency (Chart 59-1). Ask the patient to describe the pain, including its intensity and duration, precipitating factors, and any measures that relieve it. Pain may be described as indigestion of varying intensity, ranging from a mild, persistent ache to a steady, constant pain in the right upper abdominal quadrant. It may radiate to the right shoulder or scapula. In some cases the abdominal pain of chronic cholecystitis may be vague and nonspecific. The usual pattern is episodic. Patients often refer to acute pain episodes as “gallbladder attacks.”

### Chart 59-1

## Key Features

### Cholecystitis

- Episodic or vague upper abdominal pain or discomfort that can radiate to the right shoulder
- Pain triggered by a high-fat or high-volume meal
- Anorexia
- Nausea and/or vomiting
- Dyspepsia (indigestion)
- Eructation (belching)
- Flatulence (gas)
- Feeling of abdominal fullness
- Rebound tenderness (Blumberg's sign)
- Fever
- Jaundice, clay-colored stools, dark urine, steatorrhea (most common with chronic cholecystitis)

## Considerations for Older Adults

### Patient-Centered Care QSEN

Older adults and patients with diabetes mellitus may have atypical symptoms of cholecystitis, including the absence of pain and fever. Localized tenderness may be the only presenting sign. The older patient may become acutely confused (delirium) as the first symptom of gallbladder disease.

The severe pain of **biliary colic** is produced by obstruction of the cystic duct of the gallbladder or movement of one or more stones. When a stone is moving through or is lodged within the duct, tissue spasm occurs in an effort to get the stone through the small duct.

## Nursing Safety Priority QSEN

### Critical Rescue

Biliary colic may be so severe that it occurs with tachycardia, pallor, diaphoresis, and prostration (extreme exhaustion). Assess the patient for possible shock caused by biliary colic. **Notify the**

**health care provider or Rapid Response Team if these symptoms occur.** Stay with the patient and keep the head of the bed flat.

Ask patients to describe their daily activity or exercise routines to determine whether they are sedentary. Sedentary lifestyle, rapid weight loss, prolonged fasting, and pregnancy are risk factors for developing gallstones. Question whether there is a family history of gallbladder disease. Ask the patient about taking current or previous hormone replacement therapy (HRT). If the patient is female, ask if she is taking or has recently been on oral contraceptives (birth control pills).

Assessment for rebound tenderness (Blumberg's sign) and deep palpation are performed only by physicians and advanced practice nurses. To elicit rebound tenderness, the health care provider pushes his or her fingers deeply and steadily into the patient's abdomen and then quickly releases the pressure. Pain that results from the rebound of the palpated tissue may indicate peritoneal inflammation. Deep palpation below the liver border in the right upper quadrant may reveal a sausage-shaped mass, representing the distended, inflamed gallbladder. Percussion over the posterior rib cage worsens localized abdominal pain.

In *chronic* cholecystitis, patients may have slowly developing symptoms and may not seek medical treatment until late symptoms such as jaundice (yellowing of the skin), clay-colored stools, and dark urine occur from biliary obstruction. Yellowing of the sclera (icterus) and oral mucous membranes may also be present. **Steatorrhea** (fatty stools) occurs because fat absorption is decreased as a result of the lack of bile. Bile is needed for the absorption of fats and fat-soluble vitamins in the intestine. As with any inflammatory process, the patient may have an elevated temperature of 99° to 102° F (37.2° to 38.9° C), tachycardia, and dehydration from fever and vomiting. He or she often will decline NUTRITION intake because of pain or symptoms that arise when food is eaten.

## Considerations for Older Adults

### Patient-Centered Care QSEN

Older adults become dehydrated much quicker than other age-groups, and they may not present with a fever. Monitor for a new onset of disorientation or acute confusion due to decreased blood volume available to oxygenate the cells of the brain (hypoxia)

### Diagnostic Assessment.

A differential diagnosis rules out other diseases that may cause similar symptoms, such as peptic ulcer disease, hepatitis, and pancreatitis. An increased *white blood cell (WBC)* count indicates inflammation. Serum levels of *alkaline phosphatase*, *aspartate aminotransferase (AST)*, and *lactate dehydrogenase (LDH)* may be elevated, indicating abnormalities in liver function in patients with severe biliary obstruction. The direct (conjugated) and indirect (unconjugated) *serum bilirubin levels* are also elevated. If the pancreas is involved, serum amylase and lipase levels are elevated.

Calcified gallstones are easily viewed on abdominal x-ray. Stones that are not calcified cannot be seen. *Ultrasonography (US) of the right upper quadrant is the best initial diagnostic test for cholecystitis.* It is safe, accurate, and painless. Acute cholecystitis is seen as edema of the gallbladder wall and pericholecystic fluid.

A hepatobiliary scan (sometimes called an *HIDA scan*) can be performed to visualize the gallbladder and determine patency of the biliary system. In this nuclear medicine test, a radioactive tracer or chemical is injected IV. About 20 minutes after the injection, a gamma camera tracks the flow of the tracer from the gallbladder to determine the ejection rate of bile into the biliary duct. A decreased bile flow indicates gallbladder disease with obstruction. Teach patients having this test to have nothing by mouth before the procedure. Remind the patient that the camera is large and close to the body for most of the procedure.

When the cause of cholecystitis or cholelithiasis is not known or the patient has symptoms of biliary obstruction (e.g., jaundice), an *endoscopic retrograde cholangiopancreatography (ERCP)* may be performed. Some patients have the less invasive and safer *magnetic resonance cholangiopancreatography (MRCP)*, which can be performed by an interventional radiologist. For this procedure, the patient is given oral or IV contrast material (gadolinium) before having an MRI scan.

Before the test, ask the patient about any history of urticaria (hives) or other allergy. MRI is also contraindicated in patients with pacemaker or other incompatible devices. Gadolinium does not contain iodine, which decreases the risk for an allergic response. [Chapter 52](#) discusses these tests in more detail.

### ◆**Analysis: Interpreting**

The priority collaborative problems for patients with cholecystitis include:

1. Weight loss due to decreased intake because of pain, nausea, and inflammation
2. Acute pain due to cholecystitis

### ◆**Planning and Implementation: Responding**

Acute cholecystitis is diagnosed on the basis of clinical findings, laboratory tests, and abdominal imaging. If acute gallbladder infection is diagnosed, an emergency cholecystectomy is usually performed the same or the following day. Laparoscopic cholecystectomy is the treatment of choice for patients with acute and long-term chronic cholecystitis. This minimally invasive procedure achieves the desired outcomes of shorter recovery time, decreased expense, less postoperative pain, and minimal scarring after surgery. NUTRITION status, pain levels, and risk for infection must be addressed before and after surgery.

## **Promoting Nutrition**

### **Planning: Expected Outcomes.**

The patient will maintain appropriate weight and NUTRITION status as evidenced by laboratory reports free of signs of malnutrition and stabilized weight.

### **Interventions.**

The patient with cholecystitis may decline food because of abdominal discomfort, nausea, and anorexia. Collaborate with the dietitian to structure a plan for enhancement of NUTRITION. The patient's diet should be high in fiber and low in fat. Gas-producing foods should be avoided. Small, frequent meals are often preferable to three standard meals daily. Ask the patient about appealing food preferences because favorite foods are tolerated more readily than randomly selected foods. Weigh the patient regularly to assess for stabilization of weight or concerns associated with weight loss. Monitor laboratory results such as blood urea nitrogen (BUN), prealbumin, albumin, and total protein and transferrin levels to assess ongoing NUTRITION status; report abnormal findings to the health care provider right away. See information later in this chapter that addresses postoperative NUTRITION interventions.

## **Managing Acute Pain**

### **Planning: Expected Outcomes.**

The patient with acute pancreatitis is expected to report a decrease in, or absence of, alterations in abdominal COMFORT, as evidenced by a pain intensity scale measurement.

### **Interventions.**

The priorities for patient care to address pain include providing supportive care by relieving symptoms, increasing COMFORT, and decreasing inflammation. Pain assessment to measure the effectiveness of these interventions is an essential part of nursing care.

### **Nonsurgical Management.**

Many patients with gallstones have no symptoms. Acute pain is present when gallstones partially or totally obstruct the cystic or common bile duct. Most patients find that they need to avoid fatty foods to prevent further episodes of biliary colic, which causes variations in COMFORT. Withhold food and fluids if nausea and vomiting occur. IV therapy is used for hydration.

### **Drug Therapy.**

Acute biliary pain requires opioid analgesia, such as morphine or hydromorphone (Dilaudid). All opioids may cause some degree of sphincter of Oddi spasm.

Ketorolac (Toradol), an NSAID, may be used for mild-to-moderate alterations in COMFORT. Be sure to monitor the patient for signs and symptoms of GI distress and pain because the drug can cause GI bleeding. The health care provider prescribes antiemetics to control nausea and vomiting. IV antibiotic therapy may also be given, depending on the cause of cholecystitis or as a one-time dose for surgery.

An option for a small number of patients with cholelithiasis (gallstones) is the use of oral bile acid dissolution or gallstone-stabilizing agents. Drugs such as ursodiol (Actigall) and chenodiol (Chenodal) may be given as long-term therapy to dissolve or stabilize gallstones. A gallbladder ultrasound is required every 6 months for the first year of therapy to determine the effectiveness of the drug. Teach patients on this type of drug therapy to report diarrhea, vomiting, or severe abdominal pain, especially if it radiates to the shoulders, to their health care provider immediately. Remind them to take the medication with food and milk.

### Other Nonsurgical Interventions.

For some patients with small stones or for those who are not good surgical candidates, a treatment that is commonly used for kidney stones can be used to break up gallstones—*extracorporeal shock wave lithotripsy (ESWL)*. This procedure can be used only for patients who have a normal weight, cholesterol-based stones, and good gallbladder function. The patient lies on a water-filled pad, and shock waves break up the large stones into smaller ones that can be passed through the digestive system. During the procedure, the patient might have alterations in COMFORT experienced from the movement of the stones or duct or gallbladder spasms. A therapeutic bile acid, such as ursodeoxycholic acid (UDCA), may be used after the procedure to help dissolve the remaining stone fragments.

Another treatment option for patients who cannot have surgery is the insertion of a percutaneous transhepatic biliary catheter (drain) using CT or ultrasound guidance to open the blocked duct(s) so bile can flow (cholecystostomy). Catheters can be placed several ways, depending on the condition of the biliary ducts, in an internal, external, or internal/external drain. Biliary catheters usually divert bile from the liver into the duodenum to bypass a stricture. When all of the bile enters the duodenum, it is called an *internal* drain. However, in some cases a patient has an *internal/external* drain in which part of the bile empties into a drainage bag. Patients who need this drain for an extended period may have the external drain capped. If jaundice or leakage around the catheter site occurs, teach the patient to reconnect the catheter to a drainage bag and have a follow-up cholangiogram injection done by an interventional radiologist. An *external*-only catheter is connected either temporarily or permanently to a drainage bag. A reduction in bile drainage indicates that the drain is no longer working.

### Surgical Management.

**Cholecystectomy** is the surgical removal of the gallbladder. One of two procedures is performed: the laparoscopic cholecystectomy and, far less often, the traditional open-approach cholecystectomy.

#### Laparoscopic Cholecystectomy.

Laparoscopic cholecystectomy, a minimally invasive surgery (MIS), is the “gold standard” and is performed far more often than the traditional open approach. The advantages of MIS when compared with the open approach include:

- Complications are not common.
- The death rate is very low.
- Bile duct injuries are rare.
- Patient recovery is quicker.
- Postoperative pain is less severe.

The laparoscopic procedure (often called a *lap chole*) is commonly done on an ambulatory-care basis in a same-day surgery suite. The surgeon explains the procedure, and the nurse answers questions and reinforces the instructions. Reinforce what to expect after surgery and review pain management, deep-breathing exercises, incisional care, and leg exercises to prevent deep vein

thrombosis. There is no special preoperative preparation other than the routine preparation for surgery under general anesthesia described in [Chapter 14](#). Evidence regarding the use of prophylactic antibiotics before a laparoscopic cholecystectomy is mixed ([Soper & Malladi, 2017](#)); check facility policy when caring for a patient who will undergo this procedure.

During the surgery the surgeon makes a very small midline puncture at the umbilicus. Additional small incisions may be needed, although single-incision laparoscopic cholecystectomy (SILC) using a flexible endoscope is often done. The abdominal cavity is insufflated with 3 to 4 liters of carbon dioxide. Gasless laparoscopic cholecystectomy using abdominal wall–lifting devices are used in some centers. This technique results in improved pulmonary and cardiac function. A trocar catheter is inserted, through which a laparoscope is introduced. The laparoscope is attached to a video camera, and the abdominal organs are viewed on a monitor. The gallbladder is dissected from the liver bed, and the cystic artery and duct are closed. The surgeon aspirates the bile and crushes any large stones, if present, and then extracts the gallbladder through the umbilical port.

Removing the gallbladder with the laparoscopic technique reduces the risk for wound complications. Some patients have mild-to-severe discomfort from carbon dioxide retention in the abdomen, which may be felt throughout the thorax and shoulders.

## Nursing Safety Priority QSEN

### Action Alert

After a laparoscopic cholecystectomy, assess the patient's oxygen saturation level frequently until the effects of the anesthesia have passed. Remind the patient to perform deep-breathing exercises every hour.

Other postoperative care for the patient after a laparoscopic procedure is similar to that for any patient having minimally invasive endoscopic surgery (see [Chapter 16](#)). Offer the patient food and water when fully awake, and monitor for the nausea and/or vomiting that often results from anesthesia. If needed, administer an antiemetic drug, such as ondansetron hydrochloride (Zofran), either IV push or as a disintegrating tablet. Several drug doses may be needed. Maintain an IV line to administer fluids until nausea and/or vomiting subside. Be sure to have the head of the bed elevated in the same-day surgery unit to prevent aspiration from vomiting. After nausea subsides, assist the patient to the bathroom to void. Early ambulation also promotes absorption of the carbon dioxide, which can decrease postoperative discomfort.

Administer an oral or IV push opioid as needed immediately after surgery. Continuous IV pain control is usually not required because there is only one or a few small incisions, which are covered with Steri-Strips and small adhesive bandages (e.g., Band-Aids) or are surgically glued. The glue or Steri-Strips lose their adhesiveness in about a week to 10 days and can be removed or fall off as the incision heals.

The patient is usually discharged from the hospital or surgery center the same day, although older and obese patients may stay overnight. Provide postoperative teaching regarding pain management, incision care, and follow-up appointments. Teach the patient to use ice and oral opioids for incisional pain, if needed, for a few days. For abdominal or thoracic discomfort from carbon dioxide retention, many patients report that heat application is helpful. The patient is typically allowed to bathe or shower the day after surgery.

After laparoscopic surgery, the patient can return to usual activities much sooner than those having an open cholecystectomy. Instruct the patient to rest for the first 24 hours and then begin to resume usual activities. Most patients are able to resume usual activities within a week.

Some patients are able to return to their usual diet after surgery, whereas others must carefully monitor their diet to avoid high-fat foods. A large intake of fatty foods may result in abdominal pain and diarrhea, which could result in a mild post-cholecystectomy syndrome (PCS) (see later discussion of PCS in the [Traditional Cholecystectomy](#) section). Teach patients to introduce foods high in fat one at a time to determine which foods are best tolerated.

A new minimally invasive surgical procedure is *natural orifice transluminal endoscopic surgery* (NOTES) for removal or repair of organs. Surgery can be performed on many body organs through the mouth, vagina, and rectum. For removal of the gallbladder, the vagina is used most often in women because it can be easily decontaminated with Betadine or other antiseptic and allows easy

access into the peritoneal cavity. The surgeon makes a small internal incision through the cul-de-sac of Douglas between the rectum and uterine wall to access the gallbladder. The main advantages of this procedure are the lack of visible incisions and minimal, if any, postoperative complications (Roberts & Kate, 2016).

### Traditional Cholecystectomy.

Use of the open surgical approach (abdominal laparotomy) has greatly declined during the past several decades. Patients who have this type of surgery usually have severe biliary obstruction, and the ducts are explored to ensure patency.

The surgical nurse provides the usual preoperative care and teaching in the operating suite on the day of surgery (see Chapter 14). The surgeon removes the gallbladder through an incision and explores the biliary ducts for the presence of stones or other cause of obstruction. The surgeon usually inserts a drainage tube such as a Jackson-Pratt (JP) drain. This tube is placed in the gallbladder bed to prevent fluid accumulation. The drainage is usually serosanguineous (serous fluid mixed with blood) and is stained with bile in the first 24 hours after surgery. Antibiotic therapy is given to prevent infection.

Patient care for a patient who has had a traditional open cholecystectomy is similar to the care for any patient who has had abdominal surgery under general anesthesia as described in Chapter 16. Postoperative incisional pain after a traditional cholecystectomy is controlled with opioids using a patient-controlled analgesia (PCA) pump. Encourage the patient to use coughing and deep-breathing exercises when pain is controlled and the incision is splinted.

Antiemetics may be necessary for episodes of postoperative nausea and vomiting. Administer the antiemetic early, as prescribed, to prevent retching associated with vomiting and thus to decrease pain related to muscle straining.

Provide care for the incision and the surgical drain. The surgeon typically removes the surgical dressing and drain within 24 hours after surgery.

The patient is NPO until fully awake after surgery. Document his or her level of consciousness, vital signs, and pain level. Assess the surgical incision for signs of infection, such as excessive redness or purulent drainage. Report changes to the surgeon immediately. Begin ambulation as soon as possible to prevent deep vein thrombosis and promote peristalsis.

Advance the diet from clear liquids to solid foods as peristalsis returns to promote enhanced NUTRITION status. The patient usually resumes solid foods and is discharged to home 1 to 2 days after surgery, depending on any complications and the patient's general condition. In the early postoperative period, if bile flow is reduced, a low-fat diet may reduce discomfort and prevent nausea. For most patients, a special diet is not required. Advise them to eat nutritious meals and avoid excessive intake of fatty foods, especially fried food, butter, and "fast food." If the patient is obese, recommend a weight-reduction program.

Teach the patient to keep the incision clean and report any changes that may indicate infection. Remind him or her to report repeated abdominal or epigastric pain with vomiting and/or diarrhea that may occur several weeks to months after surgery. These symptoms indicate possible **postcholecystectomy syndrome (PCS)**. There are multiple causes of PCS, some of which are related to the biliary system, and others are not. Common causes of PCS are listed in Table 59-2. Not all patients experience PCS. Often the pain returns because of one of the underlying conditions listed in Table 59-2, not as a result of the cholecystectomy itself.

**TABLE 59-2**  
**Common Causes of Postcholecystectomy Syndrome**

BILIARY	NONBILIARY
<ul style="list-style-type: none"> <li>• Pseudocyst</li> <li>• Common bile duct (CBD) leak</li> <li>• CBD or pancreatic duct stricture or obstruction</li> <li>• Sphincter of Oddi dysfunction</li> <li>• Retained or new CBD gallstone</li> <li>• Pancreatic or liver mass</li> <li>• Primary sclerosing cholangitis</li> <li>• Diverticular compression</li> </ul>	<ul style="list-style-type: none"> <li>• Coronary artery disease</li> <li>• Intercostal neuritis</li> <li>• Unexplained pain syndrome</li> <li>• Psychiatric or neurologic disorder</li> </ul>

Management depends on the exact cause but usually involves the use of endoscopic retrograde cholangiopancreatography (ERCP) to find the cause of the problem and repair it. This procedure and related nursing care are described in Chapter 52. Collaborative care includes pain management, antibiotics, NUTRITION and hydration therapy (possibly short-term parenteral nutrition), and control

of nausea and vomiting.

## **NCLEX Examination Challenge 59-2**

### **Physiological Integrity**

The nurse will include what postoperative teaching when caring for the client who is preparing to undergo endoscopic cholecystectomy? **Select all that apply.**

- A. "You'll have a small, midline abdominal incision."
- B. "You can't eat or drink for a few days after the procedure."
- C. "You won't be able to return to regular activity for several weeks."
- D. "Generally the pain associated with this procedure is minimal."
- E. "This procedure has a low incidence of infection."
- F. "The hospital stay after this procedure is typically 3 to 4 days."

### **Care Coordination and Transition Management**

Some patients may have uncomfortable experiences with cholecystitis that can be managed by nutrition intervention; others may require surgery and subsequent hospitalization. Home care preparation is individual, based on each patient's circumstances. Collaborate with the case manager to plan the best recovery for the patient and anticipate resources that may be needed.

Education needs to be started as soon as a patient has an initial experience with cholecystitis and has been provided appropriate pain relief. Assess the patient's and family's knowledge of the disease and provide teaching as needed. The desired outcomes for discharge planning and education are to avoid further episodes of cholecystitis. Key teaching points include reminding the patient to avoid fatty, fried, and "fast" food and to report any signs of postoperative complications to the health care provider immediately (see [Chapter 16](#)).

### **◆ Evaluation: Reflecting**

Evaluate the care of the patient with cholecystitis based on the identified priority patient problems. The expected outcomes include that the patient will:

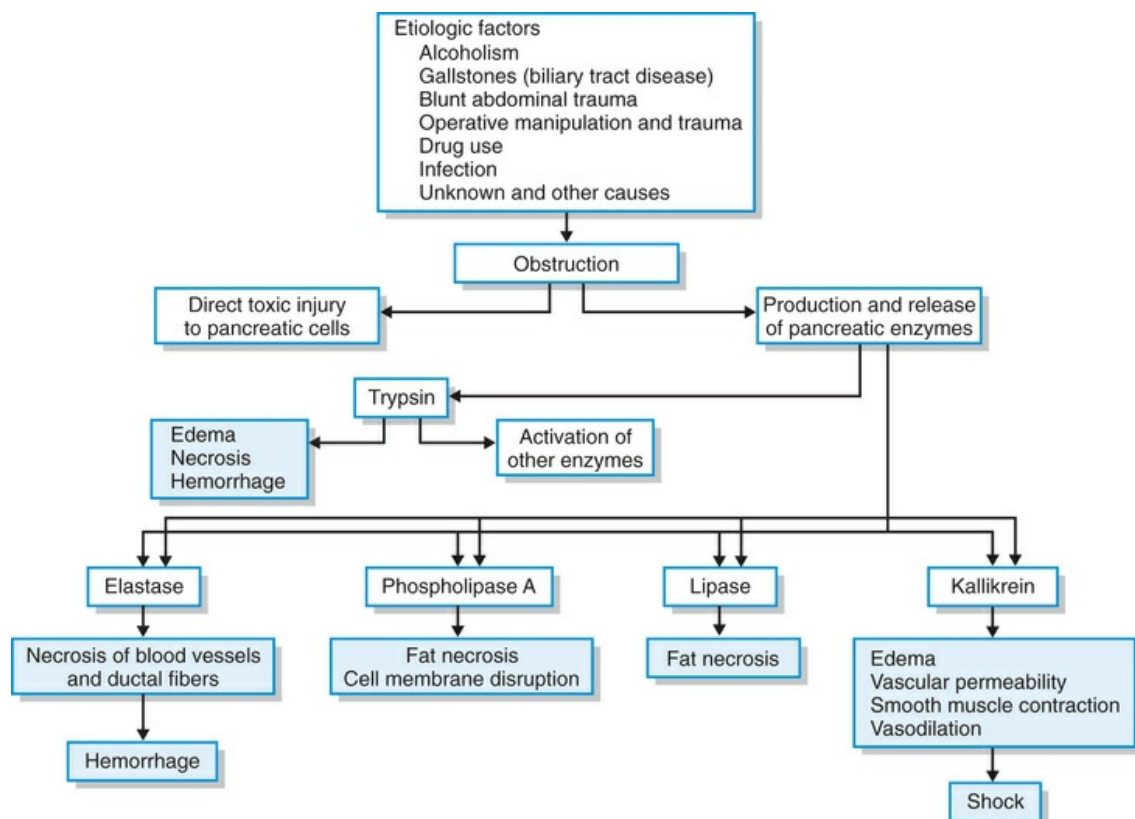

- Have adequate NUTRITION available to meet metabolic needs
- Report control of abdominal pain, as indicated by self-report and pain scale measurement

## Immunity Concept Exemplar Acute Pancreatitis

### Pathophysiology

**Acute pancreatitis** is a serious and, at times, life-threatening inflammation of the pancreas. This process, which affects the body's IMMUNITY, is caused by a premature activation of excessive pancreatic enzymes that destroy ductal tissue and pancreatic cells, resulting in autodigestion and fibrosis of the pancreas. The pathologic changes occur in different degrees. The severity of pancreatitis depends on the extent of inflammation and tissue damage. Pancreatitis can range from mild involvement evidenced by edema and inflammation to **necrotizing hemorrhagic pancreatitis (NHP)**. NHP is diffusely bleeding pancreatic tissue with fibrosis and tissue death.

The pancreas is unusual in that it functions as both an exocrine gland and an endocrine gland. The primary *endocrine* disorder is diabetes mellitus and is discussed in [Chapter 64](#). The *exocrine* function of the pancreas is responsible for secreting enzymes that assist in the breakdown of starches, proteins, and fats. These enzymes are normally secreted in the inactive form and become activated once they enter the small intestine. Early activation (i.e., activation within the pancreas rather than the intestinal lumen) results in the inflammatory process of pancreatitis. Direct toxic injury to the pancreatic cells and the production and release of pancreatic enzymes (e.g., trypsin, lipase, elastase) result from the obstructive damage. After pancreatic duct obstruction, increased pressure may contribute to ductal rupture, allowing spillage of trypsin and other enzymes into the pancreatic parenchymal tissue. Autodigestion of the pancreas occurs as a result ([Fig. 59-2](#)). In *acute* pancreatitis, four major pathophysiologic processes occur: lipolysis, proteolysis, necrosis of blood vessels, and inflammation, all of which impact the body's IMMUNITY.

**FIG. 59-2** The process of autodigestion in acute pancreatitis.

The hallmark of pancreatic necrosis is enzymatic fat necrosis of the endocrine and exocrine cells of the pancreas caused by the enzyme *lipase*. Fatty acids are released during this *lipolytic process* and combine with ionized calcium to form a soaplike product. The initial rapid lowering of serum calcium levels is not readily compensated for by the parathyroid gland. Because the body needs

ionized calcium and cannot use bound calcium, hypocalcemia occurs (McCance et al., 2014).

*Proteolysis* involves the splitting of proteins by hydrolysis of the peptide bonds, resulting in the formation of smaller polypeptides. Proteolytic activity may lead to thrombosis and gangrene of the pancreas. Pancreatic destruction may be localized and confined to one area or may involve the entire organ.

Elastase is activated by trypsin and causes elastic fibers of the blood vessels and ducts to dissolve. The *necrosis of blood vessels* results in bleeding, ranging from minor bleeding to massive hemorrhage of pancreatic tissue. Another pancreatic enzyme, kallikrein, causes the release of vasoactive peptides, bradykinin, and a plasma kinin known as *kallidin*. These substances contribute to vasodilation and increased vascular permeability, further compounding the hemorrhagic process. This massive destruction of blood vessels by necrosis may lead to generalized hemorrhage, with blood escaping into the retroperitoneal tissues. *The ultimate impact to a patient's IMMUNITY occurs in the presence of hemorrhagic pancreatitis. The patient with this disorder is critically ill, and extensive pancreatic destruction and shock may lead to death. The majority of deaths in patients with acute pancreatitis result from irreversible shock.*

The *inflammatory stage* occurs when leukocytes cluster around the hemorrhagic and necrotic areas of the pancreas. A secondary bacterial process may lead to suppuration (pus formation) of the pancreatic parenchyma or the formation of an abscess. (See the following discussion of [Pancreatic Abscess](#).) Mild infected lesions may be absorbed. When infected lesions are severe, calcification and fibrosis occur. If the infected fluid becomes walled off by fibrous tissue, a pancreatic pseudocyst is formed. (See the following discussion of [Pancreatic Pseudocyst](#).)

## Complications of Acute Pancreatitis

Acute pancreatitis may result in severe, life-threatening complications ([Table 59-3](#)) that affect the body's ability to protect itself via its IMMUNITY. Jaundice occurs from swelling of the head of the pancreas, which slows bile flow through the common bile duct. The bile duct may also be compressed by calculi (stones) or a pancreatic pseudocyst. The resulting total bile flow obstruction causes severe jaundice. Intermittent hyperglycemia occurs from the release of glucagon, as well as the decreased release of insulin due to damage to the pancreatic islet cells. Total destruction of the pancreas may occur, leading to type 1 diabetes mellitus (McCance et al., 2014).

---

**TABLE 59-3**

### Potential Complications of Acute Pancreatitis

---

- |  |
|--|
| <ul style="list-style-type: none"><li>• Pancreatic infection (causes septic shock)</li><li>• Hemorrhage (necrotizing hemorrhagic pancreatitis [NHP])</li><li>• Acute kidney failure</li><li>• Paralytic ileus</li><li>• Hypovolemic shock</li><li>• Pleural effusion</li><li>• Acute respiratory distress syndrome (ARDS)</li><li>• Atelectasis</li><li>• Pneumonia</li><li>• Multi-organ system failure</li><li>• Disseminated intravascular coagulation (DIC)</li><li>• Type 2 diabetes mellitus</li></ul> |
|--|

Left lung pleural effusions frequently develop in the patient with acute pancreatitis. *Atelectasis and pneumonia may occur also, especially in older patients.*

Multi-system organ failure is caused by necrotizing hemorrhagic pancreatitis (NHP). The patient is at risk for acute respiratory distress syndrome (ARDS). This severe form of pulmonary edema is caused by disruption of the alveolar-capillary membrane and is a serious complication of acute pancreatitis. (See [Chapter 32](#) for a discussion of ARDS.) In acute pancreatitis, pulmonary failure accounts for more than half of all deaths that occur in the first week of the disease.

Coagulation defects are another major potential complication and may result in death. Complex physiologic changes in the pancreas cause the release of necrotic tissue and enzymes into the bloodstream, resulting in altered coagulation. Disseminated intravascular coagulation (DIC) involves hypercoagulation of the blood, with consumption of clotting factors and the development of microthrombi.

Shock in acute pancreatitis results from peripheral vasodilation from the released vasoactive substances and the retroperitoneal loss of protein-rich fluid from proteolytic digestion. Hypovolemia may result in decreased renal perfusion and acute renal failure. Paralytic (adynamic) ileus results from peritoneal irritation and seepage of pancreatic enzymes into the abdominal cavity.

## NCLEX Examination Challenge 59-3

### Physiological Integrity

The nurse closely monitors the client with acute pancreatitis for which life-threatening complication?

- A. Jaundice
- B. Type I diabetes mellitus
- C. Abdominal pain
- D. Disseminated intravascular coagulation (DIC)

### Etiology and Genetic Risk

In many cases the cause of pancreatitis is not known, but many factors can injure the pancreas. The most common cause is biliary tract disease, with gallstones accounting for almost half of the cases of obstructive pancreatitis (McCance et al., 2014). Acute pancreatitis may occur as a result of trauma from surgical manipulation after biliary tract, pancreatic, gastric, and duodenal procedures, such as cholecystectomy, the Whipple procedure, and partial gastrectomy. The trauma may also occur as a complication of the diagnostic procedure *endoscopic retrograde cholangiopancreatography (ERCP)*, although this rarely occurs.

Other causative factors include:

- Trauma: external (blunt trauma, stab wounds, gunshot wounds [GSWs])
- Pancreatic obstruction: tumors, cysts, or abscesses; abnormal organ structure
- Metabolic disturbances: hyperlipidemia, hyperparathyroidism, or hypercalcemia
- Renal disturbances: failure or transplantation
- Familial, inherited pancreatitis
- Penetrating gastric or duodenal ulcers, resulting in peritonitis
- Viral infections such as coxsackievirus B and human immune deficiency virus [HIV] infection
- Alcoholism
- Toxicities of drugs, including opiates, sulfonamides, thiazides, steroids, and oral contraceptives (less common)
- Cigarette smoking
- Cystic fibrosis
- Gallstones
- Abdominal surgery

### Incidence and Prevalence

Pancreatic “attacks” are especially common during holidays and vacations when alcohol consumption may be high, especially in men. Women are affected most often after cholelithiasis and biliary tract problems. They are also most at risk for pancreatitis within several months after childbirth.

Death occurs in a small percentage of patients with acute pancreatitis, but with early diagnosis and treatment, mortality can be reduced. It occurs at a higher rate in *older adults* and in patients with postoperative pancreatitis. The prognosis for recovery is usually good for pancreatitis associated with biliary tract disease and poor if pancreatitis accompanies alcoholism.

### Interprofessional Collaborative Care

Care for the patient with acute pancreatitis usually takes place in the hospital setting for pain control and possible surgical intervention. Members of the interprofessional team who collaborate most closely to care for the patient with acute pancreatitis include the health care provider, surgeon

if surgery is required, nurse, and dietitian.

### ◆ **Assessment: Noticing**

#### **History.**

Most often the patient reports severe and constant abdominal pain. Conduct the interview *after pain is controlled*. Ask whether the abdominal pain occurs when drinking alcohol or eating a high-fat meal. Obtain information about alcohol usage, including the amount of alcohol consumed during what period of time (i.e., years of consumption, how much usually consumed over a particular period). Question the patient about a family or personal history of alcoholism, pancreatitis, trauma, or biliary tract disease. Ask whether any abdominal surgical interventions such as cholecystectomy, or diagnostic procedures such as ERCP, have been performed recently.

Ask about other medical problems known to cause pancreatitis, including peptic ulcer disease, renal failure, vascular disorders, hyperparathyroidism, and hyperlipidemia. Inquire about recent viral infections. Ask the patient or family member to list all prescription and over-the-counter (OTC) drugs taken recently, including nutritional and herbal supplements.

#### **Physical Assessment/Signs and Symptoms.**

The diagnosis of pancreatitis is made based on the clinical presentation combined with the results of diagnostic studies, both laboratory and imaging assessments. Symptoms of acute pancreatitis vary widely and depend on the severity of the inflammation. Typically, a patient is diagnosed after presenting with severe abdominal pain in the mid-epigastric area or left upper quadrant. Assess the intensity and quality of pain. The patient often states that the pain had a sudden onset and radiates to the back, left flank, or left shoulder. The pain is described as intense, **boring** (feeling that it is going through the body), and continuous and is worsened by lying in the supine position. Often the patient finds relief by assuming the fetal position (with the knees drawn up to the chest and the spine flexed) or by sitting upright and bending forward. He or she may report weight loss resulting from nausea and vomiting. Obtain the patient's weight.

When performing an abdominal assessment, inspect for:

- Generalized jaundice
- Gray-blue discoloration of the abdomen and periumbilical area
- Gray-blue discoloration of the flanks, caused by pancreatic enzyme leakage to cutaneous tissue from the peritoneal cavity

Listen for bowel sounds; absent or decreased bowel sounds usually indicate paralytic (adynamic) ileus. On light palpation, note abdominal tenderness, rigidity, and guarding as a result of peritonitis. A palpable mass may be found if a pancreatic pseudocyst is present. Pancreatic ascites creates a dull sound on percussion.

Monitor and record vital signs frequently to assess for elevated temperature, tachycardia, and decreased blood pressure or delegate and closely supervise this activity. Respiratory problems, such as left lung pleural effusions, atelectasis, and pneumonia, are common in patients with acute pancreatitis. Auscultate the lung fields for adventitious sounds or diminished breath sounds and observe for dyspnea or orthopnea.

### **Nursing Safety Priority** QSEN

#### **Critical Rescue**

For the patient with acute pancreatitis, monitor for significant changes in vital signs that may indicate the life-threatening complication of shock. Hypotension and tachycardia may result from pancreatic hemorrhage, excessive fluid volume shifting, or the toxic effects of abdominal sepsis from enzyme damage. Observe for changes in behavior and level of consciousness (LOC) that may be related to alcohol withdrawal, hypoxia, or impending sepsis with shock.

#### **Psychosocial Assessment.**

If excessive alcohol is a causative factor, tactfully explore the patient's alcohol intake history.

Provide patient privacy and establish a trusting relationship. Discuss the intake of alcohol and the reasons for overindulging. Using the CAGE questionnaire to assist with determining alcohol use may be beneficial. Ask the patient when increased drinking episodes occur and, in particular, whether binges occur during holidays, vacations, or weekends or revolve around particular activities, such as television viewing. Question him or her about any recent traumatic or stressful event that may have contributed to increased alcohol consumption, such as the death of a family member or a job loss.

### Laboratory Assessment.

Diagnostic laboratory abnormalities are typical in patients with acute pancreatitis (Table 59-4). A variety of pancreatic and nonpancreatic disorders can cause increased serum amylase levels. In patients with pancreatitis, *amylase* levels usually increase within 12 to 24 hours and remain elevated for 2 to 3 days. Persistent elevations may be an indicator of duct obstruction or pancreatic duct leak (Pagana et al., 2017).

**TABLE 59-4**  
**Causes of Diagnostic Laboratory Abnormalities in Acute Pancreatitis**

ABNORMAL FINDING	CAUSE
<b>Cardinal Diagnostic Tests</b>	
Increased serum amylase	Pancreatic cell injury
Elevated serum lipase	Pancreatic cell injury
Elevated serum trypsin	Pancreatic cell injury
Elevated serum elastase	Pancreatic cell injury
<b>Other Diagnostic Tests</b>	
Elevated serum glucose	Pancreatic cell injury, resulting in impaired carbohydrate metabolism; decreased insulin release
Decreased serum calcium and magnesium	Fatty acids combined with calcium; seen in fat necrosis
Elevated bilirubin	Hepatobiliary obstructive process
Elevated alanine aminotransferase (ALT)	Hepatobiliary involvement
Elevated aspartate aminotransferase (AST)	Hepatobiliary involvement
Elevated leukocyte count	Inflammatory response

*Lipase* also helps determine the presence of acute pancreatitis. Serum levels may rise later than amylase and remain elevated for up to 2 weeks. Because these levels stay elevated for such a long time, the health care provider may find this test useful in diagnosing patients who are not examined until several days after the initial onset of symptoms. An increase in lipase and amylase in the urine is also expected (Pagana et al., 2017).

If pancreatitis is accompanied by biliary dysfunction (biliary pancreatitis), serum *bilirubin* and *alkaline phosphatase* levels are usually elevated. A sensitive indicator of biliary obstruction in acute pancreatitis is serum *alanine aminotransferase (ALT)*. A threefold or greater rise in concentration indicates that the diagnosis of acute biliary pancreatitis is valid. Elevated *white blood cell (WBC) count and differential*, *erythrocyte sedimentation rate (ESR)*, and serum *glucose* levels are also common in acute pancreatitis. The levels often correlate with disease severity.

Decreased serum *calcium* and *magnesium* levels are seen with fat necrosis. Calcium levels may fall and remain decreased for 7 to 10 days. Those that consistently remain below 8 mg/dL are associated with a poor prognosis. Other tests include the basic metabolic panel (BMP), complete blood count (CBC), triglycerides, serum total protein, and albumin. The blood urea nitrogen (BUN), serum glucose, and triglycerides are usually elevated. Hemoconcentration is common as a result of third-space fluid loss. Leukocytosis (elevated WBCs) and thrombocytopenia (decreased platelets) are common. Albumin levels are decreased because cytokines (e.g., tumor necrosis factor [TNF]) released as part of the inflammatory response allow it to move from the bloodstream into the extravascular space. The presence of C-reactive protein suggests possible pancreatic inflammation and necrosis.

### Imaging Assessment.

Abdominal ultrasound is the most sensitive test to diagnose causes of pancreatitis, such as gallstones, and can be performed at the bedside. However, it is not helpful in viewing the pancreas because of overlying bowel gas. Therefore *contrast-enhanced CT* provides a more reliable image and diagnosis of acute pancreatitis. This noninvasive technique may also be used to rule out pancreatic pseudocyst or ductal calculi.

An abdominal x-ray may also reveal gallstones. A chest x-ray may show elevation of the left side of the diaphragm or pleural effusion. Pancreatic stones are best diagnosed through ERCP.

### ◆Analysis: Interpreting

The priority collaborative problems for patients with acute pancreatitis include:

1. Acute pain due to pancreatic inflammation and enzyme leakage
2. Weight loss due to inability to ingest food and absorb nutrients

### ◆Planning and Implementation: Responding

#### Managing Acute Pain

##### Planning: Expected Outcomes.

The patient with acute pancreatitis is expected to state that he or she has a decrease in or absence of abdominal pain, as evidenced by a pain intensity scale measurement.

##### Interventions.

The priorities for patient care are to provide supportive care by relieving symptoms, to decrease inflammation, and to anticipate or treat complications. *As for any patient, continually assess for and support the ABCs (airway, breathing, and circulation).* In collaboration with the respiratory therapist, if available, provide oxygen and other respiratory support as needed. The collaborative plan of care depends on the severity of the illness.

*Abdominal pain is the most common symptom of pancreatitis.* The main focus of nursing care is aimed at controlling pain by interventions that decrease GI tract activity, thus decreasing pancreatic stimulation. Pain assessment to measure the effectiveness of these interventions is an essential part of nursing care.

##### Nonsurgical Management.

*Mild* pancreatitis requires hydration with IV fluids, pain control, and drug therapy. The health care team initially attempts to relieve pain with nonsurgical interventions, which include fasting and rest, drug therapy, and COMFORT measures. If the patient has a life-threatening complication or requires frequent assessment, he or she is admitted to a critical care unit for invasive hemodynamic monitoring.

To rest the pancreas and reduce pancreatic enzyme secretion, withhold food and fluids (NPO) during the acute period. The health care provider prescribes IV isotonic fluid administration to maintain hydration. IV replacement of calcium and magnesium may also be needed. Measure and document intake and output. Some patients have an indwelling urinary catheter to obtain accurate measurements.

Nasogastric drainage and suction are reserved for more *severely ill* patients who have continuous vomiting or biliary obstruction. Gastric decompression using a nasogastric tube (NGT) prevents gastric juices from flowing into the duodenum.

## ■Nursing Safety Priority QSEN

### Action Alert

Because paralytic (adynamic) ileus is a common complication of acute pancreatitis, prolonged nasogastric intubation may be necessary. Assess frequently for the return of peristalsis by asking the patient if he or she has passed flatus or had a stool. The return of bowel sounds is not reliable as an indicator of peristalsis return; passage of flatus or a bowel movement is the most reliable indicator. See the discussion of intestinal obstructions in Chapter 56.

To decrease pain, the primary drug class used is opioid. Other drugs may also be prescribed. Pain management for acute pancreatitis typically begins with the administration of opioids by patient-controlled analgesia (PCA). Drugs such as morphine or hydromorphone (Dilaudid) are typically used because meperidine (Demerol) can cause seizures, especially in older adults. Other options that have been used successfully to manage acute pain include IV or transdermal fentanyl and epidural analgesia.

In *mild* pancreatitis, the pain usually subsides in 2 to 3 days. However, with *severe* acute pancreatitis, the abdominal pain and tenderness may persist for up to 2 weeks. Drug dosages and intervals are individualized according to the severity of the disease and the symptoms.

Histamine receptor antagonists (e.g., ranitidine [Zantac]) and proton pump inhibitors (e.g., omeprazole [Prilosec]) help decrease gastric acid secretion. Antibiotics may be used, but they are indicated primarily for patients with acute necrotizing pancreatitis. The health care provider will prescribe appropriate antibiotics, if needed.

Helping the patient assume a side-lying position (with the legs drawn up to the chest) may decrease the abdominal pain of pancreatitis (“fetal position”). Sitting with the knees flexed toward the chest is also helpful.

If the patient is NPO or has an NGT, remind assistive nursing personnel to implement frequent oral and nares hygiene measures to keep mucous membranes moist and free of inflammation or crusting. Because of the drying effect of drugs and the absence of oral fluids, the mouth and oral cavity may be extremely dry, resulting in considerable discomfort and possibly parotitis (inflammation of the parotid [salivary] glands).

## Nursing Safety Priority QSEN

### Action Alert

For the patient with acute pancreatitis, monitor his or her respiratory status every 4 to 8 hours or more often as needed and provide oxygen to promote comfort in breathing. Respiratory complications such as pleural effusions increase patient discomfort. Fluid overload can be detected by assessing for weight gain, listening for crackles, and observing for dyspnea. Carefully monitor for signs of respiratory failure.

Observe for signs and symptoms of hypocalcemia by assessing for Chvostek's and Trousseau's signs. These tests cause muscle spasms after stimulating the associated nerves. [Chapter 11](#) discusses assessment and care of patients with hypocalcemia in more detail.

Lowering the patient's anxiety level may also substantially reduce pain. Explain all procedures and other aspects of patient care thoroughly. Provide reassurance, offer diversional activities such as music and reading material, and encourage visitors to direct attention away from the pain.

If pancreatitis was caused by gallstones, an ERCP with a [sphincterotomy](#) (opening of the sphincter of Oddi) may be performed on an urgent or emergent basis. If this procedure is not successful, surgery is required. ERCP is described in detail in [Chapter 52](#).

### Surgical Management.

Surgical intervention for acute pancreatitis is usually not indicated. However, if an ERCP is not successful in removing gallstones, a laparoscopic cholecystectomy may be performed as described in the Surgical Management discussion in the Cholecystitis section.

Complications of pancreatitis, such as pancreatic pseudocyst and abscess, may also require surgical intervention. Laparoscopy (minimally invasive surgery [MIS]) may be done to drain an abscess or pseudocyst. For patients who are high surgical risks, pseudocysts or abscesses can be treated by percutaneous drainage under CT guidance.

### Promoting Nutrition

#### Planning: Expected Outcomes.

The patient with acute pancreatitis is expected to have adequate NUTRITION to meet his or her metabolic needs.

#### Interventions.

The patient is maintained on NPO status in the early stages of pancreatitis. Antiemetics for nausea and vomiting are prescribed as needed. Patients who have severe pancreatitis and are unable to eat for 24 to 48 hours after illness onset may begin jejunal tube feeding unless paralytic ileus is present. *Early* NUTRITION intervention enhances immune system functioning and may prevent complications and worsening inflammation. Enteral feeding is preferred over total parenteral nutrition (TPN)

because it causes fewer episodes of glucose elevation and other complications associated with TPN. Be sure that the patient is weighed every day. Collaborate with the health care provider, dietitian, and pharmacist to plan and implement the most appropriate nutritional intervention. [Chapter 60](#) describes collaborative care of patients receiving enteral feeding and TPN.

When food is tolerated during the healing phase, the health care provider prescribes small, frequent, moderate- to high-carbohydrate, high-protein, low-fat meals. Food should be bland with little spice. GI stimulants such as caffeine-containing food (tea, coffee, cola, and chocolate), as well as alcohol, should be avoided. Monitor the patient beginning to resume oral food intake for nausea, vomiting, and diarrhea. *If any of these symptoms occur, notify the health care provider immediately.*

To boost caloric intake, commercial liquid nutritional preparations supplement the diet. The health care provider may also prescribe fat-soluble and other vitamin and mineral replacement supplements. Glutamine, omega-3 fatty acids, fiber, antioxidants, and/or nucleotides may be added to the patient's nutrition plan.

## Care Coordination and Transition Management

### Home Care Management.

Home care preparation is individualized for each patient's circumstances. Some patients may be severely weakened from their acute illness and need to confine activity to one floor, limiting stair climbing and other strenuous activities until they regain their strength. Collaborate with the case manager to plan the best place for the patient to recover and resources that may be needed.

### Self-Management Education.

Education needs to be started early in the hospitalization period—as soon as the acute episodes of pain have subsided. Assess the patient's and family's knowledge of the disease.

The desired outcomes for discharge planning and education are to avoid further episodes of pancreatitis and prevent progression to a chronic disease. If the patient uses alcohol, instruct him or her to abstain from drinking to prevent further pain attacks and extension of inflammation and pancreatic insufficiency. Tell the patient that, if alcohol is consumed, acute pain will return, and further autodigestion of the pancreas may lead to chronic pancreatitis.

Teach the patient to notify the health care provider after discharge to home if acute abdominal pain or biliary tract disease (as evidenced by jaundice, clay-colored stools, or darkened urine) occurs. These signs and symptoms are possible indicators of complications or disease progression.

### Health Care Resources.

Patients with acute pancreatitis may require several visits by a home care nurse if the hospital course was complicated. In these cases, home care may be needed for wound care and assistance with ADLs. The patient requires medical follow-up with the primary care provider to monitor the disease process. For those with alcoholism, provide information about groups such as Alcoholics Anonymous (AA). Family members may attend support groups such as Al-Anon and Alateen.

### ◆ Evaluation: Reflecting

Evaluate the care of the patient with acute pancreatitis based on the identified priority patient problems. The expected outcomes include that the patient will:

- Have control of abdominal pain, as indicated by self-report and pain scale measurement
- Have adequate NUTRITION available to meet metabolic needs

# Chronic Pancreatitis

## ❖ Pathophysiology

**Chronic pancreatitis** is a progressive, destructive disease of the pancreas that has remissions and exacerbations (“flare-ups”). Inflammation and fibrosis of the tissue contribute to pancreatic insufficiency and diminished function of the organ.

Chronic pancreatitis can be classified into several categories. *Alcoholism* is the primary risk factor for **chronic calcifying pancreatitis (CCP)**, the most common type. In the early stages of the disease, pancreatic secretions precipitate as insoluble proteins that plug the pancreatic ducts and flow of pancreatic juices. As the protein plugs become more widespread, the cellular lining of the ducts changes and ulcerates. This inflammatory process causes fibrosis of the pancreatic tissue.

Intraductal calcification and marked pancreatic tissue destruction (necrosis) develop in the late stages. The organ becomes hard and firm as a result of cell atrophy and pancreatic insufficiency.

Chronic calcifying pancreatitis is found predominantly in men, but the incidence in women is increasing. In women, chronic pancreatitis occurs more commonly among those with biliary tract disease (cholecystitis and cholelithiasis).

**Chronic obstructive pancreatitis** develops from inflammation, spasm, and obstruction of the sphincter of Oddi, often from cholelithiasis (gallstones). Inflammatory and sclerotic lesions occur in the head of the pancreas and around the ducts, causing an obstruction and backflow of pancreatic secretions. (See the [Complications of Acute Pancreatitis](#) section.)

**Autoimmune pancreatitis** is a chronic inflammatory process in which immunoglobulins invade the pancreas. Other organs may also be infiltrated, including the lungs and liver. There is evidence to show that autoimmune pancreatitis puts the patient at risk for pancreatic cancer ([Kawa et al., 2013](#)).

**Idiopathic** and **hereditary chronic pancreatitis** may be associated with *SPINK1* and *CFTR* gene mutations and with mutations in the *BRCA2* gene. Individuals with hereditary pancreatitis have been shown to have a 53-fold increased risk of pancreatic cancer ([Klein, 2012](#)).

The protein encoded by the *SPINK1* gene is a trypsin inhibitor. The *CFTR* gene is associated with cystic fibrosis. Research on these gene mutations can help develop targeted drug therapy for treatment of these diseases.

Pancreatic insufficiency in any type of chronic pancreatitis causes loss of *exocrine* function. Most patients with chronic pancreatitis have decreased pancreatic secretions and bicarbonate. Pancreatic enzyme secretion must be greatly reduced to produce steatorrhea resulting from severe malabsorption of fats. These characteristic stools are pale, bulky, and frothy and have an offensive odor. The action of colonic bacteria on unabsorbed lipids and proteins is responsible for the extremely foul odor. On inspection of the stools, the fat content is visible. In severe chronic pancreatitis, stool fat output may be more than 40 g/day.

Fat malabsorption also contributes to weight loss and muscle wasting (a decrease in muscle mass) and leads to general debilitation. Protein malabsorption results in a “starvation” edema of the feet, legs, and hands caused by decreased levels of circulating albumin.

The loss of pancreatic *endocrine* function is responsible for the development of diabetes mellitus in patients with chronic pancreatic insufficiency. (See [Chapter 64](#) for a complete discussion of diabetes mellitus.)

The patient with chronic pancreatitis may have pulmonary complications, such as pleuritic pain, pleural effusions, and pulmonary infiltrates. Pancreatic ascites may decrease diaphragmatic excursion and lung expansion, resulting in impaired ventilation. In the ill patient with chronic pancreatitis, acute respiratory distress syndrome (ARDS) may develop.

## ❖ Interprofessional Collaborative Care

Care for the patient with chronic pancreatitis takes place in the home or community setting but moves to the hospital setting for pain control and possible surgical intervention. Members of the interprofessional team who collaborate most closely to care for the patient with chronic pancreatitis include the health care provider, surgeon if surgery is required, nurse, and dietitian.

## ◆ Assessment: Noticing

Many symptoms of chronic pancreatitis differ from those of an acute inflammation. Abdominal pain is the major symptom for most types of pancreatitis (Chart 59-2). For those with chronic pancreatitis, pain is typically described as a continuous burning or gnawing dullness with periods of acute exacerbation (flare-ups). The pain is very intense and relentless. The frequency of acute exacerbations may increase as the pancreatic fibrosis develops.

#### Chart 59-2

### Key Features

#### Chronic Pancreatitis

- Intense abdominal pain, a major symptom, that is continuous and burning or gnawing
- Abdominal tenderness
- Ascites
- Possible left upper quadrant mass (if pseudocyst or abscess is present)
- Respiratory compromise manifested by adventitious or diminished breath sounds, dyspnea, or orthopnea
- Steatorrhea; clay-colored stools
- Weight loss
- Jaundice
- Dark urine
- Polyuria, polydipsia, polyphagia (diabetes mellitus)

Perform an abdominal assessment. Abdominal tenderness is less intense in patients with chronic pancreatitis than in those with acute pancreatitis. A mass may be palpated in the left upper quadrant, which may suggest a pancreatic pseudocyst or abscess. Massive pancreatic ascites may be present, producing dullness on abdominal percussion. Because respiratory complications can occur, auscultate the lung fields for adventitious sounds or decreased aeration and observe for dyspnea or orthopnea.

Ask the patient to collect a random stool specimen if able or ask him or her to describe the stools. The specimen may show **steatorrhea** (foul-smelling fatty stools that may increase in volume as pancreatic insufficiency progresses and lipase production decreases). Assess for unintentional weight loss; muscle wasting; jaundice; dark urine; and the symptoms of diabetes mellitus, such as polyuria (increased urinary output), polydipsia (excessive thirst), and polyphagia (increased appetite).

Diagnosis is based on the patient's symptoms and laboratory and imaging assessment. *Endoscopic retrograde cholangiopancreatography* (ERCP) is done to visualize the pancreatic and common bile ducts. *Imaging studies* such as CT scanning, contrast-enhanced MRI, abdominal ultrasound (US), and endoscopic ultrasound (EUS) are also useful in making the diagnosis. In chronic pancreatitis, laboratory findings include normal or moderately elevated serum *amylase* and *lipase* levels. Obstruction of the intrahepatic bile duct can cause elevated serum *bilirubin* and *alkaline phosphatase* levels. Intermittent elevations in serum *glucose* levels are common and can be detected by blood glucose monitoring, both fasting and nonfasting.

#### ◆ Interventions: Responding

The focuses of caring for the patient with chronic pancreatitis are to manage pain, assist in maintaining sufficient NUTRITION, and prevent recurrence.

## Nonsurgical Management.

Nonsurgical interventions include drug and NUTRITION therapy. The major intervention for the pain of chronic pancreatitis is drug therapy. Medicate the patient as prescribed according to the assessment of the intensity of pain. Evaluate the effectiveness of the drug intervention. Initially opioid analgesia is used most frequently, but dependency may occur. Nonopioid analgesics may be tried to relieve pain. (See [Chapter 4](#) for other interventions for chronic pain.)

Pancreatic-enzyme replacement therapy (PERT) is the standard of care to prevent malnutrition, malabsorption, and excessive weight loss ([Chart 59-3](#)). Pancrelipase is usually prescribed in capsule or tablet form and contains varying amounts of amylase, lipase, and protease. Teach patients not to chew or crush pancrelipase delayed-release capsules (Creon) or enteric tablets and teach them to take the medications with all meals and snacks.

### Chart 59-3

## Patient and Family Education: Preparing for Self-Management

### Enzyme Replacement for the Patient With Chronic Pancreatitis

- Take pancreatic enzymes with meals and snacks and follow with a glass of water.
- Administer enzymes after antacid or H<sub>2</sub> blockers. (Decreased pH inactivates drug.)
- Swallow the tablets or capsules without chewing to minimize oral irritation and allow the drug to be released slowly.
- If you cannot swallow the capsule, pierce the gelatin casing and place contents in applesauce.
- Do not mix enzyme preparations in protein-containing foods.
- Wipe your lips after taking enzymes to avoid skin irritation.
- Do not crush enteric-coated preparations.
- Follow up on all scheduled laboratory testing. (Pancrelipase can cause an increase in uric acid levels.)

The dosage of pancreatic enzymes depends on the severity of the malabsorption. Record the number and consistency of stools per day to monitor the effectiveness of enzyme therapy. If pancreatic enzyme treatment is effective, the stools should become less frequent and less fatty.

### Nursing Safety Priority QSEN

#### Action Alert

If the patient has diabetes, insulin or oral antidiabetic agents for glucose control are prescribed. Patients maintained on total parenteral nutrition (TPN) are particularly susceptible to elevated glucose levels and require regular insulin additives to the solution. Monitor blood glucose to control hyperglycemia. Check fingerstick blood glucose (FSBG) or sugar (FSBS) levels every 2 to 4 hours. [Chapter 60](#) describes in detail the care associated with TPN.

The health care provider may also prescribe drug therapy to decrease gastric acid. Gastric acid destroys the lipase needed to break down fats. Controlling the acidity of the stomach with H<sub>2</sub> blockers or proton pump inhibitors or neutralizing stomach acid with oral sodium bicarbonate may enhance the effectiveness of PERT.

Protein and fat malabsorption result in significant weight loss and decreased muscle mass in the

patient with chronic pancreatitis. Therefore the nutritional interventions for acute pancreatitis are also used for chronic pancreatitis. The patient often limits food intake to avoid increased pain. For this reason, nutrition maintenance is often difficult to achieve. Patients receive either total parenteral nutrition (TPN) or total enteral nutrition (TEN), including vitamin and mineral replacement.

Collaborate with the dietitian to teach the patient about long-term dietary management. He or she needs an increased number of calories, up to 4000 to 6000 calories/day, to maintain weight. Food high in carbohydrates and protein also assists in the healing process. Food high in fat is avoided because it causes or increases diarrhea. Teach all patients to avoid alcohol. Alcohol-cessation programs may be recommended.

### **Surgical Management.**

Surgery is not a primary intervention for the treatment of chronic pancreatitis. However, it may be indicated for ongoing abdominal pain, incapacitating relapses of pain, or complications such as abscesses and pseudocysts.

The underlying pathologic changes determine the procedure indicated. Using laparoscopy, the surgeon incises and drains an abscess or pseudocyst. Laparoscopic cholecystectomy or choledochotomy (incision of the common bile duct) may be indicated if biliary tract disease is an underlying cause of pancreatitis. If the pancreatic duct sphincter is fibrotic, the surgeon performs a sphincterotomy (incision of the sphincter) to enlarge it. Endoscopic sphincterotomy may be used for patients who are poor surgical candidates.

In some cases laparoscopic distal pancreatectomy may be appropriate for resection of the distal pancreas or pancreas head. Endoscopic pancreatic necrosectomy and natural orifice transluminal endoscopic surgery (NOTES) are becoming more common for removing necrosed pancreatic tissue. Both procedures are performed through the GI wall without a visible skin incision. The NOTES procedure is discussed in Surgical Management in the Cholecystitis section.

In a few cases, pancreas transplantation may be done. However, this procedure is performed most often for patients with severe, uncontrolled diabetes. [Chapter 64](#) discusses pancreas transplantation.

## **Care Coordination and Transition Management**

### **Home Care Management.**

Collaborate with the hospital-based case manager (CM) or discharge planner about home care or follow-up in another setting. A community-based CM may continue to follow the patient after hospital discharge. If the patient is discharged to home, the living area should be limited to one floor until he or she regains strength and can increase activity. Teach patients and families that toilet facilities must be easily accessible because of chronic steatorrhea and frequent defecation. If they are not easily accessible, a bedside commode is obtained for the home.

### **Self-Management Education.**

Because there is no known cure for chronic pancreatitis, patient and family education is aimed at preventing acute episodes of the disease, providing long-term care, and promoting health maintenance ([Chart 59-4](#)). Teach the patient to avoid known irritating substances, such as caffeinated beverages (stimulates the GI system) and alcohol. Collaborate with the dietitian in diet teaching, which focuses on eating bland, low-fat, frequent meals and avoiding rich, fatty foods. Stress the importance of adhering to the nutritional recommendations. Written instructions are essential, with consideration of personal and cultural food preferences.

#### **Chart 59-4**

## **Patient and Family Education: Preparing for Self-Management**

### **Prevention of Exacerbations of Chronic Pancreatitis**

- Avoid things that make your symptoms worse, such as drinking caffeinated beverages.
- Avoid alcohol ingestion; refer to self-help group for assistance.
- Avoid nicotine.
- Eat bland, low-fat, high-protein, and moderate-carbohydrate meals; avoid gastric stimulants such as spices.
- Eat small meals and snacks high in calories.
- Take the pancreatic enzymes that have been prescribed for you with meals.
- Rest frequently; restrict your activity to one floor until you regain your strength.

Remind the patient and family members or significant others of the importance of adhering to pancreatic enzyme replacement. The patient must take the prescribed enzymes with meals and snacks to aid in the digestion of food and promote the absorption of fats and proteins. Teach the patient to take the enzymes before or at the beginning of the meal. Instruct him or her to report any increase in abdominal distention, cramping, and foul-smelling, frothy, fatty stools to the health care provider so these supplements may be increased as needed. Remind the patient to report any skin breakdown so therapeutic interventions to promote skin integrity can be started. Abdominal fistulas are common and present a difficult challenge because pancreatic secretions irritate the skin.

The frequency of defecation (whether continent or incontinent) poses challenging skin care problems. Instruct the patient to keep the skin dry and free of the abrasive fatty stools, which damage the skin. The skin should be cleaned thoroughly after each stool, and a moisture barrier applied to prevent breakdown and maintain skin integrity. Many products on the market actively repel stool from the skin.

If the patient develops diabetes mellitus as a result of chronic pancreatitis, management of elevated glucose levels after discharge from the hospital may require oral antidiabetic agents or insulin injections. If this is the case, collaborate with the certified diabetic educator (CDE) to provide in-depth teaching concerning diabetes, its signs and symptoms, medical management, drug therapy, nutrition therapy, blood glucose monitoring, and general care.

Chronic illnesses are devastating for families. The high costs of medical insurance, medical treatment, and drug therapy cause serious financial problems. Often the patient with chronic pancreatitis is unable to work. Collaborate with the CM about ways to assist the patient with resources for financial help.

### Health Care Resources.

The patient may require several home visits by nurses, depending on the severity of the chronic health problems and home maintenance and support needs. The nurse assesses the patient for pain, enzyme therapy, and psychosocial adaptation to a chronic illness. Refer him or her and the family to a counselor or a self-help group, such as Alcoholics Anonymous ([www.aa.org](http://www.aa.org)) and Al-Anon ([www.al-anon.org](http://www.al-anon.org)), if appropriate.

## NCLEX Examination Challenge 59-4

### Physiological Integrity

Which teaching will the nurse provide when discharging a client with chronic pancreatitis?

- Weight reduction and daily exercise regimen
- Constipation precautions, including daily laxative use
- Dietary adjustments to include avoiding high-fat food, caffeine, and alcohol
- Relaxation techniques and stress management

## Pancreatic Abscess

**Pancreatic abscesses** are the most serious complication of acute necrotizing pancreatitis. If untreated, they are always fatal. After surgery, the recurrence rate is high. The abscesses form from collections of purulent liquefaction of the necrotic pancreas.

Patients with pancreatic abscesses often appear more seriously ill than those with pseudocysts. Signs and symptoms are similar. However, the temperature in patients with abscesses may spike to as high as 104° F (40° C). Drainage via the percutaneous method or laparoscopy should be performed as soon as possible to prevent sepsis. Antibiotic treatment alone does not resolve the abscess. Death rates remain high even after surgical drainage. Many patients require multiple drainage procedures for repeated abscesses.

# Pancreatic Pseudocyst

## ❖ Pathophysiology

**Pancreatic pseudocysts**, or false cysts, are so named because, unlike true cysts, they do not have an epithelial lining. They are encapsulated, saclike structures that form on or surround the pancreas. The pseudocyst wall is inflamed, vascular, and fibrotic. It may contain up to several liters of straw-colored or dark brown viscous fluid, the enzymatic exudate of the pancreas (McCance et al., 2014). Risk factors for pseudocysts are acute pancreatitis, abdominal trauma, and chronic pancreatitis.

## ❖ Interprofessional Collaborative Care

Care for the patient with pancreatic pseudocyst takes place in the hospital setting when surgical intervention is required. Members of the interprofessional team who collaborate most closely to care for the patient with pancreatic pseudocyst include the health care provider, surgeon, and nurse.

### ◆ Assessment: Noticing

A pseudocyst can be palpated as an epigastric mass in about half of all cases. The primary presenting symptom is epigastric pain radiating to the back. Other common symptoms include abdominal fullness, nausea, vomiting, and jaundice. Pseudocysts are diagnosed, and their growth and resolution monitored by serial pancreatic diagnostic testing. Complications of pseudocyst formation include:

- Hemorrhage
- Infection
- Obstruction of the bowel, biliary tract, or splenic vein
- Abscess
- Fistula formation
- Pancreatic ascites

### ◆ Interventions: Responding

Pseudocysts may resolve spontaneously, or they may rupture and produce hemorrhage. Surgical intervention is necessary if the pseudocyst does not resolve within 6 to 8 weeks or if complications develop. To provide external drainage, the surgeon inserts a sump drainage tube to remove pancreatic secretions and exudate. Pancreatic fistulas are common after surgery, and skin breakdown from corrosive pancreatic enzymes in patients who have external drainage presents a major nursing care challenge.

# Pancreatic Cancer

## ❖ Pathophysiology

Cancer of the pancreas is a leading cause of cancer deaths each year in the United States. It is difficult to diagnose early because the pancreas is hidden and surrounded by other organs. Treatment has limited results, and 5-year survival rates are low ([American Cancer Society, 2017](#)).

Pancreatic tumors usually originate from epithelial cells of the pancreatic ductal system. If the tumor is discovered in the early stages, the tumor cells may be localized within the glandular organ. However, this is highly unlikely. Most often, the tumor is discovered in the late stages of development and may be a well-defined mass or diffusely spread throughout the pancreas.

The tumor may be a primary cancer, or it may result from metastasis from cancers of the lung, breast, thyroid, kidney, or skin. Primary tumors are generally adenocarcinomas and grow in well-differentiated glandular patterns. They grow rapidly and spread to surrounding organs (stomach, duodenum, gallbladder, and intestine) by direct extension and invasion of lymphatic and vascular systems. This highly metastatic lesion may eventually invade the lung, peritoneum, liver, spleen, and lymph nodes.

Signs and symptoms depend on the site of origin or metastasis. The head of the pancreas is the most common site. The tumors are usually small lesions with poorly defined margins. Jaundice results from tumor compression and obstruction of the common bile duct and from gallbladder dilation, causing the organ to enlarge.

Cancers of the body and tail of the pancreas are usually large and invade the entire tail and body. These tumors may be palpable abdominal masses, especially in the thin patient. Through metastatic spread via the splenic vein, metastasis to the liver may cause **hepatomegaly** (enlargement of the liver up to two to three times its normal size). Cancers of the body and tail spread more extensively than do pancreatic head carcinomas, with invasion of the retroperitoneum, vertebral column, spleen, adrenal glands, colon, or stomach. Regardless of where it originates, it spreads rapidly through the lymphatic and venous systems to other organs.

*Venous thromboembolism is a common complication of pancreatic cancer.* Necrotic products of the pancreatic tumor are believed to have thromboplastic properties resulting in the blood's hypercoagulable state. In addition, the patient is at high risk because of decreased mobility and extensive surgical manipulation.

The exact cause of pancreatic cancer is unknown. High-risk populations are those in their sixth to eighth decades of life and those with a personal history of smoking.

## ⌘ Genetic/Genomic Considerations

### Patient-Centered Care QSEN

A small number of those with pancreatic cancer have an inherited risk. Mutations in certain oncogenes have been identified. Mutations have also been revealed in tumor suppressor genes, such as *p16* and *BRCA2*—the same mutation that makes some women susceptible to breast and ovarian cancer. Genes responsible for hereditary nonpolyposis colorectal cancer can also increase an individual's risk for pancreatic cancer (Ducreux et al., 2015).

Other risk factors associated with the disease include:

- Diabetes mellitus
- Chronic pancreatitis
- Cirrhosis
- High intake of red meat, especially processed meat such as steak
- Long-term exposure to chemicals such as gasoline and pesticides
- Obesity
- Older age
- Male gender

- Cigarette smoking
- Family history
- Genetic syndromes

## ❖ Interprofessional Collaborative Care

Care for the patient with pancreatic cancer usually takes place in the hospital setting, and eventually with hospice. Members of the interprofessional team who collaborate most closely to care for the patient with pancreatic cancer include the health care provider, surgeon if surgery is required, nurse, dietitian, social worker, and spiritual leader of the patient's choice.

### ◆ Assessment: Noticing

Pancreatic cancer often presents in a slow and vague manner. The presenting symptoms depend somewhat on the location of the tumor. The first sign may be jaundice, which suggests late, advanced disease (Chart 59-5). Jaundice occurs because the gallbladder and liver are commonly involved. As the tumor spreads, the yellow skin color associated with obstructive jaundice progressively worsens. Ask the patient whether the color of the stool and urine has changed. As a result of the obstructive process, the stool is clay colored, and the urine is dark and frothy. Inspect the skin for dryness and scratch marks, indicating pruritus from jaundice caused by bile salt collection. Assess the sclera for icterus (yellowing) and the mucous membranes for signs of jaundice.

#### ▶ Chart 59-5

### Key Features

#### Pancreatic Cancer

- Jaundice
- Clay-colored (light) stools
- Dark urine
- Abdominal pain: usually vague, dull, or nonspecific that radiates into the back
- Weight loss
- Anorexia
- Nausea or vomiting
- Glucose intolerance
- Splenomegaly (enlarged spleen)
- Flatulence
- Gastrointestinal bleeding
- Ascites (abdominal fluid)
- Leg or calf pain (from thrombophlebitis)
- Weakness and fatigue

The enlarged gallbladder and liver may be palpable. In advanced cases of pancreatic carcinoma, the tumor may be felt as a firm, fixed mass in the left upper abdominal quadrant or epigastric

region.

The most common concern is fatigue, which is described as a diminished energy level and an increased need for rest relative to the level of activity. The patient notices an inability to perform usual physical or intellectual activities.

Question the patient about abdominal pain, which is usually described as a vague, constant dullness in the upper abdomen and nonspecific in nature. Pain also indicates advanced stages of the disease and may be related to eating or activity. Ask whether the patient has pain in other areas of the body. Referred back pain may be caused by pressure on the nerve plexus. Some patients have leg or calf pain with swelling and redness as a result of deep vein thrombosis or thrombophlebitis.

Weigh the patient to determine the extent of weight loss and whether it has occurred rapidly. Ask about food intake and intolerances. Anorexia accompanied by early satiety, nausea, flatulence (gas), and vomiting is common. GI bleeding may develop from esophageal or gastric varices caused by the tumor pressing on the portal vein. A new diagnosis of diabetes is found in some patients.

In addition to the focused history, perform a general abdominal assessment. In particular, observe for distention and swelling, which may be **ascites** (abdominal fluid). Percussion over the ascitic abdomen elicits dullness, seen in the advanced stages of the disease process.

No specific blood tests diagnose pancreatic cancer. Serum *amylase* and *lipase* levels and *alkaline phosphatase* and *bilirubin* levels are increased. The degree of elevation depends on the acuteness or chronicity of the pancreatic and biliary damage. Elevated *carcinoembryonic antigen* (CEA) levels occur in most patients with pancreatic cancer. This test may provide early information about the presence of tumor cells. The tumor marker CA 19-9 has been found to be a useful serologic test for monitoring a proven diagnosis and continuing surveillance for potential spread or recurrence (Pagana et al., 2017).

Abdominal *ultrasound* and *contrast-enhanced CT* are the most commonly used imaging techniques for confirming a tumor and can differentiate the tumor from a cyst. Endoscopic ultrasonography can also be performed to sample tissue for diagnosis and provide information on tumor type and size (Ducreux et al., 2015). Contrast harmonic echo-endoscopic ultrasound increases the accuracy of diagnosing solid pancreatic masses (Ducreux et al., 2015).

*Endoscopic retrograde cholangiopancreatography* (ERCP) also provides visual diagnostic data. An alternative to ERCP is a percutaneous transhepatic biliary cholangiogram with placement of a percutaneous transhepatic biliary drain (PTBD). This drain decompresses the blocked biliary system by draining bile, internally, externally, or both. Aspiration of pancreatic ascitic fluid by abdominal paracentesis may reveal cancer cells and elevated amylase levels.

### ◆ **Interventions: Responding**

Management of the patient with pancreatic cancer is geared toward preventing tumor spread and decreasing pain. These measures are not curative, only palliative. The cancers are often metastatic and recur despite treatment.

### **Nonsurgical Management.**

As in other types of cancer, chemotherapy or radiation is used to relieve pain by shrinking the tumor. It may be used before, after, or instead of surgery. *Chemotherapy* has had limited success in increasing survival time. In most cases, combining agents has been more successful than single-agent chemotherapy. 5-Fluorouracil (5-FU), a commonly used drug, may be given alone or with gemcitabine (Gemzar) for locally advanced, or unresectable, pancreatic cancers. Observe for adverse drug effects, such as fatigue, rash, anorexia, and diarrhea. Chapter 22 discusses nursing implications of chemotherapy in more detail.

Other targeted therapies being investigated include growth factor inhibitors, anti-angiogenesis factors, and kinase inhibitors (also known as *tyrosine kinase inhibitors*). Kinase inhibitors are a newer group of drugs that focus on cancer cells with little or no effect on healthy cells. Chapter 22 describes general nursing interventions associated with chemotherapy.

To control pain, the patient takes high doses of opioid analgesics (usually morphine) as prescribed and uses other COMFORT measures before the pain escalates and peaks. Because of the poor prognosis, drug dependency is not a consideration. Chapter 4 describes in detail the care of the patient with chronic cancer pain.

Intensive external beam *radiation* therapy to the pancreas may offer pain relief by shrinking tumor cells, alleviating obstruction, and improving food absorption. It does not improve survival rates.

The patient may experience discomfort during and after the radiation treatments. [Chapter 22](#) describes radiation therapy in more detail.

For patients experiencing biliary obstruction who are high surgical risks, **biliary stents** placed percutaneously (through the skin) can ensure patency to relieve pain. These stents are devices made of plastic materials that keep the ducts of the biliary system open. Using another approach, self-expandable stents may be inserted endoscopically to relieve obstruction.

### **Surgical Management.**

Complete surgical resection of the pancreatic tumor offers the patient with pancreatic cancer the only effective treatment, but it is done only in patients with small tumors. *Partial pancreatectomy* is the preferred surgery for tumors smaller than 3 cm in diameter, depending on location and length of time since diagnosis. Recent technologic advances have expanded the role of **minimally invasive surgery (MIS)** via laparoscopy in the staging, palliation, and removal of pancreatic cancers. The procedure selected depends on the purpose of the surgery and stage of the disease. For example, if the patient has a biliary obstruction, a laparoscopic procedure to relieve it is performed. This procedure diverts bile drainage into the jejunum.

For larger tumors, the surgeon may perform either a *radical pancreatectomy* or the *Whipple procedure (pancreaticoduodenectomy)*. These procedures have traditionally been done using an open surgical approach. Because of new advances in laparoscopic technology using a hand-assist device, this method is beginning to replace the conventional method. Some surgeons are not yet trained in how to perform this technique. Therefore the traditional open surgical approach remains the most common method of performing these surgeries.

### **Preoperative Care.**

The patient with pancreatic cancer may be a poor surgical risk because of malnutrition and debilitation. Specific care depends on the type of surgical approach being used.

Often, in the late stages of pancreatic cancer or before the Whipple procedure, the physician inserts a small catheter into the jejunum (**jejunostomy**) so enteral feedings may be given. This feeding method is preferred to prevent reflux and facilitate absorption. Feedings are started in low concentrations and volumes and gradually increased as tolerated. Provide feedings using a pump to maintain a constant volume and assess for diarrhea frequency to determine tolerance. [Chapter 60](#) provides additional information about enteral feeding.

For optimal NUTRITION, TPN may be necessary in addition to tube feedings or as a single measure to provide NUTRITION. When central venous access is required, a peripherally inserted central catheter (PICC) or other type of IV catheter may be necessary. Meticulous IV line care is an important nursing measure to prevent catheter sepsis. Sterile dressing changes and site observation are extremely important. Additional nursing care measures for the patient receiving TPN are given in [Chapter 60](#). Monitor nutrition indicators such as serum prealbumin and albumin.

For the laparoscopic procedure, no bowel preparation is needed. However, either approach requires that the patient have nothing by mouth (NPO) for at least 6 to 8 hours before surgery. Surgeon preference and agency policy determine the preferred protocol for preoperative preparation.

### **Operative Procedures.**

The **Whipple procedure (radical pancreaticoduodenectomy)** involves extensive surgical manipulation and is used most often to treat cancer of the head of the pancreas. The procedure entails removal of the proximal head of the pancreas, the duodenum, a portion of the jejunum, the stomach (partial or total **gastrectomy**), and the gallbladder, with anastomosis of the pancreatic duct (**pancreaticojejunostomy**), the common bile duct (**choledochojejunostomy**), and the stomach (**gastrojejunostomy**) to the jejunum ([Fig. 59-3](#)). In addition, the surgeon may remove the spleen (**splenectomy**).

**FIG. 59-3** The three anastomoses that constitute the Whipple procedure: cholecystojejunostomy, pancreaticojejunostomy, and gastrojejunostomy.

### Postoperative Care.

In addition to routine postoperative care measures, the patient who has undergone an open radical pancreaticoduodenectomy requires intensive nursing care and is usually admitted to a surgical critical care unit. Observe for multiple potential complications of the open Whipple procedure as listed in [Table 59-5](#).

**TABLE 59-5**  
**Potential Complications of the Whipple Procedure**

<b>Cardiovascular Complications</b>
<ul style="list-style-type: none"> <li>• Hemorrhage at anastomosis sites with hypovolemia</li> <li>• Myocardial infarction</li> <li>• Heart failure</li> <li>• Thrombophlebitis</li> </ul>
<b>Pulmonary Complications</b>
<ul style="list-style-type: none"> <li>• Atelectasis</li> <li>• Pneumonia</li> <li>• Pulmonary embolism</li> <li>• Acute respiratory distress syndrome</li> <li>• Pulmonary edema</li> </ul>
<b>Metabolic Complications</b>

<ul style="list-style-type: none"> <li>• Infection</li> <li>• Dehiscence</li> <li>• Fistulas: pancreatic, gastric, and biliary</li> </ul>

The primary benefits of MIS for the patient are a shorter postoperative recovery and less pain than with traditional open procedures. The patient having the laparoscopic Whipple surgery or radical pancreatectomy is also less at risk for severe complications. For patients having one of these procedures, observe for and implement preventive measures for these surgical complications:

- Diabetes (Check blood glucose often.)
- Hemorrhage (Monitor pulse, blood pressure, skin color, and mental status [e.g., LOC].)
- Wound infection (Monitor temperature and assess wounds for redness and induration [hardness].)
- Bowel obstruction (Check bowel sounds and stools.)

- Intra-abdominal abscess (Monitor temperature and patient's report of severe pain.)

Immediately after surgery the patient is NPO and usually has a nasogastric tube (NGT) to decompress the stomach. Monitor GI drainage and tube patency. In open surgical approaches, biliary drainage tubes are placed during surgery to remove drainage and secretions from the area and prevent stress on the anastomosis sites. Assess the tubes and drainage devices for tension or kinking and maintain them in a dependent position.

Monitor the drainage for color, consistency, and amount. The drainage should be serosanguineous. The appearance of clear, colorless, bile-tinged drainage or frank blood with an increase in output may indicate disruption or leakage of an anastomosis site. Most of the disruptions of the site occur within 7 to 10 days after surgery. Hemorrhage can occur as an early or late complication.

Place the patient in the semi-Fowler's position to reduce tension on the suture line and anastomosis site and to optimize lung expansion. Stress can be decreased by maintaining NGT drainage at a low or high intermittent suction level to keep the remaining stomach (if a partial gastrectomy is done) or the jejunum (if a total gastrectomy is done) free of excessive fluid buildup and pressure. The NGT also reduces stimulation of the remaining pancreatic tissue.

*The development of a fistula (an abnormal passageway) is the most common and most serious postoperative complication. Biliary, pancreatic, or gastric fistulas result from partial or total breakdown of an anastomosis site. The secretions that drain from the fistula contain bile, pancreatic enzymes, or gastric secretions, depending on which site is ruptured. These secretions, particularly pancreatic fluid, are corrosive and irritating to the skin; and internal leakage causes chemical peritonitis. **Peritonitis** (inflammation and infection of the peritoneum causing boardlike abdominal rigidity) requires treatment with multiple antibiotics. If you suspect any postoperative complications resulting from MIS or open surgical approaches, call the surgeon immediately and provide assessment findings that support your concerns.*

Because the *open* Whipple procedure is extensive and can take many hours to complete, maintaining fluid and electrolyte balance can be difficult. Patients often have significant intraoperative blood loss and postoperative bleeding. The intestine is exposed to air for long periods, and fluid evaporates. Significant losses of fluid and electrolytes occur from the NGT and other drainage tubes. In addition, these patients may be malnourished and have low serum levels of protein and albumin, which maintain colloid osmotic pressure within the circulating system. Reduction in the serum osmotic pressure makes the patient likely to develop third spacing of body fluids, with fluid moving from the vascular to the interstitial space, resulting in shock. These problems are less likely to occur when MIS is used. Therefore, when possible, the trained surgeon prefers to perform laparoscopic Whipple procedures to shorten operating time and prevent the many complications that can occur.

## Nursing Safety Priority QSEN

### Action Alert

To detect early signs of hypovolemia and prevent shock, closely monitor vital signs for decreased blood pressure and increased heart rate, decreased vascular pressures with a pulmonary artery catheter (Swan-Ganz catheter) (in ICU setting), and decreased urine output. Be alert for pitting edema of the extremities, dependent edema in the sacrum and back, and an intake that far exceeds output. Maintain sequential compression devices to prevent deep vein thrombosis.

Maintenance of prescribed IV isotonic fluid replacement with colloid replacements is important. Monitor hemoglobin and hematocrit values to assess for blood loss and the need for blood transfusions. Review electrolyte values for decreased serum levels of sodium, potassium, chloride, and calcium. IV fluid concentrations must be altered to correct these electrolyte imbalances. The physician prescribes replacement of electrolytes as needed.

Immediately after the Whipple procedure, the patient may have hyperglycemia or hypoglycemia as a result of stress and surgical manipulation of the pancreas. Most of the endocrine cells (responsible for insulin and glucagon secretion) are located in the body and tail of the pancreas. In some patients, up to half of the gland remains, and diabetes does not develop. However, a large number of patients have diabetes before surgery. For patients having a radical pancreatectomy,

administer insulin as prescribed because the entire pancreas is removed. Monitor glucose levels frequently during the early postoperative period and administer insulin injections as prescribed.

## Clinical Judgment Challenge 59-1

### Patient-Centered Care; Evidence-Based Practice; Teamwork and Collaboration; Informatics QSEN

You are the nurse on a critical care unit, caring for a 79-year-old woman who has had a Whipple procedure after being diagnosed with pancreatic cancer. She is sleeping soundly, and vital signs are stable. While you continue your assessment, the patient's 82-year-old husband states, "I'm so glad she had this surgery, but I'm exhausted from taking care of her and don't know how I'll manage when she is allowed to go home."

1. What specific assessment findings will you document in the electronic health record?
2. For which conditions will you monitor the patient, recognizing the surgical procedure she has just had?
3. What laboratory values will you closely follow, and why?
4. What is your response to the patient's husband?

## NCLEX Examination Challenge 59-5

### Psychosocial Integrity

The hospice nurse is caring for a client with pancreatic cancer who has been given 2 to 3 months to live. What is the appropriate nursing response when the client's wife states, "I know he's going to get better."?

- A. Use therapeutic silence and say nothing.
- B. "Your spouse will die in 2 to 3 months."
- C. "Let's talk about how you're feeling about your spouse's prognosis."
- D. "If your spouse adheres to the entire treatment plan, recovery is possible."

### Care Coordination and Transition Management

The patient with pancreatic cancer is usually followed by a case manager (CM), both in the hospital and in the home or other community-based setting. Collaborate with the CM to ensure that the patient receives cost-effective treatment and that his or her needs are met.

### Home Care Management.

The stage of progression of pancreatic cancer and available home care resources determine whether the patient can be discharged to home or whether additional care is needed in a skilled nursing facility or with a hospice provider. Home care preparations depend on the patient's physical and activity limitations and should be tailored to his or her needs. Coordinate care with the patient, family, or whoever will be providing care after discharge from the hospital (i.e., home care provider, hospice care provider, or extended-care provider).

The patient and family need compassionate emotional support to deal with issues related to this illness. The diagnosis of pancreatic cancer can frighten and overwhelm the patient and family. Help family members look realistically and objectively at the amount of physical care required. Tell family members that their own physical and emotional health is at risk during this stressful period and that supportive counseling may be needed. If the family does not have a religious affiliation or a spiritual leader (e.g., a minister or a rabbi) to provide support, suggest alternative counseling

options. Refer patients and families to the certified hospital chaplain if desired. It is appropriate for the nurse to make the initial contact or appointment according to the patient's or family's wishes.

### **Self-Management Education.**

When the patient is discharged to home, many interventions are palliative and aimed at managing symptoms such as pain. In many cases the diagnosis of pancreatic cancer is made a few months before death occurs. The patient needs time to adjust to the diagnosis, which is usually made too late for cure or prolonged survival. Help the patient identify what needs to be done to prepare for death, including end-of-life care. For example, he or she may want to write a will or see family members and friends whom he or she has not seen recently. The patient needs to make known to family members or others his or her specific requests for the funeral or memorial service. These actions help prepare for death in a dignified manner. [Chapter 7](#) discusses in detail anticipatory grieving and preparation for death, as well as symptom management during the end of life.

### **Health Care Resources.**

Regular home care nursing and assistive nursing personnel visits may be scheduled to assist the patient and family by providing physical, psychological, and supportive care. Supply information about local palliative and hospice care (see [Chapter 7](#)) and cancer support groups.

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Collaborate with the dietitian, pharmacist, health care provider, and case manager when planning care for patients with pancreatic cancer. **QSEN: Teamwork and Collaboration**
- Refer patients with end-stage pancreatic cancer for palliative and hospice care. **Ethics**
- Refer patients with pancreatitis who use alcohol to community resources such as Alcoholics Anonymous. **QSEN: Patient-Centered Care**

### Health Promotion and Maintenance

- Recognize that obese, middle-age women are most likely to have gallbladder disease. **QSEN: Patient-Centered Care**
- Teach patients to avoid losing weight too quickly and to keep weight under control to help prevent gallbladder disease. **QSEN: Evidence-Based Practice**
- Teach patients to avoid alcohol consumption to help prevent alcohol-induced acute pancreatitis. **QSEN: Evidence-Based Practice**
- Instruct patients about ways to prevent exacerbations of chronic pancreatitis as outlined in [Chart 59-4](#).

### Psychosocial Integrity

- Refer patients with pancreatic cancer to support services such as spiritual leaders and counselors for coping strategies and facilitation of the grieving process. **Ethics**
- Help prepare the pancreatic cancer patient and family for the death and dying process. **Ethics**

### Physiological Integrity

- Be aware that autodigestion of the pancreas causes severe pain in patients with acute pancreatitis (see [Fig. 59-2](#)).
- Monitor serum laboratory values, especially amylase and lipase (both elevated), in patients with pancreatitis (see [Table 59-4](#)). **QSEN: Evidence-Based Practice**
- Assess for common symptoms of cholecystitis as listed in [Chart 59-1](#).
- Provide pain management, including opioid analgesia, for patients with acute pancreatitis. **QSEN: Patient-Centered Care**
- Recognize that acute pain relief is the first priority of care for patients with acute pancreatitis. **QSEN: Evidence-Based Practice**
- Be aware that patients with biliary and pancreatic disorders are at high risk for biliary obstruction, a serious and painful complication. **QSEN: Safety**
- Assess for common symptoms of chronic pancreatitis as listed in [Chart 59-2](#).
- Document health teaching about enzyme replacement therapy as described in [Chart 59-3](#). **QSEN: Informatics**
- Assess patients with symptoms of pancreatic cancer as described in [Chart 59-5](#).
- Observe for and implement interventions to prevent life-threatening complications of the Whipple procedure as outlined in [Table 59-5](#). **QSEN: Safety**

## CHAPTER 60

# Care of Patients With Malnutrition

## Undernutrition and Obesity

Laura M. Willis, Cherie Rebar

### PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is NUTRITION.**

 The NUTRITION concept exemplars for this chapter are:

- Malnutrition, p. 1215
- Obesity, p. 1225

**The interrelated concept for this chapter is FLUID AND ELECTROLYTE BALANCE.**

### LEARNING OUTCOMES

#### Safe and Effective Care Environment

1. Collaborate with the interprofessional team members to protect and provide care for the patient with undernutrition or obesity.
2. Identify community resources to ensure appropriate transition management for the patient with undernutrition or obesity.

#### Health Promotion and Maintenance

3. Teach adults the importance of lifestyle habits that promote NUTRITION health.
4. Perform and interpret a nutrition screening for adults.

#### Psychosocial Integrity

5. Implement nursing interventions to minimize stressors for the patient with undernutrition or obesity.

#### Physiological Integrity

6. Interpret assessment findings associated with undernutrition or obesity.
7. Prioritize care for the patient with undernutrition or obesity.
8. Create an evidence-based plan of care for the patient with undernutrition or obesity.
9. Describe nursing interventions to prevent complications of total parenteral nutrition (TPN) and maintain FLUID AND ELECTROLYTE BALANCE.
0. Describe nursing interventions to address postoperative care of the patient having bariatric surgery.
  1. Identify the role of supplements and drug therapy in restoring or maintaining NUTRITION status.

In healthy adults, most energy supplied by carbohydrates, protein, and fat undergo digestion and are absorbed from the GI tract. Proper NUTRITION plays a major role in promoting and maintaining health; and this helps the body to maintain temperature, respiration, cardiac output, muscle function, protein synthesis, and the storage and metabolism of food sources. The relationship

between energy used and energy stored is referred to as *energy balance*. Weight is gained when food intake is more than energy used, and weight loss occurs when energy used is more than intake. The body attempts to meet its calorie requirements even if it is at the expense of protein needs; when calorie intake is insufficient, body proteins are used for energy.

## Nutrition Standards for Health Promotion and Maintenance

Current focuses on NUTRITION are targeted toward health promotion and the prevention of disease by healthy eating and exercise. The entity formerly known as the Institute of Medicine, now known as the Health Medicine Division of the National Academies of Sciences, Engineering, and Medicine (HMDNASEM) developed the **Dietary Reference Intakes (DRIs)** to serve as a nutrition guide that provides a scientific basis for food guidelines in the United States and Canada. Age, gender, and life stage influence the nutrient reference values of more than 40 nutrient substances ([United States Department of Agriculture \[USDA\], 2017](#)). In the United States, the **Dietary Guidelines for Americans** are revised by the U.S. Department of Agriculture (USDA) and the U.S. Department of Health and Human Services (DHHS) every 5 years. The 2015-2020 guidelines emphasize the need to focus on “shifts,” which involves making active choices to consumer nutrient-dense foods and beverages instead of less healthy ones. Examples of other guidelines are listed in [Table 60-1](#).

**TABLE 60-1**

### Examples of 2015-2020 Dietary Guidelines for Americans

- Follow a healthy eating pattern across the lifespan.
- Focus on variety, nutrient density, and amount.
- Limit calories from added sugars and saturated fats and reduce sodium intake.
- Shift to healthier food and beverage choices.
- Support healthy eating patterns for all.

Source: *Dietary Guidelines for Americans 2015-2020* (8th ed.). (2015). [http://health.gov/dietaryguidelines/2015/resources/2015-2020\\_Dietary\\_Guidelines.pdf](http://health.gov/dietaryguidelines/2015/resources/2015-2020_Dietary_Guidelines.pdf).

To remind adults about healthy eating habits, the USDA designed “MyPlate,” a picture to demonstrate that half of each meal should consist of fruits and vegetables ([Fig. 60-1](#)). When grains are consumed, half of them should be whole grains rather than refined grain products.

**FIG. 60-1** The U.S. Department of Agriculture MyPlate. (From U.S. Department of Agriculture, 2011, [www.ChooseMyPlate.gov](http://www.ChooseMyPlate.gov).)

Some adults follow vegetarian diet patterns for health, environmental, or moral reasons. In general, vegetarians are leaner than those who consume meat. The **lacto-vegetarian** eats milk, cheese, and dairy foods but avoids meat, fish, poultry, and eggs. The **lacto-ovo-vegetarian** includes eggs in his or her diet. The **vegan** eats only foods of plant origin. Some adults among these groups eat fish as well. Vegans can develop anemia as a result of vitamin B<sub>12</sub> deficiency. Therefore they should include a daily source of vitamin B<sub>12</sub> in their diets, such as a fortified breakfast cereal, fortified soy beverage, or meat substitute. All vegetarians should ensure that they get adequate amounts of calcium, iron, zinc, and vitamins D and B<sub>12</sub>. Well-planned vegetarian diets can provide adequate NUTRITION. The [Academy of Nutrition and Dietetics \(2016\)](#) publishes a number of credible resources regarding vegetarian health at [www.eatright.org](http://www.eatright.org).

## Cultural/Spiritual Considerations

### Patient-Centered Care QSEN

Many adults have specific food preferences based on their ethnicity or race. For example, for adults of Hispanic descent, tortillas, beans, and rice *may* be desired over pasta, risotto, and potatoes. *Never assume that an adult's racial or ethnic background means that he or she eats only foods associated with his or her primary ethnicity.* Health teaching about nutrition should incorporate any cultural preferences.

Some adults have food allergies or intolerances. For instance, lactose intolerance (lactose is found in milk and milk products) is a common problem that occurs in a number of ethnic groups. It is found more often in Mexican Americans and black adults and in some American Indian groups, Asian Americans, and Ashkenazi Jews. A small percentage of white adults, particularly those of Mediterranean descent (e.g., Greek, Italian), are also lactose intolerant. The cause of **lactose intolerance** is an inadequate amount of the lactase enzyme, which converts lactose into absorbable glucose. Patients may benefit from learning more about the management of lactose intolerance from resources provided by organizations such as the American Dietetic Association or the Dietitians of Canada.

## Considerations for Older Adults

### Patient-Centered Care QSEN

The USDA recommends that older adults drink eight glasses of water a day and eat plenty of fiber to prevent or manage constipation. It also suggests daily calcium and vitamins D and B<sub>12</sub> supplements and a reduction in sodium and cholesterol-containing foods.

Health Canada publishes the Canada Food Guide, which was originally created in 2011. Compared with previous documents, it includes more culturally diverse foods, information on *trans* fats, customized individual recommendations, and exercise guidelines. Several booklets can be purchased to help adults select the best foods and nutrients from the new guide, such as *Eating Well with Canada's Food Guide* ([Minister of Health Canada, 2016](#)). In addition, Canada has published a separate booklet in 2007 to address the special needs of some of its Aboriginal population, which places emphasis on cultural, spiritual, and physical importance of food ([Health Canada, 2016](#)).

## Nutrition Assessment

Nutrition status reflects the balance between nutrient requirements and intake. Common factors that affect these requirements include age, gender, disease, infection, and psychological stress. Eating behavior, economic implications, emotional stability, disease, drug therapy, and cultural factors influence nutrient intake. Malnutrition (also called *undernutrition*) and obesity, discussed later in this chapter, are common nutrition health problems that may lead to many comorbidities and complications, including death.

Evaluation of nutrition status is an important part of total patient assessment and includes:

- Review of the nutrition history
- Food and fluid intake record
- Laboratory data
- Food-drug interactions
- Health history and physical assessment
- Anthropometric measurements
- Psychosocial assessment

Monitor the NUTRITION status of a patient during hospitalization as an important part of your initial assessment. Collaborate with the interdisciplinary health care team to identify patients at risk for nutrition problems.

## Initial Nutrition Screening

An initial screening provides an inexpensive, quick way of determining which patients need more extensive nutrition assessment by the health care team. The Joint Commission Patient Care Standards require that a nutrition screening occur within 24 hours of the patient's hospital admission. If indicated, an in-depth nutrition assessment should be performed. When patients are in the hospital for more than a week, nutrition assessment should be part of the daily plan of care.

The initial **nutrition screening** includes inspection, measured height and weight, weight history, usual eating habits, ability to chew and swallow, and any recent changes in appetite or food intake. Examples of questions that help identify patients at risk for nutrition problems are part of the history and physical assessment (Chart 60-1).

### Chart 60-1

## Best Practice for Patient Safety & Quality Care QSEN

### Nutrition Screening Assessment

#### General

- Does the patient have any conditions that cause nutrient loss, such as malabsorption syndromes, draining abscesses, wounds, fistulas, or prolonged diarrhea?
- Does the patient have any conditions that increase the need for nutrients, such as fever, burns, injury, sepsis, or antineoplastic therapies?
- Has the patient been NPO for 3 days or more?
- Is the patient receiving a modified diet or a diet restricted in one or more nutrients?
- Is the patient being enterally or parenterally fed?
- Does the patient describe food allergies, lactose intolerance, or limited food preferences?
- Has the patient experienced a recent unexplained weight loss?

- Is the patient on drug therapy—either prescription, over-the-counter, or herbal/natural products?

### Gastrointestinal

- Does the patient report nausea, indigestion, vomiting, diarrhea, or constipation?
- Does the patient exhibit glossitis (tongue inflammation), stomatitis (oral inflammation), or esophagitis?
- Does the patient have difficulty chewing or swallowing?
- Does the patient have a partial or total GI obstruction?
- What is the patient's state of dentition?

### Cardiovascular

- Does the patient have ascites or edema?
- Is the patient able to perform ADLs?
- Does the patient have heart failure?

### Genitourinary

- Is fluid intake about equal to fluid output?
- Does the patient have an ostomy?
- Is the patient hemodialyzed or peritoneally dialyzed?

### Respiratory

- Is the patient receiving mechanical ventilatory support?
- Is the patient receiving oxygen via nasal prongs?
- Does the patient have chronic obstructive pulmonary disease (COPD) or asthma?

### Integumentary

- Does the patient have abnormal nail or hair changes?
- Does the patient have rashes or dermatitis?
- Does the patient have dry or pale mucous membranes or decreased skin turgor?
- Does the patient have pressure areas on the sacrum, hips, heels, or ankles?

### Extremities

- Does the patient have pedal edema?
- Does the patient have cachexia?

Modified Courtesy Ross Products Division, Abbott Laboratories, Columbus, OH.

The Mini Nutritional Assessment (MNA), a two-part tool that has been tested worldwide, provides a reliable, rapid assessment for patients in the community and in any health care setting. The *first* part (A-F) is a screening section that takes 3 minutes to complete and asks about food intake, mobility, and body mass index (BMI) (described in [Anthropometric Measurements](#)). It also

screens for weight loss, acute illness, and psychological health problems. If the patient scores 11 points or less, the *second* part (G-R) of the MNA is completed, for an additional 12 questions. The entire assessment takes only minutes to complete (Fig. 60-2). The MNA Short Form can be used as a stand-alone tool to evaluate whether the older patient is well nourished, at risk for malnutrition, or malnourished. The alternative is to take the patient's calf circumference, which can be a reliable alternative if BMI is unavailable.

# Mini Nutritional Assessment MNA<sup>®</sup>

Nestlé  
Nutrition Institute

Last name:		First name:		
Sex:	Age:	Weight, kg:	Height, cm:	Date:

Complete the screen by filling in the boxes with the appropriate numbers.  
Add the numbers for the screen. If score is 11 or less, continue with the assessment to gain a Malnutrition Indicator Score.

Screening	
<b>A Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing or swallowing difficulties?</b> 0 = severe decrease in food intake 1 = moderate decrease in food intake 2 = no decrease in food intake	<input type="checkbox"/>
<b>B Weight loss during the last 3 months</b> 0 = weight loss greater than 3kg (6.6lbs) 1 = does not know 2 = weight loss between 1 and 3kg (2.2 and 6.6 lbs) 3 = no weight loss	<input type="checkbox"/>
<b>C Mobility</b> 0 = bed or chair bound 1 = able to get out of bed / chair but does not go out 2 = goes out	<input type="checkbox"/>
<b>D Has suffered psychological stress or acute disease in the past 3 months?</b> 0 = yes      2 = no	<input type="checkbox"/>
<b>E Neuropsychological problems</b> 0 = severe dementia or depression 1 = mild dementia 2 = no psychological problems	<input type="checkbox"/>
<b>F Body Mass Index (BMI) = weight in kg / (height in m)<sup>2</sup></b> 0 = BMI less than 19 1 = BMI 19 to less than 21 2 = BMI 21 to less than 23 3 = BMI 23 or greater	<input type="checkbox"/>
<b>Screening score (subtotal max. 14 points)</b> 12-14 points: Normal nutritional status 8-11 points: At risk of malnutrition 0-7 points: Malnourished For a more in-depth assessment, continue with questions G-R	<input type="checkbox"/> <input type="checkbox"/>
Assessment	
<b>G Lives independently (not in nursing home or hospital)</b> 1 = yes      0 = no	<input type="checkbox"/>
<b>H Takes more than 3 prescription drugs per day</b> 0 = yes      1 = no	<input type="checkbox"/>
<b>I Pressure sores or skin ulcers</b> 0 = yes      1 = no	<input type="checkbox"/>
<b>J How many full meals does the patient eat daily?</b> 0 = 1 meal 1 = 2 meals 2 = 3 meals	<input type="checkbox"/>
<b>K Selected consumption markers for protein intake</b> • At least one serving of dairy products (milk, cheese, yoghurt) per day      yes <input type="checkbox"/> no <input type="checkbox"/> • Two or more servings of legumes or eggs per week      yes <input type="checkbox"/> no <input type="checkbox"/> • Meat, fish or poultry every day      yes <input type="checkbox"/> no <input type="checkbox"/> 0.0 = if 0 or 1 yes 0.5 = if 2 yes 1.0 = if 3 yes	<input type="checkbox"/> <input type="checkbox"/>
<b>L Consumes two or more servings of fruit or vegetables per day?</b> 0 = no      1 = yes	<input type="checkbox"/>
<b>M How much fluid (water, juice, coffee, tea, milk...) is consumed per day?</b> 0.0 = less than 3 cups 0.5 = 3 to 5 cups 1.0 = more than 5 cups	<input type="checkbox"/> <input type="checkbox"/>
<b>N Mode of feeding</b> 0 = unable to eat without assistance 1 = self-fed with some difficulty 2 = self-fed without any problem	<input type="checkbox"/>
<b>O Self view of nutritional status</b> 0 = views self as being malnourished 1 = is uncertain of nutritional state 2 = views self as having no nutritional problem	<input type="checkbox"/>
<b>P In comparison with other people of the same age, how does the patient consider his / her health status?</b> 0.0 = not as good 0.5 = does not know 1.0 = as good 2.0 = better	<input type="checkbox"/> <input type="checkbox"/>
<b>Q Mid-arm circumference (MAC) in cm</b> 0.0 = MAC less than 21 0.5 = MAC 21 to 22 1.0 = MAC greater than 22	<input type="checkbox"/> <input type="checkbox"/>
<b>R Calf circumference (CC) in cm</b> 0 = CC less than 31 1 = CC 31 or greater	<input type="checkbox"/>
<b>Assessment (max. 16 points)</b>	<input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/>
<b>Screening score</b>	<input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/>
<b>Total Assessment (max. 30 points)</b>	<input type="checkbox"/> <input type="checkbox"/> <input type="checkbox"/>
<b>Malnutrition Indicator Score</b> 24 to 30 points <input type="checkbox"/> Normal nutritional status 17 to 23.5 points <input type="checkbox"/> At risk of malnutrition Less than 17 points <input type="checkbox"/> Malnourished

## Anthropometric Measurements

Anthropometric measurements are noninvasive methods of evaluating NUTRITION status. These measurements include height and weight and assessment of BMI.

Obtain a current *height and weight* to provide a baseline. Be sure to obtain accurate measurements because patients tend to overestimate height and underestimate weight. Measurements taken days or weeks later may indicate an early change in nutrition status. *You may delegate this activity to unlicensed assistive personnel (UAP) under your supervision.*

Patients should be measured and weighed while wearing minimal clothing and no shoes. Determine the height in inches or centimeters using the measuring stick of a weight scale if the patient can stand. He or she should stand erect and look straight ahead, with the heels together and the arms at the sides. For patients who cannot stand or those who cannot stand erect (e.g., some older adults), use a sliding-blade **knee height caliper**, if available. This device uses the distance between the patient's patella and heel to estimate height. It is especially useful for patients who have knee or hip contractures.

Remind UAP to weigh ambulatory patients with an upright balance-beam or digital scale. Nonambulatory patients can be weighed with a digital wheelchair or bed scale. If a bed scale is used, document in the electronic health record the number of sheets, pillows, and blankets that were on the bed during baseline measurement. The patient should be wearing the same clothing and have the same bedding on the bed from day to day thereafter to ensure accurate measurement. Lines, devices, and equipment should be lifted off the bed when the measurement is taking place.

## Nursing Safety Priority QSEN

### Action Alert

For daily or sequential weights, obtain the weight at the same time each day, if possible, preferably before breakfast. Conditions such as congestive heart failure and renal disease cause weight gain; dehydration and conditions such as cancer cause weight loss. *Weight is the most reliable indicator of fluid gain or loss, so accurate weights are essential!*

Normal weights for adult men and women are available from several reference standards, such as the Metropolitan Life tables. Some health care professionals prefer these tables because they consider body-build differences by gender and body frame size.

Changes in body weight can be expressed by three different formulas:  
Weight as a percentage of ideal body weight (IBW):

$$\% \text{ IBW} = \frac{\text{Current weight}}{\text{Ideal body weight}} \times 100$$

Current weight as a percentage of usual body weight (UBW):

$$\% \text{ UBW} = \frac{\text{Current weight}}{\text{Usual body weight}} \times 100$$

Change in weight:

$$\text{Weight change} = \frac{\text{Usual weight} - \text{Current weight}}{\text{Usual weight}} \times 100$$

*An unintentional weight loss of 10% over a 6-month period at any time significantly affects nutrition status and should be evaluated.* Depending on the patient's needs, weights may need to be taken daily, several times a week, or weekly for monitoring status and the effectiveness of nutrition support.

In the health care setting, *assessment of body fat* is usually calculated by the dietitian. For adults who participate in a structured exercise program in the community, this assessment is typically performed by a fitness trainer or physical therapist.

The **body mass index (BMI)** is a measure of nutrition status that does not depend on frame size (Centers for Disease Control and Prevention [CDC], 2015). It indirectly estimates total fat stores within the body by the relationship of weight to height. *Therefore an accurate height is as important as an accurate weight.*

A simple calculation for estimating BMI can be programmed into handheld computers or calculators using one of these two formulas:

$$\text{BMI} = \frac{\text{Weight (lb)}}{\text{Height (in inches)}^2} \times 703$$

$$\text{BMI} = \frac{\text{Weight (kg)}}{\text{Height (in meters)}^2}$$

BMI can also be determined using a table that is linked with height and weight. The least risk for malnutrition is associated with scores between 18.5 and 25. BMIs above and below these values are associated with increased health risks (CDC, 2015).

## Considerations for Older Adults

### Patient-Centered Care OSEN

Body weight and BMI usually increase throughout adulthood until about 60 years of age. As adults get older, they often become less hungry and eat less, even if they are healthy. Ideally, older adults should have a BMI between 23 and 27.

The average daily energy intake expended by this group tends to be more than the average energy intake. This physiologic change has been called the “anorexia of aging” (Martone et al., 2013). Many older adults are underweight, leading to undernutrition and increased risk for illness.

## NCLEX Examination Challenge 60-1

### Health Promotion and Maintenance

An older adult is admitted to the hospital. The client's height is 5 feet, 10 inches (1.78 meters), and weight is 286 lb (129.7 kg). The nurse calculates the client's current body mass index (BMI) as \_\_\_\_\_. **Fill in the blank. Round your answer to the nearest whole number.**

**Skinfold measurements** estimate body fat and can be measured by either the nurse or the dietitian. The *triceps and subscapular* skinfolds are most commonly measured with a special caliper. Both are compared with standard measurements and recorded as percentiles.

The *midarm circumference (MAC)* and *calf circumference (CC)* can be obtained to measure muscle mass and subcutaneous fat. These measurements are needed if the Mini Nutritional Assessment tool is used. To measure MAC, place a flexible tape around the upper arm at the midpoint, taking care to hold the tape firmly but gently to avoid compressing the tissue. This measurement is usually recorded in centimeters. The midarm muscle mass (MAMM) measures the amount of muscle in the body and is a sensitive indicator of protein reserves. It can be computed from the MAC and the triceps skinfold measure. The CC is obtained using a similar procedure on the calf.

## Nutrition Concept Exemplar Malnutrition

### Pathophysiology

**Protein-energy malnutrition (PEM)**, also known as **protein-calorie malnutrition (PCM)**, may present in three forms:

**Marasmus:** a calorie malnutrition in which body fat and protein are wasted. Serum proteins are often preserved.

**Kwashiorkor:** a lack of protein quantity and quality in the presence of adequate calories. Body weight is more normal, and serum proteins are low.

**Marasmic-kwashiorkor:** a combined protein and energy malnutrition. This problem often presents clinically when metabolic stress is imposed on a chronically starved patient.

The outcome of unrecognized or untreated PEM is often dysfunction or disability and increased morbidity and mortality.

Malnutrition (also called *undernutrition*) is a multinutrient problem because foods that are good sources of calories and protein are also good sources of other nutrients. In the malnourished patient many problems may be identified such as:

- Protein catabolism that exceeds protein intake and synthesis
- Negative nitrogen balance
- Weight loss
- Decreased muscle mass
- Weakness
- Decrease in serum proteins (**hypoproteinemia**) as protein synthesis in the liver decreases
- Vital capacity reduced as a result of respiratory muscle atrophy
- Diminished cardiac output
- Malabsorption because of atrophy of GI mucosa and the loss of intestinal villi

Common complications of *severe* malnutrition in adults include:

- Leanness and **cachexia** (muscle wasting with prolonged malnutrition)
- Decreased activity tolerance
- Lethargy
- Intolerance to cold
- Edema
- Dry, flaking skin and various types of dermatitis
- Poor wound healing
- Infection, particularly postoperative infection and sepsis
- Possible death

Malnutrition results from inadequate nutrient intake, increased nutrient losses, and increased nutrient requirements. Inadequate nutrient intake can be linked to:

- Poverty
- Lack of education
- Substance abuse
- Decreased appetite
- Vomiting
- Decline in functional ability to eat independently
- Infectious diseases, such as tuberculosis and human immune deficiency virus (HIV) infection
- Diseases that produce diarrhea and infections leading to anorexia. (Anorexia then leads to poor food intake.)

- Medical treatments such as chemotherapy
- Catabolic processes, such as prolonged immobility, that increase nutrient requirements and metabolic losses

Inadequate nutrient intake can also result when an adult is admitted to the hospital or long-term care facility. For example, decreased staffing may not allow time for patients who need to be fed, especially older adults, who may eat slowly. Many diagnostic tests, surgery, trauma, and unexpected medical complications require a period of NPO or cause **anorexia** (loss of appetite).

## Cultural/Spiritual Considerations

### Patient-Centered Care QSEN

In some cases, malnutrition results when the provided meals are different from what the patient usually eats. Be sure to identify specific food preferences that the patient can eat and enjoy that are in keeping with his or her cultural practices.

## Considerations for Older Adults

### Patient-Centered Care QSEN

Older adults in the community or in any health care setting are most at risk for poor nutrition, especially PEM. Risk factors include physiologic changes of aging, environmental factors, and health problems. Chart 60-2 lists some of these major factors. Chapter 3 discusses NUTRITION for older adults in more detail.

### Chart 60-2

## Nursing Focus on the Older Adult

### Risk Assessment for Malnutrition

Assess for:

- Decreased appetite
- Weight loss
- Poor-fitting or no dentures/poor dental health
- Poor eyesight
- Dry mouth
- Limited income
- Lack of transportation
- Inability to prepare meals because of functional decline or fatigue
- Loneliness and/or depression
- Chronic constipation (e.g., in patients with Alzheimer's disease)
- Decreased meal enjoyment
- Chronic physical illness
- “Failure to thrive” (a combination of three of five symptoms, including weakness, slow walking

speed, low physical activity, unintentional weight loss, exhaustion)

- Prescription and over-the-counter (OTC) drugs (including herbs, vitamins, and minerals)
- Acute or chronic pain

*Acute* PEM may develop in patients who were adequately nourished before hospitalization but experience starvation while in a catabolic state from infection, stress, or injury. *Chronic* PEM can occur in those who have cancer, end-stage kidney or liver disease, or chronic neurologic disease.

Eating disorders such as anorexia nervosa and bulimia nervosa, which are seen most often in teens and young adults, also lead to malnutrition. **Anorexia nervosa** is a self-induced starvation resulting from a fear of fatness, even though the patient is underweight. **Bulimia nervosa** is characterized by episodes of binge eating in which the patient ingests a large amount of food in a short time. The binge eating is followed by some form of purging behavior, such as self-induced vomiting or excessive use of laxatives and diuretics. If not treated, death can result from starvation, infection, or suicide. Information about eating disorders can be found in textbooks on mental/behavioral health nursing.

### Health Promotion and Maintenance

One in three patients in health care settings is malnourished. This may be caused by inadequate intake before being hospitalized or lack of nutrition while hospitalized because of the illness or injury. Those diagnosed with malnutrition have a length of stay that may be three times higher than those who do not have altered nutrition. The annual burden of disease-associated malnutrition across eight diseases in the United States is over \$156 billion (American Society for Parenteral and Enteral Nutrition [ASPEN], 2016). Nurses can have a significant impact on patient length of stay when adequately advocating for their client's nutrition status.

### Incidence and Prevalence

At the World Food Summit in 1996, a target was set to reduce the number of undernourished people in the world by 50% by 2015 (Bhutta, 2013). At that time, an estimated 824 million people were undernourished (Bhutta, 2013). In 2010, it was estimated that 925 million people worldwide were undernourished (Bhutta, 2013).

### ❖ Interprofessional Collaborative Care

Care for the patient with malnutrition takes place in a variety of settings (i.e., the home, the community, and the hospital setting) if more comprehensive management is needed. Members of the interprofessional team who collaborate most closely to care for the patient with malnutrition include the health care provider, nurse, and dietitian. For patients who experience psychological impact from or related to malnutrition, a psychologist or therapist will also have an important role in care.

### ◆ Assessment: Noticing

#### History.

Review the medical history to determine the possibility of increased metabolic needs or NUTRITION losses, chronic disease, trauma, recent surgery of the GI tract, drug and alcohol use, and recent significant weight loss. Each of these conditions can contribute to malnutrition. For older adults, explore mental status changes; note poor eyesight, diseases affecting major organs, constipation or incontinence, and slowed reactions. Review prescription and over-the-counter (OTC) drugs, including vitamin, mineral, herbal, and other nutrition supplements.

For patients who live independently in the community, the nurse may assess their performance of *instrumental activities of daily living* (IADLs). Functional status can best be evaluated for institutionalized patients by assessing their ADL performance. Poor NUTRITION is a major contributing factor to decreased functional ability.

In collaboration with the dietitian, obtain information about the patient's:

- Usual daily food intake

- Eating behaviors
- Change in appetite
- Recent weight changes.

Ask the patient or family if patient cannot communicate, about:

- Usual foods eaten
- Cultural food preferences
- Times of meals and snacks

The dietitian can more thoroughly analyze the diet, if necessary, based on your initial nutrition screening.

Ask about changes in eating habits as a result of illness and document any change in appetite, taste, and weight loss. A weight loss of 5% or more in 30 days, a weight loss of 10% in 6 months, or a weight that is below ideal may indicate malnutrition.

## Nursing Safety Priority QSEN

### Action Alert

When assessing for malnutrition, assess for difficulty or pain chewing or swallowing. Unrecognized dysphagia is a common problem among nursing home residents and can cause malnutrition, dehydration, and aspiration pneumonia. Ask the patient whether any foods are avoided and why. Ask UAP to report any choking while the patient eats. Record the occurrence of nausea, vomiting, heartburn, or any other symptoms of discomfort with eating.

Ask the patient about dental health problems, including the presence of dentures. Dentures or partial plates that do not fit well interfere with food intake. Dental caries (decay) or missing teeth may also cause discomfort while eating.

### Physical Assessment/Signs and Symptoms.

Assess for signs and symptoms of various nutrient deficiencies (Table 60-2). Inspect the patient's hair, eyes, oral cavity, nails, and musculoskeletal and neurologic systems. Examine the condition of the skin, including any reddened or open areas. Anthropometric measurements may also be obtained as described in the section of the same name. The nurse or UAP monitors all food and fluid intake and notes any mouth pain or difficulty chewing or swallowing. A 3-day caloric intake may be collected and then calculated by the dietitian.

**TABLE 60-2**  
**Manifestations of Nutrient Deficiencies**

SIGN/SYMPOM	POTENTIAL NUTRIENT DEFICIENCY
<b>Hair</b>	
Alopecia	Zinc
Easy to remove	Protein
Lackluster hair	Protein
"Corkscrew" hair	Vitamin C
Decreased pigmentation	Protein
<b>Eyes</b>	
Xerosis of conjunctiva	Vitamin A
Corneal vascularization	Riboflavin
Keratomalacia	Vitamin A
Bitot's spots	Vitamin A
<b>GI Tract</b>	
Nausea, vomiting	Pyridoxine
Diarrhea	Zinc, niacin
Stomatitis	Pyridoxine, riboflavin, iron
Cheilosis	Pyridoxine, iron
Glossitis	Pyridoxine, zinc, niacin, folic acid, vitamin B <sub>12</sub>
Magenta tongue	Vitamin A, riboflavin
Swollen, bleeding gums	Vitamin C
Fissured tongue	Niacin
Hepatomegaly	Protein
<b>Skin</b>	
Dry and scaling	Vitamin A
Petechiae/ecchymoses	Vitamin C
Follicular hyperkeratosis	Vitamin A
Nasolabial seborrhea	Niacin
Bilateral dermatitis	Niacin
<b>Extremities</b>	
Subcutaneous fat loss	Calories

Muscle wastage	Calories, protein
Edema	Protein
Osteomalacia, bone pain, rickets	Vitamin D
<b>Hematologic</b>	
Anemia	Vitamin B <sub>12</sub> , iron, folic acid, copper, vitamin E
Leukopenia, neutropenia	Copper
Low prothrombin time, prolonged clotting time	Vitamin K, manganese
<b>Neurologic</b>	
Disorientation	Niacin, thiamine
Confabulation	Thiamine
Neuropathy	Thiamine, pyridoxine, chromium
Paresthesia	Thiamine, pyridoxine, vitamin B <sub>12</sub>
<b>Cardiovascular</b>	
Congestive heart failure, cardiomegaly, tachycardia	Thiamine
Cardiomyopathy	Selenium
Cardiac dysrhythmias	Magnesium

## Psychosocial Assessment.

The psychosocial history provides information about the patient's economic status, occupation, educational level, gender orientation, ethnicity/race, living and cooking arrangements, and mental status. Determine whether financial resources are adequate for providing the necessary food. If resources are inadequate, the social worker or case manager may refer the patient and family to available community services. [Chapter 3](#) discusses NUTRITION in older adults in more detail.

## Laboratory Assessment.

Laboratory tests supply objective data that can support subjective data and identify deficiencies. Interpret laboratory data carefully with regard to the total patient; focusing on an isolated value may yield an inaccurate conclusion.

A low *hemoglobin* level may indicate anemia, recent hemorrhage, or hemodilution caused by fluid retention. Hemoglobin may also be decreased secondary to conditions such as low serum albumin, infection, catabolism, or chronic disease. High levels may indicate hemoconcentration or dehydration or may be found secondary to liver disease.

Low *hematocrit* levels may reflect anemia, hemorrhage, excessive fluid, renal disease, or cirrhosis. High hematocrit levels may indicate dehydration or hemoconcentration.

Serum albumin, thyroxine-binding prealbumin, and transferrin are measures of **visceral proteins**. Serum *albumin* is a plasma protein that reflects the nutrition status of the patient a few weeks before testing; therefore it is not considered to be a sensitive test. Patients who are dehydrated often have high levels of albumin, and those with fluid excess have a lowered value. The normal serum albumin level for men and women is 3.5 to 5.0 g/dL or 35 to 50 g/L (SI units) (Pagana et al., 2017).

Thyroxine-binding **prealbumin (PAB)** is a plasma protein that provides a more sensitive indicator of nutrition deficiency because of its short half-life of 2 days. Depending on the laboratory test used, the normal PAB range is 15 to 36 mg/dL or 150 to 360 mg/L (SI units) (Pagana et al., 2017). Although not used as commonly, serum **transferrin**, an iron-transport protein, can be measured directly or calculated as an indirect measurement of total iron-binding capacity (TIBC). It has a short half-life of 8 to 10 days and therefore is also a more sensitive indicator of protein status than albumin.

*Cholesterol* levels normally range between 160 and 200 mg/dL in adult men and women. Values are typically low with malabsorption, liver disease, pernicious anemia, end-stage cancer, or sepsis. A cholesterol level below 160 mg/dL has been identified as a possible indicator of malnutrition. Cholesterol levels are discussed in more detail in [Chapter 36](#).

*Total lymphocyte count (TLC)* can be used to assess immune function. Malnutrition suppresses the immune system and leaves the patient more likely to get an infection. When a patient is malnourished, the TLC is usually decreased to below 1500/mm<sup>3</sup>.

### ◆ Analysis: Interpreting

The priority collaborative problem for the patient with malnutrition is:

1. Weight loss due to inability to ingest or digest food or absorb nutrients

### ◆ Planning and Implementation: Responding

#### Improving Nutrition

### Planning: Expected Outcomes.

The patient with malnutrition is expected to have nutrients available to meet his or her metabolic needs as evidenced by normal serum proteins and adequate hydration.

### Interventions.

The preferred route for food intake is through the GI tract because it enhances the immune system and is safer, easier, less expensive, and more enjoyable.

### Meal Management.

The dietitian calculates the nutrients required daily and plans the patient's diet. In collaboration with the health care provider and dietitian, provide high-calorie, nutrient-rich foods (e.g., milkshakes, cheese, supplement drinks such as Boost or Ensure). Assess the patient's food likes and dislikes. A feeding schedule of six small meals may be tolerated better than three large ones. A pureed or dental soft diet may be easier for those who have problems chewing or are **edentulous** (toothless).

## Nursing Safety Priority QSEN

### Action Alert

Malnourished ill patients often need to be encouraged to eat. Instruct UAP who are feeding patients to keep food at the appropriate temperature and to provide mouth care before feeding. Assess for other needs, such as pain management, and provide interventions to make the patient comfortable. Pain can prevent patients from enjoying their meals. Remove bedpans, urinals, and emesis basins from sight. Provide a quiet environment, which is conducive to eating. Soft music may calm those with advanced dementia or delirium. Appropriate time should be taken so the patient does not feel rushed through a meal.

## Considerations for Older Adults

### Patient-Centered Care QSEN

Some patients, especially older adults, may take a long time to eat even small quantities of food because they tend to be less hungry than younger adults. If available, suggest that family members bring in favorite or ethnic foods that the patient might be more likely to eat. Teach them about ways to encourage the patient to increase food intake. Chart 60-3 describes additional interventions to promote food intake in older adults.

### Chart 60-3

## Nursing Focus on the Older Adult

### Promoting Nutrition Intake

- Be sure that patient is toileted and receives mouth care before mealtime.
- Be sure that patient has glasses and hearing aids in place, if appropriate, during meals.
- Be sure that bedpans, urinals, and emesis basins are removed from sight.
- Give analgesics to control pain and/or antiemetics for nausea at least 1 hour before mealtime.
- Remind unlicensed assistive personnel (UAP) to have patient sit in chair, if possible, at mealtime.
- If needed, open cartons and packages and cut up food at the patient's and/or family's request.
- Observe the patient during meals for food intake.

- Ask the patient about food likes and dislikes and ethnic food preferences.
- Encourage self-feeding or feed the patient slowly; *delegate* this activity to UAP if desired and provide appropriate supervision.
- If feeding patient, sit at eye level if culturally appropriate.
- Create an environment that is conducive to eating and socialization and relaxation, if possible.
- Decrease distractions, such as environmental noise from television, music, or other people.
- Provide adequate, nonglaring lighting.
- Keep patient away from offensive or medicinal odors.
- Keep eye contact with the patient during the meal if culturally appropriate.
- Serve snacks with activities, especially in long-term care settings; *delegate* this activity to UAP if desired.
- Document the percentage of food eaten at each meal and snack; *delegate* this activity to UAP if appropriate.
- Ensure that meals are visually appealing, appetizing, appropriately warm or cold, and properly prepared.
- Do not interrupt patients during mealtime for nonurgent procedures or rounds.
- Assess for need for supplements between meals and at bedtime.
- Review the patient's drug profile and discuss with the health care provider the use of drugs that might be suppressing appetite.
- If the patient is depressed, be sure that the depression is treated by the health care provider.

Restorative feeding programs help nursing home residents who need special assistance. These residents often eat in a separate dining area so time and attention can be given to them. Some nursing homes have designated food and nutrition nursing assistants and/or trained volunteers who are primarily responsible for promoting and maintaining nutrition and hydration. Delegate and supervise appropriate feeding tasks to UAPs during resident mealtime.

### Nutrition Supplements.

If the patient cannot take in enough nutrients in food, fortified **medical nutrition supplements (MNSs)** (e.g., Ensure, Sustacal, Carnation Instant Breakfast [also available as lactose-free supplement]) may be given, especially to older adults. Many commercial enteral products are available. For patients with medical diagnoses such as liver and renal disease or diabetes, special products that meet these needs are available (e.g., Glucerna for patients with diabetes). Nutrition supplements used in acute care, long-term care, and home care can be costly. In addition, patients may refuse them, and the supplements are then wasted. In a classic study, [Bender et al. \(2000\)](#) found that a more successful alternative to having the MNS given by nursing assistant staff in the nursing home was to have the supplements delivered by nurses during their usual medication passes. In this study, the nurses gave 60 mL or more of the MNS at least four times a day with the residents' medications. As a result, the patients gained weight and had fewer pressure injuries, thus making the program very cost-effective and providing positive clinical outcomes.

NUTRITION supplements are supplied as liquid formulas, powders, soups, coffee, and puddings in a variety of flavors. They come in different degrees of sweetness and are also available as modular supplements that provide single nutrients. Examples of modular supplements are Polycose glucose polymers for carbohydrates and Resource Beneprotein for protein, both available in liquid and powder form. Carbohydrate modulators are useful only if additional calories are needed. Protein

modulars are indicated when metabolic stress causes a need for higher protein intake.

The dietitian may ask the nursing staff to keep a food and fluid intake record for at least 3 consecutive days to help assess the patient's nutrition status. Delegate this activity to UAP under your ongoing supervision. UAPs also weigh the patient daily, every 3 days, or once a week, depending on the health care setting and severity of malnutrition; review this information, and supervise and intervene accordingly.

### Drug Therapy.

Multivitamins, zinc, and an iron preparation are often prescribed to treat or prevent anemia. Monitor the patient's hemoglobin and hematocrit levels. Drug therapy can affect nutrition and elimination. For example, iron can cause constipation, and zinc can cause nausea and vomiting.

If the patient still does not receive enough nutrition by mouth using the interventions just mentioned, request nutrition therapy in the form of **specialized nutrition support (SNS)**. SNS consists of either total enteral nutrition (TEN) or total parenteral nutrition (TPN).

### Total Enteral Nutrition.

Patients often cannot meet the desired outcomes of adequate nutrition via their usual oral intake because of increased metabolic demands or a decreased ability to eat. Therefore TEN using enteral tube feeding may be necessary to supplement oral intake or to provide total nutrition.

Patients likely to receive TEN can be divided into three groups:

- Those who can eat but cannot maintain adequate NUTRITION by oral intake of food alone
- Those who have permanent neuromuscular impairment and cannot swallow
- Those who do not have permanent neuromuscular impairment but cannot eat because of their condition

Patients in the first group are often older adults or patients receiving cancer treatment who cannot meet their calorie and protein needs. In some cases, this artificial nutrition and hydration may not be desired. For example, some patients have advance directives stating that they do not want to be kept alive by artificial nutrition and hydration if certain conditions exist. *However, legal and ethical questions arise when patients are not able to make their wishes known!*

For many years it was believed that withholding food and fluids would cause discomfort. Terminally or chronically ill patients who do not eat and drink may not suffer. In fact, they may be more comfortable if food and fluids are withheld. *The decision to feed is complex, and there is no clear right or wrong answer. To compound this legal and ethical dilemma, medical complications (e.g., aspiration, pressure injuries) are common in older adults who are tube-fed.*

Decisions about these dilemmas are aided by the advice of interdisciplinary ethics committees in health care facilities. When clinicians are making decisions about the desirability of tube feedings in these cases, the focus should be on achieving consensus by:

- Reviewing what is known about tube feedings, especially their risks and benefits
- Reviewing the medical facts about the patient
- Investigating any available evidence that would help understand the patient's wishes
- Obtaining the opinions of all stakeholders in the situation
- Delaying any action until consensus is achieved

Those in the second group of patients likely to receive TEN usually have permanent swallowing problems and require some type of feeding tube for delivery of the enteral product on a long-term basis. Examples of conditions that can cause permanent swallowing problems are strokes, severe head trauma, and advanced multiple sclerosis. Patients in the third group receive enteral NUTRITION for as long as their illness lasts. The feeding is discontinued when the patient's condition improves and he or she can eat again. Many commercially prepared enteral products are available. A therapeutic combination of carbohydrates, fat, vitamins, minerals, and trace elements is available in liquid form. Differences among products allow the dietitian to select the right formula for each patient. A prescription from the health care provider is required for enteral nutrition, but the dietitian usually makes the recommendation and computes the amount and type of product needed for each patient.

## Health Promotion and Maintenance

A hospitalized client reports lack of appetite to the nurse. What nursing intervention is appropriate to encourage nutrition intake? **Select all that apply.**

- A. Assess the client's level of pain and provide interventions as necessary.
- B. Remove objects from sight in the client's room such as bedpans or urinals at mealtime.
- C. Provide a quiet environment during mealtime.
- D. Provide washcloth and towel for washing hands before each meal.
- E. Encourage the client to eat quickly to get the entire meal consumed.
- F. Provide food to the client only when hunger is reported.

### Methods of Administering Total Enteral Nutrition.

TEN is administered as “tube feedings” through one of the available GI tubes, either through a nasoenteric or enterostomal tube. It can be used in the patient's home or any health care setting.

A **nasoenteric tube (NET)** is any feeding tube inserted nasally and then advanced into the GI tract, such as a Keofeed, Entriflex, or Dobbhoff tube. Commonly used NETs include the **nasogastric (NG) tube** and the smaller (small-bore) **nasoduodenal tube (NDT)** (Fig. 60-3A).

**FIG. 60-3** Feeding tubes used for total enteral nutrition. A, Nasoduodenal tube. B and C, Gastrostomy tubes. (A from Lilley, L., Rainforth Collins, S., Harrington, S., & Snyder, J. [2011]. *Pharmacology and the nursing process* [6th ed.]. St. Louis: Mosby; B from Harkreader, H. [2007]. *Fundamentals of nursing* [3rd ed.]. St. Louis: Saunders; courtesy C.R. Bard, Inc., Billerica, MA; C from Harkreader, H. [2007]. *Fundamentals of nursing* [3rd ed.]. St. Louis: Saunders; courtesy Ballard Medical Products, Draper, UT.)

A nasogastric tube (NGT) is also available but is used less often than the other NETs.

The NDTs are used for delivering *short-term* enteral feedings (usually less than 4 weeks) because they are easy to use and safer for the patient at risk for aspiration *if the tip of the tube is placed below the pyloric sphincter of the stomach and into the duodenum*. Small-bore polyurethane or silicone tubes from 8 to 12 Fr external diameter are preferred. The smaller tubes are more comfortable and are less likely to cause complications such as nasal irritation, sinusitis, tissue erosion, and pulmonary compromise.

**Enterostomal feeding tubes** are used for patients who need *long-term* enteral feeding. The most common types are gastrostomies and jejunostomies. The surgeon directly accesses the GI tract using various surgical, endoscopic, and laparoscopic techniques.

A **gastrostomy** is a stoma created from the abdominal wall into the stomach, through which a short feeding tube is inserted by the surgeon. It may require a small abdominal incision or be placed endoscopically. This tube is called a **percutaneous endoscopic gastrostomy (PEG)** or dual-access gastrostomy-jejunostomy (PEG/J) tube. The PEG requires monitored conscious sedation for placement and is secure and durable. An alternative to either device is the **low-profile gastrostomy device (LPGD)** (Fig. 60-3B-C). The LPGD is available with a firm or balloon-style internal bumper or retention disk. An anti-reflux valve keeps GI contents from leaking onto the skin. This device is less irritating to the skin, longer lasting, and more cosmetically pleasing. It also allows greater patient independence. However, skin-level devices do not allow easy access for checking **residuals** (the amount of feeding that remains in the stomach).

Jejunostomies are used less often than gastrostomies. A **jejunostomy** is used for long-term feedings when it is desirable to bypass the stomach, such as with gastric disease, upper GI obstruction, and abnormal gastric or duodenal emptying.

Tube feedings are administered by bolus feeding, continuous feeding, and cyclic feeding. **Bolus feeding** is an intermittent feeding of a specified amount of enteral product at set intervals during a 24-hour period, typically every 4 hours. This method can be accomplished manually or by infusion through a mechanical pump or controller device. Another method of tube feeding is continuous enteral feeding. **Continuous feeding** is similar to IV therapy in that small amounts are continuously infused (by gravity drip or by a pump or controller device) over a specified time. The most commonly seen method, **cyclic feeding**, is the same as continuous feeding except that the infusion is stopped for a specified time in each 24-hour period, usually 6 hours or longer (“down time”). Down time typically occurs in the morning to allow bathing, treatments, and other activities.

Infusion rates for cyclic feedings (and to some extent for intermittent bolus feeding) vary with the total amount of solution to be infused, the specific composition of the product, and the response of the patient to the feeding. The health care provider and dietitian usually decide the type, rate, and method of tube feeding, as well as the amount of additional water (“free water”) needed. If the patient can swallow small amounts of food, he or she may also eat orally while the tube is in place.

The nurse is responsible for the care and maintenance of the feeding tube and the enteral feeding. **Chart 60-4** lists best practices for the patient receiving TEN.

#### Chart 60-4

### Best Practice for Patient Safety & Quality Care QSEN

#### Tube-Feeding Care and Maintenance

- If nasogastric or nasoduodenal feeding is prescribed, use a soft, flexible, small-bore feeding tube (smaller than 12 Fr). *The initial placement of the tube should be confirmed by x-ray study.* Secure the tube with tape or a commercial attachment device after applying a skin protectant; change the tape regularly.
- Check tube placement by x-ray study when the correct position of the tube is in question; *an x-ray study is the most reliable method.*
- **Per The Joint Commission's National Patient Safety Goals, if a gastrostomy or jejunostomy tube is used, assess the insertion site for signs of infection or excoriation (e.g., excessive redness, drainage). Rotate the tube 360 degrees each day and check for in-and-out play of**

**about ¼ inch (0.6 cm). If the tube cannot be moved, notify the health care provider immediately because the retention disk may be embedded in the tissue. Cover the site with a dry, sterile dressing and change the dressing at least once a day.**

- Check and record the residual volume every 4 to 6 hours or per facility policy by aspirating stomach contents into a syringe. If residual feeding is obtained, check with the health care provider for the appropriate intervention (usually to slow or stop the feeding for a time) or use the American Society of Parenteral and Enteral Nutrition (ASPEN) best practice recommendations.
- Check the feeding pump to ensure proper mechanical operation.
- Ensure that the enteral product is infused at the prescribed rate (mL/hr).
- Change the feeding bag and tubing every 24 to 48 hours; label the bag with the date and time of the change with your initials. Use an irrigation set for no more than 24 hours.
- For continuous or cyclic feeding, add only 4 hours of product to the bag at a time to prevent bacterial growth. *A closed system is preferred, and each set should be used no longer than 24 hours.*
- Wear clean gloves when changing or opening the feeding system or adding product; wipe the lid of the formula can with clean gauze; wear sterile gloves for critically ill or immunocompromised patients.
- Label open cans with date and time opened; cover and keep refrigerated. Discard any unused open cans after 24 hours.
- *Do not use blue (or any color) food dye in formula because it does not assess aspiration and can cause serious complications.*
- To prevent aspiration, keep the head of the bed elevated at least 30 degrees during the feeding and for at least 1 hour after the feeding for bolus feeding; continuously maintain semi-Fowler's position for patients receiving cyclic or continuous feeding.
- Monitor laboratory values, especially blood urea nitrogen (BUN), serum electrolytes, hematocrit, prealbumin, and glucose.
- Monitor for complications of tube feeding, especially diarrhea.
- Monitor and carefully record the patient's weight and intake and output as requested by the physician or dietitian.

### **Complications of Total Enteral Nutrition.**

*The nursing priority for care is patient safety, including preventing, assessing, and managing complications associated with tube feeding. Some complications of therapy result from the type of tube used to administer the feeding, and others result from the enteral product itself. The most common problem is the development of an obstructed (“clogged”) tube. Use the tips in [Chart 60-5](#) to maintain tube patency.*

#### **Chart 60-5**

### **Best Practice for Patient Safety & Quality Care** OSEN

#### **Maintaining a Patent Feeding Tube**

- Flush the tube with 20 to 30 mL of water (or the amount prescribed by the health care provider or dietitian):

- At least every 4 hours during a continuous tube feeding
- Before and after each intermittent tube feeding
- Before and after drug administration (use warm water)
- After checking residual volume
- If the tube becomes clogged, use 30 mL of water for flushing, applying gentle pressure with a 50-mL piston syringe.
- Avoid the use of a carbonated beverage, except for existing clogs *when water is not effective*. Do not use cranberry juice.
- Whenever possible, use liquid medications instead of crushed tablets unless liquid forms cause diarrhea; make sure that the drug is compatible with the feeding solution.
- Do not mix drugs with the feeding product before giving. Crush tablets as finely as possible and dissolve in warm water. (*Check to see which tablets are safe to crush. For example, do not crush slow-acting [SA] or slow-release [SR] drugs.*)
- Consider use of automatic-flush feeding pump such as Flexiflo or Kangaroo.

Patients receiving TEN are at risk for several other complications, including refeeding syndrome; tube misplacement and dislodgment; abdominal distention and nausea/vomiting; and FLUID AND ELECTROLYTE imbalance, often associated with diarrhea. These problems can be prevented if the patient is monitored carefully and complications are detected early.

### Refeeding Syndrome.

**Refeeding syndrome** is a potentially life-threatening metabolic complication that can occur when nutrition is restarted for a patient who is in a *starvation* state. When a patient is starved for nutrition, the body breaks down fat and protein, rather than carbohydrates, for energy. Protein catabolism leads to muscle and cell loss, often in major organs such as the heart, liver, and lungs. The body's cells lose valuable electrolytes, including potassium and phosphate, into the plasma. Insulin secretion decreases in response to these changes. When *refeeding* begins, insulin production resumes; and the cells take up glucose and electrolytes from the bloodstream, thus depleting serum levels.

## Nursing Safety Priority QSEN

### Critical Rescue

Recognize that the electrolyte shift of refeeding syndrome can cause cardiovascular, respiratory, and neurologic problems, primarily as a result of hypophosphatemia, according to a classic study by Mehanna et al. (2008). Observe for signs and symptoms to recognize this electrolyte imbalance, including shallow respirations, weakness, acute confusion, seizures, and increased bleeding tendency. Respond by reporting to the health care provider and documenting your findings immediately. More information on FLUID AND ELECTROLYTE imbalance can be found in Chapter 11.

Refeeding syndrome can be prevented if patients are carefully assessed and managed for nutrition needs. Interventions to supplement or replace NUTRITION should be implemented early before the patient is in a starvation state. Patients receiving parenteral nutrition (described later in this chapter) also may experience refeeding syndrome.

### Tube Misplacement and Dislodgment.

A serious complication is misplacement or dislodgment of the tube, *which can cause aspiration and possible death. Immediately remove any tube that you suspect is dislodged!* **The Joint Commission's National Patient Safety Goals and the Centers for Medicare and Medicaid Services require all health care facilities to establish and implement procedures and systems to prevent patient harm from medical complications.**

Several techniques should be used to confirm proper placement to prevent harm and to keep the patient safe. *An x-ray is the most accurate confirmation method and should always be done on initial tube insertion.* After the initial placement is confirmed, check the placement before each intermittent feeding or at least every 4 to 8 hours during feeding. Also check placement before each drug administration.

*The traditional auscultatory method for checking tube placement may not be reliable, especially for patients with small-bore tubes.* In this method, the nurse instills 20 to 30 mL of air into the tube (“insufflation”) while listening over the epigastric area (stomach) with a stethoscope. *The resulting “whooshing” sound does not guarantee correct tube placement!*

Several safer procedures have been recommended for checking tube placement *after the initial placement has been confirmed by x-ray.* These methods include:

- Testing aspirated contents for pH, bilirubin, trypsin, or pepsin
- Assessing for carbon dioxide using capnometry

Some hospitals and nursing homes support testing the *pH of GI contents* at the bedside. To perform this procedure, aspirate a sample of the GI content, observe its color, and test its pH. When aspirating fluid, wait at least 1 hour after drug administration and then flush the tube with 20 mL of air to clear it. Collect the aspirate and test it with pH paper. The pH of gastric fluid ranges from 0 to 4.0. If the tube has moved down into the intestines, the pH will be between 7.0 and 8.0. If the tube is in the lungs, the pH will be greater than 6.0. The pH may also be as high as 6.0 if the patient takes certain drugs, such as H<sub>2</sub> blockers (e.g., ranitidine [Zantac] and famotidine [Pepcid]). Because these drugs affect pH, bilirubin testing or capnometry may be a more reliable and valid method for predicting tube location.

*Capnometry can determine if carbon dioxide is emitted from the tube (Kodali & Urman, 2014).* A device to measure the presence of the gas is attached to the end of the tube after placement. The test is positive for carbon dioxide if the tube is placed into the lungs rather than the stomach. *The tube should be removed immediately if the gas is detected.*

## Nursing Safety Priority QSEN

### Action Alert

If enteral tubes are misplaced or become dislodged, the patient is likely to aspirate. Aspiration pneumonia is a life-threatening complication associated with TEN, especially for older adults. Observe for increasing temperature and pulse and for other signs of dehydration such as dry mucous membranes and decreased urinary output. Auscultate lungs every 4 to 8 hours to check for diminishing breath sounds, especially in lower lobes. Patients may become short of breath and report chest discomfort. A chest x-ray confirms this diagnosis, and treatment with antibiotics is started.

### Abdominal Distention and Nausea/Vomiting.

Abdominal distention, nausea, and vomiting during tube feeding are often caused by overfeeding. To *prevent* overfeeding, check gastric residual volumes every 4 to 6 hours, depending on facility policy and the needs of the patient. The American Society of Parenteral and Enteral Nutrition (ASPEN) (2011) recommends holding a feeding if the gastric residual volumes are more than 200 mL on two consecutive assessments. In some facilities, feedings are temporarily held if the gastric residual is 100 mL or more, depending on the patient. After a period of rest, the feeding can be restarted at a lower flow rate.

### Fluid and Electrolyte Imbalances.

*Patients receiving enteral nutrition therapy are at an increased risk for fluid imbalances.* They are often older or debilitated and may also have cardiac or renal problems. Fluid imbalances associated with

enteral nutrition are usually related to the body's response to increased serum osmolarity, but *fluid overload* from too much tube feeding can also occur.

Osmolarity is the amount or concentration of particles dissolved in solution. This concentration exerts a specific osmotic pressure within the solution. Normal osmolarity of extracellular fluid (ECF) ranges between 270 and 300 mOsm. Enteral feeding products range in osmolarity from isotonic (about 300 mOsm) to extremely hypertonic (600 mOsm). Electrolytes (including sodium) contribute to this hypertonicity, but more of the osmolarity is determined by the concentration of proteins and sugar molecules in the enteral product. Even when the product is isotonic, the ECF can become hyperosmolar unless some hypotonic fluids are also administered to the patient. This situation is most likely to develop in patients who are unconscious, unable to respond to the thirst reflex, on fluid restrictions, or receiving hyperosmotic enteral preparations.

Because increased plasma osmolarity is largely a result of extra glucose and proteins (which tend to remain in the plasma rather than move to interstitial spaces), the plasma osmotic pressure (water-pulling pressure) is increased. In this situation, intracellular and interstitial water move into and expand the plasma volume. This volume expansion results in an increased renal excretion of water (in patients with normal renal function) and leads to osmotic *dehydration*.

## Considerations for Older Adults

### Patient-Centered Care QSEN

If patients do *not* have normal renal and cardiac function, expansion of the plasma volume can lead to circulatory overload and pulmonary edema, especially in older adults. Therefore early identification of patients at risk for impairment of renal and/or cardiac function is important. Assess for signs and symptoms of circulatory overload, such as peripheral edema, sudden weight gain, crackles, dyspnea, increased blood pressure, and bounding pulse. Collaborate with the dietitian and health care provider to plan the correct amount of fluid to be provided.

Excessive *diarrhea* may develop when hyperosmolar enteral preparations are delivered quickly. This situation can also lead to *dehydration* through excessive water loss. Collaborate with the health care provider and dietitian for recommendations to prevent diarrhea. The dietitian usually changes the feeding to a more iso-osmolar formula. Most of these formulas can be started full strength but slowly at 15 to 20 mL/hr. The rate is gradually increased as the patient tolerates and as the expected nutrition outcome is achieved.

If diarrhea continues, especially if it has a very foul odor, evaluate the patient for *Clostridium difficile* or other infectious organisms. Contamination can occur because of repeated and often faulty handling of the feeding solution and system. **Per The Joint Commission's National Patient Safety Goals, wear clean gloves when changing systems and adding product. Sterile gloves may help prevent infection in critically ill or immunocompromised patients.** A closed feeding system is preferred over an open one because the chance of contamination is lessened (see [Chart 60-4](#)). Tubes with ports also minimize contamination by eliminating the need to open the feeding system to administer drugs.

In some cases, diarrhea may be the result of multiple liquid medications, such as elixirs and suspensions that have a very high osmolarity. Examples include acetaminophen (Tylenol), furosemide (Lasix), and phenytoin (Dilantin). Patients receiving multiple liquid drugs should be evaluated by the health care provider to determine whether their drug regimen can be changed to prevent diarrhea. Diluting these liquids may also be an option.

Depending on the patient's state of health, some electrolyte imbalances can be avoided. This is achieved by the use of enteral preparations containing lower concentrations of the electrolytes that the patient cannot handle well. For example, renal patients with high potassium levels receive a special formula that is used for this imbalance.

*The two most common electrolyte imbalances associated with enteral nutrition therapy are hyperkalemia and hyponatremia.* Both of these conditions may be related to hyperglycemia-induced hyperosmolarity of the plasma and the resultant osmotic diuresis. Risks for disturbances in FLUID AND ELECTROLYTE BALANCE are discussed in detail in [Chapter 11](#).

### Parenteral Nutrition.

When a patient cannot effectively use the GI tract for NUTRITION, either partial or total parenteral nutrition therapy may be needed. This form of IV therapy differs from standard IV therapy in that any or all nutrients (carbohydrates, proteins, fats, vitamins, minerals, and trace elements) can be given. One liter of IV fluid containing 5% dextrose, which is often used as standard therapy, provides only 170 kcal. A hospitalized patient typically receives 3 to 4 L a day, for a total number of calories ranging between 500 and 700 a day. This calorie intake is not sufficient when the patient requires IV therapy for a prolonged period and cannot eat an adequate diet or has increased calorie needs for tissue repair and building.

### Partial Parenteral Nutrition.

Partial, or peripheral, parenteral nutrition (PPN) is usually given through a cannula or catheter in a large distal vein of the arm or through a peripherally inserted central catheter (PICC line). (See [Chapter 13](#) for care of patients with PICC lines.) The alternative is used for some patients who can eat but are not able to take in enough nutrients to meet their needs. The patient must have adequate peripheral vein access and be able to tolerate large volumes of fluid to have PPN. Two types of solutions are commonly used in various combinations for PPN: IV fat (lipid) emulsions (IVFEs) and amino acid–dextrose solutions. IVFEs are usually given using a piggyback method.

## Nursing Safety Priority QSEN

### Critical Rescue

Recognize that you must monitor patients receiving fat emulsions for fever, increased triglycerides, clotting problems, and multi-system organ failure to recognize indications of fat overload syndrome, especially in those who are critically ill. If any of these signs and symptoms is present, respond by discontinuing the IVFE infusion and reporting the changes to the health care provider immediately.

Most IVFEs (20% fat emulsion) are isotonic, but the tonicity of commercially prepared amino acid–dextrose solutions ranges from 300 mOsm to nearly 900 mOsm for PPN. Amino acid–dextrose solutions are considered more stable than IVFEs; therefore additives (e.g., vitamins, minerals, electrolytes, trace elements) tend to be mixed with them. These solutions must be delivered through an in-line filter and are administered by an infusion pump for an accurate and constant delivery rate.

Some PPN products are a *mixture* of lipids (10% or 20% fat emulsion) and an amino acid–dextrose (usually 10%) solution. This mixture of three types of nutrients is referred to as a 3 : 1, *total nutrient admixture (TNA)*, or *triple-mix solution*.

### Total Parenteral Nutrition.

When the patient requires intensive NUTRITION support for an extended time, the health care provider prescribes centrally administered **total parenteral nutrition (TPN)**. TPN is delivered through access to central veins, usually through a PICC line or the subclavian or internal jugular veins. Central venous catheters and associated nursing care are described in detail in [Chapter 13](#).

Total parenteral nutrition solutions contain higher concentrations of dextrose and proteins, usually in the form of synthetic amino acids or protein hydrolysates (3% to 5%). These solutions are hyperosmotic (three to six times the osmolarity of normal blood). The base solutions are available as commercially prepared solutions. The hospital or community pharmacist adds components (specific electrolytes, minerals, trace elements, and insulin) according to the patient's nutrition needs. This therapy provides needed calories and spares body proteins from catabolism for energy requirements.

The TPN solutions are administered with an infusion pump. The osmolarity of the fluid and the concentrations of the specific components make controlled delivery essential.

Patients receiving parenteral nutrition fluids are at risk for a wide variety of serious and potentially life-threatening complications. Complications may result from the solutions or from the peripheral or central venous catheter. The following discussion is limited to the complications that involve FLUID AND ELECTROLYTE BALANCE. Complications of IV cannulas and central venous catheters are discussed in [Chapter 13](#), including infection and sepsis.

Patients receiving parenteral nutrition therapy are at high risk for fluid imbalance. If the patient also has cardiac or renal dysfunction, he or she may develop fluid overload, congestive heart failure, and pulmonary edema. Monitor the infusion rate of the parenteral fluid, and give insulin as prescribed. Monitor for these complications by taking daily weights and documenting accurate intake and output while the patient is receiving parenteral nutrition. Serum glucose and electrolyte values are also monitored (Chart 60-6). Report any major changes or abnormalities to the health care provider and document all assessments and interventions.

### Chart 60-6

## Best Practice for Patient Safety & Quality Care QSEN

### Care and Maintenance of Total Parenteral Nutrition

- Check each bag of total parenteral nutrition (TPN) solution for accuracy by comparing it with the physician's or pharmacist's prescription.
- Monitor the IV pump for accuracy in delivering the prescribed hourly rate.
- If the TPN solution is temporarily unavailable, give 10% dextrose/water (D<sub>10</sub>W) or 20% dextrose/water (D<sub>20</sub>W) until the TPN solution can be obtained.
- If the TPN administration is not on time ("behind"), do not attempt to "catch up" by increasing the rate.
- Monitor the patient's weight daily or according to facility protocol.
- Monitor serum electrolytes and glucose daily or per facility protocol. (Many facilities require fingerstick blood sugars [FSBSs] every 4 hours, especially if the patient is receiving insulin. Urine testing for ketones may also be requested.)
- Monitor for, report, and document complications, including fluid and electrolyte imbalances.
- Monitor and carefully record the patient's intake and output.
- Assess the patient's IV site for signs of infection or infiltration (see Chapter 13).
- Change the IV tubing every 24 hours or per facility protocol.
- Change the dressing around the IV site every 48 to 72 hours or per facility protocol.
- Before administering TPN, have a second nurse check the prescription and solution to prevent patient harm.

Patients receiving TPN are at an increased risk for many different disturbances of FLUID AND ELECTROLYTE BALANCE, depending on the composition of the solution and whether a fluid imbalance occurs. The health care provider usually requests frequent determinations of serum electrolyte levels to detect these imbalances. The risk for metabolic and electrolyte complications is reduced when the rate of administration is carefully controlled and patients are closely monitored for response to treatment. Potassium and sodium imbalances are common, especially when insulin is also administered as part of the therapy. Calcium imbalances, particularly hypercalcemia, are associated with TPN.

### Care Coordination and Transition Management

Malnourished patients can be cared for in a variety of settings, including the acute care hospital, transitional care unit, nursing home, or their own home. Malnutrition is often diagnosed when the patient is admitted to the acute care hospital or shortly after hospitalization if complications such as poor wound healing or sepsis occur. If the patient is severely compromised, he or she may require

admission to a traditional nursing home for either transitional or long-term care. If adequate home support is available, he or she may be discharged to home in the care of a family member or other caregiver. Home care nurses may be needed to monitor and direct the care.

### **Home Care Management.**

The malnourished patient needs a variety of resources at home to continue aggressive NUTRITION support. If he or she can consume food by the oral route, the case manager or other discharge planner determines whether financial resources are available for the necessary nutrition supplements. If the hospital provides ambulatory nutrition counseling services, the patient is scheduled for follow-up after discharge for assessment of weight gain.

### **Self-Management Education.**

The dietitian teaches the malnourished patient and family about high-calorie, high-protein diet and NUTRITION supplements. It is important to educate the patient and family about the following:

- Reinforce the importance of adhering to the prescribed diet.
- Review any drugs the patient may be taking.
- If using an iron preparation, teach the importance of taking the drug immediately before or during meals.
- Caution the patient that iron tends to cause constipation.
- For the patient already susceptible to constipation, emphasize the importance of measures for prevention, including adequate fiber intake, adequate fluids, and exercise. Teach the family or other caregiver how to continue these therapies.
- Remind caregivers to consider the psychosocial aspects of these alternative methods for nutrition.
- Moving the feeding equipment out of view of the patient when it is not in use is also helpful.

### **Health Care Resources.**

The malnourished patient discharged to home on enteral or parenteral nutrition support needs the specialized services of a home nutrition therapy team. This team generally consists of the physician, nurse, dietitian, pharmacist, and case manager or social worker. Several commercial companies supply these services to patients at home in addition to the feeding supplies and formulas and health teaching.

### **◆Evaluation: Reflecting**

Evaluate the care of the malnourished patient based on the identified priority patient problem. The primary expected outcome is that the patient consumes available nutrients to meet the metabolic demands for maintaining weight and total protein and has adequate hydration.

## Nutrition Concept Exemplar Obesity

### Pathophysiology

Obesity is not just one disease; it includes many conditions with varying causes. The terms *obesity* and *overweight* are often used interchangeably, but they refer to different health problems. For both problems, the patient often does not consume enough healthy nutrients and may not receive adequate NUTRITION. **Overweight** is an increase in body weight for height compared with a reference standard, or up to 10% greater than ideal body weight (IBW) and a body mass index (BMI) of 25 to 29. This weight may not reflect excess body fat. For example, well-developed athletes may appear overweight because of increased muscle (lean) mass, in which the proportion of muscle to fat is greater than average.

**Obesity** refers to an excess amount of body fat when compared with lean body mass. The normal amount of body fat in *men* is between 15% and 20% of body weight. For *women*, the normal amount is 18% to 32%. An obese adult weighs at least 20% above the upper limit of the normal range for ideal body weight and has a BMI of 30 or more. **Morbid obesity** refers to a weight that has a severely negative effect on health—usually more than 100% above IBW and a BMI over 40.

More than one third of Americans have obesity (CDC, 2016). About 10% or more of adults are morbidly obese. *This problem is the second leading cause of preventable deaths in the United States, second only to smoking, and has become a national crisis.* Obesity across the life span is considered an epidemic in the United States and Canada. Worldwide, it is recognized as a major global health problem, costing billions of dollars for health care and lost productivity.

The pathophysiology of obesity is very complex. A number of chemicals in the body, including hormones known as *adipokines*, work together to affect appetite and fat metabolism:

- **Leptin**: a hormone released by fat cells and possibly by gastric cells; it also acts on the hypothalamus to control appetite
- **Adiponectin**: an anti-inflammatory and insulin-sensitizing hormone
- **Resistin**: a hormone produced by fat cells that creates resistance to insulin activity
- **Inflammatory cytokines**: such as inflammatory interleukins and tumor necrosis factor- $\alpha$
- **Apolipoprotein E**: one of several regulators of lipoprotein metabolism
- **Cholecystokinin**: a hormone that stimulates digestive juices and may work with leptin to increase or decrease appetite
- **Ghrelin**: the “hunger hormone” that is secreted in the stomach; increases in a fasting state and decreases after a meal

Some adipokines are neuropeptides, including orexins and anorexins, which play a role in body weight. **Orexins** are appetite stimulants; examples are ghrelin secreted by the stomach and peptide YY from the intestines. **Anorexins** decrease appetite and include leptin and insulin (McCance et al., 2014). Increased circulating plasma levels of orexins are associated with the development of obesity. However, in some, adults high levels of leptin may not be effective in suppressing appetite—a condition known as *leptin resistance*. In this case, overeating and excessive weight gain can result. Hyperleptinemia also stimulates the autonomic nervous system and contributes to blood vessel inflammation and ventricular hypertrophy. Obesity is also associated with insulin resistance, which predisposes patients with obesity to type 2 diabetes mellitus (see Chapter 64).

The distribution of excess body fat rather than the degree of obesity has been used to predict increased health risks. For example, the waist circumference (WC) is a stronger predictor of coronary artery disease (CAD) than is the BMI. A WC greater than 35 inches (89 cm) in women and greater than 40 inches (102 cm) in men indicates central obesity (National Institute of Diabetes and Digestive and Kidney Diseases, 2017). Central obesity is a major risk factor for CAD, stroke, type 2 diabetes, some cancers (e.g., colon, breast), sleep apnea, and early death.

The waist-to-hip ratio (WHR) is also a predictor of CAD. This measure differentiates peripheral lower body obesity from central obesity. A WHR of 0.95 or greater in men (0.8 or greater in women) indicates android obesity with excess fat at the waist and abdomen.

### Complications of Obesity

The major complications of obesity affect primarily the cardiovascular and respiratory systems.

However, excess weight can also cause degeneration of the musculoskeletal system, especially the weight-bearing joints such as hips and knees (osteoarthritis). Obese adults are also more susceptible to infections and infectious diseases than are thinner adults and tend to heal more slowly. [Table 60-3](#) lists some of the most common complications of obesity.

**TABLE 60-3**  
**Common Complications of Obesity**

<ul style="list-style-type: none"><li>• Type 2 diabetes mellitus</li><li>• Hypertension</li><li>• <b>Hyperlipidemia</b> (increased serum lipids)</li><li>• Coronary artery disease (CAD)</li><li>• Stroke</li><li>• Peripheral artery disease (PAD)</li><li>• Metabolic syndrome</li><li>• Obstructive sleep apnea</li><li>• Obesity hypoventilation syndrome</li><li>• Depression and other mental health/behavioral health problems</li><li>• Urinary incontinence</li><li>• <b>Cholelithiasis</b> (gallstones)</li><li>• Gout</li><li>• Chronic back pain</li><li>• Early osteoarthritis</li><li>• Decreased wound healing</li></ul>
---

### Etiology and Genetic Risk

The causes of obesity involve complex interrelationships of many environmental, genetic, and behavioral factors. One of the most common causes of being overweight or obese is eating *high-fat and high-cholesterol diets*. Obesity is associated with diet when it contains a significant amount of *saturated fat*, which increases low-density lipoproteins (LDL, or LDL-C for low-density lipoproteins cholesterol). *Trans* fatty acids (TFAs), saturated fats, and cholesterol are linked to a higher risk for heart disease ([American Heart Association, 2017](#)). By contrast, monounsaturated and polyunsaturated fats are healthy fats.

*Physical inactivity* has been identified as another cause of overweight and obesity. The major barriers to increasing physical activity include:

- Lack of time
- Learned behaviors regarding a sedentary lifestyle
- Decreased mobility associated with prolonged illness.

Regular exercise is associated with:

- Lower death rates for adults of any age
- Increased lean muscle
- Decreased body fat
- Weight control
- Enhanced psychological well-being.

Some adults think that regular exercise has to include joining a fitness program or exercising for long periods; simple forms of exercise such as walking 20 minutes provide the same type of benefit. Older adults can engage in this type of exercise. It does not cost money (like joining a program) and provides health benefits such as strengthening joints and improving cardiovascular health.

Another cause of obesity is *drug therapy*. Some prescribed drugs contribute to weight gain when they are taken on a long-term basis. Examples include:

- Corticosteroids
- Estrogens and certain progestins
- NSAIDs
- Antihypertensives
- Antidepressants and other psychoactive drugs
- Antiepileptic drugs
- Certain oral antidiabetic agents

## Genetic/Genomic Considerations

## Patient-Centered Care QSEN

Familial and genetic factors play an important role in obesity. When both parents are overweight, about 80% of their children will be overweight. If neither parent is overweight, fewer than 10% of the children will be overweight. In studies of nonidentical twins, when one twin is obese, the second twin also is obese about 30% of the time. In studies of identical twins, when one twin is obese, the second twin also is obese about 80% of the time. These results indicate a strong genetic component to obesity along with lifestyle (environmental) influences. Genome-wide association studies indicate that mutations in many genes are associated with the development of obesity (Online Mendelian Inheritance in Man [OMIM], 2016).

Genetic composition may predispose some adults but not others to obesity. Leptin, the hormone encoded by the *ob* gene, appears to send a message to the brain that the body has stored enough fat. This message serves as a signal to stop eating. An abnormality of this gene has been found in some adults with obesity. In some obese adults, other gene mutations have been identified that appear to contribute to obesity (e.g., activation of the melanocortin-4 receptor, which normally inhibits appetite). In some families with a history of obesity, an abnormality in the gene coding for this receptor causes appetite to be less inhibited.

## Health Promotion and Maintenance

Obesity is a major public health problem and is associated with many complications, including death. As a result of this increasing problem, the *Healthy People 2020* agenda addresses the need to reduce the proportion of children, adolescents, and adults who are obese. *Healthy People 2020 Objectives for Nutrition and Weight Status* include specific population targets related to obesity and healthy nutrition habits (Table 60-4). In collaboration with the dietitian, teach the importance of weight management and exercise to improve health. Even a 5% weight loss can drastically decrease the risk for coronary artery disease (CAD) and diabetes mellitus. Nurses who practice healthful behaviors and value a healthy lifestyle are more likely to be seen by patients as credible teachers of this information (Marchiondo, 2014).

**TABLE 60-4**

### Meeting *Healthy People 2020* Sample Objectives and Targets: Nutrition and Weight Status

- Reduce the proportion of adults who are obese (by 10%).
- Increase the proportion of adults who are at a healthy weight (by 10%).
- Increase the proportion of physician visits made by adult patients that include counseling about nutrition or diet (by 15.2%).
- Increase the proportion of primary care physicians who regularly assess body mass index (BMI) in their adult patients (by 10%).
- Increase the contribution of total vegetables to the diets of the population age 2 years and older (to 1.1 cups per 1000 calories).
- Increase the contribution of fruits to the diets of the population age 2 years and older (to 0.9 cups per 1000 calories).
- Reduce consumption of saturated fat in the population age 2 years and older (by 9.5%).

## NCLEX Examination Challenge 60-3

### Psychosocial Integrity

A client with obesity tells the nurse, "I wouldn't be overweight if it weren't for my genes." What is the appropriate nursing response? **Select all that apply.**

- A. "Genes are responsible for obesity."
- B. "Tell me about your family history."
- C. "Let's talk about your nutrition intake."
- D. "How do you feel about exercise?"
- E. "You should get bariatric surgery."

### Incidence and Prevalence

Between 2011 and 2014, 36.5% of U.S. adults were identified as obese, with the prevalence of obesity

being greater in women than in men and greater in adults 40 to 59 years of age than in younger adults ([National Center for Health Statistics, 2015](#)). Worldwide, approximately 2.8 million people die annually from complications associated with overweight or obesity ([World Health Organization, 2017](#)).

## ❖ Interprofessional Collaborative Care

Care for the patient with obesity takes place in a variety of settings, from the home, to the community, and in the hospital setting if more comprehensive management or surgery is needed. Members of the interprofessional team who collaborate most closely to care for the patient with malnutrition include the health care provider, surgeon if surgery is required, nurse, social worker, and dietitian. For patients who experience psychological impact from or related to obesity, a psychologist or therapist will also have an important role in care.

### ◆ Assessment: Noticing

#### History.

Patients with obesity may be embarrassed or reluctant to talk about their weight or fear judgment because of the stigma that can be attached to this condition. Approach patients with obesity by using the acronym RESPECT, created by The Ohio State University ([Budd & Peterson, 2015](#)). Create a rapport with them in an environment that is safe. Ensure their safety and privacy, encourage them to set realistic goals (in the planning phase), provide compassion, and use fact in conversation. In addition to taking a complete history regarding present and past health problems, collect this information about the patient in collaboration with the dietitian:

- Economic status
- Usual food intake
- Eating behavior
- Cultural background
- Attitude toward food
- Appetite
- Chronic diseases
- Drugs (prescribed and over-the-counter [OTC], including herbal preparations)
- Physical activity/functional ability
- Family history of obesity
- Developmental level

A nutrition history usually includes a 24-hour recall of food intake and the frequency with which foods are consumed. The adequacy of the diet can be evaluated by comparing the amount and types of foods consumed daily with the established standards. The dietitian then provides a more detailed analysis of nutrition intake. You should be aware that patients who live in food deserts (i.e., urban areas where fresh, healthy food is in low supply or unaffordable) may have difficulty obtaining food that is densely nutritious.

#### Physical Assessment/Signs and Symptoms.

Obtain an accurate height and weight. The dietitian calculates the percentage of ideal body weight (% IBW) and the body mass index (BMI). He or she may also:

- Measure the waist circumference
- Calculate the waist-to-hip ratio
- Determine arm and calf circumferences

Examine the skin of the patient with obesity for reddened or open areas. Lift skinfold areas, such as pendulous breasts and abdominal aprons (**panniculus**), to observe for *Candida* (yeast) (a condition called *intertrigo*) or other infections or lesions. Infection of the panniculus is referred to as **panniculitis**.

#### Psychosocial Assessment.

Obtain a psychosocial history to determine the patient's circumstances and emotional factors that might prevent successful therapy or that might be worsened by therapy. Interview the patient to determine his or her perception of current weight and weight reduction. Some patients do not view weight as a problem, which affects planning, treatment, and outcome. Ask the patient questions about his or her health beliefs related to being overweight, such as:

- What does food mean to you?
- Do you want to lose weight?
- What prevents you from losing weight?
- What do you think will motivate you to lose weight?
- How do you think you might benefit from losing weight?

Many patients report that they have tried multiple diets to lose weight but either the diets have not worked or they regained the weight they had initially lost. Adults who attempt restrictive diets become easy targets for the billion-dollar weight-loss industry, yet most dieters regain lost weight. This problem can be even more concerning for the older adult who loses weight and then regains it.

The results of dieting and other efforts can lead to a sense of failure and lowered self-esteem, which often stimulates more overeating. Many overweight and obese adults eat in response to environmental and emotional stressors rather than because they are hungry. Ask patients to identify their perceived stressors and what triggers their need for food.

Lifestyle changes are difficult without adequate family and community support. Assess useful coping strategies and support systems that the patient can use during treatment for obesity.

Explore the patient's history to assess:

- Attempts at weight-reduction diets and outcomes
- Effects of obesity on lifestyle
- Effects of obesity on social interactions
- Mental health/behavioral health problems, such as depression
- Effects of obesity on intimate relationships, especially sexuality

Obese men often experience erectile dysfunction (ED), which can cause or worsen depression. Women often experience changes in their menstrual cycles and may have problems getting pregnant.

### ◆**Analysis: Interpreting**

The priority collaborative problem for the patient with obesity is:

1. Weight gain due to excessive intake of calories

### ◆**Planning and Implementation: Responding**

#### **Improving Nutrition.**

Weight is lost when energy used is greater than intake. Weight loss may be accomplished by nutrition modification with or without the aid of drugs and in combination with a regular exercise program. Patients who may be candidates for surgical treatment include those who have:

- Repeated failure of nonsurgical interventions
- A BMI equal to or greater than 40
- Weight more than 100% above IBW (i.e., morbidly obese)

#### **Nonsurgical Management.**

Various nutrition approaches and drug therapy have been attempted to help patients with obesity achieve permanent weight loss.

#### **Diet Programs.**

Diets for helping adults lose weight include fasting, very-low-calorie diets, balanced and unbalanced low-energy diets, and novelty diets.

*Short-term fasting programs* have not been successful in treating morbidly obese patients, and prolonged fasting does not produce permanent benefits. Most patients regain the weight that was

lost by this method. In addition, the risks associated with fasting (e.g., severe ketosis) require close medical supervision.

*Very-low-calorie diets* generally provide 200 to 800 calories/day. Two types of these diets are the *protein-sparing modified fast* and the *liquid formula diet*. The protein-sparing modified fast provides protein of high biologic value (1.5 g/kg of desirable body weight daily) within a limited number of calories. This diet produces rapid weight loss while preserving lean body mass. The liquid formula diet provides between 33 and 70 g of protein daily.

Both diets require an initial cardiac evaluation, supervision by an interdisciplinary health care team with monitoring by a physician, nutrition counseling by a dietitian, and supplementation with vitamins and minerals. Patients who are on these diets should receive nutrition education, psychological counseling, exercise, and behavior therapy. Comparable weight losses have been achieved with both diets; but, again, most patients regain the weight they lost.

*Nutritionally balanced diets* generally provide about 1200 calories/day with a conventional distribution of carbohydrate, protein, and fat. Vitamin and mineral supplements may be necessary if energy intakes fall below 1200 calories for women and 1800 calories for men. These diets provide conventional food that is economical and easy to obtain. Thus the outcome of weight loss is facilitated, and it is hoped that loss is maintained. For example, Weight Watchers is an organization that provides education about nutritionally balanced diets based on a point system. They offer on-site weekly group support meetings or the option of an online community.

*Unbalanced low-energy diets*, such as the low-carbohydrate diet (e.g., Atkins or South Beach diet), restrict one or more nutrients. Protein and vegetables are encouraged, but certain carbohydrates and high-fat foods are not. Although they remain controversial in the medical community, these diets are extremely popular. Scientific outcome data have been conflicting.

*Novelty* diets, such as the grapefruit diet, the Cookie diet, and the Hollywood diet, are often nutritionally *inadequate*. This type of diet implies that a certain food or liquid increases metabolic rate or accelerates the oxidation of body fat. Weight loss is achieved because energy is restricted by food choice, but patients do not sustain weight loss after stopping the diet.

### Nutrition Therapy.

Nutrition recommendations for each patient are developed through close interaction among the patient, family, physician, nurse, and dietitian. The diet must meet the patient's needs, habits, and lifestyle and should be realistic.

The dietitian develops a diet plan and instructs the patient. At a minimum, the diet should:

- Have a scientific rationale
- Be nutritionally adequate for all nutrients
- Have a low risk-benefit ratio
- Be practical and conducive to long-term success

Calorie estimates are easily calculated. Resting metabolic rate is determined using a gender-specific formula that incorporates the appropriate activity factor. This figure reflects the total calories needed daily for maintaining current weight. To encourage a weight loss of 1 lb (0.45 kg) a week, the dietitian subtracts 500 calories each day. To encourage a weight loss of 2 lb (0.9 kg) a week, 1000 calories each day are subtracted. The amount of weight lost varies with the patient's food intake, level of physical activity, and water losses. A reasonable expected outcome of 5% to 10% loss of body weight has been shown to improve glycemic control and reduce cholesterol and blood pressure. These benefits continue if the weight loss is sustained.

### Exercise Program.

Along with change in eating habits, a major intervention to manage obesity is to increase the type and amount of daily exercise to burn calories. For most adults, adding exercise to a nutrition intervention produces more weight loss than just dieting alone. More of the weight lost is fat, which preserves lean body mass. An increase in exercise can reduce the waist circumference and the waist-to-hip ratio.

A minimum-level workout should be developed so consistency can be achieved. The expected outcome is to maintain a lifetime of increased physical activity. The patient is likely to be less fatigued and discouraged with a low-intensity, short-duration program. Encourage sedentary (physically inactive) patients to increase their activity by walking 30 to 40 minutes at least 5 days

each week. The activity may be performed all at once or divided over the course of the day. Structured national programs with support staff may be helpful for some patients. The staff typically offers diet counseling and cardiovascular and muscle-toning activities.

### Drug Therapy.

A BMI of 30 or a BMI of 27 with comorbidities is one indicator for the use of drug therapy.

**Anorectic drugs** suppress appetite, which reduces food intake and, over time, may result in weight loss. Over the years, the U.S. Food and Drug Administration (FDA) has removed several drugs from the market and not approved other drugs because of concerns about cardiovascular complications associated with long-term use. Prescription drugs still available for longer-term treatment of obesity include orlistat (Xenical), lorcaserin (Belviq), phentermine-topiramate (Qsymia), naltrexone SR/bupropion SR (Contrave), and liraglutide (Saxenda, Victoza 🍀).

Orlistat (Xenical) inhibits lipase and leads to partial hydrolysis of triglycerides. Because fats are only partially digested and absorbed, calorie uptake is decreased. Most patients taking this drug have GI symptoms that include loose stools, abdominal cramps, and nausea unless they reduce their fat intake to less than 30% of their food intake each day. Therefore the drug should be used with caution and limited to adults between 18 and 75 years of age. Treatment is usually not extended beyond 12 months. A lower-dose 60-mg orlistat tablet (Alli) is the only *over-the-counter* weight-loss aid product that has received FDA approval for long-term use.

Lorcaserin (Belviq) works by activating the serotonin 2C receptor in the brain to help decrease appetite and create a sense of feeling full after eating small amounts of food. Side effects may include headaches, dizziness, dry mouth, and constipation. Teach patients to report the signs of the rare but serious side effect of serotonin syndrome, including suicidal thoughts, psychiatric concerns, and problems with memory or comprehension.

Phentermine-topiramate (Qsymia) combines a short-term weight-loss drug (phentermine) with a drug that is used to control seizures (topiramate). Side effects may include an increased heart rate, hand and feet tingling, insomnia, dizziness, dry mouth, and constipation. Teach patients that a rare but serious side effect associated with this drug is suicidal thoughts, which should immediately be reported to the prescribing health care provider.

Naltrexone HCl/bupropion HCl (Contrave) combines the opioid antagonist naltrexone with the antidepressant bupropion. Patients with uncontrolled hypertension or seizure disorders should not take this drug. Teach patients about the possibility of an onset or increase in suicidal ideation and behaviors, as well as neuropsychiatric reactions.

Liraglutide (Saxenda, Victoza 🍀) injection activates appetite regulation in the brain, which decreases caloric intake. Patients taking insulin should not take this medication. Serious side effects can include a risk for medullary thyroid carcinoma, hypoglycemia, renal impairment, suicidal behaviors, and acute pancreatitis.

Other sympathomimetic drugs suppress appetite for *short-term* use along with a structured weight-management and exercise program. These drugs act on the central nervous system, including suppressing the appetite center in the hypothalamus. Examples include phentermine hydrochloride (Adipex-P), diethylpropion hydrochloride (Tenuate, Tenuate Dospan), and phendimetrazine tartrate (Bontril PDM).

## Nursing Safety Priority QSEN

### Drug Alert

Patients with hypertension, heart disease, and hyperthyroidism should not take anorectic drugs because they may worsen their symptoms. These drugs are not prescribed for any patient taking psychoactive agents because they cause similar side effects. Teach patients who are candidates for sympathomimetic drugs about side effects, which include:

- Palpitations
- Diarrhea or constipation
- Restlessness

- Insomnia
- Dry mouth
- Blurred vision (especially with Bontril PDM)
- Change in sex drive or activity
- Anxiety

### Behavioral Management.

Behavioral management of obesity helps the patient change daily eating habits to lose weight. Self-monitoring techniques include keeping a record of foods eaten (food diary), exercise patterns, and emotional and situational factors. Stimulus control involves controlling the external cues that promote overeating. Reinforcement techniques are used to self-reward the behavior change. Cognitive restructuring involves modifying negative beliefs by learning positive coping self-statements. Counseling by health care professionals must continue before, during, and after treatment. The 12-step program offered by Overeaters Anonymous ([www.aa.org](http://www.aa.org)) has helped many adults lose weight, especially those who are compulsive eaters.

### Complementary and Integrative Health.

Many complementary and integrative therapies have been tested and used for obesity. These modalities aim to suppress appetite and therefore limit food intake to lose weight:

- Acupuncture
- Acupressure
- Ayurveda (a combination of holistic approaches)
- Hypnosis

### Surgical Management.

At any weight, some patients seek to improve their appearance by having a variety of cosmetic procedures to reduce the amount of adipose tissue in selected areas of the body. A typical example of this type of surgery is **liposuction**, which can be done in a physician's office or ambulatory surgery center. Although the patient's appearance improves, if weight gain continues, the fatty tissue will return. This procedure is not a solution for adults who are morbidly obese.

Morbidly obese adults who do not respond to traditional interventions may be considered for a major surgical procedure aimed at producing permanent weight loss. Patients with a body mass index (BMI) of 40 or greater or a BMI of 35 or greater along with additional risk factors are considered for surgery. Surgery has been perceived as a last resort to address weight issues, but it is *the only method that has a long-term impact on morbid obesity*.

### Bariatrics.

**Bariatrics** is a branch of medicine that manages patients with obesity and its related diseases. Surgical procedures include these three types: gastric restrictive, malabsorption, or both. *Restrictive* surgeries decrease the volume capacity of the stomach to limit the amount of food that can be eaten at one time. As the name implies, *malabsorption* procedures interfere with the absorption of food and nutrients from the GI tract.

In 2014, more than 179,000 adults in the United States had bariatric surgical procedures ([American Society for Metabolic and Bariatric Surgery, 2014](#)), and that number continues to increase. The surgeon may use a conventional open approach or minimally invasive surgery (MIS). Most patients have MIS by having either the laparoscopic adjustable gastric band (LAGB) procedure or the laparoscopic sleeve gastrectomy (LSG). Both procedures are classified as restrictive surgeries. The decision of whether the patient is a candidate for the MIS is based on weight, body build, history of abdominal surgery, and co-existing medical complications. With any surgical approach, patients must agree to modify their lifestyle and follow stringent protocols to lose weight and keep the weight off. After bariatric surgery, many patients no longer have complications of obesity, such as diabetes mellitus, hypertension, depression, or sleep apnea.

### Preoperative Care.

Preoperative care is similar to that for any patient undergoing abdominal surgery or laparoscopy (see [Chapter 14](#)). However, patient with obesity are at increased surgical risks of pulmonary and thromboembolic complications, as well as death. Some surgeons require limited weight loss before bariatric surgery to decrease these complications. Patients also have a thorough psychological assessment and testing to detect depression, substance abuse, or other mental health/behavioral health problems that could interfere with their success after surgery. Cognitive ability, coping skills, development, motivation, expectations, and support systems are also assessed. Patients who are not alert and oriented or do not have sufficient strength and mobility are not considered for bariatric surgery. *The primary role of the nurse is to reinforce health teaching in preparation for surgery.* Most bariatric surgical centers provide education sessions for groups of patients who plan to have the procedure.

### Operative Procedures.

*Gastric restriction* surgeries allow for normal digestion without the risk for nutrition deficiencies. In the LAGB procedure, the surgeon places an adjustable band to create a small proximal stomach pouch through a laparoscope ([Fig. 60-4A](#)). The band may or may not be inflatable. For example, the REALIZE® band requires that saline be injected into a balloon to control the tightness of the band. This type of procedure is considered to be restrictive; malabsorption complications usually do not occur. For the LSG, the surgeon removes the portion of the stomach where ghrelin, the “hunger hormone,” is secreted. Restrictive surgeries are the easiest to perform. However, weight lost is often regained after a period of time. By contrast, patients having the malabsorption procedures maintain 60% to 70% of their weight loss even after 20 years.

**FIG. 60-4** Bariatric surgical procedures. A, Adjustable banded gastroplasty. B, Roux-en-Y gastric bypass (RYGB).

The most common *malabsorption surgery* performed in the United States is the *Roux-en-Y gastric bypass (RNYGB)*, which is often done as a robotic-assistive surgical procedure. This procedure results in quick weight loss, but it is more invasive with a higher risk for postoperative complications. In RNYGB, most commonly just called a **gastric bypass**, gastric resection is combined with malabsorption surgery. The patient's stomach, duodenum, and part of the jejunum are bypassed so fewer calories can be absorbed (Fig. 60-4B).

### Postoperative Care.

Postoperative care depends on the type of surgery (i.e., the conventional open approach or the minimally invasive technique). Although many patients have MIS, they are considered as having major abdominal surgery along with all its risks and are cared for accordingly. These patients may require less than 24 hours in the hospital; some may need 1 to 2 days. Patients with open procedures may need several days to recover.

Patients having one of the MIS procedures have less pain, scarring, and blood loss. They typically have a faster recovery time and a faster return to daily activities.

*The priority for immediate care of postoperative bariatric surgery patients is airway management.* Patients with short and thick necks often have compromised airways and need aggressive respiratory support—possibly mechanical ventilation in the critical care unit.

All patients experience some degree of pain, but it is usually less severe when MIS is done. Patients may use patient-controlled analgesia (PCA) with morphine for up to the first 24 hours. All patients receive oral opioid analgesic agents as prescribed after the PCA is discontinued. Liquid forms of drug therapy are preferred. Acute pain management is discussed in detail in [Chapter 4](#).

Care of the bariatric surgical patient is similar to that of any patient having abdominal or laparoscopic surgery. *A major focus is patient and staff safety.* Special bariatric equipment and accommodations, including an extra-wide bed and additional personnel for moving the patient, are needed for both the surgical suite and postoperative care units. Weight-rated beds must be wide enough to allow the patient to turn. Bed rails should not be touching the body because they can cause pressure areas. Pressure between skinfolds and tubes and catheters can also cause skin breakdown. Monitor the skin in these areas and keep it clean and dry.

## Nursing Safety Priority QSEN

### Action Alert

Some patients who have bariatric surgery have a nasogastric (NG) tube put in place, especially after open surgical procedures. In gastroplasty procedures, the NG tube drains both the proximal pouch and the distal stomach. Closely monitor the tube for patency. *Never reposition the tube because its movement can disrupt the suture line!* The NG tube is removed on the second day if the patient is passing flatus.

Clear liquids are introduced slowly if the patient can tolerate water, and 1-ounce cups are used for each serving. Pureed foods; juice; and soups thinned with broth, water, or milk are added to the diet 24 to 48 hours after clear liquids are tolerated. Typically, the patient can increase the volume to 1 ounce over 5 minutes or until satisfied, but the diet is limited to liquids or pureed food for 6 weeks. The patient then progresses to regular food, with an emphasis on nutrient-dense foods. Nausea, vomiting, or discomfort occurs if too much liquid is ingested.

## Nursing Safety Priority QSEN

### Critical Rescue

Anastomotic leaks are the most common serious complication and cause of death after gastric bypass surgery. Recognize that you must monitor for symptoms of this life-threatening problem, which includes increasing back, shoulder, or abdominal pain; restlessness; and unexplained tachycardia and oliguria (scant urine). If any of these findings is present, report it to the surgeon immediately!

In addition to the postoperative complications typically associated with abdominal and laparoscopic surgeries, bariatric patients have special needs and risks, such as the risk for anastomotic leaks (a leak of digestive juices and partially digested food through an anastomosis).

Implement these measures to prevent complications:

- Apply an abdominal binder to prevent wound dehiscence for open surgical procedures.
- Place the patient in semi-Fowler's position or use bi-level or continuous positive airway pressure (BiPAP or CPAP) ventilation at night to improve breathing and decrease risk for sleep apnea or other pulmonary complications, such as pneumonia and atelectasis.
- Monitor oxygen saturation; provide oxygen at 2 L/min as prescribed.
- Apply sequential compression stockings and administer prophylactic anticoagulant (usually heparin) therapy as prescribed to help prevent thromboembolic complications, including pulmonary embolism (PE). These are The Joint Commission Core Measure interventions to prevent venous thromboembolism (VTE).
- Observe skin areas and folds for redness, excoriation, or breakdown to treat these problems early.
- Use absorbent padding between folds to prevent pressure areas and skin breakdown; make sure that tubes and catheters are not causing pressure as well.
- **Remove urinary catheter within 24 hours after surgery to prevent urinary tract infection per the National Patient Safety Goals.**
- Assist the patient out of bed on the day of surgery; encourage and assist with turning every 2 hours using an appropriate weight-bearing overhead trapeze. Collaborate with the physical or occupational therapist if needed for transfers or ambulation assistive devices, such as walkers.
- Ambulate patient as soon as possible to prevent postoperative complications, such as deep vein thrombosis and pulmonary embolus.
- Measure and record abdominal girth daily, as requested.
- In collaboration with the dietitian, provide six small feedings and plenty of fluids to prevent dehydration.
- Observe for signs and symptoms of **dumping syndrome** (caused by food entering the small intestine instead of the stomach) after *gastric bypass*, such as tachycardia, nausea, diarrhea, and abdominal cramping.

## Clinical Judgment Challenge 60-1

### Patient-Centered Care; Evidence-Based Practice; Teamwork and Collaboration; Informatics QSEN

A 53-year-old woman with morbid obesity had a Roux-en-Y gastric bypass (RNYGB) a month ago. At a follow-up examination, the patient reports frequent problems with nausea, diarrhea, and a feeling like her heart is “racing.”

1. What patient problem do you anticipate that the patient is having? What data support your answer?
2. What priority assessment will you perform at this time, and why?
3. What patient teaching will you provide?
4. With whom will you collaborate to care for this patient?
5. What information will you document in the electronic health record?

### Care Coordination and Transition Management

Obesity is a chronic, lifelong problem. Diets, drug therapy, exercise, and behavior modification can produce short-term weight losses with reasonable safety. However, many patients who do lose weight often regain it. Treatment of obesity should focus on the long-term reduction of health risks and medical problems associated with obesity, improving quality of life, and promoting a health-

oriented lifestyle.

### Home Care Management.

The most important features of health teaching for any patient with obesity and family focus on health-related behavior patterns. In collaboration with the dietitian, counsel the patient on a healthful eating pattern. The physical therapist or exercise physiologist recommends an appropriate exercise program. A psychologist may recommend cognitive restructuring approaches that help alter dysfunctional eating patterns.

For patients who have surgery, additional discharge teaching is needed. [Chart 60-7](#) lists the important areas that should be reviewed. Bariatric surgery results in a major lifestyle change and a variety of emotions. During weight loss, the patient may become depressed or anxious. Some experience a “hibernation phase” for about a month after surgery because of physical and emotional adjustments. Patients are usually followed closely by the surgeon and dietitian for several years. Encourage them to keep all appointments and to adhere to the community-based treatment plan to ensure success. Plastic surgery, such as **panniculectomy** (removal of the abdominal apron, or **panniculus**), may be performed after weight is stabilized, usually in about 18 to 24 months.

#### **Chart 60-7**

### Patient and Family Education: Preparing for Self-Management

#### Discharge Teaching for the Patient After Bariatric Surgery

**Nutrition:** Diet progression, nutrient (including vitamin and mineral) supplements, hydration guidelines

**Drug therapy:** Analgesics and antiemetic drugs, if needed; drugs for other health problems

**Wound care:** Clean procedure for open or laparoscopic wounds; cover during shower or bath

**Activity level:** Restrictions, such as avoiding lifting; activity progression; return to driving and work

**Signs and symptoms to report:** Fever; excessive nausea or vomiting; epigastric, back, or shoulder pain; red, hot, and/or draining wound(s); pain, redness, or swelling in legs; chest pain; difficulty breathing

**Follow-up care:** Health care provider office or clinic visits, support groups and other community resources, counseling for patient and family

**Continuing education:** Nutrition and exercise classes; follow-up visits with dietitian

### Self-Care Management.

Remind patients to coordinate with their health care provider to create a manageable and appropriate physical activity plan. Focus should be placed on monitoring diet for a decrease in overall fat intake and reliance on appetite-reducing drugs. Ask patients to consider keeping a food journal that also documents mood and events that take place with eating. This can be helpful for the patient to identify eating patterns and then strive to establish a normal eating pattern in response to physiologic hunger.

Teach patients that bowel changes are common after surgery, including constipation. Vitamin and mineral supplements are often needed after surgery, especially vitamin D, B-complex vitamins, iron, and calcium.

### Health Care Resources.

Provide the patient with a list of available community resources, such as Overeaters Anonymous

([www.aa.org](http://www.aa.org)) and the American Obesity Association ([www.obesity.org](http://www.obesity.org)). For surgical patients, the American Society for Metabolic and Bariatric Surgery ([www.asmb.org](http://www.asmb.org)) may be helpful.

◆ **Evaluation: Reflecting**

Evaluate the care of the patient with obesity based on the identified priority patient problem. The primary expected outcome is that the patient consumes appropriate, nutrient-dense foods to meet metabolic demands without overeating. For surgical patients, an additional expected outcome is that the patient remains free of infection following bariatric surgery.

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Collaborate with the interdisciplinary health care team, especially the dietitian, health care provider, and case manager, when caring for patients with malnutrition or obesity. **QSEN: Teamwork and Collaboration**
- Be sure that bariatric furniture and equipment are available for the patient with obesity in the hospital or other health care setting; avoid pressure on skinfold areas. **QSEN: Safety**

### Health Promotion and Maintenance

- Perform nutrition screening for all patients to determine if they are at risk (see [Charts 60-1](#) and [60-2](#)). **QSEN: Evidence-Based Practice**
- Recognize that older patients are at increased risk for malnutrition (see [Chart 60-2](#)).
- Implement interventions to promote nutrition intake in older adults as specified in [Chart 60-3](#). **QSEN: Patient-Centered Care**

### Psychosocial Integrity

- Be aware that some patients with malnutrition or obesity may not view their weight as a problem and may be reluctant to be part of a NUTRITION plan.
- Recognize that malnutrition and obesity can contribute to depression or anxiety, low self-esteem, and a disturbed body image. **QSEN: Patient-Centered Care**
- Be aware of legal and ethical issues related to tube-feeding older adults with chronic or terminal illness. **Ethics**

### Physiological Integrity

- Review serum prealbumin, hemoglobin, and hematocrit levels to identify patients at NUTRITION risk. **Clinical Judgment**
- Assess patients with severe malnutrition for complications such as edema, lethargy, and dry, flaking skin.
- Provide evidence-based nursing interventions for managing total enteral nutrition as listed in [Chart 60-4](#). **QSEN: Evidence-Based Practice**
- Maintain feeding tube patency for patients receiving total enteral nutrition as described in [Chart 60-5](#). **QSEN: Safety**
- Ensure that feeding tube placement is verified by x-ray; check placement every 4 to 8 hours by aspirating gastric contents and assessing pH for nasogastric tubes. **QSEN: Safety**
- Place patients receiving tube feeding in a semi-Fowler's position at all times to prevent aspiration; check residual contents every 4 hours or as designated per facility policy. **QSEN: Safety**
- Use gloves when changing feeding system tubing or adding product; use sterile gloves when working with critically ill or immunocompromised patients. **QSEN: Evidence-Based Practice**
- Use a feeding pump when the patient receives continuous or cyclic tube feeding.
- Teach family members or other caregivers of patients receiving enteral or parenteral nutrition at home how to provide NUTRITION while avoiding complications. **QSEN: Safety**
- Teach patients who are undernourished to eat high-protein, high-calorie food and nutrition supplements. **QSEN: Evidence-Based Practice**

- Provide care for patients receiving total parenteral nutrition as specified in [Chart 60-6](#). **QSEN: Evidence-Based Practice**
- Recall that normal body mass index (BMI) for adults should be between 18.5 and 25; older adults should have a BMI between 23 and 27. A BMI of 27 to 30 indicates overweight, over 30 indicates obesity, and 40 and greater indicates morbid obesity.
- Recall that obesity contributes to early onset of many chronic illnesses, such as osteoarthritis, diabetes mellitus, hypertension, coronary artery disease, pulmonary problems, delayed wound healing, and infection.
- Instruct patients with obesity about the importance of a health care provider–approved exercise plan for weight reduction.
- Recognize that many adults are following low-carbohydrate rather than low-fat diets to lose weight.
- Remember that bariatric surgery includes gastric restriction procedures or gastric bypass; a panniculectomy may be performed to remove skinfolds once weight is stabilized.
- Be alert for signs and symptoms of anastomotic leak after bariatric surgery, including severe pain, restlessness, anxiety, and unexplained tachycardia. **QSEN: Safety**
- Provide postoperative care for patients having bariatric surgery to prevent complications such as wound dehiscence, respiratory distress, skin breakdown, and thromboembolic complications, such as pulmonary embolism. Establishing and maintaining an airway is the priority for patients having bariatric surgery! **QSEN: Safety**
- Observe for complications, such as dumping syndrome in patients who have a gastric bypass. Tachycardia, nausea, diarrhea, and abdominal cramping are common symptoms of dumping syndrome.
- Provide discharge teaching for patients having bariatric surgery as described in [Chart 60-7](#).

## UNIT XIV

# Interprofessional Collaboration for Patients With Problems of the Endocrine System

### OUTLINE

---

Chapter 61 Assessment of the Endocrine System

Chapter 62 Care of Patients With Pituitary and Adrenal Gland Problems

Chapter 63 Care of Patients With Problems of the Thyroid and Parathyroid Glands

Chapter 64 Care of Patients With Diabetes Mellitus

---

## CHAPTER 61

# Assessment of the Endocrine System

---

M. Linda Workman

## PRIORITY AND INTERRELATED CONCEPTS

---

**The priority concepts for this chapter are:**

- NUTRITION
- ELIMINATION

**The interrelated concept for this chapter is FLUID AND ELECTROLYTE BALANCE.**

## LEARNING OUTCOMES

---

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to perform a complete endocrine assessment, including issues with NUTRITION, ELIMINATION, and FLUID AND ELECTROLYTE BALANCE.

### Health Promotion and Maintenance

2. Teach adults about factors that increase the risk for endocrine problems.
3. Teach patients and families about pretest and post-test care for assessment of endocrine function.

### Psychosocial Integrity

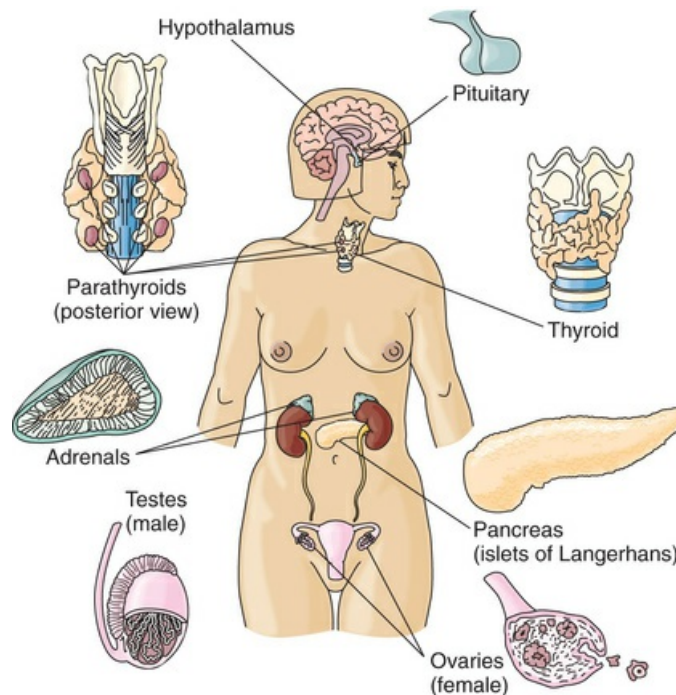

4. Implement patient-centered nursing interventions to help patients and families cope with the psychosocial impact caused by changes in endocrine function.

### Physiological Integrity

5. Apply the principles of anatomy, physiology, and the aging process to perform an evidence-based assessment for the patient with a problem of the endocrine system.
6. Explain and interpret assessment findings for the patient with an endocrine problem.
7. Coordinate appropriate care for patients and proper handling of specimens before, during, and after testing of the endocrine system.
8. Monitor for complications of diagnostic procedures used to assess endocrine function.

The endocrine system is composed of tissues and organs (glands) that are located in many body areas (Fig. 61-1) and affect all other body systems. The purpose of endocrine glands and tissues is to secrete **hormones**, which are natural chemicals that exert their effects on specific tissues known as **target tissues**. Target tissues are usually located some distance from the endocrine gland, with no connecting duct between the endocrine gland and its target tissue. For this reason, endocrine glands are called *ductless* glands and use the blood to transport secreted hormones to the target tissues (McCance et al., 2014). The major endocrine glands are:

**FIG. 61-1** Locations of various glands within the endocrine system.

- Hypothalamus (a neuroendocrine gland)
- Pituitary gland
- Adrenal glands
- Thyroid gland
- Islet cells of the pancreas
- Parathyroid glands
- Gonads

The endocrine system works with the nervous system to control overall body function and regulation, including metabolism, NUTRITION, ELIMINATION, temperature, FLUID AND ELECTROLYTE BALANCE, growth, and reproduction. Many interactions must occur between the endocrine system and all other body systems to ensure that each system maintains a constant normal balance (**homeostasis**) in response to environmental changes. For example, this regulation keeps the internal body temperature at or near 98.6° F (37° C), even when environmental temperatures vary. Other actions keep the serum sodium level between 136 and 145 mEq/L (mmol/L), regardless of whether a healthy adult eats 2 g or 12 g of sodium per day.

Table 61-1 lists hormones secreted by various endocrine glands. Hormones travel through the blood to all body areas but exert their actions only on target tissues. They recognize their target tissues and exert their actions by binding to receptors on or within the target tissue cells. In general, each receptor site type is specific for only one hormone. Hormone-receptor actions work in a “lock and key” manner in that only the correct hormone (key) can bind to and activate the receptor site (lock) (Fig. 61-2). Binding a hormone to its receptor causes the target tissue to change its activity, producing specific responses (Lazar & Birnbaum, 2016).

**TABLE 61-1**

**Principal Hormones of the Endocrine Glands**

GLAND	HORMONES
Hypothalamus	Corticotropin-releasing hormone (CRH) Thyrotropin-releasing hormone (TRH) Gonadotropin-releasing hormone (GnRH) Growth hormone-releasing hormone (GHRH) Growth hormone-inhibiting hormone (somatostatin GHIH) Prolactin-inhibiting hormone (PIH) Melanocyte-inhibiting hormone (MIH)
Anterior pituitary	Thyroid-stimulating hormone (TSH), also known as <i>thyrotropin</i> Adrenocorticotropic hormone (ACTH, corticotropin) Luteinizing hormone (LH), also known as <i>Leydig cell-stimulating hormone (LCSH)</i> Follicle-stimulating hormone (FSH)

	Prolactin (PRL) Growth hormone (GH) Melanocyte-stimulating hormone (MSH)
Posterior pituitary	Vasopressin (antidiuretic hormone [ADH]) Oxytocin
Thyroid	Triiodothyronine (T <sub>3</sub> ) Thyroxine (T <sub>4</sub> ) Calcitonin
Parathyroid	Parathyroid hormone (PTH)
Adrenal cortex	Glucocorticoids (cortisol) Mineralocorticoids (aldosterone)
Ovary	Estrogen Progesterone
Testes	Testosterone
Pancreas	Insulin Glucagon Somatostatin

**FIG. 61-2** “Lock and Key” hormone-receptor binding. *Hormone A* fits and binds to its receptors, causing a change in cell action. *Hormone B* does not fit or bind to receptors; no change in cell action results.

Disorders of the endocrine system usually are related to:

- An excess of a specific hormone
- A deficiency of a specific hormone
- Poor hormone-receptor interactions resulting in decreased responsiveness of the target tissue

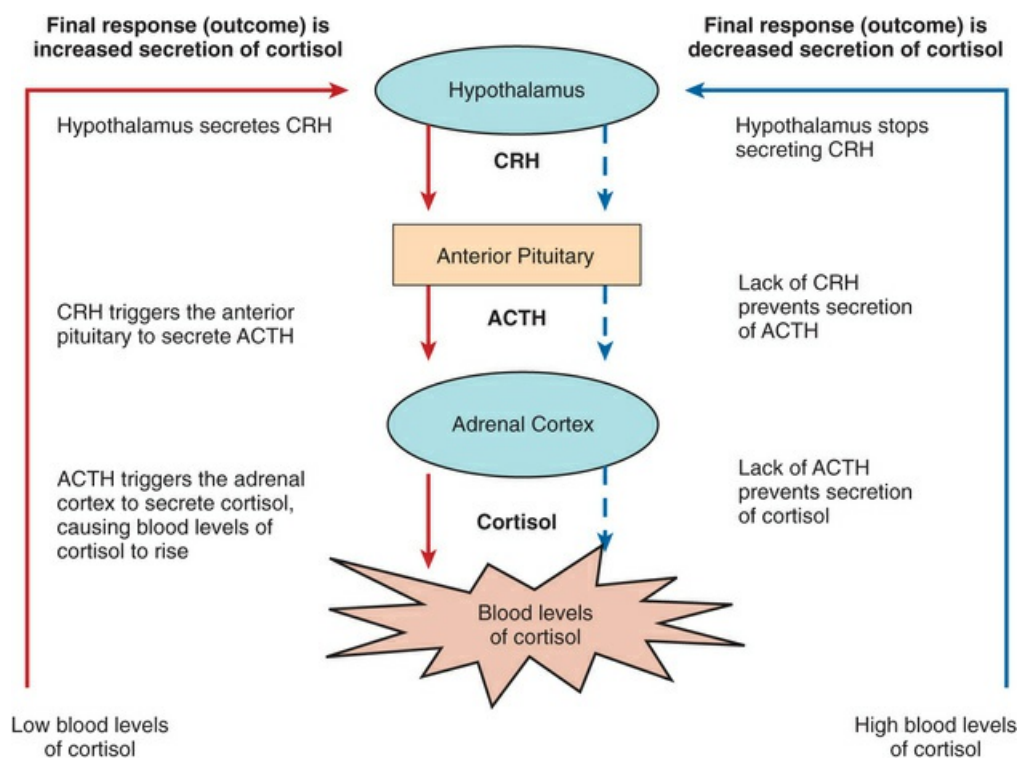

## Anatomy and Physiology Review

The control of cellular function by any hormone depends on a series of reactions working through *negative-feedback control mechanisms*. Hormone secretion usually depends on the body's need for the final action of that hormone. When a body condition starts to move away from the normal range and a specific response is needed to correct this change, secretion of the hormone capable of starting the correcting action or response is stimulated until the need (demand) is met and the body condition returns to the normal range. As the correction occurs, hormone secretion decreases (and may halt). This control of hormone synthesis is **negative feedback** because the hormone causes the *opposite* action of the initial condition change.

An example of a simple negative-feedback hormone response is the control of insulin secretion. When blood glucose levels start to rise above normal, the hormone *insulin* is secreted. Insulin increases glucose uptake by the cells, causing a *decrease* in blood glucose levels. Thus the action of insulin (decreasing blood glucose levels) is the opposite of or negative to the condition that stimulated insulin secretion (elevated blood glucose levels).

Some hormones have more complex interactions for negative feedback. These interactions involve a series of reactions in which more than one endocrine gland, as well as the final target tissues, are stimulated. In this situation, the first hormone in the series may have another endocrine gland or glands as its target tissue. The final result of complex negative feedback for endocrine function is still opposite of the initiating condition.

An example of complex control is the interaction of the hypothalamus and the anterior pituitary with the adrenal cortex (Fig. 61-3). Low blood levels of cortisol from the adrenal cortex stimulate the secretion of corticotropin-releasing hormone (CRH) in the hypothalamus. CRH stimulates the anterior pituitary gland to secrete adrenocorticotropic hormone (ACTH). ACTH then triggers the release of cortisol from the adrenal cortex, the final endocrine gland in this series. The rising blood levels of cortisol inhibit CRH release from the hypothalamus. Without CRH, the anterior pituitary gland stops secretion of ACTH. In response, normal blood cortisol levels are maintained.

**FIG. 61-3** Examples of positive and negative feedback control of hormone secretion. *ACTH*, Adrenocorticotropic hormone; *CRH*, corticotropin-releasing hormone.

The normal blood level range of each hormone is well defined. Excesses or deficiencies of

hormone secretion can lead to pathologic conditions affecting many body systems.

## Hypothalamus and Pituitary Glands

The hypothalamus is a small area of nerve and endocrine tissue located beneath the thalamus in the brain. Nerve fibers connect the hypothalamus to the rest of the central nervous system. The hypothalamus shares a small, closed circulatory system with the anterior pituitary gland, known as the *hypothalamic-hypophysial portal system*. This system allows hormones produced in the hypothalamus to travel directly to the anterior pituitary gland so only very small amounts are present in systemic circulation where they are not needed.

The function of the hypothalamus is to produce regulatory hormones (see Table 61-1). Some of these hormones are released into the blood and travel to the anterior pituitary, where they either stimulate or inhibit the release of anterior pituitary hormones.

The pituitary gland is located at the base of the brain in a protective pocket of the sphenoid bone (see Fig. 61-1). It is divided into the anterior lobe (*adenohypophysis*) and the posterior lobe (*neurohypophysis*). Nerve fibers in the hypophysial stalk connect the hypothalamus to the posterior pituitary (Fig. 61-4).

**FIG. 61-4** Hypothalamus, hypophysial stalk, anterior pituitary gland, and posterior pituitary gland. (From Guyton, A., & Hall, J. (2006). *Textbook of medical physiology* (11th ed.). Philadelphia: Saunders.)

In response to the releasing hormones of the hypothalamus, the anterior pituitary secretes some tropic (trophic) hormones that stimulate other endocrine glands. Other pituitary hormones, such as prolactin, produce their effect directly on final target tissues (Table 61-2).

**TABLE 61-2**

### Pituitary Hormones: Target Tissues and Subsequent Actions

HORMONE	TARGET TISSUE	ACTIONS
<b>Anterior Pituitary</b>		
Thyroid-stimulating hormone or thyrotropin (TSH)	Thyroid	Stimulates synthesis and release of thyroid hormone
Adrenocorticotropic hormone, corticotropin (ACTH)	Adrenal cortex	Stimulates synthesis and release of corticosteroids and adrenocortical growth
Luteinizing hormone (LH) (known as <i>Leydig cell-stimulating hormone</i> in males)	Ovary	Stimulates ovulation and progesterone secretion
	Testis	Stimulates testosterone secretion
Follicle-stimulating hormone (FSH) (known as <i>interstitial cell- or Sertoli cell-stimulating hormone</i> in males)	Ovary	Stimulates estrogen secretion and follicle maturation
	Testis	Stimulates spermatogenesis
Prolactin (PRL)	Mammary glands	Stimulates breast milk production
Growth hormone (GH)	Bone and soft tissue	Promotes growth through lipolysis, protein anabolism, and insulin antagonism
Melanocyte-stimulating hormone (MSH)	Melanocytes	Promotes pigmentation
<b>Posterior Pituitary*</b>		
Vasopressin (antidiuretic hormone [ADH])	Kidney	Promotes water reabsorption
Oxytocin	Uterus and mammary glands	Stimulates uterine contractions and ejection of breast milk

\*These hormones are synthesized in the hypothalamus and are stored in the posterior pituitary gland. They are transported from the hypothalamus down the hypothalamic stalk to the posterior pituitary while bound to proteins known as *neurophysins*.

The hormones of the posterior pituitary—vasopressin (antidiuretic hormone [ADH]) and oxytocin—are produced in the hypothalamus and delivered to the posterior pituitary where they are stored. These hormones are released from the posterior pituitary into the blood when needed.

Other factors affect hormone release from the pituitary gland. Drugs, diet, lifestyle, and pathologic conditions can change pituitary hormone secretion (McCance et al., 2014).

## Gonads

The **gonads** are the male and female reproductive endocrine glands. Male gonads are the testes, and female gonads are the ovaries. Function of the gonads is dormant until puberty when, under the influence of gonadotropic hormones secreted by the anterior pituitary, the glands and external genitalia mature. The testes are stimulated to produce testosterone, and the ovaries are stimulated to produce estrogen. These changes are responsible for the development of secondary sexual characteristics. The function of the gonads is detailed in [Chapter 69](#).

## Adrenal Glands

The adrenal glands are vascular, tent-shaped organs on the top of each kidney. They have an outer cortex and an inner medulla (see [Fig. 61-1](#)). Adrenal hormones affect the entire body.

### Adrenal Cortex

The adrenal cortex makes up about 90% of the adrenal gland and has cells divided into three layers. The main hormone types secreted by the cortex are the mineralocorticoids and the glucocorticoids. In addition, the cortex also secretes small amounts of sex hormones.

*Mineralocorticoids* are produced and secreted by the adrenal cortex to help control FLUID AND ELECTROLYTE BALANCE. **Aldosterone** is the mineralocorticoid that maintains extracellular fluid volume. It promotes sodium and water reabsorption and potassium excretion in the kidney. Aldosterone secretion is regulated by the renin-angiotensin system, serum potassium ion level, and adrenocorticotrophic hormone (ACTH).

Renin is produced by specialized cells of the kidney arterioles. Its release is triggered by a decrease in extracellular fluid volume from blood loss, sodium loss, or posture changes. Renin converts renin substrate (angiotensinogen), a plasma protein, to angiotensin I. Angiotensin I is converted by an enzyme to form angiotensin II, the active form. In turn, angiotensin II stimulates the secretion of aldosterone. [Chapter 11](#) (see [Fig. 11-6](#)) further explains the renin-angiotensin-aldosterone system (RAAS). Aldosterone causes the kidney to reabsorb sodium and water to bring the plasma volume and osmolarity back to normal.

Serum potassium level also controls aldosterone secretion. It is secreted whenever the serum potassium level increases above normal by as little as 0.1 mEq/L (mmol/L). Aldosterone then enhances kidney excretion of potassium to reduce the blood potassium level back to normal.

*Glucocorticoids* are produced by the adrenal cortex and are essential for life. The main glucocorticoid produced by the adrenal cortex is **cortisol**. Cortisol affects:

- The body's response to stress
- Carbohydrate, protein, and fat metabolism
- Emotional stability
- Immune function
- Sodium and water balance

Cortisol also influences other important body processes. For example, it must be present for epinephrine and norepinephrine action and maintaining the normal excitability of the heart muscle cells ([McCance et al., 2014](#)). Glucocorticoid functions are listed in [Table 61-3](#).

---

**TABLE 61-3**

### Functions of Glucocorticoid Hormones

---

- |  |
|--|
| <ul style="list-style-type: none"><li>• Prevent hypoglycemia by increasing liver glucose production (gluconeogenesis) and inhibiting peripheral glucose use</li><li>• Maintain excitability and responsiveness of cardiac muscle</li><li>• Increase lipolysis, releasing glycerol and free fatty acids</li><li>• Increase protein catabolism</li><li>• Degrade collagen and connective tissue</li><li>• Increase the number of mature neutrophils released from bone marrow</li><li>• Exert anti-inflammatory effects that decrease the migration of inflammatory cells to sites of injury</li><li>• Maintain behavior and cognitive functions</li></ul> |
|--|

Glucocorticoid release is regulated directly by the anterior pituitary hormone *ACTH* and indirectly by the hypothalamic corticotropin-releasing hormone (*CRH*). The release of *CRH* and *ACTH* is affected by the serum level of free cortisol, the normal sleep-wake cycle, and stress.

As described earlier and shown in [Fig. 61-3](#), when blood cortisol levels are low, the hypothalamus

secretes CRH, which triggers the pituitary to release ACTH. Then ACTH triggers the adrenal cortex to secrete cortisol. Adequate or elevated blood levels of cortisol *inhibit* the release of CRH and ACTH. This inhibitory effect is an example of a negative-feedback system.

Glucocorticoid release peaks in the morning and reaches its lowest level 12 hours after the peak. Emotional, chemical, or physical stress increases the release of glucocorticoids.

*Sex hormones* (androgens and estrogens) are secreted in low levels by the adrenal cortex in both genders. Adrenal secretion of these hormones is usually not significant because the gonads (ovaries and testes) secrete much larger amounts of estrogens and androgens. However, in women the adrenal gland is the major source of androgens.

## NCLEX Examination Challenge 61-1

### Physiological Integrity

Which hormone changes does the nurse expect when a client receives a continuous cortisol infusion for 24 hours when his or her endocrine feedback mechanisms are functioning normally?

- A. Lower than normal adrenocorticotrophic hormone (ACTH) levels; lower than normal corticotropin-releasing hormone (CRH) levels
- B. Lower than normal adrenocorticotrophic hormone (ACTH) levels; higher than normal corticotropin-releasing hormone (CRH) levels
- C. Higher than normal adrenocorticotrophic hormone (ACTH) levels; lower than normal corticotropin-releasing hormone (CRH) levels
- D. Higher than normal adrenocorticotrophic hormone (ACTH) levels; higher than normal corticotropin-releasing hormone (CRH) levels

### Adrenal Medulla

The adrenal medulla is a sympathetic nerve ganglion that has secretory cells. Stimulation of the sympathetic nervous system causes the release of adrenal medullary hormones, the **catecholamines** (which include epinephrine and norepinephrine). These hormones travel to all areas of the body through the blood and exert their effects on target cells. The adrenal medullary hormones are not essential for life because they also are secreted by other body tissues, but they do play a role in the stress response.

The adrenal medulla secretes about 15% norepinephrine (NE) and 85% epinephrine. Hormone effects vary with the specific receptor in the cell membranes of the target tissue.

These receptors are of two types: alpha adrenergic and beta adrenergic, which are further classified as alpha<sub>1</sub> and alpha<sub>2</sub> receptors and beta<sub>1</sub>, beta<sub>2</sub>, and beta<sub>3</sub> receptors. NE acts mainly on alpha-adrenergic receptors, and epinephrine acts mainly on beta-adrenergic receptors.

Catecholamines exert their actions on many target organs (Table 61-4). Activation of the sympathetic nervous system, which then releases adrenal medullary catecholamines, is an important part of the stress response. Catecholamines are secreted in small amounts at all times to maintain homeostasis. Stress triggers increased secretion of these hormones, resulting in the “fight-or-flight” response, a state of heightened physical and emotional awareness.

**TABLE 61-4**

**Catecholamine Receptors and Effects of Adrenal Medullary Hormone Stimulation on Selected Organs and Tissues**

ORGAN OR TISSUE	RECEPTORS	EFFECTS
Heart	Beta <sub>1</sub>	Increased heart rate
		Increased contractility
Blood vessels	Alpha	Vasoconstriction
	Beta <sub>2</sub>	Vasodilation
GI tract	Alpha	Increased sphincter tone
	Beta	Decreased motility
Kidneys	Beta <sub>2</sub>	Increased renin release
Bronchioles	Beta <sub>2</sub>	Relaxation; dilation
Bladder	Alpha	Sphincter contractions

	Beta <sub>2</sub>	Relaxation of detrusor muscle
Skin	Alpha	Increased sweating
Fat cells	Beta	Increased lipolysis
Liver	Alpha	Increased gluconeogenesis and glycogenolysis
Pancreas	Alpha	Decreased glucagon and insulin release
	Beta	Increased glucagon and insulin release
Eyes	Alpha	Dilation of pupils

## Thyroid Gland

The thyroid gland is in the anterior neck, directly below the cricoid cartilage (Fig. 61-5). It has two lobes joined by a thin strip of tissue (*isthmus*) in front of the trachea.

FIG. 61-5 Anatomic location of the thyroid gland.

The thyroid gland is composed of follicular and parafollicular cells. Follicular cells produce the thyroid hormones **thyroxine (T<sub>4</sub>)** and **triiodothyronine (T<sub>3</sub>)**. Parafollicular cells produce **thyrocalcitonin** (TCT or calcitonin), which helps regulate serum calcium levels.

*Control of metabolism* occurs through T<sub>3</sub> and T<sub>4</sub>. Both hormones increase metabolism, which causes an increase in oxygen use and heat production in all tissues. Most circulating T<sub>4</sub> and T<sub>3</sub> are bound to plasma proteins. The free hormone moves into the cell, where it binds to its receptor in the cell nucleus. Once in the cell, T<sub>4</sub> is converted to T<sub>3</sub>, the most active thyroid hormone. Conversion of T<sub>4</sub> to T<sub>3</sub> is impaired by stress, starvation, dyes, and some drugs. Cold temperatures increase the conversion. Table 61-5 lists thyroid hormone functions.

TABLE 61-5

### Functions of Thyroid Hormones in Adults

- Control metabolic rate of all cells
- Promote sufficient pituitary secretion of growth hormone and gonadotropins
- Regulate protein, carbohydrate, and fat metabolism
- Exert effects on heart rate and contractility
- Increase red blood cell production
- Affect respiratory rate and drive
- Increase bone formation and decrease bone resorption of calcium
- Act as insulin antagonists

Secretion of T<sub>3</sub> and T<sub>4</sub> is controlled by the hypothalamic-pituitary-thyroid gland axis negative-feedback mechanism. The hypothalamus secretes thyrotropin-releasing hormone (TRH). TRH triggers the anterior pituitary gland to secrete thyroid-stimulating hormone (TSH), which then stimulates the thyroid gland to make and release thyroid hormones. If thyroid hormone levels are high, release of TRH and TSH is inhibited. If thyroid hormone levels are low, TRH and TSH release is increased. Cold and stress are two factors that cause the hypothalamus to secrete TRH, which then stimulates the anterior pituitary to secrete TSH.

Dietary intake of protein and iodine is needed to produce thyroid hormones. Iodine is absorbed from the intestinal tract as iodide. The thyroid gland draws iodide from the blood and concentrates

it. After iodide is in the thyroid, it combines with the amino acid *tyrosine* to form  $T_4$  and  $T_3$ . These hormones bind to thyroglobulin and are stored in thyroid follicular cells. When stimulated,  $T_4$  and  $T_3$  are released into the blood. They enter all cells, where they bind to DNA receptors and turn on genes important in metabolism to regulate basal metabolic rate (BMR).

*Calcium and phosphorus balance* occurs partly through the actions of calcitonin (thyrocalcitonin [TCT]), which also is produced in the thyroid gland. Calcitonin lowers serum calcium and serum phosphorus levels by reducing bone resorption (release) of these minerals. Its actions are opposite of parathyroid hormone.

The serum calcium level determines calcitonin secretion. Low serum calcium levels suppress the release of calcitonin. Elevated serum calcium levels increase its secretion.

## Parathyroid Glands

The parathyroid glands consist of four small glands located close to or within the back surface of the thyroid gland (see Fig. 61-1). These cells secrete parathyroid hormone (PTH).

Parathyroid hormone regulates calcium and phosphorus metabolism by acting on bones, the kidneys, and the GI tract (Fig. 61-6). Bone is the main storage site of calcium. PTH increases **bone resorption** (bone release of calcium into the blood from bone storage sites), thus increasing serum calcium. In the kidneys, PTH activates vitamin D, which then increases the absorption of calcium and phosphorus from the intestines. In the kidney tubules, PTH allows calcium to be reabsorbed and put back into the blood.

FIG. 61-6 Effects of parathyroid hormone on target tissues to maintain calcium balance.

Serum calcium levels determine PTH secretion. Secretion decreases when serum calcium levels are high, and it increases when serum calcium levels are low. PTH and calcitonin work together to maintain normal calcium levels in the blood and extracellular fluid.

## Pancreas

The pancreas has exocrine and endocrine functions. The exocrine function of the pancreas involves the secretion of digestive enzymes through ducts that empty into the duodenum. The cells in the islets of Langerhans perform the pancreatic endocrine functions (Fig. 61-7). About one million islet cells are found throughout the pancreas.

**FIG. 61-7** Cells of the islets of Langerhans of the pancreas.

The islets have three distinct cell types: alpha cells, which secrete glucagon; beta cells, which secrete insulin; and delta cells, which secrete somatostatin. Glucagon and insulin affect carbohydrate, protein, and fat metabolism.

*Glucagon* is a hormone that increases blood glucose levels. It is triggered by decreased blood glucose levels and increased blood amino acid levels. This hormone helps prevent hypoglycemia. [Chapter 64](#) discusses glucagon function in more detail.

*Insulin* promotes the movement and storage of carbohydrate, protein, and fat. It lowers blood glucose levels by enhancing glucose movement across cell membranes and into the cells of many tissues. Insulin secretion rises in response to an increase in blood glucose levels. More information on insulin is presented in [Chapter 64](#).

*Somatostatin*, which is secreted not only in the pancreas but also in the intestinal tract and the brain, inhibits the release of glucagon and insulin from the pancreas. It also inhibits the release of gastrin, secretin, and other GI peptides.

## Endocrine Changes Associated With Aging

The effects of aging on the endocrine system vary but usually result in reduced glandular function and decreased hormone secretion. The three endocrine tissues that usually have reduced function with aging are the gonads, the thyroid gland, and the endocrine pancreas ([Lamberts & van den Beld, 2016](#); [Touhy & Jett, 2016](#)). It is difficult to distinguish normal from abnormal endocrine activity in older adults because of chronic illness, changes in diet and activity, sleep disturbances, decreased metabolism, and the use of drugs that may affect hormone function. Consider these factors when assessing the older adult with endocrine dysfunction.

Encourage the older adult to participate in regular screening examinations, including fasting and random blood glucose checks, calcium level determinations, and thyroid function testing. [Chart 61-1](#) lists the endocrine changes that occur in the older adult.

### Chart 61-1

## Nursing Focus on the Older Adult

### Changes in the Endocrine System Related to Aging

CHANGES	CLINICAL FINDINGS	NURSING ACTIONS/ADAPTATIONS
Decreased antidiuretic hormone (ADH) production	Urine is more dilute and may not concentrate when fluid intake is low.	The patient is at greater risk for dehydration. Assess the older patient more frequently for dehydration. If fluids are not restricted because of another health problem, teach unlicensed assistive personnel (UAP) to offer fluids at least every 2 hours while awake.
Decreased ovarian production of estrogen	Bone density decreases.	Teach the patient to engage in regular exercise and weight-bearing activity to maintain bone density. Handle the patient carefully to avoid injury from pathologic fractures.
	Skin is thinner, drier, and at greater risk for injury.	Avoid pulling or dragging the patient. Use minimal tape on the skin. Help patients confined to bed or chairs change positions at least every 2 hours. Teach patients to use skin moisturizers.
	Perineal and vaginal tissues become drier, and the risk for cystitis increases.	Perform or assist the patient to perform perineal care at least twice daily. Unless another health problem requires fluid restriction, encourage all women to drink at least 2 liters of fluids daily.

		Teach sexually active older women to urinate immediately after sexual intercourse. Teach sexually active women that using vaginal lubricants with sexual activity can reduce discomfort and the risk for tissue damage.
Decreased glucose tolerance	Weight becomes greater than ideal along with: <ul style="list-style-type: none"> <li>• Elevated fasting blood glucose level</li> <li>• Elevated random blood glucose level</li> <li>• Slow wound healing</li> <li>• Frequent yeast infections</li> <li>• Polydipsia</li> <li>• Polyuria</li> </ul>	Obtain a family history of obesity and type 2 diabetes. Encourage the patient to engage in regular exercise and to keep body weight within 10 lb (4.5 kg) of ideal. Teach patients the signs and symptoms of diabetes and instruct them to report any of these to the primary health care provider. Suggest diabetes testing for any patient with: <ul style="list-style-type: none"> <li>• Persistent vaginal candidiasis</li> <li>• Failure of a foot or leg skin wound to heal in 2 weeks or less</li> <li>• Increased hunger and thirst</li> <li>• Noticeable decrease in energy level</li> </ul>
Decreased general metabolism	There is less tolerance for cold. Appetite is decreased. Heart rate and blood pressure (BP) are decreased.	Can be difficult to distinguish from hypothyroidism. Check for additional signs and symptoms of: <ul style="list-style-type: none"> <li>• Lethargy</li> <li>• Constipation (as a change from usual bowel habits)</li> <li>• Decreased cognition</li> <li>• Slowed speech</li> <li>• Body temperature consistently below 97° F (36° C)</li> <li>• Heart rate below 60 beats/min</li> </ul> Teach patients to dress warmly in cool or cold weather.

## NCLEX Examination Challenge 61-2

### Physiological Integrity

Which problems does the nurse expect in an older adult as a result of age-related changes in endocrine function? **Select all that apply.**

- A. Increased basal metabolic rate (BMR)
- B. Decreased core body temperature
- C. Dehydration
- D. Diarrhea
- E. Hyperglycemia
- F. Polyuria

# Assessment: Noticing and Interpreting

## Patient History

The age and gender of the patient provide some baseline endocrine assessment data. Certain disorders are more common in older than in younger patients, such as diabetes mellitus, loss of ovarian function, and decreased thyroid function. Ask women at what age menarche began and whether menopause has occurred.

Symptoms of endocrine disorders can be gender related, such as the sexual effects of hyperpituitarism and hypopituitarism (see [Chapter 62](#)). Thyroid problems are more common in women ([McCance et al., 2014](#)). Assess for a history of endocrine problems, symptoms that could indicate a disorder, and hospitalizations. Ask about past and current drugs, such as cortisone, levothyroxine, oral contraceptives, and antihypertensive agents. The use of exogenous hormone drugs, when not needed for hormone replacement, can cause serious dysfunction in many endocrine glands. Use the opportunity to warn patients about the dangers of misusing hormone-based drugs such as androgens and thyroid hormones ([Burchum & Rosenthal, 2016](#)).

## Nutrition History

NUTRITION changes or GI tract disturbances may reflect many different endocrine problems. Ask about a history of nausea, vomiting, and abdominal pain. An increase or decrease in food or fluid intake may also indicate specific disorders. For example, diabetes insipidus triggers excessive thirst, and adrenal hypofunction triggers salt craving. Hunger and thirst also are associated with diabetes mellitus. Rapid changes in weight without diet changes are often associated with many endocrine disorders, including diabetes mellitus and thyroid problems.

NUTRITION deficiencies from an inadequate diet, especially of protein and iodide-containing foods (salt-water fish and seafood, iodized table salt), may be a cause of an endocrine disorder. Teach the patient about a well-balanced diet that includes at least 60 g of protein daily, less animal fat, and fewer concentrated simple sugars. Teach patients who do not eat salt-water fish on a regular basis to use iodized salt in food preparation.

## Family History and Genetic Risk

Ask the patient about any family history of obesity, growth or development difficulties, diabetes mellitus, infertility, or thyroid disorders. These problems may have an autosomal-dominant, recessive, or cluster pattern of inheritance.

## Current Health Problems

Focus on the patient's reason for seeking health care, asking questions such as:

- When did symptoms begin?
- Did symptoms occur gradually, or was the onset sudden?
- Have you been treated for this problem in the past?
- How have the current problems affected your activities of daily living?

These questions can provide clues to specific endocrine disorders. Also explore changes in energy levels, ELIMINATION patterns, sexual and reproductive functions, and physical features.

*Energy level changes* occur with many endocrine problems, especially thyroid problems (see [Chapter 63](#)) and adrenal problems (see [Chapter 62](#)). Ask the patient about any change in ability to perform ADLs and assess his or her current energy level. For instance, has he or she been sleeping longer or are fatigue and generalized weakness present?

ELIMINATION is affected by the endocrine system. Identify the patient's past pattern of elimination to determine deviations from the normal routine. Ask about the amount and frequency of urination. Does he or she urinate frequently in large amounts? Does the patient wake during the night to urinate ([nocturia](#))? Information about the frequency of bowel movements and their consistency and color may provide clues to problems in FLUID AND ELECTROLYTE BALANCE or metabolic rate (i.e., thyroid function).

*Sexual and reproductive functions* are greatly affected by endocrine disturbances. Ask about any changes in the menstrual cycle, such as increased flow, duration, and frequency of menses or a

change in the regularity of menses. Ask men whether they have experienced impotence. Ask men and women about a change in libido (sexual desire) or fertility issues.

*Physical appearance changes* can reflect an endocrine problem. Discuss any changes that the patient perceives in physical features. Ask about changes in:

- Hair texture and distribution
- Facial contours and eye protrusion
- Voice quality
- Body proportions
- Secondary sexual characteristics

For example, ask a man whether he is shaving less often or a woman if she has noticed an increase in facial hair. These changes may be associated with pituitary, thyroid, parathyroid, or adrenal dysfunction.

## Physical Assessment

### Inspection

An endocrine problem can change physical features because of its effect on growth and development, sex hormone levels, FLUID AND ELECTROLYTE BALANCE, and metabolism. Different findings can occur with many endocrine disorders or with nonendocrine problems.

Observe the patient's general appearance, and assess height, weight, fat distribution, and muscle mass in relation to age. Heredity and age rather than health problems may be responsible for some physical features (e.g., short stature). Assess scalp and body hair growth patterns.

When examining the head, focus on abnormalities of facial structure, features, and expression, such as:

- Prominent forehead or jaw
- Round or puffy face
- Dull or flat expression
- Exophthalmos (protruding eyeballs and retracted upper lids)

Check the lower neck for a visible enlargement of the thyroid gland. Normally the thyroid tissue cannot be observed. The isthmus may be noticeable when the patient swallows. Jugular vein distention may be seen on inspection of the neck and can indicate fluid overload.

Observe skin color and look for areas of pigment loss (hypopigmentation) or excess (hyperpigmentation). Fungal skin infections, slow wound healing, bruising, and petechiae are often seen in patients with adrenal hyperfunction. Skin infections, foot ulcers, and slow wound healing often occur with diabetes mellitus. With some types of adrenal gland dysfunction, the skin over the joints, as well as any scar tissue, may show increased pigmentation due to increased levels of adrenocorticotropic hormone (ACTH) and melanocyte-stimulating hormone.

**Vitiligo** (patchy areas of pigment loss) is seen with primary hypofunction of the adrenal glands and is caused by autoimmune destruction of melanocytes in the skin. It is seen most often on the face, neck, arms, hands, legs, and fold areas (Jarvis, 2016). Mucous membranes may have large areas of uneven pigmentation. Document the location, color, distribution, and size of skin color changes.

Inspect the fingernails for malformation, thickness, or brittleness, all of which may suggest thyroid gland problems. Examine the extremities and the base of the spine for edema, which suggests impaired FLUID AND ELECTROLYTE BALANCE.

Check the trunk for any abnormalities in chest size and symmetry. Truncal obesity and the presence of a "buffalo hump" between the shoulders on the back may indicate adrenocortical excess. Hormonal imbalance may also change secondary sexual characteristics. Inspect the breasts of both men and women for size, symmetry, pigmentation, and discharge. **Striae** (reddish-purple "stretch marks") on the breasts or abdomen are often seen with adrenocortical excess.

Assess the patient's hair distribution for signs of endocrine gland dysfunction. Changes can include **hirsutism** (excessive body hair growth, especially on the face, chest, and the center abdominal line of women), excessive scalp hair loss, or changes in hair texture (Jarvis, 2016).

Examination of the genitalia may reveal a dysfunction in hormone secretion. Observe the size of the scrotum and penis or of the labia and clitoris in relation to standards for the patient's age. The distribution and quantity of pubic hair are often affected in hypogonadism.

## Palpation

The thyroid gland and the testes can be examined by palpation. [Chapters 69](#) and [72](#) discuss examination of the testes. The thyroid gland is palpated for size, symmetry, general shape, and the presence of nodules or other irregularities.

Palpate the thyroid gland by standing either behind or in front of the patient. The posterior approach may be easier ([Jarvis, 2016](#)). Having the patient swallow sips of water during the examination helps you palpate the thyroid gland, which is not easily felt when normal.

Ask the patient to sit and to lower the chin. Using the posterior approach, place both your thumbs on the back of the patient's neck, with the fingers curved around to the front of the neck on either side of the trachea. Ask the patient to swallow, and locate the thyroid as you feel it rising. To examine the right lobe, turn the patient's head to the right and gently displace the trachea to the right with your left fingers. Palpate the right lobe with your right hand. Reverse this procedure to examine the left lobe ([Jarvis, 2016](#)).

## Nursing Safety Priority QSEN

### Action Alert

Always palpate the thyroid gently in an adult who has or is suspected to have hyperthyroidism because vigorous palpation can stimulate a sudden release of thyroid hormones and cause a thyroid storm.

## Auscultation

Auscultate the chest to assess cardiac rate and rhythm to use later as a means of assessing treatment effectiveness. Some endocrine problems induce dysrhythmias. Many endocrine problems can cause dehydration and volume depletion. Document any difference in the patient's blood pressure and pulse in the lying, standing, or sitting positions (orthostatic vital signs).

If an enlarged thyroid gland is palpated, auscultate the area of enlargement for bruits. Hypertrophy of the thyroid gland causes an increase in vascular flow, which may result in bruits.

## Psychosocial Assessment

Many endocrine problems can change a patient's behaviors, personality, and psychological responses. Assess the patient's coping skills, support systems, and health-related beliefs. Ask whether the patient has noticed a change in how stress is handled, frequency of crying, or degree of patience and anger expression. Patients may not recognize these changes in themselves. Ask the family about changes in the patient's behaviors or personality.

A number of endocrine disorders affect the patient's perception of self. For example, body features can change greatly in disorders of the pituitary, adrenal, and thyroid glands. Infertility, impotence, and other changes in sexual function may result from endocrine problems. Encourage the patient to express his or her feelings and concerns about a change in appearance or in sexual function. Ask about any difficulty in coping with these changes.

Patients with endocrine problems may require lifelong drugs and follow-up care. Assess their readiness to learn and ability to carry out specific self-management skills. Patients may also face financial difficulties resulting from a prolonged medical regimen or loss of employment. A referral to social service agencies may be needed.

## Diagnostic Assessment

### Laboratory Tests

Laboratory tests are an essential part of the diagnostic process for possible endocrine problems. Fluids commonly used for these tests include blood, urine, and saliva. Salivary levels of the steroid hormones (cortisol, testosterone, progesterone, and estradiol) accurately reflect blood levels of these hormones ([Sluss & Hayes, 2016](#)). Protein hormones, such as those from the pituitary gland and thyroid gland, cannot be accurately assessed using saliva. Always check with the agency's laboratory for proper collection and handling of the specimen. The specialized testing for specific

disorders is described in [Chapters 62 to 64](#). Best practices for the collection of specimens for general endocrine testing are listed in [Chart 61-2](#).

### Chart 61-2

## Best Practice for Patient Safety & Quality Care QSEN

### Endocrine Testing

#### For Blood Tests:

- Check your laboratory's method of handling hormone test samples for tube type, timing, drugs to be administered as part of the test, etc. For example, blood samples drawn for catecholamines must be placed on ice and taken to the laboratory immediately.
- Explain the procedure and any restrictions to the patient.
- If you are drawing blood samples from an IV line, clear the line thoroughly. Do not use a double- or triple-lumen line to obtain samples; contamination or dilution from another port is possible.
- Emphasize the importance of taking a drug prescribed for the test on *time*. Tell the patient to set an alarm if the drug is to be taken during the night.

#### For Urine Tests:

- Instruct the patient to begin the urine collection (whether for 2, 4, 8, 12, or 24 hours) by first emptying his or her bladder.
- Remind the patient to *not* save the urine specimen that begins the collection. The timing for the urine collection begins *after* this specimen.
- Tell the patient to note the time of the discarded specimen and to plan to collect all urine from this time until the end of the urine collection period.
- To end the collection, instruct the patient to empty his or her bladder at the end of the timed period and *add* that urine to the collection.
- Check with the laboratory to determine any special handling of the urine specimen (e.g., Is a preservative needed? Does the container need to be kept cold?).
- If needed, make sure that the preservative has been added to the collection container at the *beginning* of the collection.
- Tell the patient about any preservative and the need to avoid splashing urine from the container because some preservatives make the urine caustic.
- If the specimen must be kept cool or cold, instruct the patient to place the container in an inexpensive cooler with ice. The specimen container should not be kept with food or drinks.

#### Assays.

An assay measures the level of a specific hormone in blood or other body fluid. The most common assays for endocrine testing are antibody-based immunologic assays and chromatographic assays, which include mass spectrometry. These assays are very sensitive and can detect even minute quantities of a given hormone. Many different hormone concentrations can be analyzed at the same time by the mass spectrometry method.

#### Provocative/Suppression Tests.

Measurement of specific hormone blood levels does not always distinguish between the normal and

the abnormal. The wide normal range for some hormones makes it necessary to trigger responses by provocative (“stimulation”) or suppression tests.

For the patient who might have an underactive endocrine gland, a stimulus may be used to determine whether the gland is capable of normal hormone production. This method is called *provocative testing*. Measured amounts of selected hormones are given to stimulate the target gland to maximum production. Hormone levels are then measured and compared with expected normal values. Failure of the hormone level to rise with provocation indicates hypofunction.

*Suppression tests* are used when hormone levels are high or in the upper range of normal. Drugs or other substances known to normally suppress hormone production are administered. Failure of suppression of hormone production during testing indicates hyperfunction.

### Urine Tests.

Hormone levels and their metabolites in the urine can be measured to determine endocrine function. Because many of the endocrine hormones are secreted in a pulsatile fashion, measurement of a specific hormone in a 24-hour urine collection, rather than as a single blood or urine sample, better reflects specific gland function, such as the adrenal gland. Teach the patient how to collect a 24-hour urine sample (see also [Chart 61-2](#)).

Certain hormones require additives in the container at the beginning of the collection. Instruct the patient not to discard the preservative from the container and to use caution when handling it because some are caustic. Remind him or her that this collection is timed for *exactly* 24 hours. Instruct the patient to avoid taking any unnecessary drugs during endocrine testing because some drugs can interfere with the assay.

### Genetic Testing.

When some hormone levels are too low to be measured, genetic testing may be performed. DNA analysis or RNA assessment can determine whether a genetic mutation is responsible for the lack of hormone production or the absence of hormone receptors ([Sluss & Hayes, 2016](#)).

### Tests for Glucose.

Tests for functions of the islet cells of the pancreas measure the *result* of pancreatic islet cell function. Blood glucose values and the oral glucose tolerance test help diagnose diabetes mellitus. The glycosylated hemoglobin (A1C) value indicates the *average* blood glucose level over a period of 2 to 3 months. (See [Chapter 64](#) for diabetes mellitus testing.)

### Imaging Assessment

Anterior, posterior, and lateral skull x-rays may be used to view the sella turcica, the bony pocket in the skull where the pituitary gland rests. Erosion of the sella turcica indicates invasion of the wall from an abnormal growth.

MRI with contrast is the most sensitive method of imaging the pituitary gland, although CT scans can also be used to evaluate it. The thyroid, parathyroid glands, ovaries, and testes are evaluated by ultrasound. CT scans are used to evaluate the adrenal glands, ovaries, and pancreas.

### Other Diagnostic Assessment

Needle biopsy is a safe and quick ambulatory surgery procedure used to indicate the composition of thyroid nodules. It is used to determine whether surgical intervention is needed.

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Be aware that assessment of endocrine problems requires a systematic approach because of the variety and combination of signs and symptoms. **QSEN: Evidence-Based Practice**
- Physical, psychosocial, and laboratory findings are needed for a complete and accurate endocrine assessment to avoid overlooking any problems. **QSEN: Safety**

### Health Promotion and Maintenance

- Teach all patients that abusing or misusing hormones or steroids can have an adverse effect on endocrine function. **QSEN: Patient-Centered Care**
- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for endocrine tests. **QSEN: Patient-Centered Care**

### Psychosocial Integrity

- Encourage the patient to express concerns about a change in appearance, sexual function, or fertility as a result of a possible endocrine problem. **QSEN: Patient-Centered Care**
- Ask family members about changes in the patient's personality or behavior. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Be aware that the onset of endocrine problems can be slow and insidious or abrupt and life threatening.
- The presence of excess hormone production in an older adult is more likely to be caused by an actual endocrine problem than by age-related changes.
- Ask the patient about other family members with endocrine disorders, because some problems have a genetic component. **QSEN: Evidence-Based Practice**
- Ask the patient what prescribed and over-the-counter drugs are taken on a regular basis because some drugs can alter endocrine function. **QSEN: Patient-Centered Care**
- Follow the laboratory's procedures for collecting and handling specimens for endocrine function studies. **QSEN: Evidence-Based Practice**
- Differentiate normal from abnormal laboratory test findings and signs and symptoms for patients with possible endocrine problems. **QSEN: Patient-Centered Care**

## CHAPTER 62

# Care of Patients With Pituitary and Adrenal Gland Problems

M. Linda Workman

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is FLUID AND ELECTROLYTE BALANCE.**

✚ The FLUID AND ELECTROLYTE BALANCE concept exemplar for this chapter is Hypercortisolism (Cushing's Disease), p. 1255.

**The interrelated concepts for this chapter are:**

- CELLULAR REGULATION
- IMMUNITY

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to coordinate high-quality care and promote FLUID AND ELECTROLYTE BALANCE, CELLULAR REGULATION, and IMMUNITY in patients who have pituitary or adrenal disorders.
2. Teach the patient and caregiver(s) about how impaired FLUID AND ELECTROLYTE BALANCE, CELLULAR REGULATION, and IMMUNITY resulting from pituitary or adrenal problems affect home safety.

### Health Promotion and Maintenance

3. Identify community resources for patients requiring assistance with any disorder of the pituitary or adrenal gland.

### Psychosocial Integrity

4. Implement nursing interventions to help the patient and family cope with the psychosocial impact caused by acute or chronic problems of the pituitary or adrenal gland.

### Physiological Integrity

5. Apply knowledge of anatomy, physiology, and pathophysiology to assess patients with impaired pituitary or adrenal gland function affecting FLUID AND ELECTROLYTE BALANCE, CELLULAR REGULATION, or IMMUNITY.
6. Interpret clinical changes and laboratory data to determine the effectiveness of therapy for diabetes insipidus (DI) and syndrome of inappropriate antidiuretic hormone (SIADH).
7. Prioritize evidence-based nursing care for the patient with acute adrenal insufficiency.
8. Teach the patient and caregiver(s) about common drugs and other management strategies used for pituitary or adrenal gland problems.
9. Prioritize evidence-based care for the patient with hyperaldosteronism or pheochromocytoma.

The pituitary and adrenal glands secrete hormones that affect the CELLULAR REGULATION of the entire body, including FLUID AND ELECTROLYTE BALANCE. When too much or too little of one or more hormones is secreted, physical and psychological changes are induced. The anterior pituitary hormones regulate growth, metabolism, and sexual development. The posterior pituitary hormone, **vasopressin** (antidiuretic hormone [ADH]), helps maintain FLUID AND ELECTROLYTE BALANCE. Adrenal gland hormones are life sustaining.

A complete assessment is performed to detect specific clinical findings. The patient also often undergoes many diagnostic tests and relies on the nurse for explanations. Surgical intervention may be indicated. Nursing care for the patient with pituitary or adrenal disorders includes assessment, patient education, evaluating patient response to therapy, and providing support. The patient often needs lifelong hormone replacement therapy, and physical and emotional support is critical.

# Disorders of the ANTERIOR Pituitary Gland

## Hypopituitarism

### ❖ Pathophysiology

As discussed in [Chapter 61](#), the anterior pituitary gland (adenohypophysis) secretes these hormones to maintain homeostasis:

- Growth hormone (GH; somatotropin)
- Thyrotropin (thyroid-stimulating hormone [TSH])
- Corticotropin (adrenocorticotrophic hormone [ACTH])
- Follicle-stimulating hormone (FSH)
- Luteinizing hormone (LH)
- Melanocyte-stimulating hormone (MSH)
- Prolactin (PRL)

An adult with hypopituitarism usually has a deficiency of one pituitary hormone, a condition known as *selective hypopituitarism*. Decreased production of *all* of the anterior pituitary hormones (*panhypopituitarism*) is rare.

Deficiencies of *adrenocorticotrophic hormone (ACTH)* or *thyroid-stimulating hormone (TSH)* are the *most* life threatening because they cause a decrease in the secretion of vital hormones from the adrenal and thyroid glands. Adrenal gland hypofunction is discussed later in this chapter; hypothyroidism is discussed in [Chapter 63](#).

Deficiency of the **gonadotropins** (luteinizing hormone [LH] and follicle-stimulating hormone [FSH])—hormones that stimulate the gonads to produce sex hormones) changes sexual function in both men and women. In men, gonadotropin deficiency results in testicular failure with decreased testosterone production that may cause sterility. In women, gonadotropin deficiency results in ovarian failure, amenorrhea, and infertility.

Growth hormone (GH) deficiency changes tissue growth patterns by reducing liver production of *somatomedins*. These substances, especially somatomedin C, trigger growth and maintain bone, cartilage, and other tissues throughout life.

GH deficiency results from decreased GH production, failure of the liver to produce somatomedins, or a failure of tissues to respond to the somatomedins. In adults GH deficiency alters CELLULAR REGULATION by increasing the rate of bone destructive activity, leading to thinner bones (**osteoporosis**) and an increased risk for fractures.

The cause of hypopituitarism varies. Benign or malignant pituitary tumors can compress and destroy pituitary tissue. Pituitary function can be impaired by malnutrition or rapid loss of body fat. Shock or severe hypotension reduces blood flow to the pituitary gland, leading to hypoxia, infarction, and reduced hormone secretion. Other causes of hypopituitarism include head trauma, brain tumors or infection, radiation or surgery of the head and brain, and AIDS. *Idiopathic hypopituitarism* has an unknown cause.

Postpartum hemorrhage is the most common cause of pituitary infarction, which results in decreased hormone secretion. This clinical problem is known as *Sheehan's syndrome*. The pituitary gland normally enlarges during pregnancy; and, when hypotension during delivery results from hemorrhage, ischemia and necrosis of the gland occur.

### ❖ Interprofessional Collaborative Care

Patients with hypopituitarism often require lifelong hormone replacement therapy (HRT). Such patients can be found in the community and in any care setting. It is important that HRT continues when they are admitted to an acute care setting for any reason.

### ◆ Assessment: Noticing

Changes in physical appearance and target organ function occur with deficiencies of specific pituitary hormones ([Chart 62-1](#)). Gonadotropin (LH and FSH) deficiency results in the loss of or change in secondary sex characteristics in men and women. In male patients, look for facial and body hair loss. Ask about impotence and decreased *libido* (sex drive). Women may report

**amenorrhea** (absence of menstrual periods), **dyspareunia** (painful intercourse), infertility, and decreased libido. In female patients, check for dry skin, breast atrophy, and a decrease or absence of axillary and pubic hair.

## Chart 62-1

### Key Features

#### Pituitary Hypofunction

DEFICIENT HORMONE	SIGNS AND SYMPTOMS
Anterior Pituitary Hormones	
Growth hormone (GH)	Decreased bone density Pathologic fractures Decreased muscle strength Increased serum cholesterol levels
Gonadotropins (luteinizing hormone [LH], follicle-stimulating hormone [FSH])	Women: • Amenorrhea • Anovulation • Low estrogen levels • Breast atrophy • Loss of bone density • Decreased axillary and pubic hair • Decreased libido Men: • Decreased facial hair • Decreased ejaculate volume • Reduced muscle mass • Loss of bone density • Decreased body hair • Decreased libido • Impotence
Thyroid-stimulating hormone (thyrotropin) (TSH)	Decreased thyroid hormone levels Weight gain Intolerance to cold Scalp alopecia Hirsutism Menstrual abnormalities Decreased libido Slowed cognition Lethargy
Adrenocorticotropic hormone (ACTH)	Decreased serum cortisol levels Pale, sallow complexion Malaise and lethargy Anorexia Postural hypotension Headache Hypoglycemia Hyponatremia Decreased axillary and pubic hair (women)
Posterior Pituitary Hormones	
Vasopressin (antidiuretic hormone [ADH])	Diabetes insipidus: • Greatly increased urine output • Low urine specific gravity (<1.005) • Hypotension • Dehydration • Increased plasma osmolarity • Increased thirst • Output does not decrease when fluid intake decreases

Neurologic symptoms of hypopituitarism as a result of tumor growth often first occur as changes in vision. Assess the patient's visual acuity, especially peripheral vision, for changes or loss. Headaches, **diplopia** (double vision), and limited eye movement are common.

Laboratory findings vary widely. Some pituitary hormone levels may be measured directly. As described in [Chapter 61](#), laboratory assessment of some pituitary hormones involves measuring the *effects* of the hormones rather than the actual hormone levels. For example, blood levels of triiodothyronine (T<sub>3</sub>) and thyroxine (T<sub>4</sub>) from the thyroid, testosterone and estradiol from the gonads, and prolactin levels are measured easily. If levels of any of these hormones are low, further pituitary evaluation is necessary.

Pituitary problems may cause changes in the *sella turcica* (the bony nest where the pituitary gland rests) that can be seen with skull x-rays ([McCance et al., 2014](#)). Changes may include enlargement, erosion, and calcifications as a result of pituitary tumors. CT and MRI can more distinctly define bone or soft-tissue lesions. An angiogram may be used to rule out the presence of an aneurysm or other vascular problems in the area before surgery.

#### ◆ Interventions: Responding

Management of the adult with hypopituitarism focuses on replacement of deficient hormones to ensure appropriate CELLULAR REGULATION. Men who have gonadotropin deficiency receive sex steroid replacement therapy with androgens (testosterone). The most effective routes of androgen replacement are parenteral and transdermal. Therapy begins with high-dose testosterone and is

continued until **virilization** (presence of male secondary sex characteristics) is achieved, with responses that include increases in penis size, libido, muscle mass, bone size, and bone strength. Chest, facial, pubic, and axillary hair growth also increase. Patients usually report improved body image after therapy is initiated. The dose may then be decreased, but therapy continues throughout life. Therapy to increase fertility requires gonadotropin-releasing hormone (GnRH) injections, rather than testosterone therapy (Kaiser & Ho, 2016).

Androgen therapy is avoided in men with prostate cancer to prevent enhancing tumor cell growth. Side effects of therapy include **gynecomastia** (male breast tissue development), acne, baldness, and prostate enlargement.

Women who have gonadotropin deficiency receive HRT with a combination of estrogen and progesterone. The risk for hypertension or *thrombosis* (formation of blood clots in deep veins) is increased with estrogen therapy, especially among smokers. Emphasize measures to reduce risk and the need for regular health visits. For inducing pregnancy, specific hormones may be given to trigger ovulation.

Adult patients with GH deficiency may be treated with subcutaneous injections of human GH (hGH). Injections are given at night to mimic normal GH release (Kaiser & Ho, 2016).

## Hyperpituitarism

### ❖ Pathophysiology

**Hyperpituitarism** is hormone oversecretion that occurs with anterior pituitary tumors or tissue hyperplasia (tissue overgrowth). Tumors occur most often in the anterior pituitary cells that produce growth hormone (GH), prolactin (PRL), and adrenocorticotrophic hormone (ACTH). Overproduction of PRL also may occur in response to tumors that overproduce GH and ACTH. Excess ACTH may occur with increased secretion of melanocyte-stimulating hormone (MSH).

## Genetic/Genomic Considerations

### Patient-Centered Care QSEN

One cause of hyperpituitarism is multiple endocrine neoplasia, type 1 (MEN1), in which there is inactivation of the suppressor gene *MEN1* (Online Mendelian Inheritance in Man [OMIM], 2016b). MEN1 has an autosomal-dominant inheritance pattern and may result in a benign tumor of the pituitary, parathyroid glands, or pancreas. In the pituitary, this problem causes excessive production of growth hormone and acromegaly. Ask a patient with acromegaly whether either parent also has this problem or has had a tumor of the pancreas or parathyroid glands.

The most common cause of hyperpituitarism is a pituitary adenoma—a benign tumor of one or more tissues within the anterior pituitary (Melmed et al., 2016). Adenomas are classified by the hormone secreted. As an adenoma gets larger and compresses brain tissue, neurologic changes, as well as endocrine problems, may occur. Symptoms may include visual disturbances, headache, and increased intracranial pressure.

Prolactin (PRL)-secreting tumors are the most common type of pituitary adenoma. Excessive PRL inhibits the secretion of gonadotropins and sex hormones in men and women, resulting in *galactorrhea* (breast milk production), amenorrhea, and infertility.

Overproduction of GH in adults results in *acromegaly* (Fig. 62-1). The onset may be gradual with slow progression, and changes may remain unnoticed for years before diagnosis of the disorder. Early detection and treatment are essential to prevent irreversible enlargement of the face, hands, and feet. Other changes include increased skeletal thickness, hypertrophy of the skin, and enlargement of many organs such as the liver and heart. Some changes may be reversible after treatment, but skeletal changes are permanent.

**FIG. 62-1** Progression of acromegaly. Courtesy of the Group for Research in Pathology Educations [GRIFE], Oklahoma City, OK.)

Bone thinning and bone cell overgrowth occur slowly. Breakdown of joint cartilage and hypertrophy of ligaments, vocal cords, and eustachian tubes are common. Nerve entrapment and hyperglycemia (elevated blood glucose levels) are common.

Excess ACTH overstimulates the adrenal cortex. The result is excessive production of glucocorticoids, mineralocorticoids, and androgens, which leads to the development of Cushing's disease (see [Hypercortisolism \[Cushing's Disease\]](#)).

Usually hyperpituitarism is caused by benign tumors (*adenomas*) from one pituitary cell type ([Melmed & Kleinberg, 2016](#)). It can also be caused by a hypothalamic problem of excessive production of releasing hormones, which then overstimulate a normal pituitary gland.

### ❖ **Interprofessional Collaborative Care**

Most care of a patient with hyperpituitarism occurs on an outpatient basis. When surgical intervention is required, hospitalization is necessary.

### ◆ **Assessment: Noticing**

Symptoms of hyperpituitarism vary with the hormone produced in excess. Obtain the patient's age, gender, and family history. Ask about any change in hat, glove, ring, or shoe size and the presence of fatigue. The patient with high GH levels may have backache and joint pain from bone changes. Ask specifically about headaches and changes in vision.

The patient with hypersecretion of PRL often reports sexual function difficulty. Ask women about menstrual changes, decreased libido, painful intercourse, and any difficulty in becoming pregnant. Men may report decreased libido and impotence.

Changes in appearance and target organ function occur with excesses of specific anterior pituitary hormones ([Chart 62-2](#)). Symptoms of GH excess are increases in lip and nose sizes, a prominent brow ridge, and increases in head, hand, and foot sizes. The patient often seeks health care because of these dramatic changes in appearance.

## ▶ **Chart 62-2**

### **Key Features**

#### **Anterior Pituitary Hyperfunction**

##### **Prolactin (PRL)**

- Hypogonadism (loss of secondary sexual characteristics)
- Decreased gonadotropin levels
- Galactorrhea
- Increased body fat
- Increased serum prolactin levels

## **Growth Hormone (GH)**

### **Acromegaly**

- Thickened lips
- Coarse facial features
- Increasing head size
- Lower jaw protrusion
- Enlarged hands and feet
- Joint pain
- Barrel-shaped chest
- Hyperglycemia
- Sleep apnea
- Enlarged heart, lungs, and liver

## **Adrenocorticotrophic Hormone (ACTH)**

### **Cushing's Disease (Pituitary)**

- Elevated plasma cortisol levels
- Weight gain
- Truncal obesity
- "Moon face"
- Extremity muscle wasting
- Loss of bone density
- Hypertension
- Hyperglycemia
- Striae and acne

## **Thyrotropin (Thyroid-Stimulating Hormone [TSH])**

- Elevated plasma TSH and thyroid hormone levels
- Weight loss
- Tachycardia and dysrhythmias
- Heat intolerance
- Increased GI motility
- Fine tremors

## **Gonadotropins (Luteinizing Hormone [LH], Follicle-Stimulating Hormone [FSH])**

### **Men:**

- Elevated LH and FSH levels
- Hypogonadism or hypergonadism

### Women:

- Normal LH and FSH levels

In a patient with hyperpituitarism, usually only one hormone is produced in excess because the cell types within the pituitary gland are so individually organized. The most common hormones produced in excess with hyperpituitarism are PRL, ACTH, and GH.

MRI is the best imaging assessment for diagnosis of hyperpituitarism (Melmed & Kleinberg, 2016). Skull x-rays may be used to identify abnormalities of the sella turcica.

Suppression testing can help diagnose hyperpituitarism. High blood glucose levels usually suppress the release of GH. Giving 100 g of oral glucose or 0.5 g/kg of body weight is followed by serial GH level measurements. GH levels that do not fall below 5 ng/mL (mcg/L) indicate a positive (abnormal) result.

### ◆Interventions: Responding

The expected outcomes of management for the patient who has hyperpituitarism are to return hormone levels to normal or near normal, reduce or eliminate headache and visual disturbances, prevent complications, and reverse as many of the body changes as possible.

### Nonsurgical Management.

Encourage the patient to express concerns about his or her altered physical appearance. Help him or her identify personal strengths and positive characteristics. *Galactorrhea* (fluid leakage from the breast), *gynecomastia* (breast enlargement in men), and reduced sexual functioning can disturb self-image and personal identity. Reassure the patient that treatment may reverse some of these problems.

*Drug therapy* may be used alone or in combination with surgery and/or radiation. The most common drugs used are the dopamine agonists bromocriptine (Parlodel) and cabergoline (Dostinex). These drugs stimulate dopamine receptors in the brain and inhibit the release of GH and PRL. In most cases, small tumors decrease until the pituitary gland is of normal size. Large pituitary tumors usually decrease to some extent.

Side effects of bromocriptine include orthostatic (postural) hypotension, headaches, nausea, abdominal cramps, and constipation. Give bromocriptine with a meal or a snack to reduce GI side effects. Treatment starts with a low dose and is gradually increased until the desired level is reached. *If pregnancy occurs, the drug is stopped immediately.*

## ■Nursing Safety Priority QSEN

### Drug Alert

Teach patients taking bromocriptine to seek medical care immediately if chest pain, dizziness, or watery nasal discharge occurs because of the possibility of serious side effects, including cardiac dysrhythmias, coronary artery spasms, and cerebrospinal fluid leakage.

Other agents used for acromegaly are the somatostatin analogs, especially octreotide (Sandostatin) and lanreotide (Somatuline), and a growth hormone receptor blocker, pegvisomant (Somavert). Octreotide inhibits GH release through negative feedback. Pegvisomant blocks growth hormone (GH) receptor activity and blocks production of insulin-like growth factor (IGF). Combination therapy with monthly injections of a somatostatin analog and weekly injections of pegvisomant has provided good control of the disease.

*Radiation therapy* does not have immediate effects in reducing pituitary hormone excesses, and months to years may pass before a therapeutic effect can be seen. It is not recommended to manage acromegaly (Melmed & Kleinberg, 2016). The use of the gamma knife or stereotactic confocal radiotherapy method of delivering radiation to pituitary tumors has reduced the long-term side

effects of this therapy.

### **Surgical Management.**

Surgical removal of the pituitary gland and tumor (**hypophysectomy**) is the most common treatment for hyperpituitarism. Successful surgery decreases hormone levels, relieves headaches, and may reverse changes in sexual functioning.

### **Preoperative Care.**

Explain that, because nasal packing is present for 2 to 3 days after surgery, it will be necessary to breathe through the mouth, and a “mustache” dressing (“drip” pad) will be placed under the nose. Instruct the patient not to brush teeth, cough, sneeze, blow the nose, or bend forward after surgery. These activities can increase intracranial pressure (ICP) and delay healing.

### **Operative Procedures.**

Depending on tumor size and location, a transsphenoidal approach or a minimally invasive endoscopic transnasal approach with smaller instruments is used instead of a more invasive procedure. General anesthesia is used. Nasal packing is inserted after the transsphenoidal incision is closed, and a mustache dressing is applied. These are not needed for the minimally invasive transnasal procedure. If the tumor cannot be reached by either the endoscopic transnasal or the transsphenoidal approach, a craniotomy may be indicated ([Melmed & Kleinberg, 2016](#)) (see [Chapter 45](#)).

### **Postoperative Care.**

Monitor the patient's neurologic response and document any changes in vision or mental status, altered level of consciousness, or decreased strength of the extremities. Observe the patient for complications such as transient diabetes insipidus (discussed later in this chapter), cerebrospinal fluid (CSF) leakage, infection, and increased ICP.

Teach the patient to report any postnasal drip or increased swallowing, which may indicate leakage of CSF. Keep the head of the bed elevated after surgery. Assess nasal drainage for quantity, quality, and the presence of glucose (which indicates that the fluid is CSF). A light yellow color at the edge of the clear drainage on the dressing is called the *halo sign* and indicates CSF. If the patient has persistent, severe headaches, CSF fluid may have leaked into the sinus area. Most CSF leaks resolve with bedrest, and surgical intervention is rarely needed.

*Teach the patient to avoid coughing early after surgery because it increases pressure in the incision area and may lead to a CSF leak.* Remind him or her to perform deep-breathing exercises hourly while awake to prevent pulmonary problems. Patients may have mouth dryness from mouth breathing. Instruct the patient to rinse the mouth frequently and to apply a lubricating jelly to dry lips.

Assess for indications of infection, especially meningitis, such as headache, fever, and nuchal (neck) rigidity. The surgeon may prescribe antibiotics, analgesics, and antipyretics.

If the entire pituitary gland has been removed, replacement of thyroid hormones and glucocorticoids is lifelong. Best practices for care after surgery are listed in [Chart 62-3](#).

## **Chart 62-3**

### **Best Practice for Patient Safety & Quality Care** QSEN

#### **The Patient After Hypophysectomy**

- Monitor the patient's neurologic status hourly for the first 24 hours and then every 4 hours.
- Monitor fluid balance, especially for output greater than intake.
- Encourage the patient to perform deep-breathing exercises.
- Instruct the patient not to cough, blow the nose, or sneeze.
- Instruct the patient to use dental floss and oral mouth rinses rather than toothbrushing until the surgeon gives permission.

- Instruct the patient to avoid bending at the waist to prevent increasing intracranial pressure.
- Monitor the nasal drip pad for the type and amount of drainage.
- Teach the patient methods to avoid constipation and subsequent “straining.”
- Teach the patient self-administration of the prescribed hormones.

After surgery the patient needs daily self-management regimens and frequent checkups. [Chart 62-4](#) lists areas for a focused assessment for the patient at home after a hypophysectomy. Review drug regimens and symptoms of infection and cerebral edema with the family.

#### **Chart 62-4**

### **Focused Assessment**

#### **The Patient Who Has Undergone Nasal Hypophysectomy for Hyperpituitarism**

Assess cardiovascular status:

- Vital signs, including apical pulse, pulse pressure, presence or absence of orthostatic hypotension, and the quality/rhythm of peripheral pulses

Assess cognition and mental status

Assess condition of operative site:

- Observe nasal area for drainage:
- If present, note color, clarity, and odor
- Test clear drainage for the presence of glucose

Assess neuromuscular status:

- Reactivity of patellar and biceps reflexes
- Oral temperature
- Handgrip strength
- Steadiness of gait
- Distant and near visual acuity
- Pupillary responses to light

Assess kidney function:

- Observe urine specimen for color, odor, cloudiness, and amount
- Ask about:
- Headaches or visual disturbances
- Ease of bowel movements
- 24-hour fluid intake and output
- Over-the-counter and prescribed drugs taken

Assess patient's understanding of illness and adherence with treatment:

- Symptoms to report to health care provider
- Drug plan (correct timing and dose)

After a hypophysectomy, advise the patient to avoid activities that might interfere with healing or increase intracranial pressure (ICP). Teach him or her to avoid bending over from the waist to pick up objects or tie shoes because this position increases ICP. Teach the patient to bend the knees and then lower the body to pick up fallen objects. ICP also increases when the patient strains to have a bowel movement. Suggest techniques to prevent constipation, such as eating high-fiber foods, drinking plenty of fluids, and using stool softeners or laxatives.

Teach the patient to avoid toothbrushing for about 2 weeks after transsphenoidal surgery. Frequent mouth care with mouthwash and daily flossing provide adequate oral hygiene. A decreased sense of smell is expected after surgery and usually lasts 3 to 4 months.

Hormone replacement with vasopressin may be needed to maintain fluid balance (see discussion of Interventions in the [Diabetes Insipidus](#) section). If the anterior portion of the pituitary gland is removed, instruct the patient in cortisol, thyroid, and gonadal hormone replacement. Teach the patient to report the return of any symptoms of hyperpituitarism immediately to the primary health care provider.

# Disorders of the Posterior Pituitary Gland

## Diabetes Insipidus

### ❖ Pathophysiology

Diabetes insipidus (DI) is a disorder of the posterior pituitary gland in which water loss is caused by either an antidiuretic hormone (ADH) deficiency or an inability of the kidneys to respond to ADH. The result of DI is the excretion of large volumes of dilute urine because the distal kidney tubules and collecting ducts do not reabsorb water; this leads to **polyuria** (excessive water loss through urination), dehydration, and disturbed FLUID AND ELECTROLYTE BALANCE.

Dehydration from massive water loss increases plasma osmolarity and serum sodium levels, which stimulate the sensation of thirst. Thirst promotes increased fluid intake and aids in maintaining hydration. *If the thirst mechanism is poor or absent or if the adult is unable to obtain water independently, dehydration becomes more severe and can lead to death* (Robinson & Verbalis, 2016).

### 📌 Nursing Safety Priority QSEN

#### Action Alert

Ensure that no patient suspected of having DI is deprived of fluids for more than 4 hours because he or she cannot reduce urine output and severe dehydration can result.

ADH deficiency is classified as neurogenic (primary or secondary), nephrogenic, or drug-related, depending on whether the problem is caused by insufficient production of ADH or an inability of the kidney to respond to the presence of ADH.

*Primary neurogenic diabetes insipidus* is caused by a defect in the hypothalamus or pituitary gland, resulting in a lack of ADH production or release. *Secondary neurogenic diabetes insipidus* is not caused by a direct problem with the posterior pituitary but is a result of tumors in or near the hypothalamus or pituitary gland, head trauma, infectious processes, brain surgery, or metastatic tumors.

*Nephrogenic diabetes insipidus* is a problem with the kidney's response to ADH rather than a problem with ADH production or release. Any severe kidney injury can reduce the ability of the kidney tubules to respond to ADH. In this situation, as long as the kidney is able to continue to produce urine, DI results. In some cases, a mutation in the gene responsible for producing the ADH receptor interferes with kidney response to ADH.

*Drug-related diabetes insipidus* is usually caused by lithium carbonate (Eskalith, Lithobid, Carbolith) and demeclocycline (Declomycin) (Robinson & Verbalis, 2016). These drugs can interfere with the response of the kidneys to ADH.

### 📌 Genetic/Genomic Considerations

#### Patient-Centered Care QSEN

Nephrogenic diabetes insipidus can be a genetic disorder in which the ADH receptor (vasopressin receptor) has a defect that prevents kidney tubules from interacting with ADH. The result is poor water reabsorption by the kidney, although the actual amount of hormone produced is not deficient. This problem is most commonly inherited as an X-linked recessive disorder in which the *AVPR2* gene coding for the ADH receptor is mutated and only males are affected (Online Mendelian Inheritance in Man [OMIM], 2016a). There is also an autosomal form of the disorder in which the *AQP2* gene is mutated and both males and females are affected. When assessing a patient with DI, always ask whether anyone else in the family has ever had this disorder.

### ❖ Interprofessional Collaborative Care

Management of patients with chronic DI occurs in the community unless acute problems develop.

Also, whenever patients are in an acute care setting for other health problems, care must include continuing DI management.

### ◆ **Assessment: Noticing**

Most symptoms of DI are related to dehydration ([Chart 62-5](#)). Key symptoms are an increase in urination and excessive thirst. Ask about a history of recent surgery, head trauma, or drug use (e.g., lithium). Although increased fluid intake prevents serious volume depletion, the patient who is deprived of fluids or who cannot increase oral fluid intake may develop shock from fluid loss. Symptoms of dehydration (e.g., poor skin turgor, dry or cracked mucous membranes) may be present. (See [Chapter 11](#) for discussion of dehydration.)

## ▶ **Chart 62-5**

### **Key Features**

#### **Diabetes Insipidus**

##### **Cardiovascular Symptoms**

- Hypotension
- Tachycardia
- Weak peripheral pulses
- Hemoconcentration

##### **Kidney/Urinary Symptoms**

- Increased urine output
- Dilute, low specific gravity

##### **Skin Symptoms**

- Poor turgor
- Dry mucous membranes

##### **Neurologic Symptoms**

- Decreased cognition\*
- Ataxia\*
- Increased thirst
- Irritability\*

\*Occurs when access to water is limited and rapid dehydration results.

Water loss changes blood and urine tests. The 24-hour fluid intake and output is measured without restricting food or fluid intake. DI is considered if urine output is more than 4 L during this period and is greater than the volume ingested. The amount of urine excreted in 24 hours by patients with DI may vary from 4 to 30 L/day. Urine is dilute with a low specific gravity (less than 1.005) and low osmolarity (50 to 200 mOsm/kg) or osmolality (50 to 200 mOsm/L).

## Clinical Judgment Challenge 62-1

### Safety; Patient-Centered Care QSEN

A 36-year-old man is admitted to your unit 4 hours after a surgical reduction of a compound fracture of the femur. His other health problems include hypercholesterolemia, for which he takes atorvastatin (Lipitor) 80 mg once daily, and bipolar disorder for which he takes lithium (Eskalith) 600 mg once daily. He has an IV of dextrose 5% in 0.45% saline infusing at a rate of 150 mL/hr. His blood pressure is now 96/70, down from the last reading of 128/80 obtained in the postanesthesia recovery area. His pulse is 84 and regular, and his pulse oximetry is 99%. In assessing him for possible shock, you note that the catheter drainage bag contains 800 mL of pale urine. His last output, measured 1 hour ago, was 1100 mL. According to the operative record, his output during the 3-hour surgery was 1800 mL. His total IV intake for the surgical and postoperative period was 1500 mL. He is to have his IV and Foley catheter removed when stable.

1. Is his output cause for concern? Provide a rationale for your response.
2. Will you discontinue the IV and/or the Foley? Why or why not?
3. What symptoms of shock are present?
4. What are the possible causes of his urine output volume?
5. What is your best course of action?

### ◆ Interventions: Responding

Management focuses on controlling symptoms with drug therapy. The most preferred drug is desmopressin acetate (DDAVP), a synthetic form of vasopressin given orally, as a sublingual “melt,” or intranasally in a metered spray (Robinson & Verbalis, 2016). The frequency of dosing varies with patient responses. Teach patients that each metered spray delivers 10 mcg and those with mild DI may need only one or two doses in 24 hours. For more severe DI, one or two metered doses two or three times daily may be needed. During severe dehydration, ADH may be given IV or IM. Ulceration of the mucous membranes, allergy, a sensation of chest tightness, and lung inhalation of the spray may occur with use of the intranasal preparations. If side effects occur or if the patient has an upper respiratory infection, oral or subcutaneous vasopressin is used.

## Nursing Safety Priority QSEN

### Drug Alert

The parenteral form of desmopressin is 10 times stronger than the oral form, and the dosage must be reduced.

For the hospitalized patient with DI, nursing management focuses on early detection of dehydration and maintaining adequate hydration. Interventions include accurately measuring fluid intake and output, checking urine specific gravity, and recording the patient's weight daily.

Urge the patient to drink fluids in an amount equal to urine output. If fluids are given IV, ensure the patency of the access catheter and accurately monitor the amount infused hourly.

The patient with permanent DI requires lifelong drug therapy. Check his or her ability to assess symptoms and adjust dosages as prescribed for changes in conditions. Teach that polyuria and polydipsia are signals of the need for another dose.

Drugs for DI induce water retention and can cause fluid overload (see Chapter 11). *Teach all patients taking these drugs to weigh themselves daily to identify weight gain.* Stress the importance of using the same scale and weighing at the same time of day while wearing a similar amount of clothing. If weight gain of more than 2.2 lb (1 kg) along with other signs of water toxicity occur (e.g., persistent headache, acute confusion, nausea, vomiting), instruct the patient or family that the patient must go to the emergency department or call 911. Instruct him or her to wear a medical alert

bracelet identifying the disorder and drugs.

## NCLEX Examination Challenge 62-1

### Health Promotion and Maintenance

Which statements made by a client who has diabetes insipidus indicates to the nurse that more teaching is needed? **Select all that apply.**

- A. If I gain more than 2 lb (1 kg) in a day, I'll limit my fluid intake.
- B. If I become thirstier, I'll take another dose of the drug.
- C. I'll avoid aspirin and aspirin-containing substances.
- D. I'll stop taking the drug for 24 hours before I have any dental work performed.
- E. I'll limit my intake of salt and sodium to no more than 2 g daily.
- F. I'll wear my medical alert bracelet at all times.

## Syndrome of Inappropriate Antidiuretic Hormone

### ❖ Pathophysiology

The **syndrome of inappropriate antidiuretic hormone (SIADH)** or *Schwartz-Bartter syndrome* is a problem in which vasopressin (antidiuretic hormone [ADH]) is secreted even when plasma osmolality is low or normal. A decrease in plasma osmolality normally inhibits ADH production and secretion. SIADH occurs with many conditions (e.g., cancer therapy, pulmonary infection or impairment) and with specific drugs, including selective serotonin reuptake inhibitors (Robinson & Verbalis, 2016). Table 62-1 lists common causes of SIADH.

**TABLE 62-1**

**Conditions Causing the Syndrome of Inappropriate Antidiuretic Hormone**

Malignancies	CNS Disorders
<ul style="list-style-type: none"> <li>• Small cell lung cancer</li> <li>• Pancreatic, duodenal, and GU carcinomas</li> <li>• Thymoma</li> <li>• Hodgkin's lymphoma</li> <li>• Non-Hodgkin's lymphoma</li> </ul>	<ul style="list-style-type: none"> <li>• Trauma</li> <li>• Infection</li> <li>• Tumors (primary or metastatic)</li> <li>• Strokes</li> <li>• Porphyria</li> <li>• Systemic lupus erythematosus</li> </ul>
Pulmonary Disorders	Drugs
<ul style="list-style-type: none"> <li>• Viral and bacterial pneumonia</li> <li>• Lung abscesses</li> <li>• Active tuberculosis</li> <li>• Pneumothorax</li> <li>• Chronic lung diseases</li> <li>• Mycoses</li> <li>• Positive-pressure ventilation</li> </ul>	<ul style="list-style-type: none"> <li>• Exogenous ADH</li> <li>• Chlorpropamide</li> <li>• Vincristine</li> <li>• Cyclophosphamide</li> <li>• Carbamazepine</li> <li>• Opioids</li> <li>• Tricyclic antidepressants</li> <li>• General anesthetics</li> <li>• Fluoroquinolone antibiotics</li> </ul>

ADH, Antidiuretic hormone; CNS, central nervous system; GU, genitourinary.

In SIADH, ADH continues to be released even when plasma is hypo-osmolar, leading to disturbances of FLUID AND ELECTROLYTE BALANCE. Water is *retained*, which results in dilutional **hyponatremia** (a decreased serum sodium level) and fluid overload. The increase in blood volume increases the kidney filtration and inhibits the release of renin and aldosterone, which increase urine sodium loss and lead to greater hyponatremia.

### ❖ Interprofessional Collaborative Care

Severe or sudden onset SIADH usually requires management in an acute care setting. Mild SIADH is managed in the community.

### ◆ Assessment: Noticing

Ask the patient about his or her medical history, which may reveal conditions that can cause

SIADH. Information about these conditions should be obtained:

- Recent head trauma
- Cerebrovascular disease
- Tuberculosis or other pulmonary disease
- Cancer
- All past and current drug use

Early symptoms of SIADH are related to the water-retention dilution of serum sodium levels (hyponatremia). GI disturbances, such as loss of appetite, nausea, and vomiting, may occur first, as discussed in [Chapter 11](#). Weigh the patient and document any recent weight gain. Use this information to monitor responses to therapy. In SIADH, free water (not salt) is retained; and dependent edema is not usually present, even though water is retained.

Water retention, hyponatremia, and fluid shifts affect central nervous system function, especially when the serum sodium level is below 115 mEq/L (mmol/L). The patient may have lethargy, headaches, hostility, disorientation, and a change in level of consciousness. Lethargy and headaches can progress to decreased responsiveness, seizures, and coma. Assess deep tendon reflexes, which are usually decreased.

Vital sign changes include full and bounding pulse (caused by the increased fluid volume) and hypothermia (caused by central nervous system disturbance). [Chapter 11](#) presents other findings that occur with hyponatremia.

Water retention causes urine volume to decrease and urine osmolarity to increase. At the same time, plasma volume increases, and plasma osmolarity decreases. Elevated urine sodium levels and specific gravity reflect increased urine concentration. Serum sodium levels are decreased, often as low as 110 mEq/L (mmol/L), because of fluid retention and sodium loss.

### ◆ **Interventions: Responding**

Medical interventions for SIADH focus on restricting fluid intake, promoting the excretion of water, replacing lost sodium, and interfering with the action of ADH. Nursing interventions focus on monitoring response to therapy, preventing complications, teaching the patient and family about fluid restrictions and drug therapy, and preventing injury.

*Fluid restriction* is essential because fluid intake further dilutes plasma sodium levels. In some cases, fluid intake may be kept as low as 500 to 1000 mL/24 hr ([Robinson & Verbalis, 2016](#)). Dilute tube feedings with saline rather than water and use saline to irrigate GI tubes. Mix drugs to be given by GI tube with saline.

Measure intake, output, and daily weights to assess the degree of fluid restriction needed. A weight gain of 2.2 lb (1 kg) or more per day or a gradual increase over several days is cause for concern. A 2.2-lb (1-kg) weight increase is equal to a 1000-mL fluid retention (1 kg = 1 L). Keep the mouth moist by offering frequent oral rinsing (warn patients not to swallow the rinses).

*Drug therapy* with vasopressin receptor antagonists (vaptans), such as tolvaptan (Samsca) or conivaptan (Vaprisol), is used to treat SIADH when hyponatremia is present in hospitalized patients. These drugs promote water excretion without causing sodium loss. Tolvaptan is an oral drug, and conivaptan is given IV. Tolvaptan has a black box warning that rapid increases in serum sodium levels (those greater than a 12-mEq/L [mmol/L] increase in 24 hours) have been associated with central nervous system demyelination that can lead to serious complications and death. In addition, when this drug is used at higher dosages or for longer than 30 days, there is a significant risk for liver failure and death ([Robinson & Verbalis, 2016](#)).

## **Nursing Safety Priority** QSEN

### **Drug Alert**

Administer tolvaptan or conivaptan only in the hospital setting so serum sodium levels can be monitored closely for the development of hypernatremia.

Diuretics may be used on a limited basis to manage SIADH when sodium levels are near normal and heart failure is present. With diuretics sodium loss can be potentiated, further contributing to

the problems caused by SIADH. For milder SIADH, demeclocycline (Declomycin), an oral antibiotic, may help reach FLUID AND ELECTROLYTE BALANCE, although the drug is not approved for this problem.

Hypertonic saline (i.e., 3% sodium chloride [3% NaCl]) is used to treat SIADH when the serum sodium level is very low (Robinson & Verbalis, 2016). Give IV saline cautiously because it may add to existing fluid overload and promote heart failure. If the patient needs routine IV fluids, a saline solution rather than a water solution is prescribed to prevent further sodium dilution.

Monitor the patient's response to therapy to prevent the fluid overload from becoming worse, leading to pulmonary edema and heart failure. Any patient with SIADH, regardless of age, is at risk for these complications. The older adult or one who also has cardiac, kidney, pulmonary, or liver problems is at greater risk.

Monitor for increased fluid overload (bounding pulse, increasing neck vein distention, crackles in lungs, dyspnea, increasing peripheral edema, reduced urine output) at least every 2 hours.

*Pulmonary edema can occur very quickly and can lead to death.* Notify the primary health care provider of any change that indicates the fluid overload is not responding to therapy or is worse.

*Providing a safe environment* is needed when the serum sodium level falls below 120 mEq/L (mmol/L). The risk for neurologic changes and seizures increases as a result of osmotic fluid shifts into brain tissue. Observe for and document changes in the patient's neurologic status. Assess for subtle changes, such as muscle twitching, increasing irritability, or restlessness before they progress to seizures or coma. Check orientation to time, place, and person every 2 hours because disorientation or confusion may be present. Reduce environmental noise and lighting to prevent overstimulation.

Flow sheets recording neurologic assessments and laboratory data are helpful in detecting neurologic trends. The frequency of neurologic checks depends on the patient's status. For the patient being treated for SIADH who is hyponatremic but alert, awake, and oriented, checks every 2 to 4 hours may be sufficient. For the patient who has had a change in level of consciousness, perform neurologic checks at least every hour or as prescribed. Inspect the environment every shift, making sure that basic safety measures, such as side rails being securely in place, are observed.

## NCLEX Examination Challenge 62-2

### Safe and Effective Care Environment

When reviewing the laboratory values of a client who has chronic obstructive pulmonary disease and pneumonia, the nurse observes these findings. Which one does the nurse report to the provider immediately?

- A. International normalized ratio (INR) 2.1
- B. Serum chloride 96 mEq/L (mmol/L)
- C. Serum sodium 117 mEq/L (mmol/L)
- D. pH 7.28

# Disorders of the Adrenal Gland

## Adrenal Gland Hypofunction

### ❖ Pathophysiology

Adrenocortical steroid production may decrease as a result of inadequate secretion of adrenocorticotrophic hormone (ACTH), dysfunction of the hypothalamic-pituitary control mechanism, or direct dysfunction of adrenal gland tissue. Symptoms may develop gradually or occur quickly with stress. In acute adrenocortical insufficiency (**adrenal crisis**), life-threatening symptoms may appear without warning.

Insufficiency of adrenocortical steroids causes problems through the loss of aldosterone and cortisol action. Decreased cortisol levels result in hypoglycemia. Gastric acid production and glomerular filtration decrease. Decreased glomerular filtration leads to excessive blood urea nitrogen levels, which cause anorexia and weight loss.

Reduced aldosterone secretion causes disturbances of FLUID AND ELECTROLYTE BALANCE. Potassium excretion is decreased, causing hyperkalemia. Sodium and water excretion are increased, causing hyponatremia and hypovolemia. Potassium retention also promotes reabsorption of hydrogen ions, which can lead to acidosis.

Low adrenal androgen levels decrease the body, axillary, and pubic hair, especially in women, because the adrenals produce most of the androgens in females. The severity of symptoms is related to the degree of hormone deficiency.

**Acute adrenal insufficiency** (*Addisonian crisis*) is a life-threatening event in which the need for cortisol and aldosterone is greater than the body's supply (McCance et al., 2014). It often occurs in response to a stressful event (e.g., surgery, trauma, severe infection), especially when the adrenal hormone output is already reduced. Problems are the same as those of chronic insufficiency but are more severe. *However, unless intervention is initiated promptly, sodium levels fall, and potassium levels rise rapidly* (Pereira, 2016). *Severe hypotension results from the blood volume depletion that occurs with the loss of aldosterone.* Best practices for emergency care of patients with acute adrenal insufficiency are listed in [Chart 62-6](#).

### 📊 Chart 62-6

## Best Practice for Patient Safety & Quality Care QSEN

### Emergency Care of the Patient With Acute Adrenal Insufficiency

#### Hormone Replacement

- Start rapid infusion of normal saline or dextrose 5% in normal saline.
- Initial dose of hydrocortisone sodium (Solu-Cortef) is 100 to 300 mg or dexamethasone 4 to 12 mg as an IV bolus.
- Administer additional 100 mg of hydrocortisone sodium by continuous IV infusion over the next 8 hours.
- Give hydrocortisone 50 mg IM concomitantly with hydration every 12 hours.
- Initiate an H<sub>2</sub> histamine blocker (e.g., ranitidine) IV for ulcer prevention.

#### Hyperkalemia Management

- Administer insulin (20 to 50 units) with dextrose (20 to 50 mg) in normal saline to shift potassium into cells.
- Administer potassium binding and excreting resin (e.g., Kayexalate).

- Give loop or thiazide diuretics.
- Avoid potassium-sparing diuretics, as prescribed.
- Initiate potassium restriction.
- Monitor intake and output.
- Monitor heart rate, rhythm, and ECG for signs and symptoms of hyperkalemia (slow heart rate; heart block; tall, peaked T waves; fibrillation; asystole).

### Hypoglycemia Management

- Administer IV glucose as prescribed.
- Administer glucagon as needed and prescribed.
- Maintain IV access.
- Monitor blood glucose level hourly.

Adrenal insufficiency (Addison's disease) is classified as primary or secondary. Causes of primary and secondary adrenal insufficiency are listed in Table 62-2. A common cause of secondary adrenal insufficiency is the sudden cessation of long-term glucocorticoid therapy. This therapy suppresses production of glucocorticoids through negative feedback by causing atrophy of the adrenal cortex. Glucocorticoid drugs must be withdrawn gradually to allow for pituitary production of ACTH and activation of adrenal cells to produce cortisol.

**TABLE 62-2**  
**Causes of Primary and Secondary Adrenal Insufficiency**

Primary Causes	Secondary Causes
<ul style="list-style-type: none"> <li>• Autoimmune disease*</li> <li>• Tuberculosis</li> <li>• Metastatic cancer</li> <li>• AIDS</li> <li>• Hemorrhage</li> <li>• Gram-negative sepsis</li> <li>• Adrenalectomy</li> <li>• Abdominal radiation therapy</li> <li>• Drugs (mitotane) and toxins</li> </ul>	<ul style="list-style-type: none"> <li>• Pituitary tumors</li> <li>• Postpartum pituitary necrosis</li> <li>• Hypophysectomy</li> <li>• High-dose pituitary or whole-brain radiation</li> <li>• Cessation of long-term corticosteroid drug therapy*</li> </ul>

\*Most common cause.

AIDS, Acquired immune deficiency syndrome.

### ❖ Interprofessional Collaborative Care

Acute adrenal insufficiency is an emergency and managed in an acute care setting. When detected early at a less severe stage, it is managed in the community.

### ◆ Assessment: Noticing

#### History.

Ask about symptoms and factors that cause adrenal hypofunction. Ask about any change in activity level because lethargy, fatigue, and muscle weakness are often present. Include questions about salt intake, because salt craving often occurs with hypofunction.

GI problems, such as anorexia, nausea, vomiting, diarrhea, and abdominal pain, often occur. Ask about weight loss during the past months. Women may have menstrual changes related to weight loss, and men may report impotence.

Ask whether the patient has had radiation to the abdomen or head. Abdominal radiation could directly damage the adrenal glands, whereas cranial radiation could interfere with hypothalamic or pituitary influences on adrenal function. Document medical problems (e.g., tuberculosis or previous intracranial surgery) and all past and current drugs, especially steroids, anticoagulants, opioids, and cancer drugs.

### Physical Assessment/Signs and Symptoms.

Symptoms of adrenal insufficiency vary, and the severity is related to the degree of hormone deficiency (Chart 62-7). In patients with primary insufficiency (problem with adrenal gland function), plasma ACTH and melanocyte-stimulating hormone (MSH) levels are elevated in response to the adrenal-hypothalamic-pituitary feedback system. (Both ACTH and MSH are made from the same prehormone molecule. Anything that stimulates increased production of ACTH also leads to increased production of MSH.) Elevated MSH levels result in areas of increased pigmentation (Fig. 62-2). In primary autoimmune disease, patchy areas of decreased pigmentation may occur because of destruction of skin melanocytes. Body hair may also be decreased. In secondary adrenal insufficiency (problem in the hypothalamus or pituitary gland leading to decreased ACTH and MSH levels), skin pigmentation is not changed.

#### Chart 62-7

### Key Features

#### Adrenal Insufficiency

##### Neuromuscular Symptoms

- Muscle weakness
- Fatigue
- Joint/muscle pain

##### Gastrointestinal Symptoms

- Anorexia
- Nausea, vomiting
- Abdominal pain
- Constipation or diarrhea
- Weight loss
- Salt craving

##### Skin Symptoms

- Vitiligo
- Hyperpigmentation

##### Cardiovascular Symptoms

- Anemia
- Hypotension
- Hyponatremia
- Hyperkalemia
- Hypercalcemia

**FIG. 62-2** Increased pigmentation seen in primary adrenocortical insufficiency. From Wilson, J.D., Foster, D., Kronenberg, H., & Larsen, P.R. [1998]. *Williams' textbook of endocrinology* [9th ed.]. Philadelphia: Saunders. Courtesy Dr. H. Patrick Higgins.)

Assess for hypoglycemia (e.g., sweating, headaches, tachycardia, and tremors) and fluid depletion (postural hypotension and dehydration). **Hyperkalemia** (elevated blood potassium levels) can cause dysrhythmias with an irregular heart rate and result in cardiac arrest. **Hyponatremia** (low blood sodium levels) leading to hypotension and decreased cognition is often one of the first indicators of adrenal insufficiency (Pereira, 2016).

#### Psychosocial Assessment.

Depending on the degree of imbalance, patients may appear lethargic, depressed, confused, and even psychotic. Assess the patient's orientation to person, place, and time. Families may report that the patient has wide mood swings and is forgetful.

#### Diagnostic Assessment.

Laboratory findings include low serum and low salivary cortisol levels, low fasting blood glucose, low sodium, elevated potassium, and increased blood urea nitrogen (BUN) levels (Chart 62-8). In primary disease, the eosinophil count and ACTH level are elevated. Plasma cortisol levels do not rise during provocation tests (see Chapter 61).

### Chart 62-8

## Laboratory Profile

### Adrenal Gland Assessment

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS	
		HYPOFUNCTION OF THE ADRENAL GLAND	HYPERFUNCTION OF THE ADRENAL GLAND
Sodium	136-145 mEq/L (mmol/L)	Decreased	Increased
Potassium	3.5-5.0 mEq/L (mmol/L)	Increased	Decreased
Glucose	Fasting: 70-110 mg/dL (4-6 mmol/L) Older adults: slightly increased	Normal to decreased	Normal to increased
Calcium	Total: 9-10.5 mg/dL (2.25-2.75 mmol/L) Ionized: 4.5-5.6 mg/dL (1.05-1.30 mmol/L) Older adults: slightly decreased	Increased	Decreased
Bicarbonate	23-30 mEq/L (mmol/L)	Increased	Decreased
BUN	10-20 mg/dL (3.6-7.1 mmol/L) Older adults: may be slightly higher	Increased	Normal
Cortisol (serum)	6 AM to 8 AM: 5-23 mcg/dL (138-635 nmol/L) 4 PM to 6 PM: 3-13 mcg/dL (83-359 nmol/L)	Decreased	Increased
Cortisol (salivary)	7 AM to 9 AM: 180-750 ng/dL 3 PM to 5 PM: <401 ng/dL 11 PM to midnight: <100 ng/dL	Decreased	Increased

*BUN*, Blood urea nitrogen.

Data from Pagana, K., Pagana, T., & Pike-MacDonald, S. (2013). *Mosby's Canadian manual of diagnostic and laboratory tests*. St. Louis: Mosby; and Pagana, K., Pagana, T.J., & Pagana, T.N. (2017). *Mosby's diagnostic and laboratory test reference* (13th ed.). St. Louis: Mosby.

Urinary 17-hydroxycorticosteroids are the glucocorticoid metabolites, and 17-ketosteroid levels reflect the adrenal androgen metabolites. Both levels are in the low or low-normal range in adrenal hypofunction.

An ACTH stimulation (provocation) test is the most definitive test for adrenal insufficiency. ACTH 0.25 to 1 mg is given IV, and plasma cortisol levels are obtained at 30-minute and 1-hour intervals. In primary insufficiency, the cortisol response is absent or very decreased. In secondary insufficiency, it is increased. When acute adrenal insufficiency is suspected, treatment is started without stimulation testing (Stewart & Newell-Price, 2016).

### Imaging Assessment.

CT, MRI, and arteriography may help determine the cause of pituitary problems leading to adrenal insufficiency. CT scans may show adrenal gland atrophy.

### ◆Interventions: Responding

Nursing interventions focus on promoting fluid balance, monitoring for fluid deficit, and preventing hypoglycemia. *Because hyperkalemia can cause dysrhythmias with an irregular heart rate and result in cardiac arrest, assessing cardiac function is a nursing priority.* Assess vital signs every 1 to 4 hours, depending on the patient's condition and the presence of dysrhythmias or postural hypotension. Weigh the patient daily and record intake and output. Monitor laboratory values to identify hemoconcentration (e.g., increased hematocrit or BUN). Chapter 11 discusses dehydration in detail.

Cortisol and aldosterone deficiencies are corrected by hormone replacement therapy. Hydrocortisone corrects glucocorticoid deficiency (Chart 62-9). Oral cortisol replacement regimens and dosages vary. The most common drug used for this purpose is prednisone. Generally, divided doses are given, with two thirds given on arising in the morning and one third at 6:00 PM to mimic the normal release of this hormone.

### Chart 62-9

## Common Examples of Drug Therapy

### Hypofunction of the Adrenal Gland

DRUGS	NURSING IMPLICATIONS
Cortisone	Instruct the patient to take the drug with meals or a snack to avoid gastric irritation.
Hydrocortisone (Cortef, Hycort)	Instruct the patient to report the following signs or symptoms of excessive drug therapy, which indicate Cushing's syndrome and a possible need for a dosage adjustment: <ul style="list-style-type: none"> <li>• Rapid weight gain</li> <li>• Round face</li> <li>• Fluid retention</li> </ul>
Prednisone (Winpred)	Instruct the patient to report illness because the usual daily dosage may not be adequate during periods of illness or severe stress.
Fludrocortisone (Florinef)	Monitor the patient's blood pressure to assess for the potential side effect of hypertension. Instruct the patient to report weight gain or edema because sodium intake may need to be restricted.

### ■Nursing Safety Priority QSEN

#### Drug Alert

Prednisone and prednisolone are sound-alike drugs, and care is needed not to confuse them. Although they are both corticosteroids, they are not interchangeable because prednisolone is several times more potent than prednisone and dosages are not the same.

An additional mineralocorticoid hormone, such as fludrocortisone (Florinef), may be needed to maintain or restore FLUID AND ELECTROLYTE BALANCE (especially sodium and potassium). Dosage adjustment may be needed, especially in hot weather when more sodium is lost because of excessive perspiration. *Salt restriction or diuretic therapy should not be started without considering whether it might lead to an adrenal crisis.*

### ■Fluid and Electrolyte Balance Concept Exemplar

## Hypercortisolism (Cushing's Disease)

### ❖ Pathophysiology

Cushing's disease is the excess secretion of cortisol from the adrenal cortex, causing many problems. It is caused by a problem in the adrenal cortex itself, a problem in the anterior pituitary gland, or a problem in the hypothalamus. In addition, glucocorticoid therapy can cause hypercortisolism.

The presence of excess glucocorticoids, regardless of the cause, affects metabolism and all body systems. An increase in total body fat results from slow turnover of plasma fatty acids. This fat is redistributed, producing truncal obesity, "buffalo hump," and "moon face" (Fig. 62-3). Increases in the breakdown of tissue protein result in decreased muscle mass and muscle strength, thin skin, and fragile capillaries. The effects on minerals lead to bone density loss.

**FIG. 62-3** Typical appearance of a patient with Cushing's disease or syndrome. Note truncal obesity, moon face, buffalo hump, thinner arms and legs, and abdominal striae. From Wenig, B.M., Heffess, C.S., & Adair, C.F. [1997]. *Atlas of endocrine pathology*. Philadelphia: Saunders.)

High levels of corticosteroids reduce lymphocyte production and shrink organs containing lymphocytes, such as the spleen and the lymph nodes. White blood cell cytokine production is decreased. These changes reduce IMMUNITY and increase the risk for infection.

In most cases, increased androgen production also occurs and causes acne, **hirsutism** (increased body hair growth), and occasionally clitoral hypertrophy. Increased androgens disrupt the normal ovarian hormone feedback mechanism, decreasing the ovary's production of estrogens and progesterone. **Oligomenorrhea** (scant or infrequent menses) occurs as a result.

### Etiology

Cushing's disease or syndrome is a group of clinical problems caused by an excess of cortisol. [Table 62-3](#) lists causes of cortisol excess. When the anterior pituitary gland oversecretes adrenocorticotropic hormone (ACTH), this hormone causes hyperplasia of the adrenal cortex in

both adrenal glands and an excess of glucocorticoid production (see Fig. 61-3). This problem is **pituitary Cushing's disease** because the tissue causing the problem is the pituitary, not in the adrenal gland. When excess glucocorticoids are caused by an actual problem in the actual adrenal cortex, usually a benign tumor (adrenal adenoma), the problem is called **adrenal Cushing's disease** (or primary Cushing's disease) and usually occurs in only one adrenal gland. When glucocorticoid excess results from drug therapy for another health problem, it is known as **Cushing's syndrome** (also called *secondary Cushing's syndrome*).

**TABLE 62-3**  
**Conditions Causing Increased Cortisol Secretion**

<b>Endogenous Secretion (Cushing's Disease)</b>
<ul style="list-style-type: none"> <li>• Bilateral adrenal hyperplasia*</li> <li>• Pituitary adenoma increasing the production of ACTH (pituitary Cushing's disease)</li> <li>• Malignancies: carcinomas of the lung, GI tract, pancreas</li> <li>• Adrenal adenomas or carcinomas</li> </ul>
<b>Exogenous Administration (Cushing's Syndrome)</b>
<ul style="list-style-type: none"> <li>• Therapeutic use of ACTH or glucocorticoids—most commonly for treatment of:               <ul style="list-style-type: none"> <li>• Asthma</li> <li>• Autoimmune disorders</li> <li>• Organ transplantation</li> <li>• Cancer chemotherapy</li> <li>• Allergic responses</li> <li>• Chronic fibrosis</li> </ul> </li> </ul>

\*Most common cause.

ACTH, Adrenocorticotrophic hormone.

### Incidence and Prevalence

The most common cause of Cushing's disease is a pituitary adenoma. Women are more likely than men to develop Cushing's disease. Cushing's syndrome from chronic use of exogenous corticosteroids is more common because these drugs are often used to control serious chronic inflammatory conditions.

### ❖ Interprofessional Collaborative Care

Cushing's syndrome is usually managed in the community. Cushing's disease is initially managed in an acute care setting.

### ◆ Assessment: Noticing

#### History.

Ask about the patient's other health problems and drug therapies because glucocorticoid therapy is common. Regardless of cause, the patient has many changes because of the widespread effect of excessive cortisol. He or she may report weight gain and an increased appetite. Ask about changes in activity or sleep patterns, fatigue, and muscle weakness. Ask about bone pain or a history of fractures, because osteoporosis is common in hypercortisolism. Ask about a history of frequent infections and easy bruising. Women often stop menstruating. GI problems include ulcer formation from increased hydrochloric acid secretion and decreased production of protective gastric mucus.

#### Physical Assessment/Signs and Symptoms.

The patient with hypercortisolism has specific physical changes, although all body systems are affected (see Fig. 62-3; Chart 62-10). Changes in fat distribution may result in fat pads on the neck, back, and shoulders ("buffalo hump"); an enlarged trunk with thin arms and legs; and a round face ("moon face"). Other changes include muscle wasting and weakness. Assess for and document changes and use these findings to prioritize patient problems.

### ▶ Chart 62-10

## Key Features

### Hypercortisolism (Cushing's Disease/Syndrome)

#### General Appearance

- Moon face
- Buffalo hump
- Truncal obesity
- Weight gain

### Cardiovascular Symptoms

- Hypertension
- Frequent dependent edema
- Bruising
- Petechiae

### Musculoskeletal Symptoms

- Muscle atrophy (most apparent in extremities)
- Osteoporosis (bone density loss)
- Pathologic fractures
- Decreased height with vertebral collapse
- Aseptic necrosis of the femur head
- Slow or poor healing of bone fractures

### Skin Symptoms

- Thinning skin
- Striae and increased pigmentation

### Immune System Symptoms

- Increased risk for infection
- Reduced IMMUNITY
- Decreased inflammatory responses
- Signs and symptoms of infection/inflammation possibly masked

*Skin changes* result from blood vessel fragility and include bruises, thin or translucent skin, and wounds that have not healed. Reddish-purple **striae** (“stretch marks”) occur on the abdomen, thighs, and upper arms because of the destructive effect of cortisol on collagen.

Acne and a fine coating of hair may occur over the face and body. In women, look for the presence of hirsutism, clitoral hypertrophy, and male pattern balding related to androgen excess.

*Cardiac changes* occur as a result of disturbed FLUID AND ELECTROLYTE BALANCE. Both sodium and water are reabsorbed and retained, leading to hypervolemia and edema formation. Blood pressure is elevated, and pulses are full and bounding.

*Musculoskeletal changes* occur as a result of nitrogen depletion and mineral loss. Muscle mass

decreases, especially in arms and legs (see Fig. 62-3). Muscle weakness increases the risk for falls. Bone is thinner, and osteoporosis is common, increasing the risk for fractures.

*Glucose metabolism* is affected by hypercortisolism. Fasting blood glucose levels are high because the liver releases glucose and the insulin receptors are less sensitive; therefore blood glucose does not move as easily into the tissues.

*Immune changes* caused by excess cortisol result in reduced IMMUNITY. Excess cortisol reduces the number of circulating lymphocytes, inhibits macrophage activity, reduces antibody synthesis, and inhibits production of cytokines and inflammatory chemicals (e.g., histamine). Infection risk is increased; and the patient may not have fever, purulent exudate, or redness in the affected area when an infection is present.

### **Psychosocial Assessment.**

Hypercortisolism can result in emotional instability, and patients often say that they do not feel like themselves. Ask about mood swings, irritability, confusion, or depression. Ask the patient whether he or she has been crying or laughing inappropriately or has had difficulty concentrating. Family members often report changes in the patient's mental or emotional status. The excess hormones stimulate the central nervous system, heightening the awareness of and responses to sensory stimulation. The patient often reports sleep difficulties and fatigue.

### **Laboratory Assessment.**

Laboratory tests include blood, salivary, and urine cortisol levels. These are high in patients with any type of hypercortisolism. Plasma ACTH levels vary, depending on the cause of the problem. In pituitary Cushing's disease, ACTH levels are elevated. In adrenal Cushing's disease or when Cushing's syndrome results from chronic steroid use, ACTH levels are low.

Salivary cortisol levels may be used to detect hypercortisolism because these levels accurately reflect blood levels, especially late-night specimens (Elias et al., 2014; Raff, 2015). A normal salivary cortisol level is lower than 2.0 ng/mL. Higher levels indicate hypercortisolism.

Urine is tested to measure levels of free cortisol and the metabolites of cortisol and androgens (17-hydroxycorticosteroids and 17-ketosteroids). In Cushing's disease, levels of urine cortisol and androgens are all elevated in a 24-hour specimen. Cortisol-to-creatinine ratios in the first specimen of the day can replace the 24-hour test for screening. A ratio greater than 25 nmol/mmol is a positive test (Stewart & Newell-Price, 2016)

Dexamethasone suppression testing can screen for hypercortisolism and may take place overnight or over a 3-day period. Set doses of dexamethasone are given. A 24-hour urine collection follows drug administration. When urinary 17-hydroxycorticosteroid excretion and cortisol levels are suppressed by dexamethasone, Cushing's disease is not present.

Additional laboratory findings that accompany hypercortisolism include:

- Increased blood glucose level
- Decreased lymphocyte count
- Increased sodium level
- Decreased serum calcium level

### **Imaging Assessment.**

Imaging for hypercortisolism includes CT scans, MRI, and arteriography. These images can identify lesions of the adrenal or pituitary glands, lung, GI tract, or pancreas.

### **◆Analysis: Interpreting**

The priority collaborative problems for patients with Cushing's disease or Cushing's syndrome are:

1. Fluid overload due to hormone-induced water and sodium retention
2. Potential for injury due to skin thinning, poor wound healing, and bone density loss
3. Potential for infection due to hormone-induced reduced IMMUNITY
4. Potential for acute adrenal insufficiency

## ◆Planning and Implementation: Responding

Expected outcomes of hypercortisolism management are the reduction of plasma cortisol levels, removal of tumors, and restoration of normal or acceptable body appearance. When the disorder is caused by pituitary or adrenal problems, cure is possible. When caused by drug therapy for another health problem, the focus is to prevent complications from hypercortisolism.

### Restoring Fluid Volume Balance

#### Planning: Expected Outcomes.

The patient with hypercortisolism is expected to achieve and maintain a normal or near-normal FLUID AND ELECTROLYTE BALANCE. Indicators include that these parameters are within or close to the normal range:

- Blood pressure
- Stable body weight
- Serum electrolytes, especially sodium and potassium

#### Interventions.

Interventions for patients with fluid volume excess focus on ensuring patient safety, restoring FLUID AND ELECTROLYTE BALANCE, and providing supportive care. Depending on the cause, surgical management may be used to reduce cortisol production.

#### Nonsurgical Management.

Patient safety, drug therapy, nutrition therapy, and monitoring are the basis of nonsurgical interventions for hypercortisolism and fluid overload.

*Patient safety* includes preventing fluid overload from becoming worse, leading to pulmonary edema and heart failure. Any patient with fluid overload, regardless of age, is at risk for these complications. The older adult or one who has coexisting cardiac problems, kidney problems, pulmonary problems, or liver problems is at greater risk.

Monitor for indicators of fluid overload (bounding pulse, increasing neck vein distention, lung crackles, increasing peripheral edema, reduced urine output) at least every 2 hours. *Pulmonary edema can occur very quickly and lead to death.* Notify the primary health care provider of any change that indicates the fluid overload either is not responding to therapy or is worse.

The patient with fluid volume excess and dependent edema is at risk for skin breakdown. Use a pressure-reducing or pressure-relieving overlay on the mattress. Assess skin pressure areas, especially the coccyx, elbows, hips, and heels, daily for redness or open areas. For patients receiving oxygen by mask or nasal cannula, check the skin around the mask, nares, and ears and under the elastic band. Help the patient change positions every 2 hours or ensure that others delegated to perform the intervention are diligent in this action.

*Drug therapy* involves the use of drugs that interfere with adrenocorticotropic hormone (ACTH) production or adrenal hormone synthesis for temporary relief. Metyrapone (Metopirone), aminoglutethimide (Elipten, Cytadren), and ketoconazole use different pathways to decrease cortisol production (Stewart & Newell-Price, 2016). For patients with hypercortisolism resulting from increased ACTH production, cyproheptadine (Periactin) may be used because it interferes with ACTH production. Mitotane (Lysodren) is an adrenal cytotoxic agent used for inoperable tumors causing hypercortisolism. For adults with increased ACTH production who have type 2 diabetes and who do not respond to other drug therapies, another drug is mifepristone (Korlym), which is a synthetic steroid that blocks glucocorticoid receptors.

## 📌Nursing Safety Priority QSEN

### Drug Alert

Mifepristone (Korlym) cannot be used during pregnancy because it also blocks progesterone receptors and would cause termination of the pregnancy.

A drug to manage hypercortisolism resulting from a pituitary adenoma is pasireotide (Signifor).

This subcutaneous drug binds to somatostatin receptors on the adenoma and inhibits tumor production of corticotropin. Lower levels of corticotropin lead to lower levels of cortisol production in the adrenal glands (McKeage, 2013). The drug is ineffective for patients whose tumors do not have somatostatin receptors.

Monitor the patient for response to drug therapy, especially weight loss and increased urine output. Observe for symptoms of problems with FLUID AND ELECTROLYTE BALANCE, especially changes in electrocardiogram (ECG) patterns. Assess laboratory findings, especially sodium and potassium values, whenever they are drawn.

*Nutrition therapy* for the patient with hypercortisolism may involve restrictions of both fluid and sodium intake to control fluid volume. Review the patient's serum sodium levels whenever fluid overload is present. Often sodium restriction involves only "no added salt" to ordinary table foods when fluid overload is mild. For more pronounced fluid overload, the patient may be restricted to anywhere from 2 g/day to 4 g/day of sodium. When sodium restriction is ongoing, teach the patient and family how to check food labels for sodium content and how to keep a daily record of sodium ingested. Explain to the patient and family the reason for any fluid restriction and the importance of adhering to the prescribed restriction.

*Monitor* intake and output and weight to assess therapy effectiveness. Ensure that unlicensed assistive personnel (UAP) understand that these measurements need to be accurate, not just estimated, because treatment decisions are based on the findings. Schedule fluid offerings throughout the 24 hours. Teach UAP to check urine for color and character and to report these findings. Check the urine specific gravity (a specific gravity below 1.005 may indicate fluid overload). If IV therapy is used, infuse only the amount prescribed.

*Fluid retention may not be visible. Rapid weight gain is the best indicator of fluid retention and overload.* Each 1 lb (about 500 g) of weight gained (after the first half pound) equates to 500 mL of retained water. Weigh the patient at the same time daily (before breakfast), using the same scale. Have the patient wear the same type of clothing for each weigh-in.

### **Surgical Management.**

The surgical treatment of adrenocortical hypersecretion depends on the cause of the problem. When adrenal hyperfunction is due to increased pituitary secretion of ACTH, removal of a pituitary adenoma using minimally invasive techniques may be attempted. Sometimes a total *hypophysectomy* (surgical removal of the pituitary gland) is needed. (See earlier discussion of Hypophysectomy in the Hyperpituitarism section.) If hypercortisolism is caused by an adrenal tumor, an *adrenalectomy* (removal of the adrenal gland) may be needed.

### **Preoperative Care.**

Disturbances of FLUID AND ELECTROLYTE BALANCE are corrected before surgery. Continue to monitor blood potassium, sodium, and chloride levels. Dysrhythmias from potassium imbalance may occur, and cardiac monitoring is needed. Hyperglycemia is controlled before surgery.

The patient with hypercortisolism is at risk for complications of infections and fractures. Prevent infection with handwashing and aseptic technique. Decrease the risk for falls by raising top side rails and encouraging the patient to ask for assistance when getting out of bed. A high-calorie, high-protein diet is prescribed before surgery.

Glucocorticoid preparations are given before surgery. The patient continues to receive glucocorticoids during surgery to prevent adrenal crisis because the removal of the tumor results in a sudden drop in cortisol levels. Before surgery, discuss the need for long-term drug therapy.

### **Operative Procedures.**

A unilateral adrenalectomy is performed when one gland is involved. A bilateral adrenalectomy is needed when ACTH-producing tumors cannot be treated by other means or when both adrenal glands are diseased. Surgery is most often performed by laparoscopic adrenalectomy, a minimally invasive surgical approach. If necessary, an open surgery through the abdomen or the lateral flank can be performed.

### **Postoperative Care.**

After an adrenalectomy, the patient is monitored in an ICU. Immediately after surgery, assess the patient every 15 minutes for shock (e.g., hypotension; a rapid, weak pulse; and a decreasing urine

output) resulting from insufficient glucocorticoid replacement. Monitor vital signs, central venous pressure, pulmonary wedge pressure, intake and output, daily weights, and serum electrolyte levels.

After a bilateral adrenalectomy, patients require lifelong glucocorticoid and mineralocorticoid replacement, starting immediately after surgery. In unilateral adrenalectomy, hormone replacement continues until the remaining adrenal gland increases hormone production. This therapy may be needed for up to 2 years after surgery.

## NCLEX Examination Challenge 62-3

### Physiological Integrity

In the preoperative holding area, the client who is scheduled to have an adrenalectomy for hypercortisolism is prescribed to receive cortisol by IV infusion. What is the nurse's **best** action?

- A. Request a "time-out" to determine whether this is a valid prescription.
- B. Ask the client whether he or she usually takes prednisone.
- C. Hold the dose because the client has a high cortisol level.
- D. Administer the drug as prescribed.

### Preventing Injury.

The patient is at risk for injury from skin breakdown, bone fractures, and GI bleeding. Prevention of these injuries is a major nursing care focus.

### Planning: Expected Outcomes.

The patient with hypercortisolism is expected to avoid injury. Indicators include:

- Skin is intact.
- Minimal or no bruising is present.
- Bones are intact.
- Stools, vomitus, and other GI secretions contain no gross or occult blood.

### Interventions.

Priority nursing interventions for prevention of injury focus on skin assessment and protection, coordinating care to ensure gentle handling, and patient teaching regarding drug therapy for prevention of GI ulcers.

*Skin injury* is a continuing risk even after surgery has corrected the cortisol excess because the changes induced in the skin and blood vessels remain for weeks to months. Assess the skin for reddened areas, excoriation, breakdown, and edema. If mobility is decreased, turn the patient every 2 hours and pad bony prominences.

Instruct the patient to avoid activities that can result in skin trauma. Teach him or her to use a soft toothbrush and an electric shaver. Instruct patients to keep the skin clean and dry it thoroughly after washing. Excessive dryness can be prevented by using a moisturizing lotion.

Adhesive tape often causes skin breakdown. Use tape sparingly and remove it carefully. After venipuncture, the patient may have increased bleeding because of blood vessel fragility. Exert pressure over the site until bleeding has stopped.

*Pathologic fractures* from bone density loss and osteoporosis are possible for months to years after cortisol levels return to normal. Teach the patient about safety issues and dietary needs. When helping the patient move in bed, use a lift sheet instead of grasping him or her. Remind the patient to call for help when walking. Review the use of walkers or canes, if needed. Teach UAP to use a gait belt when walking with a patient who has bone density loss.

Coordinate with a dietitian to teach the patient about nutrition therapy. A high-calorie diet that includes increased amounts of calcium and vitamin D is needed. Milk, cheese, yogurt, and green leafy and root vegetables add calcium to promote bone density. Advise the patient to avoid caffeine

and alcohol, which increase the risk for GI ulcers and reduce bone density.

*GI bleeding* is common with hypercortisolism. Cortisol (1) inhibits production of the thick, gel-like mucus that protects the stomach lining, (2) decreases blood flow to the area, and (3) triggers the release of excess hydrochloric acid. Although surgery reduces cortisol levels, the normal mucus and increased blood flow may take weeks to return. Interventions focus on drug therapy to reduce irritation, protect the GI mucosa, and decrease secretion of hydrochloric acid.

Antacids buffer stomach acids and protect the GI mucosa. Teach the patient that these drugs should be taken on a regular schedule rather than on an as-needed basis.

Some agents block the H<sub>2</sub> receptors in the gastric mucosa. When histamine binds to these receptors, a series of actions release hydrochloric acid. Drugs that block the H<sub>2</sub>-receptor site include cimetidine (Tagamet, Peptol ♣, Novo-Cimetidine ♣), ranitidine (Zantac, Apo-Ranitidine ♣), famotidine (Pepcid), and nizatidine (Axid). Omeprazole (Losec ♣, Prilosec) and esomeprazole (Nexium) inhibit the gastric proton pump and prevent the formation of hydrochloric acid.

Instruct the patient to reduce alcohol or caffeine consumption, smoking, and fasting because these actions cause gastric irritation. NSAIDs and drugs that contain aspirin or other salicylates can cause gastritis and intensify GI bleeding. These should be avoided or limited.

### Preventing Infection.

Glucocorticoids reduce both the inflammation and the immune responses of IMMUNITY, increasing the risk for infection. For the patient who is taking glucocorticoid replacement therapy, the risk is ongoing. For the patient who is recovering from surgery to prevent hypercortisolism, the infection risk continues for weeks after surgery.

### Planning: Expected Outcomes.

The patient with hypercortisolism is expected to remain free from infection and avoid situations that increase the risk for infection. Indicators include these symptoms and behaviors:

- Does not have fever and foul-smelling or purulent drainage
- Does not have cough, chest pain, and dyspnea
- Does not have urinary frequency, urgency, or pain and burning
- Avoids crowds and large gatherings
- Obtains appropriate vaccinations
- Washes hands frequently

### Interventions.

Protect the patient with reduced IMMUNITY from infection. All personnel must use extreme care during all nursing procedures. Thorough handwashing is important. Anyone with an upper respiratory tract infection who enters the patient's room must wear a mask. Observe strict aseptic technique when performing dressing changes or any invasive procedure.

Continually assess the patient for possible infection. Symptoms may not be obvious because excess cortisol suppresses infection indicators. Fever and pus formation depend on the presence of white blood cells (WBCs). The patient who has reduced IMMUNITY may have a severe infection without pus and with only a low-grade fever.

Monitor the patient's daily complete blood count (CBC) with differential WBC count, especially neutrophils. Inspect the mouth during every shift for lesions and mucosa breakdown. Assess the lungs every 8 hours for crackles, wheezes, or reduced breath sounds. Assess all urine for odor and cloudiness. Ask about any urgency, burning, or pain on urination.

Take vital signs at least every 4 hours to assess for fever. A temperature elevation of even 1° F (or 0.5° C) above baseline is significant for a patient who has reduced IMMUNITY and indicates infection until it has been proven otherwise.

Skin care is important for preventing infection because the skin may be the patient's only intact defense. Teach him or her about hygiene and urge daily bathing. If the patient is immobile, turn him or her every hour and apply skin lubricants.

Perform pulmonary hygiene every 2 to 4 hours. Listen to the lungs for crackles, wheezes, or reduced breath sounds. Urge the patient to deep breathe or use an incentive spirometer every hour while awake.

### Preventing Acute Adrenal Insufficiency.

The patient most at risk for acute adrenal insufficiency is the one who has Cushing's syndrome as a result of glucocorticoid drug therapy. The exogenous drug inhibits the feedback control pathway (see [Figure 61-3](#)), preventing the hypothalamus from secreting corticotropin-releasing hormone (CRH). The lack of CRH inhibits secretion of ACTH from the anterior pituitary gland. Without normal levels of ACTH, the adrenal glands atrophy and completely stop production of the corticosteroids. As a result, the patient completely depends on the exogenous drug. If the drug is stopped, even for a day or two, the atrophied adrenal glands cannot produce the glucocorticoids; and the patient develops acute adrenal insufficiency, a life-threatening condition. Management of this problem is described in the [Adrenal Gland Hypofunction](#) section.

## Nursing Safety Priority QSEN

### Drug Alert

Teach patients who are taking a corticosteroid for more than a week not to stop the drug suddenly. The drug should be tapered gradually under the care of the primary health care provider.

### Care Coordination and Transition Management

#### Home Care Management.

The patient with hypercortisolism usually has muscle weakness and fatigue for some weeks after surgery and remains at risk for falls and other injury. These problems may necessitate one-floor living for a short time; and a home health aide may be needed to assist with hygiene, meal preparation, and maintenance.

#### Self-Management Education.

The patient taking exogenous glucocorticoids who is discharged to home remains at continuing risk for impaired FLUID AND ELECTROLYTE BALANCE, especially fluid volume excess. Teach him or her and the family to monitor the patient's weight. Suggest that a record of these daily weights be kept to show the primary health care provider at any checkups. Also instruct the patient to call the health care provider if more than 3 lb are gained in a week or more than 1 to 2 lb are gained in a 24-hour period.

Lifelong hormone replacement is needed after bilateral adrenalectomy. Teach the patient and family about adherence to the drug regimen and its side effects ([Chart 62-11](#)).

## Chart 62-11

### Patient and Family Education: Preparing for Self-Management

#### Cortisol Replacement Therapy

- Take your medication in divided doses, as prescribed (e.g., the first dose in the morning and the second dose between 4 PM and 6 PM).
- Take your medication with meals or snacks.
- Weigh yourself daily and keep a record to show your primary health care provider.
- Increase your dosage as directed by your primary health care provider for increased physical stress or severe emotional stress.
- Never skip a dose of medication. If you have persistent vomiting or severe diarrhea and cannot take your medication by mouth for 24 to 36 hours, call your physician. If you cannot reach your primary health care provider, go to the nearest emergency department. You may need an

injection to take the place of your usual oral medication.

- Always wear your medical alert bracelet or necklace.
- Make regular visits for health care follow-up.
- Learn how to give yourself an intramuscular injection of hydrocortisone.

Protecting the patient with reduced IMMUNITY from infection at home is important. Urge him or her to use proper hygiene and to avoid crowds or others with infections. Encourage the patient and all people living in the same home with him or her to have yearly influenza vaccinations. Stress that the patient should immediately notify the primary health care provider if he or she has a fever or any other sign of infection. [Chart 40-10](#) lists guidelines for patients for infection prevention.

### Health Care Resources.

Immediately after returning home, the patient may need a support person to stay and provide more attention than could be given by a visiting nurse or home care aide. Contact with the health care team is needed for follow-up and identification of potential problems. The patient taking corticosteroid therapy may have symptoms of adrenal insufficiency if the dosage is inadequate. Suggest that the patient obtain and wear a medical alert bracelet listing the condition and the drug replacement therapy.

### ◆Evaluation: Reflecting

Evaluate the care of the patient with hypercortisolism based on the identified priority patient problems. The expected outcomes are that the patient will:

- Maintain fluid and electrolyte balance
- Remain free from injury
- Remain free from infection
- Not experience acute adrenal insufficiency

## Hyperaldosteronism

### ❖Pathophysiology

**Hyperaldosteronism** is an increased secretion of aldosterone with mineralocorticoid excess. Primary hyperaldosteronism (*Conn's syndrome*) diagnosed in adults results from excessive secretion of aldosterone from one or both adrenal glands, usually caused by an adrenal adenoma. In secondary hyperaldosteronism, excessive secretion of aldosterone is caused by the high levels of angiotensin II that are stimulated by high plasma renin levels. Some causes include kidney hypoxia, diabetic nephropathy, and excessive use of some diuretics.

Increased aldosterone levels cause disturbances of FLUID AND ELECTROLYTE BALANCE, which then trigger the kidney tubules to retain sodium and excrete potassium and hydrogen ions. Hyponatremia, hypokalemia, and metabolic alkalosis result. Sodium retention increases blood volume, which raises blood pressure, increasing the risk for strokes, heart attacks, and kidney damage. (See [Chapter 11](#) for discussion of specific electrolyte imbalances.)

### ❖Interprofessional Collaborative Care

Patients are hospitalized for surgery. After surgery, they self-manage hormone replacement therapy in the community.

### ◆Assessment: Noticing

Hypokalemia and elevated blood pressure are the most common problems that patients with hyperaldosteronism develop. He or she may have headache, fatigue, muscle weakness, dehydration, and loss of stamina. **Polydipsia** (excessive fluid intake) and **polyuria** (excessive urine output) occur less frequently. **Paresthesias** (sensations of numbness and tingling) may occur if potassium depletion is severe.

Hyperaldosteronism is diagnosed on the basis of laboratory studies and imaging with CT or MRI.

Serum potassium levels are decreased, and sodium levels are elevated. Plasma renin levels are low, and aldosterone levels are high. Hydrogen ion loss leads to metabolic alkalemia (elevated blood pH). Urine has a low specific gravity and high aldosterone levels.

### ◆Interventions: Responding

Surgery is a common treatment for hyperaldosteronism. One or both adrenal glands may be removed. The patient's potassium level must be corrected before surgery. Drugs used to increase potassium levels include spironolactone (Aldactone, Spiro, Sincomen ♣), a potassium-sparing diuretic and aldosterone antagonist. Potassium supplements may be prescribed to increase potassium levels before surgery. The patient may also benefit from a low-sodium diet before surgery.

The patient who has undergone a unilateral adrenalectomy may need temporary glucocorticoid replacement. Replacement is lifelong if both adrenal glands are removed. Glucocorticoids are given before surgery to prevent adrenal crisis. The patient receiving long-term replacement therapy should wear a medical alert bracelet. (See the discussion of adrenalectomy in the Hypercortisolism [Cushing's disease] section for more information about care after surgery and patient education.)

When surgery cannot be performed, spironolactone therapy is continued to control hypokalemia and hypertension. *Because spironolactone is a potassium-sparing diuretic, hyperkalemia can occur in patients who have impaired kidney function or excessive potassium intake.* Advise the patient to avoid potassium supplements and food rich in potassium (see [Chapter 11](#)). Hyponatremia can occur with spironolactone therapy, and the patient may need increased dietary sodium. Instruct patients to report symptoms of hyponatremia, such as mouth dryness, thirst, lethargy, or drowsiness. Teach them to report any additional side effects of spironolactone therapy, including gynecomastia, diarrhea, drowsiness, headache, rash, **urticaria** (hives), confusion, erectile dysfunction, hirsutism, and amenorrhea. Additional drug therapy to control hypertension is often needed.

## Pheochromocytoma

### ❖Pathophysiology

**Pheochromocytoma** is a catecholamine-producing tumor of the adrenal medulla. These tumors usually occur in one adrenal gland, although they can be bilateral or in the abdomen. Pheochromocytomas are usually benign, but about 10% are malignant ([Young, 2016](#)).

The tumors produce, store, and release epinephrine and norepinephrine (NE). Excessive epinephrine and NE stimulate adrenergic receptors and can have wide-ranging adverse effects mimicking the action of the sympathetic nervous system.

The cause is unknown, but some pheochromocytomas occur with inherited disorders such as neurofibromatosis (type 1), multiple endocrine neoplasia (MEN-2), von Hippel-Lindau disease, and pheochromocytoma-paraganglioma syndrome ([OMIM, 2016c](#)). These tumors are rare and appear most commonly in patients between 30 and 50 years of age ([Young, 2016](#)).

### ❖Interprofessional Collaborative Care

Although most pheochromocytomas are benign, they must be surgically removed to prevent life-threatening complications. Because intensive monitoring is required immediately after surgery, this treatment takes place in an ICU.

### ◆Assessment: Noticing

The patient often has intermittent episodes of hypertension or attacks that range from a few minutes to several hours. During these episodes, the patient has severe headaches, palpitations, profuse diaphoresis, flushing, apprehension, or a sense of impending doom. Pain in the chest or abdomen, with nausea and vomiting, can also occur. Increased abdominal pressure, defecation, and vigorous abdominal palpation can provoke a hypertensive crisis. Drugs such as tricyclic antidepressants, droperidol, glucagon, metoclopramide, phenothiazines, and naloxone can induce a hypertensive crisis in the patient with pheochromocytoma. Foods or beverages high in tyramine (e.g., aged cheese, red wine) also induce hypertension. The patient may also report heat intolerance, weight loss, and tremors.

The most common diagnostic test is blood and 24-hour urine collection for fractionated

metanephrine and catecholamine levels, all of which are elevated in the presence of a pheochromocytoma. Another test that may be conducted when catecholamine levels are not consistent is the clonidine suppression test (Young, 2016). MRI or CT scans can precisely locate tumors in the adrenal gland, as well as in the chest or abdomen.

### ◆Interventions: Responding

Surgery is the main treatment for a pheochromocytoma. One or both adrenal glands are removed (depending on whether the tumor is bilateral). After surgery, nursing interventions focus on promoting adequate tissue perfusion, nutritional needs, and comfort measures.

Hypertension is the main sign of the disease and the most common complication after surgery. Monitor the blood pressure regularly and place the cuff consistently on the same arm, with the patient in lying and standing positions. Teach the patient not to smoke, drink caffeine-containing beverages, or change position suddenly, which can stimulate blood pressure changes. Provide a diet rich in calories, vitamins, and minerals.

## !Nursing Safety Priority QSEN

### Action Alert

Do not palpate the abdomen of a patient with a pheochromocytoma, because this action could stimulate a sudden release of catecholamines and trigger severe hypertension.

The patient is hydrated before surgery because decreased blood volume increases the risk for hypotension during and after surgery. Assess the patient's hydration status and report symptoms of dehydration or fluid overload.

The patient's blood pressure is stabilized with adrenergic blocking agents such as phenoxybenzamine (Dibenzylamine) starting 7 to 10 days before surgery because of the increased risk for severe hypertension during surgery. Drug dosages are adjusted until blood pressure is controlled and hypertensive attacks do not occur. The blood volume expands, and blood pressure in the supine position returns to normal.

Anesthetic agents and touching the tumor during surgery can cause a catecholamine release. Short-acting alpha-adrenergic blockers are given by IV bolus or continuous infusion for a hypertensive crisis.

Nursing care after surgery is similar to that for the patient who has undergone an adrenalectomy (see the [Hypercortisolism \[Cushing's Disease\]](#) section). Monitor the patient for hypertension and hypotension (from the sudden decrease in catecholamine levels) and for hypovolemia. Hemorrhage and shock are possible, and plasma expanders or fluids may be needed. Monitor vital signs, as well as fluid intake and output. If opioids are given, check for their effect on blood pressure.

When tumors are inoperable, management is medical, with alpha-adrenergic and beta-adrenergic blocking agents. For these patients, self-measurement of blood pressure with home-monitoring equipment is essential. (See [Chapter 36](#) for teaching priorities and community-based care of the patient with chronic hypertension.)

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Handle all patients with bone density loss carefully, using lift sheets whenever possible. **QSEN: Safety**
- Use good handwashing techniques before providing any care to a patient who has reduced IMMUNITY. **QSEN: Safety**
- Ensure that hormone replacement drugs are given as close to the prescribed times as possible. **QSEN: Safety**
- Teach the patient with diabetes insipidus the indicators of dehydration.

### Health Promotion and Maintenance

- Instruct the patient with adrenal insufficiency to wear a medical alert bracelet and to carry simple carbohydrates with him or her at all times. **QSEN: Patient-Centered Care**
- Teach the patient and family about the symptoms of infection and when to seek medical advice. **QSEN: Patient-Centered Care**
- Teach patients who have permanent endocrine hypofunction the proper techniques and timing of hormone replacement therapy. **QSEN: Patient-Centered Care**
- Teach patients taking bromocriptine to seek medical care immediately if chest pain, dizziness, or watery nasal discharge occurs. **QSEN: Safety**

### Psychosocial Integrity

- Encourage the patient and family to express concerns about a change in health status. **QSEN: Patient-Centered Care**
- Explain all treatment procedures, restrictions, and follow-up care to the patient. **QSEN: Patient-Centered Care**
- Allow patients who experience a change in physical appearance to mourn this change. **QSEN: Patient-Centered Care**

### Physiological Integrity

- During the immediate period after a hypophysectomy, teach the patient to avoid activities that increase intracranial pressure (e.g., bending at the waist, straining to have a bowel movement, coughing). **QSEN: Patient-Centered Care**
- Measure intake and output accurately on patients who have either diabetes insipidus or syndrome of inappropriate antidiuretic hormone (SIADH). **QSEN: Evidence-Based Practice**
- Teach patients who are taking a corticosteroid for more than a week not to stop the drug suddenly. **QSEN: Safety**
- Ensure that no patient suspected of having DI is deprived of fluids for more than 4 hours. **QSEN: Evidence-Based Practice**
- Do not confuse prednisone with prednisolone. **QSEN: Safety**
- Do not palpate the abdomen of a patient who has a pheochromocytoma. **QSEN: Safety**
- Teach patients with diabetes insipidus the proper way to self-administer desmopressin orally or by nasal spray. **QSEN: Patient-Centered Care**

## CHAPTER 63

# Care of Patients With Problems of the Thyroid and Parathyroid Glands

M. Linda Workman

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is CELLULAR REGULATION.**

✚ The CELLULAR REGULATION concept exemplar for this chapter is Hypothyroidism, p. 1270.

**The interrelated concepts for this chapter are:**

- NUTRITION
- GAS EXCHANGE

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to coordinate high-quality care and promote CELLULAR REGULATION and optimal NUTRITION in patients who have thyroid or parathyroid disorders.
2. Teach the patient and caregiver(s) about home safety issues affected by inadequate NUTRITION or CELLULAR REGULATION resulting from thyroid or parathyroid problems.

### Health Promotion and Maintenance

3. Identify community resources for patients requiring assistance with any disorder of the thyroid or parathyroid glands.

### Psychosocial Integrity

4. Implement nursing interventions to help the patient and family cope with the psychosocial impact caused by acute or chronic problems of the thyroid gland or parathyroid glands.

### Physiological Integrity

5. Apply knowledge of anatomy, physiology, and pathophysiology to assess patients with impaired thyroid or adrenal parathyroid function affecting NUTRITION or CELLULAR REGULATION.
6. Interpret clinical changes and laboratory data to determine the effectiveness of therapy for hyperthyroidism and hypothyroidism.
7. Prioritize evidence-based nursing care for the patient with thyroid storm.
8. Teach the patient and caregiver(s) about common drugs and other management strategies used for thyroid gland or parathyroid gland problems.
9. Prioritize evidence-based care for the patient with myxedema coma.

The hormones secreted by the thyroid gland and parathyroid glands affect whole-body metabolism, CELLULAR REGULATION, NUTRITION, GAS EXCHANGE, electrolyte balance, and excitable membrane activity. Because of the widespread effects of these hormones, problems of either gland can lead to symptoms in many body systems and can range from mild to life-threatening.

# Thyroid Disorders

## Hyperthyroidism

### ❖ Pathophysiology

**Hyperthyroidism** is excessive thyroid hormone secretion from the thyroid gland. The symptoms of hyperthyroidism are called **thyrotoxicosis**, regardless of the origin of the thyroid hormones. This term is correct even when an adult takes a large amount of synthetic thyroid hormones and has symptoms of thyrotoxicosis although his or her thyroid gland is normal. Thyroid hormones increase metabolism in all body organs, producing many different symptoms. Hyperthyroidism can be temporary or permanent, depending on the cause.

The excessive thyroid hormones stimulate most body systems, causing hypermetabolism and increased sympathetic nervous system activity. Symptoms are listed in [Chart 63-1](#).

### Chart 63-1

## Key Features

### Hyperthyroidism

#### Skin Symptoms

- Diaphoresis (excessive sweating)
- Fine, soft, silky body hair
- Smooth, warm, moist skin
- Thinning of scalp hair

#### Cardiopulmonary Symptoms

- Palpitations
- Chest pain
- Increased systolic blood pressure
- Tachycardia
- Dysrhythmias
- Rapid, shallow respirations

#### Gastrointestinal Symptoms

- Weight loss
- Increased appetite
- Increased stools

#### Neurologic Symptoms

- Blurred or double vision
- Eye fatigue
- Increased tears

- Injected (red) conjunctiva
- Photophobia
- Exophthalmos\*
- Eyelid retraction, eyelid lag
- Globe lag
- Hyperactive deep tendon reflexes
- Tremors
- Insomnia

### Metabolic Symptoms

- Increased basal metabolic rate
- Heat intolerance
- Low-grade fever
- Fatigue

### Psychological/Emotional Symptoms

- Decreased attention span
- Restlessness and irritability
- Emotional instability
- Manic behavior

### Reproductive Symptoms

- Amenorrhea
- Increased libido

### Other Symptoms

- Goiter
- Wide-eyed or startled appearance (exophthalmos)\*
- Enlarged spleen
- Muscle weakness and wasting

---

\*Present in Graves' disease only.

Thyroid hormones stimulate the heart, increasing rate and stroke volume. These responses increase cardiac output, blood pressure, and blood flow (McCance et al., 2014).

Elevated thyroid hormone levels affect protein, fat, and glucose metabolism. Protein buildup and breakdown are increased; but breakdown exceeds buildup, causing a net loss of body protein known as a **negative nitrogen balance**. Glucose tolerance is decreased, and the patient has

**hyperglycemia** (elevated blood glucose levels). Fat metabolism is increased, and body fat decreases. Although the patient has an increased appetite, the increased metabolism causes weight loss and NUTRITION deficits.

Thyroid hormones are produced in response to the stimulation hormones secreted by the hypothalamus and anterior pituitary glands. Thus oversecretion of thyroid hormones changes the secretion of hormones from the hypothalamus and the anterior pituitary gland through negative feedback (see [Chapter 61](#)). Thyroid hormones also have some influence over sex hormone production. Women have menstrual problems and decreased fertility. Both men and women with hyperthyroidism have an increased **libido** (sexual interest).

### Etiology and Genetic Risk

Hyperthyroidism has many causes. The most common form of the disease is Graves' disease, also called *toxic diffuse goiter*. **Graves' disease** is an autoimmune disorder resulting from Hashimoto's thyroiditis (HT) ([Davies et al., 2016](#)). HT results in the production of autoantibodies to different substances and structures within the thyroid gland. In Graves' disease, these antibodies (thyroid-stimulating immunoglobulins [TSIs]) attach to the thyroid-stimulating hormone (TSH) receptors on the thyroid gland. This increases the number of glandular cells, which enlarges the gland, forming a **goiter**, and overproduces thyroid hormones (**thyrotoxicosis**). When HT causes production of antibodies to other structures within the thyroid gland, hypothyroidism results (see the discussion of Etiology in the Hypothyroidism section).

In Graves' disease, all the general symptoms of hyperthyroidism are present. In addition, other changes specific to Graves' disease may occur, including **exophthalmos** (abnormal protrusion of the eyes) and **pretibial myxedema** (dry, waxy swelling of the front surfaces of the lower legs that resembles benign tumors or keloids).

Hyperthyroidism caused by multiple thyroid nodules is termed **toxic multinodular goiter**. The nodules may be enlarged thyroid tissues or benign tumors (adenomas). These patients usually have had a goiter for years. The symptoms are milder than those seen in Graves' disease, and the patient does not have exophthalmos or pretibial myxedema.

Hyperthyroidism also can be caused by excessive use of thyroid replacement hormones. This type of problem is called **exogenous hyperthyroidism**.

## Genetic/Genomic Considerations

### Patient-Centered Care QSEN

Susceptibility to Graves' disease is associated with several gene mutations (*GRD1*, *GRD2*, *GRDX1*, *GRDX2*). The pattern of inheritance is autosomal-recessive with sex limitation to females. Graves' disease is associated with other autoimmune disorders, such as diabetes mellitus, vitiligo, and rheumatoid arthritis and often occurs in both members of identical twins (Online Mendelian Inheritance in Man [OMIM], 2016). Ask the patient with Graves' disease whether any other family members also have the problem.

### Incidence and Prevalence

Hyperthyroidism is a common endocrine disorder. Graves' disease can occur at any age but is diagnosed most often in women between 20 and 40 years of age ([Davies et al., 2016](#)). Toxic multinodular goiter usually occurs after the age of 50 years and affects women four times more often than men ([McCance et al., 2014](#)).

### Interprofessional Collaborative Care

Depending on the severity of the hyperthyroid symptoms at the time of diagnosis, initial therapy may start in an acute care environment or in the community. When thyroid storm is present, an intensive care environment may be required. Once the disorder is controlled, the patient manages his or her disorder in the community.

### Assessment: Noticing

## History.

Many changes and problems occur because hyperthyroidism affects all body systems, although changes may occur over such a long period that patients may be unaware of them. Record age, gender, and usual weight. The increased metabolic rate affects NUTRITION. The patient may report a recent unplanned weight loss, an increased appetite, and an increase in the number of bowel movements per day.

A hallmark of hyperthyroidism is heat intolerance. The patient may have increased sweating even when environmental temperatures are comfortable for others. He or she often wears lighter clothing in cold weather. The patient may also report palpitations or chest pain as a result of the cardiovascular effects. Ask about changes in breathing patterns because dyspnea (with or without exertion) is common.

Visual changes may be the earliest problem the patient or family notices, especially exophthalmos with Graves' disease (Fig. 63-1). Ask about changes in vision, such as blurring or double vision and tiring of the eyes.

FIG. 63-1 Exophthalmos.

Ask about changes in energy level or in the ability to perform ADLs. Fatigue and insomnia are common. Families may report that the patient has become irritable or depressed.

Ask women about changes in menses, because amenorrhea or a decreased menstrual flow is common. Initially both men and women may have an increase in libido, but this changes as the patient becomes more fatigued.

Ask about previous thyroid surgery or radiation therapy to the neck, because some adults remain hyperthyroid after surgery or are resistant to radiation therapy. Ask about past and current drugs, especially the use of thyroid hormone replacement or antithyroid drugs.

## Physical Assessment/Signs and Symptoms.

Exophthalmos is common in patients with Graves' disease. The wide-eyed or "startled" look is due to edema in the extraocular muscles and increased fatty tissue behind the eye, which pushes the eyeball forward and may cause problems with focusing. Pressure on the optic nerve may impair vision. If the eyelids fail to close completely and the eyes are unprotected, they may become dry, and corneal ulcers may develop. Observe the eyes for excessive tearing and a bloodshot appearance. Ask about sensitivity to light (**photophobia**).

Two other eye problems are common in all types of hyperthyroidism: eyelid retraction (eyelid lag) and globe (eyeball) lag. In eyelid lag, the upper eyelid fails to descend when the patient gazes slowly downward. In globe lag, the upper eyelid pulls back faster than the eyeball when the patient gazes upward. During assessment, ask the patient to look down and then up and document the response.

Observe the size and symmetry of the thyroid gland. Palpate the thyroid gland to assess its consistency. In goiter, a generalized thyroid enlargement, the thyroid gland may increase to four times its normal size (Fig. 63-2). Goiters are common in Graves' disease and are classified by size (Table 63-1). *Not all patients with a goiter have hyperthyroidism.* Bruits (turbulence from increased blood flow) may be heard in the neck with a stethoscope. (See Chapter 61 for thyroid palpation and auscultation.)

**FIG. 63-2** Goiter.

**TABLE 63-1**  
**Goiter Classification**

GOITER GRADE	DESCRIPTION
0	There is no palpable or visible goiter.
1	Mass is not visible with neck in the normal position. Goiter can be palpated and moves up when the patient swallows.
2	Mass is visible as swelling when the neck is in the normal position. Goiter is easily palpated and is usually asymmetric.

The cardiovascular problems of hyperthyroidism include increased systolic blood pressure, tachycardia, and dysrhythmias. Usually the diastolic pressure is decreased, causing a widened pulse pressure.

Inspect the hair and skin. Fine, soft, silky hair and smooth, warm, moist skin are common. Many patients notice thinning of scalp hair. Muscle weakness and hyperactive deep tendon reflexes are common. Observe motor movements of the hands for tremors. The patient may appear restless, irritable, and fatigued.

#### Psychosocial Assessment.

The patient often has wide mood swings, irritability, decreased attention span, and manic behavior. Hyperactivity often leads to fatigue because of the inability to sleep well. Some patients describe their activity as having two modes (i.e., either “full speed ahead” or “completely stopped”). Ask whether he or she cries or laughs without cause or has difficulty concentrating. Family members often report a change in the patient's mental or emotional status.

#### Laboratory Assessment.

Testing for hyperthyroidism involves measurement of blood levels for triiodothyronine ( $T_3$ ), thyroxine ( $T_4$ ), and thyroid-stimulating hormone (TSH). Antibodies to the TSH receptor (thyrotropin receptor [TRAbs]) are measured to diagnose Graves' disease. The most common changes in laboratory tests for hyperthyroidism are listed in Chart 63-2.

#### Chart 63-2

## Laboratory Profile

### Thyroid Function for Adults

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS	
		HYPERTHYROIDISM	HYPOTHYROIDISM
Serum T <sub>3</sub>	70-205 ng/dL (1.7-5.2 pmol/L)	Increased	Decreased
Serum T <sub>4</sub> (total)	4-12 mcg/dL (51-154 nmol/L)	Increased	Decreased
Free T <sub>4</sub> index	0.8-2.8 ng/dL (10-36 pmol/L)	Increased	Decreased
TSH stimulation test (thyroid stimulation test)	>10% in RAIU or >1.5 mcg/dL	N/A (test differentiates primary from secondary hypothyroidism)	No response in primary hypothyroidism Normal response in secondary hypothyroidism
Thyroid-stimulating immunoglobulins (TSI)	<130% of basal activity	Elevated in Graves' disease Normal in other types of hyperthyroidism	No change
Thyrotropin receptor antibodies (TRAb)	Titer: 0%	80%-95% indicates Graves' disease	No response
TSH	2-10 µU/mL (2-10 mU/L)	Low in Graves' disease High in secondary or tertiary hyperthyroidism	High in primary disease Low in secondary or tertiary disease

T<sub>3</sub>, Triiodothyronine; T<sub>4</sub>, thyroxine; TSH, thyroid-stimulating hormone.

Data from Pagana, K., Pagana, T., & Pike-MacDonald, S. (2013). *Mosby's Canadian manual of diagnostic and laboratory tests*. St. Louis: Mosby, and Pagana, K., Pagana, T.J., & Pagana, T.N. (2017). *Mosby's diagnostic and laboratory test reference* (13th ed.). St. Louis: Mosby.

### Other Diagnostic Assessment.

*Thyroid scan* evaluates the position, size, and functioning of the thyroid gland. Radioactive iodine (RAI [<sup>123</sup>I]) is given by mouth, and the uptake of iodine by the thyroid gland (radioactive iodine uptake [RAIU]) is measured. The half-life of <sup>123</sup>I is short, and radiation precautions are not needed. Pregnancy should be ruled out before the scan is performed. The normal thyroid gland has an uptake of 5% to 35% of the given dose at 24 hours. RAIU is increased in hyperthyroidism and can be used to identify active thyroid nodules. It is no longer the most common test for thyroid function (Davies et al., 2016).

*Ultrasonography* of the thyroid gland can determine its size and the general composition of any masses or nodules. This outpatient procedure takes about 30 minutes to perform and is painless. No special instructions are required.

*ECG* usually shows supraventricular tachycardia. Other ECG changes include atrial fibrillation, dysrhythmias, and premature ventricular contractions.

### ◆ Interventions: Responding

Because Graves' disease is the most common form of hyperthyroidism, the interventions discussed in the following sections include those specific for the problems that occur with Graves' disease. In North America, the most common interventions are drug therapy and radioablation. Surgery is reserved for severe disease that is not responsive to other forms of management. Medical management is used to decrease the effect of thyroid hormone on cardiac function and to reduce thyroid hormone secretion. The priorities for nursing care focus on monitoring for complications, reducing stimulation, promoting comfort, and teaching the patient and family about therapeutic drugs and procedures.

### Nonsurgical Management.

*Monitoring* includes measuring the patient's apical pulse, blood pressure, and temperature at least every 4 hours. Instruct the patient to report immediately any palpitations, dyspnea, vertigo, or chest pain. Increases in temperature may indicate a rapid worsening of the patient's condition and the onset of *thyroid storm*, a life-threatening event that occurs with uncontrolled hyperthyroidism and is characterized by high fever and severe hypertension (discussed later in the Hyperthyroidism section). *Immediately report a temperature increase of even 1 degree Fahrenheit*. If this task is delegated to unlicensed assistive personnel (UAP), instruct them to report the patient's temperature to you as soon as it has been obtained. If temperature is elevated, immediately assess the patient's cardiac status. If the patient has a cardiac monitor, check for dysrhythmias.

*Reducing stimulation* helps prevent increasing the symptoms of hyperthyroidism and the risk for cardiac complications. Encourage the patient to rest. Keep the environment as quiet as possible by closing the door to the room, limiting visitors, and eliminating or postponing nonessential care or treatments.

*Promoting comfort* includes reducing the room temperature to decrease discomfort caused by heat

intolerance. Instruct UAP to ensure that the patient always has a fresh pitcher of ice water and to change the bed linen whenever it becomes damp from diaphoresis. Suggest that the patient take a cool shower or sponge bath several times each day. For patients with exophthalmos, prevent eye dryness by encouraging the use of artificial tears.

*Drug therapy* with antithyroid drugs is the initial treatment for hyperthyroidism and causes some patients to go into remission for as long as 10 years (Davies et al., 2016). Chart 63-3 lists teaching priorities for the patient receiving drug therapy for hyperthyroidism. The preferred drugs are the thionamides, especially methimazole (Tapazole). Propylthiouracil (PTU) is used less often because of its liver toxic effects (Davies et al., 2016). These drugs block thyroid hormone production by preventing iodide binding in the thyroid gland. The response to these drugs is delayed because the patient may have large amounts of stored thyroid hormones that continue to be released.

### Chart 63-3

## Common Examples of Drug Therapy

### Hyperthyroidism

DRUGS	NURSING IMPLICATIONS
Propylthiouracil (PTU, Propyl-Thyracil) Methimazole (NORTHX, Tapazole)	Teach patient to avoid crowds and people who are ill because the drug reduces the immune response, increasing the risk for infection. Teach patients to check for weight gain, slow heart rate, and cold intolerance, which are indications of hypothyroidism and the need for a lower drug dose. Teach patients taking propylthiouracil to report darkening of the urine or a yellow appearance to the skin or whites of the eyes, which indicate possible liver toxicity or failure, a serious side effect of propylthiouracil. Remind women taking methimazole to notify their primary health care providers if they become pregnant because the drug causes birth defects and should not be used during pregnancy.
Lugol's solution Saturated solution of potassium iodide (SSKI)	Administer these drugs orally 1 hour after a thionamide has been given because initially the iodine agents can cause an increase in the production of thyroid hormones. Giving a thionamide first prevents this initial increase in thyroid hormone production. Check patient for a fever or rash and ask about a metallic taste, mouth sores, sore throat, or GI distress as these are indications of iodism, a toxic effect of the drugs, and may require that the drug be discontinued.

### Nursing Safety Priority QSEN

#### Drug Alert

Although similar in action, methimazole and propylthiouracil are not interchangeable. The dosages for propylthiouracil are much higher than those for methimazole.

### Nursing Safety Priority QSEN

#### Drug Alert

Methimazole can cause birth defects and should not be used during pregnancy, especially during the first trimester. Instruct women to notify their primary health care provider if pregnancy occurs.

Iodine preparations may be used for short-term therapy before surgery. They decrease blood flow through the thyroid gland, reducing the production and release of thyroid hormone. Improvement usually occurs within 2 weeks, but it may be weeks before metabolism returns to normal. This treatment can result in hypothyroidism, and the patient is monitored closely for the need to adjust the drug regimen.

Beta-adrenergic blocking drugs, such as propranolol (Inderal, Detensol) may be used as supportive therapy. These drugs relieve diaphoresis, anxiety, tachycardia, and palpitations but do not inhibit thyroid hormone production. See Chapters 34 and 36 for a discussion of the actions and nursing implications of these agents.

*Radioactive iodine (RAI) therapy* is not used in pregnant women because  $^{131}\text{I}$  crosses the placenta and can damage the fetal thyroid gland. The patient with hyperthyroidism may receive RAI in the form of oral  $^{131}\text{I}$ . The dosage depends on the thyroid gland's size and sensitivity to radiation. The thyroid gland picks up the RAI, and some of the cells that produce thyroid hormone are destroyed by the local radiation. Because the thyroid gland stores thyroid hormones to some degree, the patient may not have complete symptom relief until 6 to 8 weeks after RAI therapy. Additional drug therapy for hyperthyroidism is still needed during the first few weeks after RAI treatment.

RAI therapy is performed on an outpatient basis. One dose may be sufficient, although some

patients need a second or third dose. The radiation dose is low and is usually completely eliminated within a month; however, the source is unsealed, and some radioactivity is present in the patient's body fluids and stool for a few weeks after therapy. Radiation precautions are needed to prevent exposure to family members and other people. [Chart 63-4](#) lists precautions to teach the patient during the first few weeks after receiving  $^{131}\text{I}$ .

#### **Chart 63-4**

### **Patient and Family Education: Preparing for Self-Management**

#### **Safety Precautions for the Patient Receiving an Unsealed Radioactive Isotope**

- Use a toilet that is not used by others for at least 2 weeks after receiving the radioactive iodine.
- Sit to urinate (males and females) to avoid splashing the seat, walls, and floor.
- Flush the toilet three times after each use.
- If urine is spilled on the toilet seat or floor, use paper tissues or towels to clean it up, bag them in sealable plastic bags, and take them to the hospital's radiation therapy department.
- Men with urinary incontinence should use condom catheters and a drainage bag rather than absorbent gel-filled briefs or pads.
- Women with urinary incontinence should use facial tissue layers in their clothing to catch the urine rather than absorbent gel-filled briefs or pads. These tissues should then be flushed down the toilet exclusively used by the patient.
- Using a laxative on the second and third days after receiving the radioactive drug helps you excrete the contaminated stool faster (this also decreases the exposure of your abdominal organs to radiation).
- Wear only machine-washable clothing and wash these items separately from others in your household.
- After washing your clothing, run the washing machine for a full cycle on empty before it is used to wash the clothing of others.
- Avoid close contact with pregnant women, infants, and young children for the first week after therapy. Remain at least 3 feet (about 1 meter) away from these people and limit your exposure to them to no more than 1 hour daily.
- Some radioactivity will be in your saliva during the first week after therapy. Precautions to avoid exposing others to this contamination (both household members and trash collectors) include:
  - Not sharing toothbrushes or toothpaste tubes
  - Using disposable tissues rather than cloth handkerchiefs and either flushing used ones down the toilet or keeping them in a plastic bag and turning them in to the radiation department of the hospital for disposal
  - Using disposable utensils, plates, and cups

- Selecting foods that can be eaten completely and that do not result in a saliva-coated remnant (Foods to avoid are fruit with a core that can be contaminated, meat with a bone [e.g., chicken wings or legs, ribs]. Consider preparing these foods by cutting out the core and removing the bone before eating.)

Data from Al-Shakhrh, I. (2008). Radioprotection using iodine-131 for thyroid cancer and hyperthyroidism: A review. *Clinical Journal of Oncology Nursing*, 12(6), 905-912.

The degree of thyroid destruction varies. Some patients become hypothyroid as a result of treatment. The patient then needs lifelong thyroid hormone replacement. All patients who have undergone RAI therapy should be monitored regularly for changes in thyroid function.

## NCLEX Examination Challenge 63-1

### Health Promotion and Maintenance

Which statement by a client undergoing radioactive iodine (RAI) therapy demonstrates to the nurse **correct understanding** of postprocedure precautions?

- A. "I'll wear a wig until my hair grows back in."
- B. "I'll be sure to use only one toilet and not let others use it for 2 weeks."
- C. "I'll avoid crowds and people who are ill to reduce the risk for an infection."
- D. "I'll avoid having a manicure or pedicure during the first month after treatment."

## Cultural/Spiritual Considerations

### Patient-Centered Care OSEN

A potentially life-threatening complication of thyrotoxicosis is periodic paralysis (thyrotoxic periodic paralysis, TPP), which results from low blood potassium levels caused by increased skeletal muscle uptake of potassium. The potassium movement is thought to result from direct thyroid hormone action or the increased adrenergic response of hyperthyroidism. The change in both intracellular and extracellular potassium levels reduces skeletal muscle membrane excitability and leads to temporary paralysis, including paralysis of the respiratory muscles. TPP is most common in men of Chinese and Japanese descent (Patel et al., 2013).

Emergency management involves treating the thyrotoxicosis and the hypokalemia. In addition to antithyroid drug therapy, potassium is replaced IV. This condition is increasing in frequency in North America and is not always recognized. Be alert to any adult male of Asian descent who has lower limb paralysis or weakness along with signs and symptoms of hyperthyroidism.

### Surgical Management.

Surgery to remove all or part of the thyroid gland is used for Graves' disease that does not respond to other therapies. It is also used when a large goiter causes tracheal or esophageal compression. Removal of all (**total thyroidectomy**) or part (**subtotal thyroidectomy**) of the thyroid tissue decreases the production of thyroid hormones. After a total thyroidectomy, patients must take lifelong thyroid hormone replacement.

### Preoperative Care.

The patient is treated with thionamide drug therapy first to have near-normal thyroid function (**euthyroid**) before thyroid surgery. Iodine preparations also are used to decrease thyroid size and vascularity, thereby reducing the risk for hemorrhage and the potential for thyroid storm during

surgery. (Thyroid storm is discussed in the Hyperthyroid section.)

Hypertension, dysrhythmias, and tachycardia must be controlled before surgery. The patient with hyperthyroidism may need to follow a high-protein, high-carbohydrate diet for days or weeks before surgery.

Teach the patient to perform deep-breathing exercises. Stress the importance of supporting the neck when coughing or moving by placing both hands behind the neck to reduce strain on the incision. Explain that hoarseness may be present for a few days as a result of endotracheal tube placement during surgery.

Explain the surgery and the care after surgery to the patient. Remind him or her that a drain and a dressing may be in place after surgery. Answer any questions the patient and family have.

### Operative Procedures.

Many thyroidectomies are now performed as minimally invasive surgeries or mini-incision surgeries. With these surgeries, as with the traditional open approach, the parathyroid glands and recurrent laryngeal nerves are avoided to reduce the risk for complications and injury.

With a subtotal thyroidectomy, the remaining thyroid tissues are sutured to the trachea. With a total thyroidectomy, the entire thyroid gland is removed, but the parathyroid glands are left with an intact blood supply to prevent causing hypoparathyroidism.

### Postoperative Care.

*Monitoring the patient for complications is the most important nursing action after thyroid surgery.* Monitor vital signs every 15 minutes until the patient is stable and then every 30 minutes. Increase or decrease the monitoring of vital signs based on changes in the patient's condition.

Assess the patient's level of discomfort. Use pillows to support the head and neck. Place the patient, while he or she is awake, in a semi-Fowler's position. Avoid positions that cause neck extension. Give prescribed drugs for pain control as needed.

Help the patient deep-breathe every 30 minutes to 1 hour. Suction oral and tracheal secretions when necessary.

Thyroid surgery can cause hemorrhage, respiratory distress with reduced GAS EXCHANGE, parathyroid gland injury (resulting in **hypocalcemia** [low serum calcium levels] and **tetany** [hyperexcitability of nerves and muscles]), damage to the laryngeal nerves, and thyroid storm. Remain alert to the potential for complications and identify symptoms early.

*Hemorrhage* is most likely to occur during the first 24 hours after surgery. Inspect the neck dressing and behind the patient's neck for blood. A drain may be present, and a moderate amount of serosanguineous drainage is normal. Hemorrhage may be seen as bleeding at the incision site or as respiratory distress caused by tracheal compression.

*Respiratory distress and reduced GAS EXCHANGE* can result from swelling, tetany, or damage to the laryngeal nerve, resulting in spasms. Laryngeal **stridor** (harsh, high-pitched respiratory sounds) is heard in acute respiratory obstruction. Keep emergency tracheostomy equipment in the patient's room. Check that oxygen and suctioning equipment are nearby and in working order.

## Nursing Safety Priority QSEN

### Critical Rescue

Monitor the patient to identify symptoms of obstruction and poor GAS EXCHANGE (stridor, dyspnea, falling oxygen saturation, inability to swallow, drooling) after thyroid surgery. If any indications of obstruction are present, respond by immediately notifying the Rapid Response Team.

*Hypocalcemia and tetany* may occur if the parathyroid glands are removed or damaged or their blood supply is impaired during thyroid surgery, resulting in decreased parathyroid hormone (PTH) levels. Ask the patient hourly about tingling around the mouth or of the toes and fingers. Assess for muscle twitching as a sign of calcium deficiency. Calcium gluconate or calcium chloride for IV use should be available in an emergency situation. (For information on the later signs of hypocalcemia, see the discussion of postoperative care in the Hyperparathyroidism section and the Assessment discussion in the Hypoparathyroidism section. Hypocalcemia is also discussed in [Chapter 11](#).)

*Laryngeal nerve damage* may occur during surgery. This problem results in hoarseness and a weak voice. Assess the patient's voice at 2-hour intervals and document any changes. Reassure the patient that hoarseness is usually temporary.

## NCLEX Examination Challenge 63-2

### Safe and Effective Care Environment

Which assessment finding of a client 10 hours after a subtotal thyroidectomy indicates to the nurse possible airway obstruction?

- A. The client is drooling.
- B. The oxygen saturation is 97%.
- C. The dressing has a moderate amount of serosanguinous drainage.
- D. The client responds to questions correctly but does not open the eyes while talking.

**Thyroid storm** or **thyroid crisis** is a life-threatening event that occurs in patients with uncontrolled hyperthyroidism, most often with Graves' disease. Symptoms develop quickly, and the problem is fatal if left untreated (Devereaux & Tewelde, 2014). It is often triggered by stressors such as trauma, infection, diabetic ketoacidosis, and pregnancy. Other conditions that can lead to thyroid storm include vigorous palpation of the goiter, exposure to iodine, and radioactive iodine (RAI) therapy. Although thyroid storm after surgery is less common because of drug therapy before thyroid surgery, it can still occur.

Symptoms of thyroid storm are caused by excessive thyroid hormone release, which dramatically increases metabolic rate. *Key symptoms include fever, tachycardia, and systolic hypertension.* The patient may have abdominal pain, nausea, vomiting, and diarrhea. Often he or she is very anxious and has tremors. As the crisis progresses, the patient may become restless, confused, or psychotic and may have seizures, leading to coma. *Even with treatment, thyroid storm may lead to death.*

## Nursing Safety Priority QSEN

### Critical Rescue

When caring for a patient with hyperthyroidism, even after a thyroidectomy, assess temperature often because an increase of even 1° F may indicate an impending thyroid crisis. If an increase occurs, respond by reporting it immediately to the primary health care provider.

Emergency measures to prevent death vary with the intensity and type of changes. Interventions focus on maintaining airway patency, promoting adequate ventilation and GAS EXCHANGE, reducing fever, and stabilizing the hemodynamic status. [Chart 63-5](#) outlines the best practices for emergency management of thyroid storm.

### Chart 63-5

## Best Practice for Patient Safety & Quality Care QSEN

### Emergency Care of the Patient During Thyroid Storm

- Maintain a patent airway and adequate ventilation.
- Give oral antithyroid drugs as prescribed: methimazole (Tapazole), up to 60 mg daily; propylthiouracil (PTU, Propyl-Thyracil), 300 to 900 mg daily.
- Administer sodium iodide solution, 2 g IV daily as prescribed.

- Give propranolol (Inderal, Detensol), 1 to 3 mg IV as prescribed. Give slowly over 3 minutes. The patient should be connected to a cardiac monitor, and a central venous pressure catheter should be in place.
- Give glucocorticoids as prescribed: hydrocortisone, 100 to 500 mg IV daily; prednisone, 4 to 60 mg orally daily; or dexamethasone, 2 mg IM every 6 hours.
- Monitor continually for cardiac dysrhythmias.
- Monitor vital signs every 30 minutes.
- Provide comfort measures, including a cooling blanket.
- Give nonsalicylate antipyretics as prescribed.
- Correct dehydration with normal saline infusions.
- Apply cooling blanket or ice packs to reduce fever.

*Eye and vision problems* of Graves' disease are not corrected by treatment for hyperthyroidism, and management is symptomatic. Teach the patient with mild problems to elevate the head of the bed at night and use artificial tears. If **photophobia** (sensitivity to light) is present, dark glasses may be helpful. For those who cannot close the eyelids completely, recommend gently taping the lids closed at bedtime. These actions prevent irritation and injury. If pressure behind the eye continues and forces the eye forward, blood supply to the eye can be compromised, leading to ischemia and blindness.

In severe cases, short-term glucocorticoid therapy is prescribed to reduce swelling and halt the infiltrative process. Prednisone (Deltasone, Winpred 🍀) is given in high doses (often 120 mg daily) at first and then is tapered down according to the patient's response. Explain the need to reduce the prednisone gradually and review its side effects with the patient.

Other management strategies include external radiation combined with lower-dose glucocorticoid therapy. Surgical intervention (orbital decompression) may be needed if loss of sight or damage to the eyeball is possible. Rituximab injections have been successful on a limited basis for this problem (Davies et al., 2016).

*Health teaching* includes reviewing with the patient and family the symptoms of hyperthyroidism and instructing the patient to report any increase or recurrence of these. Also teach about the symptoms of hypothyroidism (discussed in the next section) and the need for thyroid hormone replacement. Reinforce the need for regular follow-up because hypothyroidism can occur several years after radioactive iodine therapy.

The discharged patient may continue to have mood changes. Explain the reason for mood swings to the patient and family and reassure them that these will decrease with continued treatment.

## 🏠 Cellular Regulation Concept Exemplar Hypothyroidism

### ❖ Pathophysiology

Symptoms of hypothyroidism (Chart 63-6) are the result of decreased metabolism from low levels of thyroid hormones. Thyroid cells may fail to produce sufficient levels of thyroid hormones (THs) for several reasons. Sometimes the cells themselves are damaged and no longer function normally. At other times the thyroid cells are functional, but the adult does not ingest enough of the substances needed to make thyroid hormones, especially iodide and tyrosine. When the production of thyroid hormones is too low or absent, the blood levels of TH are very low, and the patient has a decreased metabolic rate. This lowered metabolism causes the hypothalamus and anterior pituitary gland to make stimulatory hormones, especially thyroid-stimulating hormone (TSH), in an attempt to trigger hormone release from the poorly responsive thyroid gland. The TSH binds to thyroid cells and causes the thyroid gland to enlarge, forming a goiter, although thyroid hormone production does not increase.

## Chart 63-6

### Key Features

#### Hypothyroidism

##### Skin Symptoms

- Cool, pale or yellowish, dry, coarse, scaly skin
- Thick, brittle nails
- Dry, coarse, brittle hair
- Decreased hair growth, with loss of eyebrow hair
- Poor wound healing

##### Pulmonary Symptoms

- Hypoventilation
- Pleural effusion
- Dyspnea

##### Cardiovascular Symptoms

- Bradycardia
- Dysrhythmias
- Enlarged heart
- Decreased activity tolerance
- Hypotension

##### Metabolic Symptoms

- Decreased basal metabolic rate
- Decreased body temperature
- Cold intolerance

##### Psychological/Emotional Symptoms

- Apathy
- Depression
- Paranoia

##### Gastrointestinal Symptoms

- Anorexia
- Weight gain
- Constipation

- Abdominal distention

### Neuromuscular Symptoms

- Slowing of intellectual functions:
- Slowness or slurring of speech
- Impaired memory
- Inattentiveness
- Lethargy or somnolence
- Confusion
- Hearing loss
- Paresthesia (numbness and tingling) of the extremities
- Decreased tendon reflexes
- Muscle aches and pain

### Reproductive Symptoms

#### Women

- Changes in menses (amenorrhea or prolonged menstrual periods)
- Anovulation
- Decreased libido

#### Men

- Decreased libido
- Impotence

### Other Symptoms

- Periorbital edema
- Facial puffiness
- Nonpitting edema of the hands and feet
- Hoarseness
- Goiter (enlarged thyroid gland)
- Thick tongue
- Increased sensitivity to opioids and tranquilizers
- Weakness, fatigue
- Decreased urine output

- Easy bruising
- Iron deficiency anemia
- Vitamin deficiencies

Most tissues and organs are affected by the low metabolic rate caused by hypothyroidism. Cellular energy is decreased, and metabolites that are compounds of proteins and sugars called *glycosaminoglycans* (GAGs) build up inside cells. This GAG buildup increases the mucus and water, forms cellular edema, and changes organ texture. The edema is mucinous and called **myxedema**, rather than edema caused by water alone. This edema changes the patient's appearance (Fig. 63-3). Nonpitting edema forms everywhere, especially around the eyes, in the hands and feet, and between the shoulder blades. The tongue thickens; and edema forms in the larynx, making the voice husky. General physiologic function is decreased.

**FIG. 63-3** Myxedema.

**Myxedema coma**, sometimes called *hypothyroid crisis*, is a rare, serious complication of untreated or poorly treated hypothyroidism and has a mortality rate of 60% (Dubbs & Spangler, 2014). The decreased metabolism causes the heart muscle to become flabby and the chamber size to increase. The result is decreased cardiac output with decreased perfusion and GAS EXCHANGE in the brain and other vital organs, which makes the already slowed cellular metabolism worse, resulting in tissue and organ failure. *The mortality rate for myxedema coma is extremely high, and this condition is a life-threatening emergency.* Myxedema coma can be caused by a variety of events, drugs, or conditions.

### Etiology

Most cases of hypothyroidism in the United States occur as a result of thyroid surgery and radioactive iodine (RAI) treatment of hyperthyroidism. Worldwide, hypothyroidism is common in areas where the soil and water have little natural iodide, causing endemic goiter. Hypothyroidism is also caused by a variety of other conditions (Table 63-2).

**TABLE 63-2**

#### Causes of Hypothyroidism

Primary Causes
<b>Decreased Thyroid Tissue</b>
<ul style="list-style-type: none"> <li>• Surgical or radiation-induced thyroid destruction</li> <li>• Autoimmune thyroid destruction</li> <li>• Congenital poor thyroid development</li> <li>• Cancer (thyroidal or metastatic)</li> </ul>
<b>Decreased Synthesis of Thyroid Hormone</b>

<ul style="list-style-type: none"> <li>• Endemic iodine deficiency</li> <li>• Drugs: <ul style="list-style-type: none"> <li>• Lithium</li> <li>• Propylthiouracil</li> <li>• Sodium or potassium perchlorate</li> <li>• Aminoglutethimide</li> </ul> </li> </ul>
<b>Secondary Causes</b>
<b>Inadequate Production of Thyroid-Stimulating Hormone</b>
<ul style="list-style-type: none"> <li>• Pituitary tumors, trauma, infections, or infarcts</li> <li>• Congenital pituitary defects</li> <li>• Hypothalamic tumors, trauma, infections, or infarcts</li> </ul>

## Incidence and Prevalence

Hypothyroidism occurs most often in women between 30 and 60 years of age. Women are affected 7 to 10 times more often than men (McCance et al., 2014).

### ❖ Interprofessional Collaborative Care

Depending on the severity of the symptoms at the time of diagnosis, initial therapy for hypothyroidism may start in an acute care environment or in the community. When symptoms are severe or if myxedema coma is present, an intensive care environment may be required. Drug therapy is lifelong, and patients learn to manage their disorders in the community.

### ◆ Assessment: Noticing

#### History.

A decrease in thyroid hormones produces many symptoms related to decreased metabolism. However, changes may have occurred slowly, and the patient may not have noticed them. Ask him or her to compare activity now with that of a year ago. The patient often reports an increase in time spent sleeping, sometimes up to 14 to 16 hours daily. Generalized weakness, anorexia, muscle aches, and paresthesias may also be present. Constipation and cold intolerance are common. Ask whether more blankets at night or extra clothing, even in warm weather, has been needed. Some changes may be subtle and are often missed, especially in older adults.

Both men and women may report a decreased libido. Women may have had difficulty becoming pregnant or have changes in menses (heavy, prolonged bleeding or amenorrhea). Men may have problems with impotence and infertility.

Ask about current or previous use of drugs, such as lithium, thiocyanates, aminoglutethimide, sodium or potassium perchlorate, or cobalt. All of these drugs can impair thyroid hormone production. In particular, the cardiac drug amiodarone (Cordarone) often has damaging effects on the thyroid gland (Brent & Weetman, 2016; Devereaux & Tewelde, 2014). Also ask whether the patient has ever been treated for hyperthyroidism and what specific treatment was used.

#### Physical Assessment/Signs and Symptoms.

Observe the patient's overall appearance. Fig. 63-3 shows the typical appearance of an adult with hypothyroidism. Common changes include coarse features, edema around the eyes and face, a blank expression, and a thick tongue. The patient's overall muscle movement is slow. He or she may not speak clearly and may take a longer time to respond to questions.

Cardiac and respiratory functions are decreased, leading to reduced GAS EXCHANGE. Heart rate may be below 60 beats/min, and respiratory rate may be slow. Body temperature is often lower than 97° F (36.1° C).

Weight gain is very common, even when the adult is not overeating. Weigh the patient and ask whether the result is the same or different from his or her weight a year ago.

Depending on the cause of hypothyroidism, the patient may have a goiter. However, some types of hypothyroidism do not induce a goiter, and some types of hyperthyroidism do. The presence of a goiter *suggests* a thyroid problem but does not indicate whether the problem is excessive hormone secretion or too little hormone secretion.

#### Psychosocial Assessment.

Hypothyroidism causes many problems in psychosocial functioning. Depression is the most common reason for seeking medical attention. Family members often bring the patient for the initial evaluation. The patient may be too lethargic, apathetic, or drowsy to recognize changes in his or her condition. Families may report that the patient is withdrawn and has reduced cognition. Assess his or her attention span and memory, both of which can be impaired by hypothyroidism. The mental

slowness can contribute to social isolation.

### Laboratory Assessment.

Laboratory findings for hypothyroidism are the opposite of those for hyperthyroidism. Triiodothyronine ( $T_3$ ) and thyroxine ( $T_4$ ) serum levels are decreased. TSH levels are high in primary hypothyroidism but can be decreased or near normal in patients with secondary hypothyroidism (see [Chart 63-2](#)). Patients older than 80 years may have lower-than-normal levels of thyroid hormones without symptoms of hypothyroidism, and hormone replacement is not used until other symptoms are present ([Touhy & Jett, 2016](#)).

## NCLEX Examination Challenge 63-3

### Physiological Integrity

Which symptoms are **most** often seen in hypothyroidism? **Select all that apply.**

- A. Increased appetite
- B. Cold intolerance
- C. Constipation
- D. Hypotension
- E. Exophthalmia
- F. Palpitations
- G. Tremors
- H. Weight gain

### ◆Analysis: Interpreting

The priority collaborative problems for patients who have hypothyroidism are:

1. Decreased GAS EXCHANGE and oxygenation due to decreased energy, obesity, muscle weakness, and fatigue
2. Hypotension and reduced perfusion due to decreased heart rate from decreased myocardial metabolism
3. Reduced cognition due to reduced brain metabolism and formation of edema
4. Potential for the complication of myxedema coma

### ◆Planning and Implementation: Responding

Respiratory and cardiac problems are serious, and their management is a priority. *The most common cause of death among patients with myxedema coma is respiratory failure.*

### Improving Gas Exchange

#### Planning: Expected Outcomes.

With appropriate management, the patient with hypothyroidism is expected to have improved GAS EXCHANGE. Indicators include:

- Maintenance of  $SpO_2$  of at least 90%
- Absence of cyanosis
- Maintenance of cognitive orientation

### Interventions.

Observe and record the rate and depth of respirations and adequacy of GAS EXCHANGE. Measure oxygen saturation by pulse oximetry and apply oxygen if the patient has hypoxemia. Auscultate the lungs for a decrease in breath sounds or presence of crackles. If hypothyroidism is severe, the patient may require ventilatory support. Severe respiratory distress occurs with myxedema coma.

Sedating a patient with hypothyroidism can make GAS EXCHANGE worse and is avoided if possible. When sedation is needed, the dosage is reduced because hypothyroidism increases sensitivity to these drugs. For the patient receiving sedation, assess for adequate gas exchange.

### Preventing Hypotension

#### Planning: Expected Outcomes.

The patient is expected to have adequate cardiovascular function and tissue perfusion with GAS EXCHANGE. Indicators include that the patient:

- Maintains heart rate above 60 beats/min
- Maintains blood pressure within normal limits for his or her age and general health
- Has no dysrhythmias, peripheral edema, or neck vein distention

### Interventions.

The patient may have decreased blood pressure, bradycardia, and dysrhythmias. Nursing priorities are monitoring for condition changes and preventing complications. Monitor blood pressure and heart rate and rhythm and observe for indications of shock (e.g., hypotension, decreased urine output, changes in mental status).

If hypothyroidism is chronic, the patient may have cardiovascular disease. *Instruct the patient to report episodes of chest pain or chest discomfort immediately.*

The patient requires lifelong thyroid hormone replacement. Synthetic hormone preparations are usually prescribed. The most common is levothyroxine sodium (Synthroid, T<sub>4</sub>, Eltroxin ). Therapy is started with low doses and gradually increased over a period of weeks. *The patient with more severe symptoms of hypothyroidism is started on the lowest dose of thyroid hormone replacement.* This precaution is especially important when the patient has known cardiac problems. Starting at too high a dose or increasing the dose too rapidly can cause severe hypertension, heart failure, and myocardial infarction. With myxedema coma, the drug may need to be given IV because of the severely reduced motility and absorption of the GI tract (Hampton, 2013).

## Nursing Safety Priority QSEN

### Drug Alert

Teach patients and families who are beginning thyroid replacement therapy to take the drug exactly as prescribed and not to change the dose or schedule without consulting the primary health care provider. Instruct them not to switch brands because the response to different drug brands can vary.

Assess the patient for chest pain and dyspnea during initiation of therapy. The final dosage is determined by blood levels of TSH and the patient's physical responses. The dosage and time required for symptom relief vary with each patient. Monitor for and teach the patient and family about the symptoms of hyperthyroidism (see [Chart 63-1](#)), which can occur with replacement therapy.

### Supporting Cognition

#### Planning: Expected Outcomes.

The patient is expected to return to the same level of cognitive function as before the thyroid problem started. Indicators include that the patient:

- Demonstrates immediate memory
- Communicates clearly and appropriately for age and ability

- Is attentive during conversations

### Interventions.

Observe for and record the presence and severity of lethargy, drowsiness, memory deficit, poor attention span, and difficulty communicating. These problems should decrease with thyroid hormone treatment, and mental awareness usually returns to the patient's normal level within 2 weeks. Orient the patient to person, place, and time and explain all procedures slowly and carefully. Provide a safe environment.

Family members may have difficulty coping with the patient's behavior. Encourage them to accept the mood changes and mental slowness as symptoms of the disease. Remind the family that these problems should improve with therapy.

### Preventing Myxedema Coma.

Any patient with hypothyroidism who has any other health problem or who is newly diagnosed is at risk for myxedema coma. Factors leading to myxedema coma include acute illness, surgery, chemotherapy, discontinuing thyroid replacement therapy, and the use of sedatives or opioids. Problems that often occur with this condition include:

- Coma
- Respiratory failure
- Hypotension
- Hyponatremia
- Hypothermia
- Hypoglycemia

## Nursing Safety Priority QSEN

### Action Alert

Myxedema coma can lead to shock, organ damage, and death. Assess the patient with hypothyroidism at least every 8 hours for changes that indicate increasing severity, especially changes in mental status, and report these promptly to the primary health care provider.

Treatment is instituted quickly according to the patient's symptoms and without waiting for laboratory confirmation. Best practices for emergency care of the patient with myxedema coma are listed in [Chart 63-7](#).

### Chart 63-7

## Best Practice for Patient Safety & Quality Care QSEN

### Emergency Care of the Patient During Myxedema Coma

- Maintain a patent airway.
- Replace fluids with IV normal or hypertonic saline as prescribed.
- Give levothyroxine sodium IV as prescribed.
- Give glucose IV as prescribed.
- Give corticosteroids as prescribed.
- Check the patient's temperature hourly.
- Monitor blood pressure hourly.

- Cover the patient with warm blankets.
- Monitor for changes in mental status.
- Turn every 2 hours.
- Institute Aspiration Precautions.

### Care Coordination and Transition Management

Hypothyroidism is usually chronic. Patients usually live in the community and are managed on an outpatient basis. Patients in acute care settings, subacute care settings, and rehabilitation centers may have long-standing hypothyroidism in addition to other health problems. Ensure that whoever is responsible for overseeing the patient's daily care is aware of the condition and understands its management.

#### Home Care Management.

The patient with hypothyroidism does not usually require changes in the home unless cognition has decreased to the point that he or she poses a danger to himself or herself. Activity intolerance and fatigue may necessitate one-floor living for a short time. If symptoms have not improved before discharge, discuss the need for extra heat or clothing because of cold intolerance. The patient may need help with the drug regimen. Discuss this issue with the family and patient and develop a plan for drug therapy. One person should be clearly designated as responsible for drug preparation and delivery so doses are neither missed nor duplicated.

#### Self-Management Education.

*The most important educational need for the patient with hypothyroidism is about hormone replacement therapy and its side effects.* Emphasize the need for lifelong drugs and review the symptoms of both hyperthyroidism and hypothyroidism. Teach the patient to wear a medical alert bracelet. Teach the patient and family when to seek medical interventions for dosage adjustment and the need for periodic blood tests of hormone levels. Instruct the patient not to take any over-the-counter (OTC) drugs without consulting his or her primary health care provider because thyroid hormone preparations interact with many other drugs. Older patients may need additional information about the effects of aging on the thyroid gland ([Chart 63-8](#)).

### Chart 63-8

## Nursing Focus on the Older Adult

### Thyroid Problems

Teach the patient these facts about changes in the thyroid gland related to aging:

- Thyroid hormone secretion decreases with age, but the hormone level remains stable because storage site clearance of the hormone also decreases with age.
- The basal metabolic rate decreases with age, which changes body composition from predominantly muscular to predominantly fatty.
- Older patients require lower doses of replacement thyroid hormone. Too large a dose may adversely affect the heart muscle.

Advise the patient to maintain NUTRITION by eating a well-balanced diet with adequate fiber and fluid intake to prevent constipation. Caution him or her that use of fiber supplements may interfere with the absorption of thyroid hormone. Thyroid hormones should be taken on an empty stomach, at least 4 hours before or after a meal. Remind the patient about the importance of adequate rest.

Help the family understand that the time required for resolution of hypothyroidism varies. During this time the patient may continue to have mental slowness. Teach the family to orient the patient often and to explain everything clearly, simply, and as often as needed.

Teach the patient to monitor himself or herself for therapy effectiveness. The two easiest parameters to check are need for sleep and bowel elimination. When the patient requires more sleep and is constipated, the dose of replacement hormone may need to be increased. When the patient has difficulty getting to sleep and has more bowel movements than normal for him or her, the dose may need to be decreased.

#### Health Care Resources.

Immediately after returning home, the patient may need a support person to stay and provide day and night attention. Contact with the health care team is needed for follow-up and identification of potential problems. The patient taking thyroid drugs may have symptoms of hypothyroidism if the dosage is inadequate or symptoms of hyperthyroidism if the dose is too high. A home care nurse performs a focused assessment at every home visit for the patient with thyroid dysfunction (Chart 63-9).

#### Chart 63-9

### Focused Assessment

#### The Patient With Thyroid Dysfunction

Assess cardiovascular status:

- Vital signs, including apical pulse, pulse pressure, presence or absence of orthostatic hypotension, and the quality and rhythm of peripheral pulses
- Presence or absence of peripheral edema
- Weight gain or loss

Assess cognition and mental status:

- Level of consciousness
- Orientation to time, place, and person
- Ability to accurately read a seven-word sentence containing no words greater than three syllables
- Ability to count backward from 100 by 3s

Assess condition of skin and mucous membranes:

- Moistness of skin, most reliable on chest and back
- Skin temperature and color

Assess neuromuscular status:

- Reactivity of patellar and biceps reflexes
- Oral temperature
- Handgrip strength
- Steadiness of gait
- Presence or absence of fine tremors in the hand

Ask about:

- Sleep in the past 24 hours
- Patient warm enough or too warm indoors
- 24-hour diet recall
- 24-hour activity recall
- Over-the-counter and prescribed drugs taken
- Last bowel movement

Assess patient's understanding of illness and adherence with therapy:

- Symptoms to report to primary health care provider
- Drug therapy plan (correct timing and dose)

#### ◆ **Evaluation: Reflecting**

Evaluate the care of the patient with hypothyroidism based on the identified priority patient problems. The expected outcomes are that with proper management the patient should:

- Maintain normal cardiovascular function
- Maintain adequate respiratory function and GAS EXCHANGE
- Experience improvement in thought processes

### **Clinical Judgment Challenge 63-1**

#### **Patient-Centered Care; Safety** QSEN

A patient diagnosed with moderate hypothyroidism 1 week ago is brought for follow-up to the clinic by her adult daughter. The patient seems confused. Her heart rate is 88 and thready. Her blood pressure is 102/84. Respirations are 26 and shallow. When you check her oxygen saturation, it is 85%. The patient seems confused, so you direct your questions to the daughter. When asked whether her mother has been taking her prescribed thyroid hormone replacement, she replies, "Yes, and I have been increasing it daily to make her better faster."

1. What assessment should you perform next? Provide a rationale for your choice.
2. Should you apply oxygen? Why or why not?
3. Is this situation an emergency? Why or why not?
4. When the time is appropriate, what will you tell the daughter about her mother's drug therapy?

## Thyroiditis

### ❖Pathophysiology

**Thyroiditis** is an inflammation of the thyroid gland. There are three types: acute, subacute, and chronic. Chronic thyroiditis (Hashimoto's disease) is the most common type.

*Acute thyroiditis* is caused by bacterial invasion of the thyroid gland. Symptoms include pain, neck tenderness, malaise, fever, and dysphagia (difficulty swallowing). It usually resolves with antibiotic therapy.

*Subacute or granulomatous thyroiditis* results from a viral infection of the thyroid gland after a cold or other upper respiratory infection. Symptoms include fever, chills, dysphagia, and muscle and joint pain. Pain can radiate to the ears and the jaw. The thyroid gland feels hard and enlarged on palpation. Thyroid function can remain normal, although hyperthyroidism or hypothyroidism may develop.

*Chronic thyroiditis* (Hashimoto's disease) is a common type of hypothyroidism that affects women more often than men. Hashimoto's disease is an autoimmune disorder that is usually triggered by a bacterial or viral infection. The thyroid is invaded by antithyroid antibodies and lymphocytes, causing selective thyroid tissue destruction. When large amounts of the gland are destroyed, serum thyroid hormone levels are low, and secretion of thyroid-stimulating hormone (TSH) is increased.

### ❖Interprofessional Collaborative Care

Symptoms of Hashimoto's disease include dysphagia and painless enlargement of the gland. Diagnosis is based on circulating antithyroid antibodies and needle biopsy of the thyroid gland. Serum thyroid hormone levels and TSH levels vary with disease stage.

The patient is given thyroid hormone to prevent hypothyroidism and to suppress TSH secretion, which decreases the size of the thyroid gland. Surgery (subtotal thyroidectomy) is needed if the goiter does not respond to thyroid hormone, is disfiguring, or compresses other structures. Nursing interventions focus on promoting comfort and teaching the patient about hypothyroidism, drugs, and surgery.

## Thyroid Cancer

### ❖Pathophysiology

The four distinct types of thyroid cancer are papillary, follicular, medullary, and anaplastic (American Cancer Society, 2017; Canadian Cancer Society, 2016). The initial sign of thyroid cancer is a single, painless lump or nodule in the thyroid gland. Additional signs and symptoms depend on the presence and location of **metastasis** (spread of cancer cells).

*Papillary carcinoma*, the most common type of thyroid cancer, occurs most often in younger women. It is a slow-growing tumor that can be present for years before spreading to nearby lymph nodes. When the tumor is confined to the thyroid gland, the chance for cure is good with a partial or total thyroidectomy.

*Follicular carcinoma* occurs most often in older adults. It invades blood vessels and spreads to bone and lung tissue. When it adheres to the trachea, neck muscles, great vessels, and skin, **dyspnea** (difficulty breathing) and **dysphagia** (difficulty swallowing) result. When the tumor involves the recurrent laryngeal nerves, the patient may have a hoarse voice.

*Medullary carcinoma* is most common in patients older than 50 years. It often occurs with multiple endocrine neoplasia (MEN) type 2, a familial endocrine disorder (OMIM, 2014). The tumor usually secretes a variety of hormones.

*Anaplastic carcinoma* is a rapidly growing, aggressive tumor that invades nearby tissues. Symptoms include stridor (harsh, high-pitched respiratory sounds), hoarseness, and dysphagia.

A hallmark of thyroid cancer is an elevated serum thyroglobulin (Tg) level. The normal Tg level is 0.5 to 53.0 ng/mL (mcg/L) for men and 0.5 to 43.0 ng/mL (mcg/L) for women.

### ❖ **Interprofessional Collaborative Care**

Radiation therapy is used most often for anaplastic carcinoma because this cancer has usually metastasized at diagnosis. The patient is treated with **ablative** (enough to destroy the tissue) amounts of RAI. (See [Chart 63-4](#) for precautions to teach the patient receiving unsealed RAI therapy.) If spread has occurred to the neck or mediastinum, external radiation is also used. If thyroid cancer does not respond to RAI, chemotherapy is initiated.

Surgery is the treatment of choice for other types of thyroid cancer. A total thyroidectomy is usually performed with dissection of lymph nodes in the neck if regional lymph nodes are involved. (See the postoperative care discussion in the Surgical Management section for Hyperthyroidism.) Suppressive doses of thyroid hormone are usually taken for 3 months after surgery. Thyroglobulin levels are monitored after surgery. A rising level indicates probable presence of cancer cells.

The patient is hypothyroid after treatment for thyroid cancer. Nursing interventions then focus on teaching him or her about the management of hypothyroidism. (See the discussion of patient-centered collaborative care in the Hypothyroidism section.)

# Parathyroid Disorders

## Hyperparathyroidism

### ❖ Pathophysiology

The parathyroid glands maintain calcium and phosphate balance (see Fig. 61-6). Serum calcium level is normally maintained within a narrow range. Increased levels of parathyroid hormone (PTH) act directly on the kidney, causing increased kidney reabsorption of calcium and increased phosphorus excretion. In hyperparathyroidism, these processes cause *hypercalcemia* (excessive calcium) and *hypophosphatemia* (inadequate phosphorus).

In bone, excessive PTH levels increase bone *resorption* (bone loss of calcium) by decreasing *osteoblastic* (bone production) activity and increasing *osteoclastic* (bone destruction) activity. This process releases calcium and phosphorus into the blood and reduces bone density. With chronic calcium excess and hypercalcemia, calcium is deposited in soft tissues.

Although the exact trigger is unknown, primary hyperparathyroidism results when one or more parathyroid glands do not respond to the normal feedback of serum calcium levels. The most common cause is a benign tumor in one parathyroid gland. Table 63-3 lists other causes.

**TABLE 63-3**  
**Causes of Parathyroid Dysfunction**

Causes of Hyperparathyroidism	Causes of Hypoparathyroidism
<ul style="list-style-type: none"><li>• Parathyroid tumor or cancer</li><li>• Congenital hyperplasia</li><li>• Neck trauma or radiation</li><li>• Vitamin D deficiency</li><li>• Chronic kidney disease with hypocalcemia</li><li>• Parathyroid hormone-secreting carcinomas of the lung, kidney, or GI tract</li></ul>	<ul style="list-style-type: none"><li>• Surgical or radiation-induced thyroid ablation</li><li>• Parathyroidectomy</li><li>• Congenital dysgenesis</li><li>• Idiopathic (autoimmune) hypoparathyroidism</li><li>• Hypomagnesemia</li></ul>

### ❖ Interprofessional Collaborative Care

#### ◆ Assessment: Noticing

Symptoms of hyperparathyroidism may be related to the effects of either excessive PTH or the accompanying hypercalcemia.

Ask about any bone fractures, recent weight loss, arthritis, or psychological stress. Ask whether the patient has received radiation treatment to the head or neck. The patient with chronic disease may have a waxy pallor of the skin and bone deformities in the extremities and back.

High levels of PTH cause kidney stones and deposits of calcium in the soft tissue of the kidney. Bone lesions are caused by an increased rate of bone destruction and may result in fractures, bone cysts, and osteoporosis.

GI problems (e.g., anorexia, nausea, vomiting, epigastric pain, constipation, weight loss) are common when serum calcium levels are high. Elevated serum gastrin levels are caused by hypercalcemia and lead to peptic ulcer disease. Fatigue and lethargy may be present and worsen as the serum calcium levels increase. When serum calcium levels are greater than 12 mg/dL (3.0 mmol/L), the patient may have psychosis with confusion, followed by coma and death if left untreated. (See Chapter 11 for more information about hypercalcemia.)

Serum PTH, calcium, and phosphorus levels and urine cyclic adenosine monophosphate (cAMP) levels are the laboratory tests used to detect hyperparathyroidism (Chart 63-10). X-rays may show kidney stones, calcium deposits, and bone lesions. Loss of bone density occurs in the patient with chronic hyperparathyroidism. Other diagnostic tests include arteriography, (CT scans, venous sampling of the thyroid for blood PTH levels, and ultrasonography). Explain the procedures and care for the patient undergoing diagnostic tests.

#### Chart 63-10

### Laboratory Profile

#### Parathyroid Function

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS	
		HYPERPARATHYROIDISM	HYPOPARATHYROIDISM
Serum calcium	Total: 9.0-10.5 mg/dL (2.25-2.75 mmol/L) units Ionized (active): 4.5-5.6 mg/dL (1.05-1.30 mmol/L)	Increased in primary hyperparathyroidism	Decreased
Serum phosphorus	3.0-4.5 mg/dL (0.97-1.45 mmol/L) <i>Older adults:</i> May be slightly lower	Decreased	Increased
Serum magnesium	1.8-2.6 mEq/L (0.74-1.07 mmol/L)	Increased	Decreased
Serum parathyroid hormone	C-terminal: 50-330 pg/mL (ng/L) N-terminal: 8-25 pg/mL (ng/L) Whole: 10-65 pg/mL (ng/L)	Increased	Decreased
Vitamin D (calciferol)	25-80 ng/mL (75-200 nmol/L)	Variable	Decreased
Urine cAMP	18.3-45.4 nmol/L in a 24-hour urine collection specimen	Increased	Decreased

cAMP, Cyclic adenosine monophosphate.

Pagana, K., Pagana, T., & Pike-MacDonald, S. (2013). *Mosby's Canadian manual of diagnostic and laboratory tests*. St. Louis: Mosby; and Pagana, K., Pagana, T.J., & Pagana, T.N. (2017). *Mosby's diagnostic and laboratory test reference* (13th ed.). St. Louis: Mosby.

### ◆ Interventions: Responding

Surgical management is the treatment of choice for patients with hyperparathyroidism. For those who are not candidates for surgery, drug therapy can help control the problems. Priority nursing interventions focus on monitoring and preventing injury.

#### Nonsurgical Management.

*Diuretic and hydration therapies* help reduce serum calcium levels in patients who have milder disease. Usually furosemide (Lasix, Uritol 🍀), a diuretic that increases kidney excretion of calcium, is used along with IV saline in large volumes to promote calcium excretion.

Drug therapy for patients who have more severe symptoms of hyperparathyroidism or who have hypercalcemia related to parathyroid cancer involves the use of cinacalcet (Sensipar), a calcimimetic. When taken orally, the drug binds to calcium-sensitive receptors on parathyroid tissue, reducing PTH production and release. The result is decreased serum calcium levels, stabilization of other minerals, and decreased progression of PTH-induced bone complications. The patient's serum calcium must be monitored for hypocalcemia on a regular basis for the duration of therapy.

For patients who do not respond to cinacalcet, oral phosphates are used to inhibit bone resorption and interfere with calcium absorption. IV phosphates are used only when serum calcium levels must be lowered rapidly. Calcitonin decreases the release of skeletal calcium and increases kidney excretion of calcium. It is not effective when used alone because of its short duration of action. Therapeutic effects are enhanced if calcitonin is given with glucocorticoids.

*Monitor* cardiac function and intake and output every 2 hours during hydration therapy. Continuous cardiac monitoring may be necessary. Compare recent ECG tracings with the patient's baseline tracings. Especially look for changes in the T waves and the QT interval, as well as changes in the rate and rhythm. Monitor serum calcium levels and immediately report any sudden drop to the primary health care provider. Sudden drops in calcium levels may cause tingling and numbness in the muscles.

*Preventing injury* is important because the patient with chronic hyperparathyroidism often has significant bone density loss and is at risk for fractures. Teach unlicensed assistive personnel (UAP) to handle the patient carefully and to use a lift sheet to reposition the patient rather than pulling him or her.

#### Surgical Management.

Surgical management of hyperparathyroidism is a parathyroidectomy. Before surgery the patient is stabilized, and calcium levels are decreased to near normal.

The operative procedure can be performed as minimally invasive surgery or mini-incision surgery or with a traditional transverse incision in the lower neck. All four parathyroid glands are examined for enlargement. If a tumor is present on one side but the other side is normal, the surgeon removes the glands containing tumor and leaves the remaining glands on the opposite side intact. If all four glands are diseased, they are all removed.

Nursing care before and after surgical removal of the parathyroid glands is the same as that for thyroidectomy. See the Preoperative Care and Postoperative Care sections of hyperthyroidism for specific nursing interventions.

The remaining glands, which may have atrophied as a result of PTH overproduction, require

several days to several weeks to return to normal function. A hypocalcemic crisis can occur during this critical period, and the serum calcium level is assessed frequently after surgery. Check serum calcium levels whenever they are drawn until calcium levels stabilize. Monitor for indications of hypocalcemia, such as tingling and twitching in the extremities and face. Check for Trousseau's and Chvostek's signs, either of which indicates potential tetany (see [Figs. 11-13](#) and [11-14](#)).

The recurrent laryngeal nerve can be damaged during surgery. Assess the patient for changes in voice patterns and hoarseness.

When hyperparathyroidism is caused by *hyperplasia* (tissue overgrowth), three glands plus half of the fourth gland are usually removed. If all four glands are removed, a small portion of a gland may be implanted in the forearm, where it produces PTH and maintains calcium homeostasis. If all these maneuvers fail, the patient will need lifelong treatment with calcium and vitamin D because the resulting hypoparathyroidism is permanent (see next section).

## Hypoparathyroidism

### ❖ Pathophysiology

Hypoparathyroidism is a rare disorder in which parathyroid function is decreased. Problems are directly related to a lack of parathyroid hormone (PTH) secretion or to decreased effectiveness of PTH on target tissue. Whether the problem is a lack of PTH secretion or an ineffectiveness of PTH on tissues, the result is the same: *hypocalcemia*.

*Iatrogenic hypoparathyroidism*, the most common form, is caused by the removal of all parathyroid tissue during total thyroidectomy or surgical removal of the parathyroid glands.

*Idiopathic hypoparathyroidism* can occur spontaneously. The exact cause is unknown, but an autoimmune basis is suspected, and it may occur with other autoimmune disorders.

*Hypomagnesemia* (decreased serum magnesium levels) may cause hypoparathyroidism. Low magnesium levels are seen in patients with malabsorption syndromes, chronic kidney disease, and malnutrition. Low magnesium levels suppress PTH secretion and may interfere with the effects of PTH on the bones, kidneys, and calcium regulation.

### ❖ Interprofessional Collaborative Care

#### ◆ Assessment: Noticing

Ask about any head or neck surgery or radiation therapy because these treatments may injure the parathyroid glands and cause hypoparathyroidism. Also ask whether the neck has ever sustained a serious injury in a car crash or by strangulation. Assess whether the patient has any symptoms of hypoparathyroidism, which may range from mild tingling and numbness to muscle tetany. Tingling and numbness around the mouth or in the hands and feet reflect mild-to-moderate hypocalcemia. Severe muscle cramps, spasms of the hands and feet, and seizures (with no loss of consciousness or incontinence) reflect a more severe hypocalcemia. The patient or family may notice mental changes ranging from irritability to psychosis.

The physical assessment may show excessive or inappropriate muscle contractions that cause finger, hand, and elbow flexion. This can signal an impending attack of tetany. Check for Chvostek's sign and Trousseau's sign; positive responses indicate potential tetany (see [Figs. 11-13](#) and [11-14](#)). Bands or pits may encircle the teeth, which indicates a loss of tooth calcium and enamel.

Diagnostic tests for hypoparathyroidism include electroencephalography (EEG), blood tests, and CT scans. EEG changes revert to normal with correction of hypocalcemia. Serum calcium, phosphorus, magnesium, vitamin D, and urine cyclic adenosine monophosphate (cAMP) levels may be used in the diagnostic workup for hypoparathyroidism (see [Chart 63-10](#)). The CT scan can show brain calcifications, which indicate chronic hypocalcemia.

#### ◆ Interventions: Responding

Nonsurgical management of hypoparathyroidism focuses on correcting hypocalcemia, vitamin D deficiency, and hypomagnesemia. For patients with acute and severe hypocalcemia, IV calcium is given as a 10% solution of calcium chloride or calcium gluconate over 10 to 15 minutes. Acute vitamin D deficiency is treated with oral calcitriol (Rocaltrol), 0.5 to 2 mg daily. Acute hypomagnesemia is corrected with 50% magnesium sulfate in 2-mL doses (up to 4 g daily) IV. Long-term oral therapy for hypocalcemia involves the intake of calcium, 0.5 to 2 g daily, in divided

doses.

Long-term therapy for vitamin D deficiency is 50,000 to 400,000 units of oral ergocalciferol daily. The dosage is adjusted to keep the patient's calcium level in the low-normal range (slightly hypocalcemic), enough to prevent symptoms of hypocalcemia. It must also be low enough to prevent increased urine calcium levels, which can lead to stone formation.

Nursing management includes teaching about the drug regimen and interventions to reduce anxiety. Teach the patient to eat food high in calcium but low in phosphorus. Milk, yogurt, and processed cheeses are avoided because of their high phosphorus content. *Stress that therapy for hypocalcemia is lifelong.* Advise the patient to wear a medical alert bracelet. With adherence to the prescribed drug and diet regimen, the calcium level usually remains high enough to prevent a hypocalcemic crisis.

## NCLEX Examination Challenge 63-4

### Safe and Effective Care Environment

The nurse reviewing the laboratory work of a client with hypoparathyroidism finds all the following blood values. For which value does the nurse immediately assess the client's reflexes?

- A. Sodium 131 mEq/L (mmol/L)
- B. Potassium 5.1 mEq/L (mmol/L)
- C. Calcium 7.8 mg/dL (1.76 mmol/L)
- D. pH 7.33

# Get Ready for the NCLEX<sup>®</sup> Examination

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Keep the environment of a patient at risk for thyroid storm cool, dark, and quiet. **QSEN: Safety**
- Keep emergency suctioning and tracheotomy equipment in the room of a patient who has had thyroid or parathyroid surgery. **QSEN: Safety**
- Use a lift sheet to move or reposition a patient with hypocalcemia. **QSEN: Safety**

### Health Promotion and Maintenance

- Teach all patients to take antithyroid drugs or thyroid hormone replacement therapy as prescribed. **QSEN: Patient-Centered Care**
- Teach patients to use signs and symptoms (e.g., the number of bowel movements per day, the ability to sleep) as indicators of therapy effectiveness and when the dose of thyroid hormone replacement may need to be adjusted. **QSEN: Patient-Centered Care**
- Include the person who prepares the patient's meals when teaching about dietary electrolyte restrictions. **QSEN: Patient-Centered Care**
- Collaborate with the registered dietitian to teach patients about diets that are restricted in calcium or phosphorus. **QSEN: Teamwork and Collaboration**

### Psychosocial Integrity

- Be accepting of patient behavior. **QSEN: Patient-Centered Care**
- Remind patients and family members that changes in cognition and behavior related to thyroid problems are usually temporary. **QSEN: Patient-Centered Care**
- Encourage the patient who has a permanent change in appearance (e.g., exophthalmia) to mourn the change. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Be aware that:
  - The presence of a goiter indicates a problem with the thyroid gland but can accompany either hyperthyroidism or hypothyroidism.
  - Although similar in action, methimazole and propylthiouracil are not interchangeable.
  - Methimazole can cause birth defects and should not be used during pregnancy, especially during the first trimester. Instruct women to notify their primary health care provider if pregnancy occurs.
- When stridor, dyspnea, or other symptoms of obstruction appear after thyroid surgery, notify the Rapid Response Team. **QSEN: Safety**
- When caring for a patient with hyperthyroidism, even after a thyroidectomy, immediately report a temperature increase of even 1° F because it may indicate an impending thyroid crisis. **QSEN: Evidence-Based Practice**
- Assess the cardiopulmonary status of any patient with hypothyroidism for decreased perfusion or decreased GAS EXCHANGE at least every 8 hours. **QSEN: Patient-Centered Care**
- Use sedating drugs or opioids sparingly with patients who have hypothyroidism. **QSEN: Patient-Centered Care**
- Monitor the hydration status of patients who have hypercalcemia. **QSEN: Patient-Centered Care**
- Assess the patient with hypoparathyroidism for manifestations of hypocalcemia, especially

numbness or tingling around the mouth and a positive Chvostek's sign or Trousseau's sign (see [Figs. 11-13](#) and [11-14](#)). **QSEN: Patient-Centered Care**

## CHAPTER 64

# Care of Patients With Diabetes Mellitus

Sandra Hendricks

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is GLUCOSE REGULATION.**

✚ The GLUCOSE REGULATION concept exemplar for this chapter is Diabetes Mellitus, below.

**The interrelated concepts for this chapter are:**

- NUTRITION
- TISSUE INTEGRITY
- SENSORY PERCEPTION
- PERFUSION
- IMMUNITY
- FLUID AND ELECTROLYTE BALANCE
- ACID-BASE BALANCE

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to coordinate high-quality care and promote GLUCOSE REGULATION in patients who have diabetes mellitus (DM).
2. Teach the patient and caregiver(s) about how impaired GLUCOSE REGULATION from DM and its complications affect home safety.
3. Prioritize evidence-based care for patients with common complications of DM affecting GLUCOSE REGULATION.

### Health Promotion and Maintenance

4. Identify community resources for patients with DM.
5. Teach adults how to decrease the risk for complications of DM.
6. Teach adults at risk for impaired GLUCOSE REGULATION how to prevent or delay development of type 2 DM.

### Psychosocial Integrity

7. Implement nursing interventions to help the patient and family cope with the psychosocial impact caused by DM and its complications.

### Physiological Integrity

8. Apply knowledge of pathophysiology to assess patients for problems associated with impaired GLUCOSE REGULATION and DM.
9. Implement evidence-based nursing interventions to improve GLUCOSE REGULATION and prevent complications of DM.
0. Teach the patient and caregiver(s) about common drugs and other therapies used to manage DM and its complications.
1. Implement evidence-based interprofessional collaborative care to manage patients experiencing hypoglycemia, ketoacidosis, or hyperglycemic-hyperosmolar state (HHS).

## Glucose Regulation Concept Exemplar Diabetes Mellitus

GLUCOSE REGULATION is the process of maintaining optimal blood glucose levels (Fig. 64-1) (Giddens, 2017). Diabetes mellitus (DM), once known as *sugar* diabetes, is a very common chronic endocrine disorder of impaired glucose regulation that affects the function of all cells and tissues. Complications of DM, especially hypertension and **hyperlipidemia** (high blood lipid levels), are responsible for many associated life-shortening health problems in the United States, Canada, and other affluent countries. Many adults have undiagnosed diabetes and, among those who are diagnosed, many continue to have high blood glucose levels. The complications of DM can be greatly reduced with **glycemic** (blood glucose) control along with management of hypertension and hyperlipidemia. Nursing priorities focus on helping the patient with DM achieve and maintain permanent lifestyle changes that keep blood glucose levels and cholesterol levels as close to normal as possible to slow or prevent long-term complications.

**FIG. 64-1** Fasting blood glucose levels. When GLUCOSE REGULATION is adequate, fasting levels remain in the normal range. With insufficient insulin usage, hyperglycemia results. Excess insulin or insufficient glucose results in hypoglycemia.

An interprofessional collaborative management approach helps the patient achieve desired outcomes successfully. In addition to primary health care providers, other professionals commonly involved in planning and providing continuing care for patients with diabetes include endocrinologists, diabetes educators, ophthalmologists, other medical practitioners, pharmacists, registered dietitians, podiatrists, physical therapists, wound care specialists, and home health nurses. As part of the team, you will help plan, organize, and coordinate care with other team members to promote the patient's health and well-being. These activities may take place in almost any setting.

### Pathophysiology

#### Classification of Diabetes

For all types of diabetes mellitus (DM), the main feature is chronic **hyperglycemia** (high blood glucose level) resulting from problems with GLUCOSE REGULATION that include reduced insulin secretion or reduced insulin action or both. The disease is classified by the underlying problem causing a lack of insulin or its action and the severity of the insulin deficiency. Table 64-1 outlines the types of DM.

**TABLE 64-1**

#### Classification of Diabetes Mellitus

Type 1 Diabetes (T1DM)
<ul style="list-style-type: none"> <li>• Beta-cell destruction leading to absolute insulin deficiency</li> <li>• Autoimmune</li> <li>• Idiopathic</li> </ul>

<b>Type 2 Diabetes (T2DM)</b>
• Ranges from insulin resistance with relative insulin deficiency to secretory deficit with insulin resistance
<b>Other Conditions Resulting in Hyperglycemia</b>
• Genetic defects of beta-cell function
• Genetic defects in insulin action
• Pancreatic diseases (pancreatitis, trauma, cancer, cystic fibrosis, hemochromatosis)
• Endocrine problems (acromegaly, Cushing's disease, hyperthyroidism, aldosteronism)
• Drug- or chemical-induced hyperglycemia
• Infections: congenital rubella, cytomegalovirus, human immune deficiency virus
• Genetic syndromes associated with diabetes: Down syndrome, Klinefelter syndrome, Turner syndrome, Huntington disease, and others
<b>Gestational Diabetes Mellitus (GDM)</b>
• Glucose intolerance with onset or first recognition during pregnancy. (All pregnant women should be screened.)

## The Endocrine Pancreas

The pancreas has both endocrine and exocrine functions. The exocrine functions are related to digestion, and endocrine functions ensure blood GLUCOSE REGULATION. The endocrine portion of the pancreas has about 1 million small glands, the islets of Langerhans, scattered through the organ. The islet cells are only a small portion of the gland, and most of the pancreatic tissue is devoted to the production and delivery of digestive acids. Inside the islet cells are two types of cells important to glucose regulation. These are the *alpha* cells, which secrete glucagon, and the *beta* cells, which produce insulin and amylin. **Glucagon** is a “counterregulatory” hormone that has actions opposite those of insulin. It prevents *hypoglycemia* (low blood glucose levels) by triggering the release of glucose from storage sites in the liver and skeletal muscle. Insulin prevents *hyperglycemia* by allowing body cells to take up, use, and store carbohydrate, fat, and protein.

Active insulin is a protein made up of 51 amino acids. It is initially produced as inactive *proinsulin*, a prohormone that contains an additional amino acid chain (the C-peptide chain). Proinsulin is converted in the liver to active insulin by removal of the C-peptide (**Fig. 64-2**).

**FIG. 64-2** Proinsulin, secreted by and stored in the beta cells of the islets of Langerhans in the pancreas, is transformed by the liver into active insulin. Insulin attaches to receptors on target cells, where it promotes glucose transport into the cells through the cell membranes.

Insulin is secreted daily directly into liver circulation in a two-step manner. It is secreted at low levels during fasting (basal insulin secretion) and in a two-phase release after eating (**prandial**). An early burst of insulin secretion occurs within 10 minutes of eating, followed by an increasing release

that lasts until the blood glucose level has returned to normal.

## Glucose Regulation and Homeostasis

As stated earlier, GLUCOSE REGULATION is the process of maintaining optimal blood glucose levels. Although glucose is a critical nutrient, chronically high blood glucose levels cause many serious problems, and low blood glucose levels can rapidly lead to death. Thus maintaining blood glucose levels within a relatively normal range is important for health (see Fig. 64-2). Several organs and hormones play a role in maintaining glucose regulation. During fasting, when the stomach is empty, blood glucose is maintained between 60 and 150 mg/dL (3.3 and 8.3 mmol/L) by a balance between glucose uptake by cells and glucose production by the liver. Insulin plays a pivotal role in this process.

Glucose is the main fuel for central nervous system (CNS) cells. Because the brain cannot produce or store much glucose, it needs a continuous supply from the blood to prevent neuron dysfunction and cell death. Other organs can use both glucose and fatty acids to generate energy. Glucose is stored as glycogen in the liver and skeletal muscles, and free fatty acids are stored as triglyceride in fat cells. During a prolonged fast or after illness, proteins are broken down, and some of the amino acids are converted into glucose.

Movement of glucose into most cells requires the presence of specific membrane receptors along with insulin. Insulin is like a “key” that opens “locked” membranes to glucose, allowing blood glucose to move into cells to generate energy. Insulin starts this action by binding to membrane insulin receptors, which changes membrane permeability to glucose.

Insulin exerts many effects on metabolism and cellular processes in all tissues and organs. The main metabolic effects of insulin are to stimulate glucose uptake in skeletal muscle and heart muscle and to suppress liver production of glucose and very-low-density lipoprotein (VLDL). In the liver, insulin promotes the production and storage of glycogen (**glycogenesis**) at the same time that it inhibits glycogen breakdown into glucose (**glycogenolysis**). It increases protein and lipid (fat) synthesis and inhibits **ketogenesis** (conversion of fats to acids) and **gluconeogenesis** (conversion of proteins to glucose). In muscle, insulin promotes protein and glycogen synthesis. In fat cells, it promotes triglyceride storage. Overall, insulin keeps blood glucose levels from becoming too high and helps keep blood lipid levels in the normal range.

In the *fasting state* (not eating for 8 hours), insulin secretion is suppressed, which leads to increased gluconeogenesis in the liver and kidneys, along with increased glucose generation by the breakdown of liver glycogen. In the fed state, insulin released from pancreatic beta cells reverses this process. Instead, glycogen breakdown and gluconeogenesis are inhibited. At the same time, insulin also enhances glucose uptake and use by cells and reduces both fat breakdown (**lipolysis**) and protein breakdown (**proteolysis**). When more glucose is present in liver cells than can be used for energy or stored as glycogen, insulin causes the excess glucose to be converted to free fatty acids (FFAs). These extra FFAs are deposited in fat cells.

Glucose in the blood after a meal is controlled by the emptying rate of the stomach and delivery of nutrients to the small intestine, where they are absorbed into circulation. Incretin hormones (e.g., GLP-1), secreted in response to food in the stomach, have several actions. They increase insulin secretion, inhibit glucagon secretion, and slow the rate of gastric emptying, thereby preventing hyperglycemia after meals.

Counterregulatory hormones increase blood glucose by actions opposite those of insulin when more energy is needed. Glucagon is the main counterregulatory hormone. Other hormones that increase blood glucose levels are epinephrine, norepinephrine, growth hormone, and cortisol. The combined actions of insulin and counterregulatory hormones (discussed in the next section) participate in GLUCOSE REGULATION and keep blood glucose levels in the range of 60 to 100 mg/dL (3.3 to 5.6 mmol/L) to support brain function. When blood glucose levels fall, insulin secretion stops and glucagon is released. Glucagon causes glucose release from the liver. Liver glucose is made through breakdown of glycogen to glucose (glycogenolysis) and conversion of amino acids into glucose. When liver glucose is unavailable, the breakdown of fat (lipolysis) and the breakdown of proteins (proteolysis) provide fuel for energy.

## NCLEX Examination Challenge 64-1

### Physiological Integrity

Which physiologic actions result from normal insulin secretion? **Select all that apply.**

- A. Increased liver storage of glucose as glycogen
- B. Increased gluconeogenesis
- C. Increased cellular uptake of blood glucose
- D. Increased breakdown of lipids (fats) for fuel
- E. Increased production and release of epinephrine
- F. Decreased storage of free fatty acids in fat cells
- G. Decreased blood glucose levels
- H. Decreased blood cholesterol levels

### Absence of Insulin

Insulin for GLUCOSE REGULATION is needed to move glucose into many body tissues. The lack of insulin in diabetes, from either a lack of production or a problem with insulin use at its cell receptor, prevents some cells from using glucose for energy. The body then breaks down fat and protein in an attempt to provide energy and increases levels of counterregulatory hormones to make glucose from other sources. [Table 64-2](#) outlines responses to insufficient insulin.

**TABLE 64-2**

#### Physiologic Response to Insufficient Insulin

- |  |
|--|
| <ul style="list-style-type: none"><li>• Decreased glycogenesis (conversion of glucose to glycogen)</li><li>• Increased glycogenolysis (conversion of glycogen to glucose)</li><li>• Increased gluconeogenesis (formation of glucose from noncarbohydrate sources such as amino acids and lactate)</li><li>• Increased lipolysis (breakdown of triglycerides to glycerol and free fatty acids)</li><li>• Increased ketogenesis (formation of ketones from free fatty acids)</li><li>• Proteolysis (breakdown of protein with amino acid release in muscles)</li></ul> |
|--|

Without insulin, glucose builds up in the blood, causing **hyperglycemia** (high blood glucose levels). Hyperglycemia disturbs FLUID AND ELECTROLYTE BALANCE, leading to the classic symptoms of diabetes: polyuria, polydipsia, and polyphagia.

**Polyuria** is frequent and excessive urination and results from an osmotic diuresis caused by excess glucose in the urine. With diuresis, electrolytes are excreted in the urine, and water loss is severe. Dehydration results, and **polydipsia** (excessive thirst) occurs. Because the cells receive no glucose, cell starvation triggers **polyphagia** (excessive eating). Despite eating, the adult with diabetes remains in metabolic starvation until insulin is available to move glucose into the cells.

With insulin deficiency, the body turns to stored fat for energy, releasing free fatty acids. When this stored fat is used for energy, *ketone bodies* (small acids) provide a backup energy source. **Ketone bodies** (“ketones”) are abnormal breakdown products that collect in the blood when insulin is not available, leading to the ACID-BASE BALANCE problem of metabolic acidosis.

Dehydration with DM leads to *hemoconcentration* (increased blood concentration); *hypovolemia* (decreased blood volume); poor tissue PERFUSION; and *hypoxia* (poor tissue oxygenation), especially to the brain. Hypoxic cells do not metabolize glucose efficiently, the Krebs' cycle is blocked, and lactic acid production increases, causing more acidosis.

The excess acids caused by absence of insulin increase hydrogen ion (H<sup>+</sup>) and carbon dioxide (CO<sub>2</sub>) levels in the blood, causing anion-gap metabolic acidosis. These products trigger the brain to increase the rate and depth of respiration in an attempt to “blow off” carbon dioxide and acid. This type of breathing is known as **Kussmaul respiration**. Acetone is exhaled, giving the breath a “rotting citrus fruit” odor. When the lungs can no longer offset acidosis, the blood pH drops. Arterial blood gas studies show a metabolic acidosis (decreased pH with decreased arterial bicarbonate [ $\text{HCO}_3^-$ ] levels) and compensatory respiratory alkalosis (decreased partial pressure of arterial carbon dioxide [ $\text{PaCO}_2$ ]).

Insulin lack initially causes potassium depletion. With the increased fluid loss from

hyperglycemia, excessive potassium is excreted in the urine, leading to low serum potassium levels. High serum potassium levels may occur in acidosis because of the shift of potassium from inside the cells to the blood. Serum potassium levels in DM, then, may be low (**hypokalemia**), high (**hyperkalemia**), or normal, depending on hydration, the severity of acidosis, and the patient's response to treatment. [Chapter 12](#) discusses ACID-BASE BALANCE and acidosis in more detail.

### Acute Complications of Diabetes

Three glucose-related emergencies can occur in patients with diabetes (DM):

- Diabetic ketoacidosis (DKA) caused by absence of insulin and generation of ketoacids
- Hyperglycemic-hyperosmolar state (HHS) caused by insulin deficiency and profound dehydration
- Hypoglycemia from too much insulin or too little glucose

*All three problems require emergency treatment and can be fatal if treatment is delayed or incorrect. These problems and their interventions are described later in this chapter.*

### Chronic Complications of Diabetes

Diabetes mellitus (DM) can lead to organ complications and early death because of changes in large blood vessels (*macrovascular*) and small blood vessels (*microvascular*) in tissues and organs. These blood vessel changes lead to complications from poor tissue PERFUSION and cell ischemia.

Macrovascular complications include coronary heart disease, cerebrovascular disease, and peripheral vascular disease, all of which lead to early morbidity and mortality. Microvascular complications of blood vessel structure and function lead to **nephropathy** (kidney dysfunction), **neuropathy** (nerve dysfunction), and **retinopathy** (vision problems). Such problems are responsible for increased morbidity and reduced quality of life. Causes of these diabetic vascular complications include:

- Chronic hyperglycemia thickens basement membranes, which causes organ damage.
- Glucose toxicity directly or indirectly affects functional cell integrity.
- Chronic ischemia in small blood vessels causes connective tissue hypoxia and micro-ischemia.

Chronic high blood glucose levels are the main cause of microvascular complications and allow premature development of macrovascular complications. Additional risk factors contributing to poor health outcomes for adults with DM include smoking, physical inactivity, obesity, hypertension, and high blood fat and cholesterol levels ([Frank & Gerhardt, 2015](#)). Many of these factors can be modified to reduce complications related to DM.

Hyperglycemia from poor GLUCOSE REGULATION leads to long-term complications of DM. Intensive therapy to maintain blood glucose levels as close to normal as possible delays the onset and progression of retinopathy, nephropathy, neuropathy, and macrovascular disease for patients with DM. For every percentage point decrease in A1C (glycosylated hemoglobin A1C), a 35% reduction of kidney and eye complications has been shown ([ADA, 2014a](#)).

### Macrovascular Complications

#### Cardiovascular Disease.

Patients with diabetes, prediabetes, or metabolic syndrome are at increased risk for cardiovascular disease (CVD) ([McCance et al., 2014](#)). This risk affects women to a greater degree than men and is influenced by the patient's ethnic group. DM is a “coronary heart disease risk equivalent” and a target for aggressive reduction of risk factors.

Patients with DM often have the traditional CVD risk factors of obesity, high blood lipid levels, hypertension, and sedentary lifestyle. Cigarette smoking and a positive family history also increase risk for CVD. Kidney disease, indicated by **albuminuria** (presence of albumin in the urine), and retinopathy are markers of increased risk for coronary heart disease and mortality from coronary artery disease. Patients with DM often have higher levels of C-reactive protein (CRP), an inflammatory marker associated with increased risk for cardiovascular inflammation and death.

Cardiovascular complication rates can be reduced through aggressive management of hyperglycemia, hypertension, and hyperlipidemia. The American Diabetes Association (ADA) recommends that blood pressure (BP) be measured at every routine visit and confirmed on a

separate day if elevated. The ADA also recommends that BP be maintained below 140/90 mm Hg, with a target of 130/80 in younger adults if that level can be achieved without excessive burden. Lipid profile screening is recommended at first diagnosis, at the initial medical evaluation, and/or at the age of 40 years and every 1 to 2 years thereafter. Patients with DM who do not have overt CVD are recommended to maintain low-density lipoprotein (LDL) cholesterol below 100 mg/dL (2.60 mmol/L), and patients with indications of CVD are recommended to maintain LDLs at less than 70 mg/dL (1.8 mmol/L) (ADA, 2017a). Lifestyle modifications that focus on reducing saturated fat, *trans* fat, and cholesterol intake; increasing intake of omega-3 fatty acids, fiber, and plant sterols; weight loss (if indicated); and increasing physical activity are recommended to improve the lipid profile for patients with DM (ADA, 2017a).

Priority nursing actions focus on interventions to reduce modifiable risk factors associated with CVD, such as smoking cessation, diet, exercise, blood pressure control, maintaining prescribed aspirin use, and maintaining prescribed lipid-lowering drug therapy. Teach patients to report subtle indications of ischemia, such as dyspnea with or without cough, extreme fatigue, and sudden onset of nausea and vomiting, to their primary health care provider for evaluation.

### Cerebrovascular Disease.

The risk for stroke is two to four times higher in adults with DM compared with those who do not have the disease (McCance et al., 2014). Diabetes also increases the likelihood of severe carotid atherosclerosis. Hypertension, hyperlipidemia, nephropathy, peripheral vascular disease, and alcohol and tobacco abuse further increase the risk for stroke in adults with DM.

DM also affects stroke outcomes. Patients with DM are likely to suffer brain injury with carotid emboli that produce only transient ischemic attacks in adults without DM. Elevated blood glucose levels at the time of the stroke may lead to greater brain injury and higher mortality from the event.

### Reduced Immunity.

The combination of vascular changes and hyperglycemia reduce IMMUNITY by reducing white blood cell activity, inhibiting gas exchange in tissues, and promoting the growth of microorganisms. As a result, any adult who has DM is at an increased risk for developing an infection on exposure to bacteria and other organisms. In addition, infections become serious more quickly and can lead to major complications and sepsis (McCance et al., 2014).

## Microvascular Complications

### Eye and Vision Complications.

Legal blindness (a corrected visual acuity of 20/200 or less) is 25 times more common in patients with DM (National Institute of Diabetes and Digestive and Kidney Diseases [NIDDKD], 2014). Diabetic retinopathy (DR) is strongly related to the duration of diabetes. After 20 years of DM, nearly all patients with the disease have some degree of retinopathy (ADA, 2014a). Unfortunately, DR has few symptoms until vision loss occurs.

The cause and progression of DR are related to problems that block retinal blood vessels and cause them to leak, leading to retinal hypoxia. Nonproliferative diabetic retinopathy causes structural problems in retinal vessels, including areas of poor retinal circulation, edema, hard fatty deposits in the eye, and retinal hemorrhages. Fluid and blood leak from the retinal vessels and cause retinal edema and hard exudates. Nonproliferative DR develops slowly and rarely reduces vision to the point of blindness.

**Proliferative diabetic retinopathy** is the growth of new retinal blood vessels, also known as *neovascularization*. When retinal blood flow is poor and hypoxia develops, retinal cells secrete vascular endothelial growth factors that stimulate formation of new blood vessels in the eye. These new vessels are thin, fragile, and bleed easily, leading to vision loss.

Other retinal problems are optic nerve atrophy from hypoxia and *venous beading*, which is the abnormal appearance of retinal veins with areas of swelling and constriction that resemble links of sausage. Venous beading occurs in areas of retinal ischemia.

Visual SENSORY PERCEPTION loss from DR has several mechanisms. Central vision may be impaired by macular edema, characterized by increased blood vessel permeability and deposits of hard exudates at the center of the retina. This problem is the main cause of vision loss in the adult with DM. Injections of ranibizumab (Lucentis) or aflibercept (Eylea) into the vitreous monthly can

improve vision for some adults with macular edema. Vision loss also occurs from macular degeneration, corneal scarring, and changes in lens shape or clarity.

Hyperglycemia may cause blurred vision, even with eyeglasses. Because hypoglycemia can cause temporary vision changes, it is important to wait until blood glucose levels are normal before assessing for refractory changes. Cataracts occur at a younger age and progress faster among patients with DM. Open-angle glaucoma also is more common in patients with DM. The management of cataracts and glaucoma is discussed in [Chapter 47](#).

Control of blood glucose, blood pressure, and blood lipid level is important in preventing DR. Thus patients with DM should have routine ophthalmic evaluations to detect vision problems early before vision loss occurs. The ADA recommends eye-care examinations with an ophthalmologist every year after an adult has been diagnosed with type 2 diabetes and yearly for an adult who has had type 1 diabetes for more than 5 years. The silent nature of many eye problems causes some adults with DM to not recognize the importance of annual screenings.

## Considerations for Older Adults

### Patient-Centered Care QSEN

The older patient with diabetic retinopathy also has general age-related vision changes, and the ability to perform self-care may be seriously affected. He or she may have blurred vision, distorted central vision, fluctuating vision, loss of color perception, and mobility problems resulting from loss of depth perception. When a patient has visual changes, it is especially important to assess his or her ability to measure and inject insulin and to monitor blood glucose levels to determine if adaptive devices are needed to assist in self-management (Touhy & Jett, 2016).

### Diabetic Peripheral Neuropathy.

**Diabetic peripheral neuropathy** (DPN) is a progressive deterioration of nerve function that results in loss of **SENSORY PERCEPTION**. It is a common complication of DM and often involves all parts of the body. Damage to sensory nerve fibers results in pain followed by loss of sensation. Damage to motor nerve fibers results in muscle weakness. Damage to nerve fibers in the autonomic nervous system can cause dysfunction in every part of the body. The combination of factors leading to the nerve damage in diabetic neuropathy are:

- Hyperglycemia, long duration of DM, hyperlipidemia
- Damaged blood vessels leading to reduced neuronal oxygen and other nutrients
- Autoimmune neuronal inflammation
- Increased genetic susceptibility to nerve damage
- Smoking and alcohol use

Hyperglycemia leads to DPN through blood vessel changes and reduced tissue **PERFUSION** that cause nerve hypoxia. Both the axon and its myelin sheath are damaged by reduced blood flow, resulting in blocked nerve impulse transmission. Excessive glucose is converted to sorbitol, which collects in nerves and impairs motor nerve conduction (McCance et al., 2014). Common diabetic neuropathies are listed in [Table 64-3](#).

**TABLE 64-3**

### Features of Diabetic Neuropathy

COMPLICATION		SYMPTOM
<b>Diffuse Neuropathies</b>		
Distal symmetric polyneuropathy	Sensory alterations	Paresthesias: burning/tingling sensations, starting in toes and moving up legs Dysesthesias: burning, stinging, or stabbing pain Anesthesia: loss of sensation
	Motor alterations in intrinsic muscles of foot	Foot deformities: high arch, claw toes, hammertoes; shift of weight bearing to metatarsal heads and tips of toes
Autonomic neuropathy	Anhidrosis	Drying, cracking of skin
	Gastrointestinal	Delayed gastric emptying, gastric retention, early satiety, bloating, nausea, vomiting, anorexia, constipation, diarrhea, diffuse sweating while eating Nocturnal diarrhea
	Neurogenic bladder	Atonic bladder, urinary retention
	Impotence	Erectile dysfunction
	Cardiovascular autonomic neuropathy	Early fatigue, weakness with exercise, orthostatic hypotension
Defective counterregulation	Loss of warning signs of hypoglycemia	
<b>Focal Neuropathies</b>		
Focal ischemia	Thoracolumbar radiculopathy with sensory and reflex loss	Pain radiating across back, side, and front of chest or abdomen

Cranial nerve palsies, third and sixth nerves	Sudden diplopia or ptosis; eye pain
Amyotrophy	Pain; asymmetric weakness; wasting of iliopsoas, quadriceps, and adductor muscles

Diabetic neuropathy can be focal or diffuse. *Diffuse neuropathies* are the most common neuropathies in DM and involve widespread nerve function loss and SENSORY PERCEPTION loss. The onset is slow, affects both sides of the body, involves motor and sensory nerves, progresses slowly, and is permanent. Late complications include foot ulcers and deformities.

*Focal neuropathies* in DM affect a single nerve or nerve group and usually are caused by an acute ischemic event that leads to nerve damage or nerve death. Ischemic neuropathies occur when the blood supply to a nerve or nerve group is disrupted. Symptoms begin suddenly, affect only one side of the body area, and are self-limiting. The most common neuropathies affect the nerves that control the eye muscles. Symptoms begin with pain on one side of the face near the affected eye. The eye muscles become paralyzed, resulting in double vision. The problem usually resolves in 2 to 3 months.

### Diabetic Autonomic Neuropathy.

Cardiovascular autonomic neuropathy (CAN) affects sympathetic and parasympathetic nerves of the heart and blood vessels. This problem contributes to left ventricular dysfunction, painless myocardial infarction, and exercise intolerance. Most often, CAN leads to **orthostatic** (postural) hypotension and **syncope** (brief loss of consciousness on standing). These problems are from failure of the heart and arteries to respond to position changes by increasing heart rate and vascular tone. As a result, blood flow to the brain is interrupted briefly. Orthostatic hypotension and syncope increase the risk for falls, especially among older adults.

Autonomic neuropathy can affect the entire GI system. Common GI problems from diabetic neuropathy include gastroesophageal reflux, delayed gastric emptying and gastric retention, early satiety, heartburn, nausea, vomiting, and anorexia. Sluggish movement of the small intestine can lead to bacterial overgrowth, which causes bloating, gas, and diarrhea. Diarrhea caused by DM is chronic, may be severe, and often occurs at night. Constipation, the most common GI problem with DM, is intermittent and may alternate with bouts of diarrhea. **Gastroparesis** (delay in gastric emptying) is a cause of hypoglycemia related to the mismatch of nutrient absorption and insulin action.

Urinary problems from neuropathy result in incomplete emptying and urine retention, which leads to urinary infection and kidney problems. Early symptoms include frequency and urgency. Later symptoms include an inability to sense bladder fullness and incontinence.

## NCLEX Examination Challenge 64-2

### Health Promotion and Maintenance

Which precaution is **most important** for the nurse to teach a client who has cardiovascular autonomic neuropathy (CAN) from diabetes?

- A. "Avoid drinking ice-cold beverages."
- B. "Be sure to check your blood pressure twice daily."
- C. "Change positions slowly when moving from sitting to standing."
- D. "Check your hands and feet weekly for areas of numbness or sensation change."

### Diabetic Nephropathy.

**Nephropathy** is a pathologic change in the kidney that reduces kidney function and leads to kidney failure. Diabetes is the leading cause of end-stage kidney disease (ESKD) and kidney failure in the United States (NIDDKD, 2014). Risk factors include a 10- to 15-year history of DM, poor blood glucose control, uncontrolled hypertension, and genetic predisposition. The onset of diabetic kidney disease may be prevented, and the progression to ESKD can be delayed by maintaining optimum blood GLUCOSE REGULATION, keeping blood pressure within the normal ranges, and using drug therapy to protect the kidneys (ADA, 2017b). Drugs used to protect the kidneys in patients who meet specific criteria are the angiotensin-converting enzyme inhibitors (ACEIs) and the angiotensin

receptor blockers (ARBs).

Kidney disease causes progressive albumin excretion and declining glomerular filtration rate (GFR). Annual testing for urine albumin is recommended for patients who have had type 1 DM for at least 5 years and in everyone with type 2 DM (ADA, 2017b).

Chronic high blood glucose levels cause hypertension in kidney blood vessels and excess kidney tissue PERFUSION. The increased pressure damages the kidney in many ways. The blood vessels become leakier, especially in the glomerulus. This leakiness allows filtration of albumin and other proteins, which then form deposits in the kidney tissues and blood vessels. Blood vessels narrow, decreasing kidney oxygenation and leading to kidney cell hypoxia and cell death. These processes worsen over time, with scarring of glomerular blood vessels and loss of urine filtration ability, leading to chronic kidney disease (see Chapter 68 for a detailed presentation of chronic kidney disease and end-stage kidney disease).

Kidney damage is also related to hypertension for patients with DM and cardiovascular disease. Both systolic and diastolic hypertension speed the progression of diabetic nephropathy.

### Sexual Dysfunction.

Both men and women with diabetes can develop sexual dysfunction as a result of damage to both nerve tissue and vascular tissue. This is made worse by poorly controlled blood glucose levels. Other factors include obesity, hypertension, tobacco use, and some prescribed drugs.

In men sexual dysfunction is manifested by both erectile dysfunction (ED) and retrograde ejaculation. Women may experience decreased vaginal lubrication, uncomfortable or painful sexual intercourse, and decreases in libido and sexual response.

### Cognitive Dysfunction.

Adults age 65 or older with DM are at a significantly higher risk for developing all types of dementia compared with adults who do not have the disease (ADA, 2017h). Chronic hyperglycemia with microvascular disease contributes to neuron damage, brain atrophy, and cognitive impairment. These problems are more frequent and more severe in patients with longer-duration DM and increase the complications of neuropathy and retinopathy. Depression is highly prevalent in adults with diabetes and is associated with worse outcomes.

## Etiology and Genetic Risk

### Type 1 Diabetes.

Type 1 diabetes mellitus (DM) is an autoimmune disorder in which beta cells are destroyed in a genetically susceptible person (Table 64-4). The immune system fails to recognize normal body cells as “self,” and immune system cells and antibodies take destructive actions against the insulin-secreting cells in the islets. People with certain tissue types are more likely to develop autoimmune diseases, including type 1 DM. Viral infections, such as mumps and coxsackie virus infection, may trigger autoimmune destructive actions (McCance et al., 2014).

**TABLE 64-4**  
**Differentiation of Type 1 and Type 2 Diabetes**

Features	Type 1	Type 2
Former names	Juvenile-onset diabetes Ketosis-prone diabetes Insulin-dependent diabetes mellitus (IDDM)	Adult-onset diabetes Ketosis-resistant diabetes Non-insulin-dependent diabetes mellitus (NIDDM)
Age at onset	Usually younger than 30 yr	May occur at any age in adults
Symptoms	Abrupt onset, thirst, hunger, increased urine output, weight loss	Frequently none; thirst, fatigue, blurred vision, vascular or neural complications
Etiology	Viral infection, autoimmunity	Not known
Pathology	Pancreatic beta-cell destruction	Insulin resistance Dysfunctional pancreatic beta cell
Antigen patterns	HLA-DR, HLA-DQ	None
Antibodies	Present at diagnosis	None
Endogenous insulin and C-peptide	None	Low, normal, or high
Inheritance	Complex	Autosomal-dominant, multifactorial
Nutritional status	Usually nonobese	60% to 80% obese
Insulin	All dependent on insulin	Required for 20% to 30%
Medical therapy	Mandatory	Mandatory

## Genetic/Genomic Considerations

## Evidence-Based Practice QSEN

Risk for type 1 DM is determined by inheritance of genes coding for the HLA-DR and HLA-DQA and DQB tissues types (McCance et al., 2014). However, inheritance of these genes only increases the risk, and most people with these genes do not develop type 1 DM. Development of DM is an interactive effect of genetic predisposition and exposure to certain environmental factors. When assessing adults, always ask whether any family members have been diagnosed with either type 1 or type 2 diabetes.

### Type 2 Diabetes and Metabolic Syndrome.

Type 2 DM is a progressive disorder in which the person initially has insulin resistance that progresses to decreased beta cell secretion of insulin. *Insulin resistance* (a reduced cell response to insulin) develops from obesity and physical inactivity in a genetically susceptible adult. It occurs before the onset of type 2 DM and often is accompanied by the cardiovascular risk factors of hyperlipidemia, hypertension, and increased clot formation. Many but not all patients with type 2 DM are obese. The specific causes of type 2 DM are not known, although insulin resistance and beta-cell failure have many genetic and nongenetic causes. Heredity plays a major role in the development of type 2 DM, although not all gene variations that increase the risk for type 2 DM are known.

**Metabolic syndrome** is the simultaneous presence of metabolic factors known to increase risk for developing type 2 DM and cardiovascular disease (Frazer, 2015). Features of the syndrome include:

- Abdominal obesity: waist circumference of 40 inches (100 cm) or more for men and 35 inches (88 cm) or more for women
- Hyperglycemia: fasting blood glucose level of 100 mg/dL or more or on drug treatment for elevated blood glucose levels
- Hypertension: systolic BP of 130 mm Hg or more or diastolic blood pressure of 85 mm Hg or more or on drug treatment for hypertension
- Hyperlipidemia: triglyceride level of 150 mg/dL or more or on drug treatment for elevated triglycerides; high-density lipoprotein (HDL) cholesterol less than 40 mg/dL for men or less than 50 mg/dL for women

Any one of these health problems increases the rate of atherosclerosis and the risk for stroke, coronary heart disease, and early death. Teach patients about the lifestyle changes that can improve health. (See the [Health Promotion and Maintenance](#) section.)

## Veterans' Health Considerations

### Patient-Centered Care QSEN

A suggestive risk factor for type 2 DM independent of other risk factors is exposure to the main component of agent orange, dioxin, which was used during the military conflicts in Korea and Vietnam. The risk for type 2 diabetes appears higher among U.S. military personnel deployed in those geographic areas. The risk increases with higher exposures (United States Department of Veterans Affairs, 2016). Development of DM among veterans who served in areas where agent orange was used occurs at earlier ages and with less obesity.

Assess veterans who were exposed to agent orange at every health care encounter for subtle indications of diabetes so the disease can be identified early and interventions implemented to prevent or delay complications. Also encourage them to use DM prevention strategies of maintaining a healthy weight and engaging in regular physical activity.

### Incidence and Prevalence

In the United States, more than 29 million people are living with DM, and 27.8% (8.1 million) are undiagnosed. Another 86 million have prediabetes (CDC, 2016). (**Prediabetes** is defined as impaired fasting glucose [IGF] or impaired glucose tolerance [IGT]. Over a 3- to 5-year period, adults with prediabetes have a 5-fold to 15-fold higher risk for developing type 2 DM than do those with normal blood glucose levels.). In Canada, nearly 2 million adults have diabetes, which represents

about 6% of the population (Statistics Canada, 2015).

About 90% to 95% of adults with diabetes have type 2 DM (CDC, 2016). It can be diagnosed even in preadolescents but is most often diagnosed among middle-age and older adults, affecting about 12.3% of adults over the age of 20 years and 25.9% of adults 65 years or older (Touhy & Jett, 2016). It is more common among men than women (CDC, 2015). With the prevalence of obesity rising in North America, diabetes will become even more common.

## Cultural/Spiritual Considerations

### Patient-Centered Care QSEN

Racial and ethnic minorities have a higher prevalence and greater burden of DM compared with non-Hispanic whites, and some minority groups also have higher rates of complications. The rate of DM is 13% among African Americans and 12.8% in the Hispanic population compared with non-Hispanic white Americans. At nearly 16.1%, American Indians and Alaska Indians have the highest age-adjusted prevalence of DM among U.S. racial and ethnic groups (CDC, 2015). *The increase in obesity and sedentary lifestyles in the North American population intensifies this growing problem. The ADA has identified patients who should be tested for diabetes in Table 64-5.*

**TABLE 64-5**

### Indications for Testing People for Type 2 Diabetes

- Testing for diabetes is considered at any age in adults with a BMI greater than 25 kg/m<sup>2</sup> (or greater than 23 kg/m<sup>2</sup> in Asian Americans) with one or more of these additional risk factors:
- Have a first-degree relative with diabetes
- Are physically inactive
- Are members of a high-risk ethnic population (e.g., African American, Hispanic American, American Indian, or Pacific Islander)
- Have a baby weighing more than 9 lb or have been diagnosed with GDM
- Are hypertensive (>140/90 mm Hg)
- Have a high-density lipoprotein (HDL) cholesterol level less than 35 mg/dL (0.90 mmol/L) and/or a triglyceride level greater than 250 mg/dL (2.82 mmol/L)
- Have polycystic ovary syndrome
- Have A1C greater than 5.7%, or IFG or IGT on previous testing
- Have a history of vascular disease
- If the tested adult has normal glucose values at this time but other conditions and risk factors remain the same, testing should be repeated at 3-year intervals.

*BMI*, Body mass index; *GDM*, gestational diabetes mellitus; *IFG*, impaired fasting glucose; *IGT*, impaired glucose tolerance.

Data from American Diabetes Association (ADA). (2017). Classification and diagnosis of diabetes. *Diabetes Care*, 40(Suppl. 1), S11-S24; and American Diabetes Association (ADA). (2017). Standards of medical care in diabetes—2017: Prevention or delay of type 2 diabetes. *Diabetes Care*, 40(Suppl. 1), S44-S47.

The outcomes for minority patients with diabetes is worse than for non-Hispanic whites with DM. Factors for these outcome differences include lack of access to health care, lifestyle issues, mistrust of the health care system, reduced financial resources, and lack of knowledge about GLUCOSE REGULATION and complications. Be alert to the risk for DM whenever you are interviewing or assessing adults who belong to these higher-risk groups.

## Health Promotion and Maintenance

Diabetes mellitus (DM) causes many preventable but devastating complications and is a major health problem. Control of DM and its complications is a major focus for health promotion activities. No interventions prevent type 1 DM, but health promotion activities that focus on controlling hyperglycemia can reduce its long-term complications.

Adopting a healthy lifestyle that includes a low-calorie diet and increasing physical activity with weight loss improves metabolic and cardiac risk factors (Watts & Howard, 2016). These improvements include reducing hypertension, increasing heart rate variability between resting rate and exercise rate, lowering triglyceride levels, increasing high-density lipoprotein cholesterol (“good” cholesterol) levels, and reducing low-density lipoprotein cholesterol (“bad” cholesterol) levels.

Teach all patients with DM that tight control of blood glucose levels can prevent many complications. Urge them to regularly follow up with their primary health care provider or endocrinologist, to have their eyes and vision tested yearly by an ophthalmologist, and to have urine albumin levels assessed yearly. Early detection of changes in the eye or kidney permits adjustments in treatment regimens that can slow or halt progression of retinopathy and nephropathy. Encourage all adults to maintain weight within an appropriate range for height and

body build and to engage in physical activity at least 150 minutes per week ([American Association of Diabetes Educators \[AADE\], 2015](#)).

## ❖ Interprofessional Collaborative Care

Although adults who have DM are often hospitalized for complications of the disease, diagnosis and management generally occur in a clinic or health care provider's office. Much of the essential teaching about management is performed in the community as is the overall management of the disorder. Because DM is a chronic disorder, you can expect to interact with and care for these patients in any health care setting.

### ◆ Assessment: Noticing

#### History.

Ask about risk factors and symptoms related to DM. Age is important because, although type 2 DM is more common in older patients, it is now being diagnosed increasingly in younger adults. Ask women how large their children were at birth, because many women who develop type 2 DM had gestational diabetes mellitus (GDM) or glucose intolerance during pregnancy (ADA, 2017b). Women with a history of GDM and found to have prediabetes should receive education on lifestyle interventions to prevent DM (ADA, 2017b).

Assessing weight and weight change is important, because excess weight and obesity are risk factors for type 2 DM. The patient with type 1 DM often has weight loss with increased appetite during the weeks before diagnosis. For both types of DM, patients usually have fatigue, polyuria, and polydipsia. Ask about recent major or minor infections and assess overall IMMUNITY. In particular, ask women about frequent vaginal yeast infections. Ask all patients whether they have noticed that small skin injuries become infected more easily or take longer to heal. Also ask whether they have noticed any changes in vision or in the sense of touch. Determine whether the patient is up-to-date on his or her immunizations.

#### Laboratory Assessment

##### Diagnosis of Diabetes.

Diabetes can be diagnosed by assessing blood glucose levels. The ADA defines normal blood glucose values in Chart 64-1. A test result indicating DM should be repeated to rule out laboratory error unless symptoms of hyperglycemia or hyperglycemic crisis are also present. Table 64-6 lists criteria for the diagnosis of DM.

### Chart 64-1

## Laboratory Profile

### Blood Glucose Values

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL RESULTS
Fasting blood glucose test	<100 mg/dL (5.6 mmol/L) Older adults: Levels rise 1 mg/dL per decade of age	Levels >100 mg/dL (5.6 mmol/L) but <126 mg/dL (7.0 mmol/L) indicate impaired fasting glucose (IFG). Levels >126 mg/dL (7.0 mmol/L) obtained on at least two occasions are diagnostic of diabetes, even in older adults.
Glucose tolerance test (2-hr post-load result)	<140 mg/dL (7.8 mmol/L)	Levels >140 mg/dL (7.8 mmol/L) and <200 mg/dL (11.1 mmol/L) indicate impaired glucose tolerance (IGT). Levels >200 mg/dL (11.1 mmol/L) indicate provisional diagnosis of diabetes.
Glycosylated hemoglobin (A1C) test	4%-6%	Levels of 5.7% to 6.4% indicate increased risk for development of diabetes. Levels >6.5% indicate diabetes. Levels >8% indicate poor diabetes control and need for adherence to regimen or changes in therapy.

Data from Pagana, K., Pagana, T.J., & Pagana, T.N. (2017). *Mosby's diagnostic and laboratory test reference* (13th ed.). St. Louis: Mosby; and Pagana, K., Pagana, T., & Pike-MacDonald, S. (2013). *Mosby's Canadian manual of diagnostic and laboratory tests*. St. Louis: Mosby.

**TABLE 64-6**

#### Criteria for the Diagnosis of Diabetes

A1C >6.5%. The test should be performed in a laboratory using a method that is NGSP

certified and standardized to the DCCT assay.

**Or**

Fasting blood glucose greater than or equal to 126 mg/dL (7.0 mmol/L). *Fasting* is defined as no caloric intake for at least 8 hours.

**Or**

Two-hour blood glucose equal to or greater than 200 mg/dL (11.1 mmol/L) during oral glucose tolerance test. The test should be performed using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.

**Or**

In a patient with classic manifestations of hyperglycemia or hyperglycemic crisis, a random blood glucose concentration greater than 200 mg/dL (11.1 mmol/L). *Casual* is defined as any time of the day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.

**NOTE:** In the absence of unequivocal hyperglycemia, the first three criteria should be confirmed by repeat testing.

DCCT, Diabetes Control and Complications Trial; NGSP, National Glycohemoglobin Standardization Program.

Data from American Diabetes Association (ADA). (2017). Classification and diagnosis of diabetes. *Diabetes Care*, 40(Suppl. 1), S11-S24.

The diagnosis of DM includes elevated glycosylated hemoglobin levels. **Glycosylated hemoglobin (A1C)** is a standardized test that measures how much glucose permanently attaches to the hemoglobin molecule. Because glucose binds to many proteins, including hemoglobin, through a process called *glycosylation*, the higher the blood glucose level is over time, the more glycosylated hemoglobin becomes. The ADA defines A1C levels greater than or equal to 6.5% as diagnostic of DM (ADA, 2017b).

*Fasting plasma glucose (FPG)* (fasting blood glucose [FBG]) can be used to diagnose DM in nonpregnant adults. The patient should have no caloric intake for at least 8 hours (water is permitted). A diagnosis of DM is made with two separate test results greater than 126 mg/dL (7 mmol/L) (ADA, 2017b). *Random* or *casual plasma* glucose greater than 200 mg/dL (7.0 mmol/L) is used to diagnose DM in patients with classic hyperglycemia symptoms or hyperglycemic crisis.

*Oral glucose tolerance testing (OGTT)* is a sensitive test for the diagnosis of DM. It is often used to diagnose gestational diabetes mellitus (GDM) during pregnancy and is not routinely used for general diagnosis.

*Other blood tests for diabetes* can help determine whether a patient has type 1 or type 2 DM. Type 1 DM results from autoimmune destruction of the beta cells of the pancreas. Markers of this destruction include islet cell autoantibodies (ICAs), autoantibodies to insulin, and autoantibodies to glutamic acid decarboxylase (GAD65). ICAs are present in 85% to 90% of patients with new-onset type 1 DM (McCance et al., 2014).

Measurement of C-peptide levels indicates beta secretory function of the pancreas. Low-to-absent C-peptide levels diagnose type 1 DM as well as late-stage type 2 DM when the ability of the pancreas to secrete insulin is severely impaired.

### Screening for Diabetes.

Testing to detect prediabetes and type 2 DM should be considered in patients older than 45 years and those defined as overweight (BMI greater than 25 kg/m<sup>2</sup>) (Touhy & Jett, 2016). Testing is considered for patients who are younger than 45 years and are overweight if they have additional risk factors for DM or other health problems associated with it. Screening for DM usually is done with either hemoglobin A1C levels or fasting plasma glucose levels (ADA, 2017b). The use of portable glucose meters for the diagnosis of DM is *not* recommended for screening because of imprecise results and variance in results among the different glucose monitors.

### Ongoing Assessment.

*Glycosylated hemoglobin assays* are useful as a good indicator of the average blood glucose levels. Measurement of A1C shows the average blood glucose level during the previous 120 days—the life

span of red blood cells. A1C testing can help assess long-term glycemic control and predict the risk for complications. *Unlike the fasting blood glucose test, A1C test results are not altered by eating habits the day before the test.* This testing is performed at diagnosis and at specific intervals to evaluate the treatment plan. A1C testing is recommended at least twice yearly in patients who are meeting expected treatment outcomes and have stable blood glucose control. Quarterly assessment is recommended for patients whose therapy has changed or who are not meeting prescribed glycemic levels (ADA, 2017d). Table 64-7 shows the correlation between A1C and mean blood glucose levels.

**TABLE 64-7**  
**Correlation Between A1C Level and Mean Blood Glucose Levels**

MEAN BLOOD GLUCOSE		
A1C (%)	mg/dL	mmol/L
6	126	7.0
7	154	8.6
8	183	10.2
9	212	11.8
10	240	13.4
11	269	14.9
12	298	16.5

*Fructosamine assays* are useful for short-term follow-up of treatment changes or in patients with hemoglobin abnormalities in which A1C does not accurately reflect glucose levels. When glucose binds to amino groups on serum proteins, especially albumin, the glycosylated protein product is called *fructosamine*. This product increases with elevated blood glucose levels like hemoglobin does but can indicate blood glucose control over a shorter period.

## NCLEX Examination Challenge 64-3

### Physiological Integrity

The laboratory values of a client who has diabetes mellitus include a fasting blood glucose level of 82 mg/dL (mmol/L) and hemoglobin A1C of 5.9%. What is the nurse's interpretation of these findings?

- A. The client's glucose control for the past 24 hours has been good, but the overall control is poor.
- B. The client's glucose control for the past 24 hours has been poor, but the overall control is good.
- C. The values indicate that the client has poorly managed his or her disease.
- D. The values indicate that the client has managed his or her disease well.

#### ◆Analysis: Interpreting

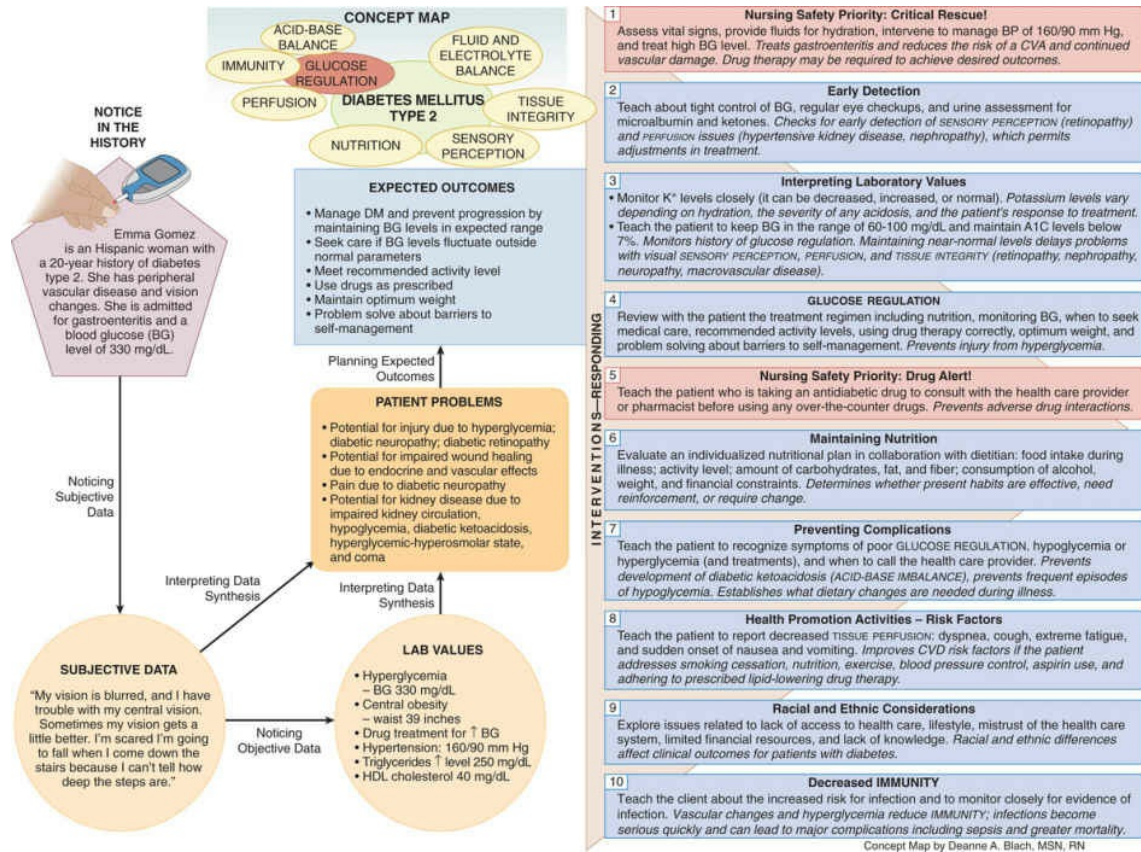

The priority collaborative problems for patients with diabetes DM include:

1. Potential for injury due to hyperglycemia
2. Potential for impaired wound healing due to endocrine and vascular effects of diabetes
3. Potential for injury due to diabetic neuropathy
4. Pain due to diabetic neuropathy
5. Potential for injury due to diabetic retinopathy–induced reduced vision
6. Potential for kidney disease due to impaired kidney circulation
7. Potential for hypoglycemia
8. Potential for diabetic ketoacidosis

## 9. Potential for hyperglycemic-hyperosmolar state and coma

### ◆ Planning and Implementation: Responding

The management of diabetes mellitus (DM) is complex and involves extensive patient education. The Concept Map highlights care issues for the patient with type 2 DM.

## Preventing Injury From Hyperglycemia

### Planning: Expected Outcomes.

The patient is expected to manage DM and prevent disease progression by maintaining blood glucose levels in his or her target range. Indicators are that the patient consistently demonstrates these behaviors:

- Performs treatment regimen as prescribed
- Follows recommended diet
- Monitors blood glucose using correct testing procedures
- Seeks health care if blood glucose levels fluctuate outside of recommended parameters
- Meets recommended activity levels
- Follows prescribed drug regimen
- Reaches and maintains optimum body weight
- Problem solves about barriers to self-management

### Interventions

### Nonsurgical Management.

Management of DM involves NUTRITION interventions, blood glucose monitoring, a planned exercise

program, and often drugs to lower blood glucose levels. The nurse and other interprofessional team members (e.g., primary health care provider, dietitian, pharmacist, case manager), along with the patient, plan, coordinate, and deliver care.

The American Diabetes Association (ADA) has proposed these treatment outcomes for glycosylated hemoglobin (A1C) and blood glucose levels (ADA, 2017d):

- A1C levels are maintained at 7.0% or below. A lower goal may be recommended for patients who can achieve a lower goal without adverse effects. A less stringent goal may be needed for patients who have hypoglycemic unawareness, advanced microvascular or macrovascular disease, or a limited life expectancy.
- The majority of premeal blood glucose levels are 70 to 130 mg/dL (3.9 to 7.2 mmol/L).
- Peak after-meal blood glucose levels are less than 180 mg/dL (< 10.0 mmol/L).

### Drug Therapy.

Drug therapy is indicated when a patient with type 2 DM does not achieve blood glucose control with diet changes, regular exercise, and stress management. Several categories of drugs are available to lower blood glucose levels. Patients with type 1 DM require insulin therapy for blood glucose control.

Drugs are started at the lowest effective dose and increased every 1 to 2 weeks until the patient reaches desired blood glucose control or the maximum dosage. If the maximum dosage of one agent does not control blood glucose levels, a second agent with a different mechanism of action may be added. Insulin therapy is indicated for the patient with type 2 DM when blood glucose goals cannot be met with the use of two or three different antidiabetic agents.

*Antidiabetic drugs are not a substitute for dietary modification and exercise.* Teach the patient about the need for continuing dietary changes and regular exercise while taking antidiabetic drugs.

## Nursing Safety Priority QSEN

### Drug Alert

To avoid drug interactions, teach the patient who is taking an antidiabetic drug to consult with his or her primary health care provider or pharmacist before using *any* over-the-counter drugs.

### Drug Selection.

The choice of antidiabetic drug is based on cost, the patient's ability to manage multiple drug dosages, age, and response to the drugs. Shorter-acting agents (e.g., glitinides) are preferable in older patients, those with irregular eating schedules, or those with liver, kidney, or cardiac dysfunction. Longer-acting agents (e.g., glyburide, glimepiride) with once-a-day dosing are better for adherence. Beta-cell function in type 2 DM often declines over time, reducing the effectiveness of some drugs. The treatment regimen for patients with type 2 DM may eventually require insulin therapy either alone or with other antidiabetic drugs.

### Antidiabetic Drugs.

Some antidiabetic drugs are oral agents, and others require subcutaneous injection. [Chart 64-2](#) lists common antidiabetic drugs in each category.

### Chart 64-2

## Common Examples of Drug Therapy

### Diabetes Mellitus

DRUG CATEGORY	NURSING IMPLICATIONS
<b>Insulin Stimulators (Secretagogues)</b>	These drugs lower blood glucose levels by triggering the release of preformed insulin from beta cells.
Second-Generation Sulfonylurea Agents (Oral)	Teach patients the signs and symptoms of hypoglycemia (hunger, headache, tremors, sweating, confusion) <i>because these drugs lower blood glucose levels even when hyperglycemia is not present.</i> Instruct patients to take these drugs with or just before meals <i>to prevent hypoglycemia.</i>
<ul style="list-style-type: none"> <li>• Glipizide (Glucotrol)</li> <li>• Glyburide (Diabeta),</li> </ul>	Instruct patients taking a sulfonylurea to check with his or her primary health care provider or a pharmacist before taking any over-the-counter drug or supplement <i>because these drugs interact with many other drugs.</i> Warn patients that nausea, headache, and weight gain are common side effects of these drugs <i>because knowing the expected side effects decreases anxiety when they appear.</i>

Micronase) • Glimepiride (Amaryl)	
Meglitinide Analogs (Oral)	
• Repaglinide (Prandin) • Nateglinide (Starlix)	
<b>Biguanides</b> —These drugs lower blood glucose levels by inhibiting liver glucose production, decreasing intestinal absorption of glucose, and increasing insulin sensitivity.	
• Metformin (Glucophage)	Instruct patients not to drink alcoholic beverages while taking this drug to <i>reduce the risk for lactic acidosis</i> . Remind patients that this drug must be discontinued before certain imaging tests using contrast agents and not started again for 48 hours after testing because of the <i>increased risk for kidney damage and lactic acidosis</i> . Warn patients that diarrhea, nausea, flatulence, indigestion, and abdominal pain are common side effects of this drug class because <i>knowing the expected side effects decreases anxiety when they appear</i> .
<b>Insulin Sensitizers</b> —These drugs lower blood glucose levels by decreasing liver glucose production and improving the sensitivity of insulin receptors.	
Thiazolidinediones (TZDs) (Oral)	Teach patients with any cardiovascular disease to weigh themselves daily and report a weight gain of more than 2 lb (1 kg) in one day or 4 lb (2 kg) in a week to the primary health care provider because <i>this class of drugs increases the risk for heart failure</i> . These drugs carry a black box warning from the FDA and are not to be given to <i>anyone with symptomatic heart failure</i> . Instruct patients to report vision changes immediately because <i>these drugs increase the risk for macular edema</i> . Warn women about an increased risk for bone fractures because <i>these drugs decrease bone density in women</i> . Warn patients that weight gain and peripheral edema are common side effects of this drug class because <i>knowing the expected side effects decreases anxiety when they appear</i> .
• Pioglitazone (Actos) • Rosiglitazone (Avandia)	
<b>Alpha-Glucosidase Inhibitors</b> —These oral drugs prevent after-meal hyperglycemia by inhibiting enzymes in the intestinal tract from breaking down starches into glucose. This action delays the digestion of starches and the absorption of glucose from the small intestine.	
• Acarbose (Precose) • Miglitol (Glyset)	Teach patients to take these drugs only with a meal because the action is in the intestinal tract. If a meal is skipped, so is the drug. Warn patients that abdominal discomfort and bloating, flatulence, nausea, diarrhea, and indigestion are common side effects of this drug class because <i>knowing the expected side effects decreases anxiety when they appear</i> .
<b>Incretin Mimetics (GLP-1 Agonists)</b> —These drugs act like natural “gut” hormones that work with insulin to lower blood glucose levels by reducing pancreatic glucagon secretion; reducing liver glucose production; and delaying gastric emptying, which slows the rate of nutrient absorption into the blood.	
• Albiglutide (Tanzeum) • Dulaglutide (Trulicity) • Exenatide (Byetta) • Exenatide extended-release (Bydureon) • Liraglutide (Victoza) • Lixisenatide (Adlyxin)	Teach patients the signs and symptoms of hypoglycemia (hunger, headache, tremors, sweating, confusion) because <i>these drugs lower blood glucose levels even when they are not elevated</i> . Instruct patients how to inject themselves because <i>these drugs are only available as subcutaneous formulations</i> . Teach patients to inspect injection sites for redness, warmth, or hard nodules because <i>injection site reactions are common</i> . Instruct patients to read exenatide, albiglutide, and dulaglutide pens carefully because <i>the extended-release form is only injected weekly (compared with others given at least daily)</i> . <i>Injecting the extended-release form daily may cause serious harm</i> . Teach patients to report persistent abdominal pain and nausea to the health care provider because <i>these drugs increase the risk for pancreatitis</i> .
<b>DPP-4 Inhibitors</b> —DPP-4 is an enzyme that breaks down the natural gut hormones (GLP-1 and GIP). DPP-4 inhibitors are oral agents that prevent the enzyme DPP-4 from breaking down the natural gut hormones (GLP-1 and GIP), which then allows these natural substances to work with insulin to lower glucagon secretion from the pancreas, leading to reduced liver glucose production. These oral drugs also reduce blood glucose levels by delaying gastric emptying, slowing the rate of nutrient absorption into the blood, and reducing food intake.	
• Alogliptin (Nesina) • Linagliptin (Tradjenta) • Saxagliptin (Onglyza) • Sitagliptin (Januvia)	Teach patients the signs and symptoms of hypoglycemia (hunger, headache, tremors, sweating, confusion) because <i>these drugs lower blood glucose levels even when hyperglycemia is not present</i> . Instruct patients to be alert and observe for rash or other sign of allergic reaction because <i>this class of drugs is associated with a moderate incidence of drug allergy</i> . Teach patients to report persistent abdominal pain and nausea to the primary health care provider because <i>these drugs increase the risk for pancreatitis</i> .
<b>Amylin Analogs</b> —These drugs are similar to amylin, a naturally occurring hormone from beta cells in the pancreas that is co-secreted with insulin and lowers blood glucose levels by decreasing endogenous glucagon, delaying gastric emptying and triggering satiety.	
• Pramlintide (Symlin)	Teach patients the signs and symptoms of hypoglycemia (hunger, headache, tremors, sweating, confusion) because <i>these drugs lower blood glucose levels even when hyperglycemia is not present</i> . Instruct patients how to inject themselves because <i>these drugs are only available as subcutaneous formulations</i> . Teach patients to inspect injection sites for redness, warmth, or hard nodules because <i>injection site reactions are common</i> . Warn patients that nausea and vomiting are common side effects of this drug class because <i>knowing the expected side effects decreases anxiety when they appear</i> .
<b>Sodium-Glucose Cotransport Inhibitors</b> —These oral drugs lower blood glucose levels by preventing kidney reabsorption of glucose and sodium that was filtered from the blood into the urine. This filtered glucose is excreted in the urine rather than moved back into the blood.	
• Canagliflozin (Invokana) • Dapagliflozin (Farxiga) • Empagliflozin (Jardiance)	Teach patients the signs and symptoms of hypoglycemia (hunger, headache, tremors, sweating, confusion) because <i>these drugs lower blood glucose levels even when they are not elevated</i> . Teach patients the signs and symptoms of dehydration (increased thirst, light-headedness, dry mouth and mucous membranes, orthostatic hypotension) because <i>these drugs increase urine output and increase dehydration risk</i> . Teach patients the signs and symptoms of hyponatremia (muscle weakness, decreased ability to concentrate, abdominal cramping, rapid heart rate, orthostatic hypotension) because <i>these drugs increase sodium excretion</i> . Teach patients the signs and symptoms of urinary tract infection (frequency, pain and burning on urination, foul urine odor) because <i>the increased glucose in the urinary tract predisposes to infection</i> . Instruct women to be alert for genital itching and vaginal discharge because <i>these drugs increase the risk for genital yeast infection</i> .
<b>Combination Products</b> —Many fixed combinations of oral drugs are available. Each ingredient has the same mechanism of action and nursing implications as the parent drug class. When a drug that has the side effect of hypoglycemia is combined with a drug that does not alone produce hypoglycemia, the development of hypoglycemia is still very much a risk for the combination agent.	

FDA, Food and Drug Administration.

## Insulin Stimulators.

Insulin stimulators (also known as insulin secretagogues) stimulate insulin release from pancreatic beta cells and are used for patients who are still able to produce insulin. Drugs in this class include the sulfonylureas and the meglitinide analogs.

*Sulfonylurea agents* lower fasting blood glucose levels by triggering the release of insulin from beta cells. Many drugs interact with sulfonylureas. Be sure to consult a drug reference book or pharmacist when instructing patients who are prescribed a drug from this class.

*Meglitinide analogs* are insulin secretagogues and have actions and adverse effects similar to those of sulfonylureas. They tend to increase meal-related insulin secretion.

## Biguanides.

Metformin (Glucophage) does not increase insulin secretion. It decreases liver glucose production and decreases intestinal absorption of glucose. It also improves insulin sensitivity by increasing peripheral glucose uptake and utilization.

## Nursing Safety Priority QSEN

### Drug Alert

Metformin can cause lactic acidosis in patients with kidney impairment and should not be used by anyone with kidney disease. To prevent lactic acidosis and acute kidney injury, the drug is withheld before and after using contrast medium or any surgical procedure requiring anesthesia until adequate kidney function is established.

#### Insulin Sensitizers.

Thiazolidinediones (TZDs, or “glitazones”) increase cellular utilization of glucose, which lowers blood glucose levels. Both of the TZDs, rosiglitazone (Avandia) and pioglitazone (Actos), are associated with an increased risk for heart-related deaths, bone fracture, and macular edema. The Food and Drug Administration (FDA) has issued a black box warning indicating that these drugs are not to be used by patients who have symptomatic heart failure or other specific types of cardiovascular disease. (A **black box warning** is a government designation indicating that a drug has at least one serious side effect and must be used with caution.)

## Nursing Safety Priority QSEN

### Drug Alert

Do not confuse Actos with Actonel. Actos is an oral antidiabetic drug from the thiazolidinedione class, and Actonel is a drug that prevents calcium loss from bones.

#### Alpha-Glucosidase Inhibitors.

Alpha-glucosidase inhibitors prevent after-meal hyperglycemia by delaying absorption of carbohydrate from the small intestine. These drugs inhibit enzymes in the intestinal tract, reducing the rate of starch digestion and glucose absorption. These actions prevent a sudden blood glucose surge after meals. These drugs do not cause hypoglycemia unless given with sulfonylureas or insulin.

#### Incretin Mimetics.

Incretin mimetics work like the natural “gut” hormones, glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP), that are released by the intestine in response to food intake and act with insulin for GLUCOSE REGULATION. Drugs in this class include the GLP-1 agonists *albiglutide* (Tanzeum), *dulaglutide* (Trulicity), *exenatide* (Byetta), *exenatide extended-release* (Bydureon), *liraglutide* (Victoza), and *lixisenatide* (Adlyxin). These drugs are used in addition to diet and exercise to improve glycemic control in adults with type 2 DM.

## Nursing Safety Priority QSEN

### Drug Alert

Albiglutide (Tanzeum), extended-release exenatide (Bydureon), and dulaglutide (Trulicity) are administered subcutaneously once *weekly*.

#### DPP-4 Inhibitors.

The incretins GLP and GIP produced by the body are rapidly metabolized and inactivated by the enzyme DPP-4. Drugs that inhibit the DPP-4 enzyme work by reducing the inactivation of the incretin hormones so they remain available for blood GLUCOSE REGULATION. The four DPP-4 inhibitors used to control type 2 DM are sitagliptin (Januvia), saxagliptin (Onglyza), linagliptin (Tradjenta), and alogliptin (Nesina).

## Nursing Safety Priority QSEN

### Drug Alert

DPP-4 inhibitors and the incretin mimetics may be associated with an increased risk for pancreatitis. Warn patients taking these drugs to immediately report signs of jaundice; sudden onset of intense abdominal pain that radiates to the back, left flank, or left shoulder; or gray-blue discoloration of the abdomen or periumbilical area to the primary health care provider.

#### **Amylin Analogs.**

Amylin analogs are drugs similar to amylin, a naturally occurring hormone produced by pancreatic beta cells that works with and is co-secreted with insulin in response to blood glucose elevation. Amylin levels are deficient in patients with type 1 DM who are also deficient in insulin. Pramlintide (Symlin), an analog of amylin, is approved for patients with DM who are treated with insulin. It works by three mechanisms: delaying gastric emptying; reducing after-meal blood glucose levels; and triggering satiety (in the brain). (Satiety leads to decreased caloric intake and eventual weight loss.)

## Nursing Safety Priority QSEN

### Drug Alert

Do not mix pramlintide and insulin in the same syringe because the pH of the two drugs is not compatible.

#### **Sodium-Glucose Cotransport Inhibitors.**

Sodium-glucose co-transport inhibitors lower blood glucose levels by preventing kidney reabsorption of glucose that was filtered from the blood into the urine. The filtered glucose is excreted in the urine rather than moved back into the blood. These oral drugs include *canagliflozin* (Invokana), *dapagliflozin* (Farxiga), and *empagliflozin* (Jardiance).

## Nursing Safety Priority QSEN

### Drug Alert

The Food and Drug Administration (FDA) has issued a warning that the use of empagliflozin increases the risk for acute kidney injury and impaired renal function (Aschenbrenner, 2017).

#### **Combination Agents.**

Combination agents combine drugs with different mechanisms of action. For example, Glucovance combines glyburide with metformin. Combining drugs with different mechanisms of action may be highly effective in maintaining desired blood glucose control. Some patients may need a combination of antidiabetic agents and insulin to control blood glucose levels.

#### **Insulin Therapy.**

Insulin therapy is required for type 1 DM and may be used for type 2 DM. The safety of insulin therapy in older patients may be affected by reduced vision, mobility and coordination problems, and decreased memory. Many types of insulin and regimens are available to achieve normal blood glucose levels. Because insulin is a small protein that is quickly digested and inactivated in the GI tract, it is usually administered as an injection.

#### **Types of Insulin.**

Insulin is manufactured using DNA technology to produce pure human insulin. Insulin analogs are synthetic human insulins in which the structure of the insulin molecule is altered to change the rate of absorption and duration of action within the body. An example is Lispro insulin, a rapid-acting

insulin analog that is created by switching the positions of lysine and proline in one area of the insulin molecule.

Rapid-, short-, intermediate-, and long-acting forms of insulin can be injected separately; and some can be mixed in the same syringe. Insulin is available in concentrations of 100 units/mL (U-100), 200 units/mL (U-200), 300 units/mL (U-300), and 500 units/mL (U-500). Insulin concentrations above 100 units/mL are usually reserved for patients who require large doses of insulin.

Teach the patient that the insulin types, the injection technique, and the site of injection can all affect the absorption, onset, degree, and duration of insulin activity. Reinforce that changing insulins may affect blood glucose control and should be done only under supervision of the primary health care provider. Table 64-8 outlines the timed activity of human insulin.

**TABLE 64-8**

**Timed Activity of Pharmaceutical Insulin**

Preparation	Brand	Onset (hr)	Peak (hr)	Duration (hr)
<b>Rapid-Acting Insulin Analogs</b>				
Insulin aspart injection	NovoLog	0.25	1-3	3-5
Insulin glulisine injection	Apidra	0.3	0.5-1.5	3-4
Human lispro injection	Humalog	0.25	0.5-1.5	5
Human lispro injection U-200	Humalog U-200	0.25	0.5-1.5	5
Insulin human inhalation powder	Afrezza	0.25	1-1.25	2.5
<b>Short-Acting Insulin</b>				
Regular human insulin injection	Humulin R	0.5	2-4	5-7
	Novolin R	0.5	2.5-5	8
	ReliOn R	0.5	2.5-5	8-12
	Humulin R (Concentrated U-500)	Humulin R (U-500)	1.5	4-12
<b>Intermediate-Acting Insulin</b>				
Isophane insulin NPH injection	Humulin N	1.5	4-12	16-24+
	Novolin N	1-4	4-14	10-24+
	ReliOn N	1-4	4-14	10-24+
	70% human insulin isophane suspension/30% human insulin injection	Humulin 70/30	0.5	2-12
Novolin 70/30				
ReliOn 70/30				
70% insulin aspart protamine suspension/30% insulin aspart injection	NovoLog Mix 70/30	0.25	1-4	24
75% insulin lispro protamine suspension/25% insulin lispro injection	Humalog Mix 75/25	0.25	1-2	24
<b>Long-Acting Insulin Analogs</b>				
Insulin glargine injection	Lantus	2-4	None	24
Insulin glargine injection U-300	Toujeo	2-4	12	24
Insulin detemir injection	Levemir	1	6-8	5.7-24
Insulin degludec injection U-100, U-200	Tresiba U-100	1	9	42
	Tresiba U-200	1	9	42

### Insulin Regimens.

Insulin regimens try to replicate the normal insulin release pattern from the pancreas. The pancreas produces a constant (*basal*) amount of insulin that balances liver glucose production with glucose use and maintains normal blood glucose levels between meals. The pancreas also produces additional mealtime (*prandial*) insulin to prevent blood glucose elevation after meals. The insulin dose required for blood glucose control varies among patients. A usual starting dose is between 0.5 and 1 unit/kg of body weight per day. For multiple-dose regimens or continuous subcutaneous insulin infusion (CSII), basal insulin makes up about 40% to 50% of the total daily dosage, with the remainder divided into premeal doses of rapid-acting insulin analogs or regular insulin. Basal insulin coverage is provided by intermediate-acting insulin or long-acting insulin analogs such as insulin glargine (Lantus), insulin detemir (Levemir), or insulin degludec (Tresiba). Dosages are adjusted based on the results of blood glucose monitoring.

*Single daily injection* protocols require insulin injection only once daily. This protocol may include one injection of intermediate- or long-acting insulin or an injection of combination short- and intermediate-acting insulin. Many patients with type 2 diabetes combine once-daily insulin injection with oral agent therapy to stimulate mealtime insulin secretion.

*Multiple-component insulin* therapy combines short- and intermediate-acting insulin injected twice daily. Two thirds of the daily dose is given before breakfast, and one third before the evening meal. Ratios of intermediate-acting and regular insulin are based on results of blood glucose monitoring.

*Intensified regimens* include a basal dose of intermediate- or long-acting insulin and a mealtime bolus dose of short- or rapid-acting insulin designed to bring the *next* blood glucose value into the target range. Blood glucose elevations above the target range are treated with “correction” doses of short- or rapid-acting insulin. The patient's blood glucose patterns determine insulin dosage. Frequency of blood glucose monitoring is based on the timed action of insulin and may occur as often as eight times daily. Blood glucose testing 1 to 2 hours after meals and within 10 minutes before the next meal helps determine the adequacy of the previous bolus dose. The patient determines the effects of basal insulin by monitoring blood glucose levels before breakfast (fasting)

and before the evening meal.

Patients on intensified insulin regimens need extensive education to achieve target blood glucose values. They need to know how to adjust insulin doses and understand NUTRITION therapy for dietary flexibility and meeting target blood glucose values. Patients must also be able to accurately monitor blood glucose levels so therapy decisions are based on accurate data.

Regardless of the specific insulin regimen, adherence to insulin injection schedules is critical in achieving glycemic control and maintaining A1C levels below the 7% needed to reduce long-term complications. At times, skipping an occasional insulin dose may be related to an unusual meal pattern for a day or a change in exercise.

### Factors Influencing Insulin Absorption.

Many factors affect insulin absorption and availability, including injection site; timing, type, or dose of insulin used; and physical activity.

*Injection site* area affects the speed of insulin absorption. Fig. 64-3 shows common insulin injection areas. Absorption is fastest in the abdomen and, except for a 2-inch radius around the navel, is the preferred injection site. Rotating injection sites allows each injection site to heal completely before the site is used again. Rotation *within* one anatomic site is preferred to rotation from one area to another to prevent day-to-day variability in absorption.

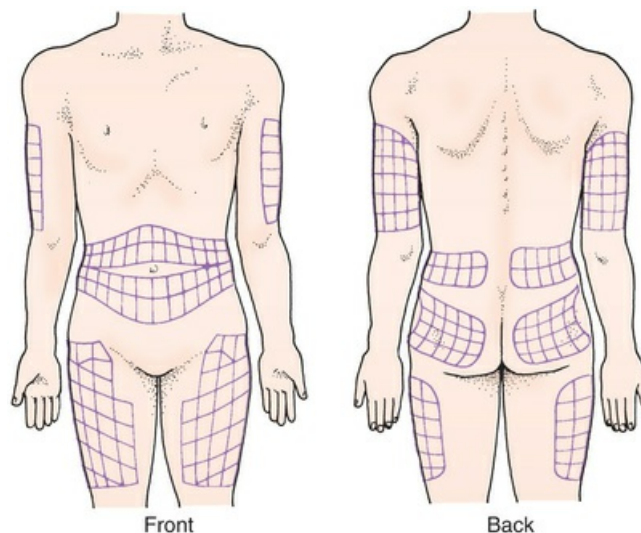

FIG. 64-3 Common insulin injection areas and sites.

*Absorption rate* is determined by insulin properties. The longer the duration of action, the more unpredictable is absorption. Larger doses of insulin also prolong the absorption. Factors that increase blood flow from the injection site, such as local application of heat, massage of the area, and exercise of the injected area, increase insulin absorption. Scarred sites often become favorite injection sites because they are less sensitive to pain, but these areas usually slow the rate of insulin absorption.

*Injection depth* changes insulin absorption. Usually injections are made into the subcutaneous tissue. IM injection has a faster absorption and is not used for routine insulin use. Most patients lightly grasp a fold of skin and inject at a 90-degree angle; however, a 45-degree angle is advised for frail older adults and those who are cachexic. Aspiration for blood is not needed. Patients with high body mass index (BMI) levels can use 4-mm or 5-mm needles to inject insulin at a 90-degree angle without pinching a skinfold before injection. Assess the older patient's ability to inject insulin and arrange for assistance when self-care is no longer possible.

*Timing of injection* affects blood glucose levels. The interval between premeal injections and eating, known as "lag time," affects blood glucose levels after meals. Insulin lispro, insulin aspart, and insulin glulisine have rapid onsets of action and are to be given within 10 minutes before mealtime when blood glucose is in the target range. If hyperglycemia or hypoglycemia is not present, these insulins can be given at any time from 10 minutes before mealtime to just before

eating or even immediately after eating. Regular insulin is given at least 20 to 30 minutes before eating when glucose levels are within the target range. When blood glucose levels are above the target range, the lag time is increased to permit insulin to begin to have a glucose-lowering effect before food enters the stomach. When blood glucose levels are below the target range, injection of regular insulin should be delayed until immediately before eating, and injection of rapid-acting insulin should be delayed until sometime *after* eating the meal.

*Mixing insulins* can change the time of peak action. Mixtures of short- and intermediate-acting insulins produce a more normal blood glucose response in some patients than does a single dose. The patient's response to mixed insulin may differ from the response to the same insulins given separately.

## Nursing Safety Priority QSEN

### Drug Alert

Do not mix any other insulin type with insulin glargine, insulin detemir, or any of the premixed insulin formulations such as Humalog Mix 75/25.

### Complications of Insulin Therapy.

Hypoglycemia from insulin excess has many causes. Its effects and treatment are discussed in the Preventing Hypoglycemia section.

Two conditions of fasting hyperglycemia (in addition to a lack of insulin) can occur (Fig. 64-4). *Dawn phenomenon* results from a nighttime release of adrenal hormones that causes blood glucose elevations at about 5 to 6 AM. It is managed by providing more insulin for the overnight period (e.g., giving the evening dose of intermediate-acting insulin at 10 PM instead of with the evening meal). *Somogyi phenomenon* is morning hyperglycemia from the counterregulatory response to nighttime hypoglycemia. It is managed by ensuring adequate dietary intake at bedtime and evaluating the insulin dose and exercise programs to prevent conditions that lead to hypoglycemia. Both problems are diagnosed by blood glucose monitoring during the night. Help identify these problems and teach the patient and family about management.

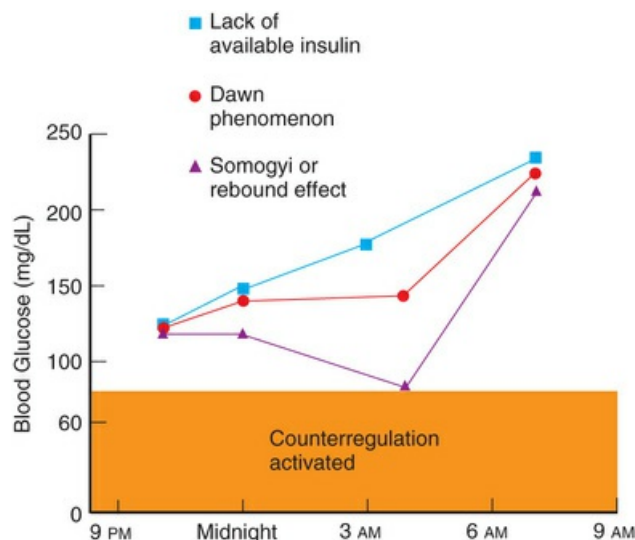

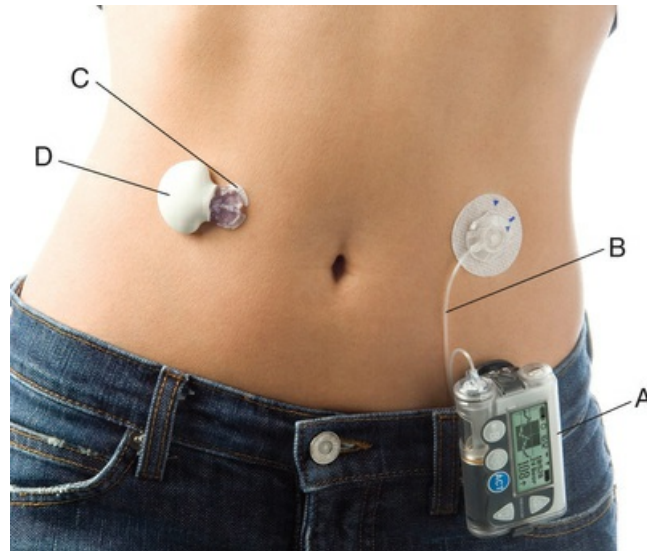

FIG. 64-4 Three blood glucose phenomena in patients with diabetes.

### Alternative Methods of Insulin Administration.

Many methods of insulin delivery are available in addition to traditional subcutaneous injections.

*Continuous subcutaneous infusion* of a basal dose of insulin (CSII) with additional insulin at mealtimes is more effective in controlling blood glucose levels than other schedules. It allows

flexibility in meal timing because, if a meal is skipped, the additional mealtime dose of insulin is not given. CSII is given by an externally worn pump containing a reservoir of rapid-acting insulin and is connected to the patient by an infusion set. Teach him or her to adjust the amount of insulin based on data from blood glucose monitoring. Rapid-acting insulin analogs are used with insulin infusion pumps (Fig. 64-5).

**FIG. 64-5** MiniMed Paradigm REAL-Time Insulin Pump and Continuous Glucose Monitoring System. **A**, Pump. **B**, Injection cannula. **C**, Glucose sensor. **D**, Data transmitter. Courtesy Medtronic Diabetes, Northridge, CA.)

Problems with CSII include skin infections that can occur when the infusion site is not cleaned or the infusion set is not changed every 2 to 3 days. Ketoacidosis may occur more often because of inexperience in pump use, infection, accidental cessation or obstruction of the infusion, or mechanical pump problems. Stress the importance of testing for ketones when blood glucose levels are greater than 300 mg/dL (16.7 mmol/L).

Patients using CSII need intensive and extensive education (Lampe, 2015). They must be able to operate the pump, adjust the settings, and respond appropriately to alarms. Removing the pump for any length of time can result in hyperglycemia. Provide supplemental insulin schedules for times when the pump is not operational.

*Injection devices* include a needleless system and an insulin pen in addition to traditional insulin syringes. With a needleless device, the needle is replaced by an ultrathin liquid stream of insulin forced through the skin under high pressure. Insulin given by jet injection is absorbed at a faster rate and has a shorter duration of action. Most types of insulin are available in pen devices, which are more convenient for multiple daily injection regimens.

### **Patient Education: Drugs.**

Provide specific instructions about insulin therapy, new drug therapies, and self-monitoring of blood glucose levels.

*Insulin storage* varies by use. Teach patients to refrigerate insulin that is not in use to maintain potency, prevent exposure to sunlight, and inhibit bacterial growth. Insulin in use may be kept at room temperature for up to 28 days to reduce injection site irritation from cold insulin.

To prevent loss of drug potency, teach the patient to avoid exposing insulin to temperatures below 36° F (2.2° C) or above 86° F (30° C), to avoid excessive shaking, and to protect insulin from direct heat and light. Insulin should not be allowed to freeze. Insulin glargine (Lantus) should be stored in a refrigerator (36° to 46° F [2.2° to 7.8° C]) even when in use. Teach patients to discard any unused insulin after 28 days.

Teach patients to always have a spare supply of each type of insulin used. A slight loss in potency may occur for bottles in use for more than 30 days, even when the expiration date has not passed. Prefilled syringes are stable up to 30 days when refrigerated. Store prefilled syringes in the upright position, with the needle pointing upward or flat, so insulin particles do not clog it. Teach patients

to roll prefilled syringes between the hands before using.

*Proper dose preparation* is critical for insulin effectiveness and patient safety. Teach patients that the person giving the insulin needs to inspect the vial before each use for changes (e.g., clumping, frosting, precipitation, or change in clarity or color) that may indicate loss in potency. Preparations containing NPH insulin are uniformly cloudy after gently rolling the vial between the hands. Other insulins should be clear when inspected in good lighting. If potency is questionable, another vial or pen of the same insulin type should be used.

*Syringes* may be used to administer insulin. The standard insulin syringes are marked in insulin units. They are available in 1-mL (100-U),  $\frac{1}{2}$ -mL (50-U), and  $\frac{3}{10}$ -mL (30-U) sizes. The unit scale on the barrel of the syringe differs with the syringe size and manufacturer. Insulin syringe needles are measured in 28-, 29-, 30-, and 31-gauge and in lengths of 6 mm, 8 mm, and 12.7 mm. To ensure accurate insulin measurement, instruct the patient to always buy the same type of syringe. [Chart 64-3](#) reviews instructions for drawing up a single insulin injection.

### **Chart 64-3**

## **Patient and Family Education: Preparing for Self-Management**

### **Subcutaneous Insulin Administration**

#### **With Vial and Syringe**

- Wash your hands.
- Inspect the bottle for the type of insulin and the expiration date.
- Gently roll the bottle of intermediate-acting insulin in the palms of your hands to mix the insulin.
- Clean the rubber stopper with an alcohol swab.
- Remove the needle cover and pull back the plunger to draw air into the syringe. The amount of air should be equal to the insulin dose. Push the needle through the rubber stopper and inject the air into the insulin bottle.
- Turn the bottle upside down and draw the insulin dose into the syringe.
- Remove air bubbles in the syringe by tapping on the syringe or injecting air back into the bottle. Redraw the correct amount.
- Make certain the tip of the plunger is on the line for your dose of insulin. Magnifiers are available to assist in measuring accurate doses of insulin.
- Remove the needle from the bottle. Recap the needle if the insulin is not to be given immediately.
- Select a site within your injection area that has not been used in the past month.
- Clean your skin with an alcohol swab. Lightly grasp an area of skin and insert the needle at a 90-degree angle.
- Push the plunger all the way down. This will push the insulin into your body. Release the pinched skin.
- Pull the needle straight out quickly. Do not rub the place where you gave the shot.
- Dispose of the syringe and needle without recapping in a puncture-proof container.

#### **With a Pen Device**

- Wash your hands.
- Check the drug label to be sure it is what was prescribed.
- Remove the cap.
- Look at the insulin to be sure it is evenly mixed if it contains NPH and that there is no clumping of particles.
- Wipe the tip of the pen where the needle will attach with an alcohol swab.
- Remove the protective pull tab from the needle and screw it onto the pen until snug.
- Remove both the plastic outer cap and inner needle cap.
- Look at the dose window and turn the dosage knob to the appropriate dose.
- Holding the pen with the needle pointing upward, press the button until at least a drop of insulin appears. This is the “cold shot,” “air shot,” or “safety shot.” Repeat this step if needed until a drop appears.
- Dial the number of units needed.
- Hold the pen perpendicular to and against the intended injection site with the thumb on the dosing knob.
- Press the dosing knob slowly all the way to dispense the dose.
- Hold the pen in place for 6-10 seconds; then withdraw from the skin.
- Replace the outer needle cap; unscrew until the needle is removed and dispose of the needle in a hard plastic or metal container.
- Replace the cap on the insulin pen.

Disposable needles are used only once. Teach the patient to discard the syringe and needle after one use. Information on needle disposal can be obtained at [www.safeneedledisposal.org](http://www.safeneedledisposal.org).

Pen-type injectors hold small, lightweight, prefilled insulin cartridges. The injectors are easy to carry and make intensive therapy with multiple injections easier. These devices allow greater accuracy than traditional insulin syringes, especially when measuring small doses. Discuss proper storage for prefilled insulin pens or cartridges. Ensure that the product is appropriate for the patient's unique needs. *Pen-type injectors are not designed for independent use by visually impaired patients or by those with cognitive impairment.* Ensure that the patient has received education on its use. Each syringe or cartridge has specific requirements. **The Institute for Safe Medication Practices (ISMP) and The Joint Commission's National Patient Safety Goals identify insulin as a High-Alert drug. (High-Alert drugs are those that have an increased risk for causing patient harm if given in error.)** The ISMP cautions that digital displays on some of the newer insulin pens can be misread. If the pen is held upside down, as a left-handed person might do, a dose of 52 units actually appears to be a dose of 25 units, and a dose of 12 units looks like a dose of 21 units.

#### **Patient Education: Blood Glucose Monitoring.**

Self-monitoring of blood glucose (SMBG) levels provides information to assess effectiveness of the management plan and assists the patient in self-care decisions. Results of SMBG are useful in preventing hypoglycemia and hyperglycemia by adjusting drug therapy, diet therapy, and physical activity (Greenwood, 2015). Assessment of blood glucose levels is very important for these situations:

- Symptoms of hypoglycemia/hyperglycemia
- Hypoglycemic unawareness
- Periods of illness

- Before and after exercise
- Gastroparesis
- Adjustment of antidiabetes drugs
- Evaluation of other drug therapies (e.g., steroids)
- Preconception planning
- Pregnancy

*Techniques for SMBG* follow principles that are the same for most self-monitoring systems. Meter systems now require a very small blood sample, which allows for alternate testing sites (e.g., arm, thigh, hand). The finger or alternate site is pricked, a drop of blood flows over or is drawn into a testing strip or disc impregnated with chemicals, and the glucose value is displayed in mg/dL or mmol/L on a screen. For vision-impaired patients, “talking-meters” are available to allow independence in blood glucose monitoring.

Data obtained from SMBG are evaluated along with other measures of blood glucose (e.g., glycosylated hemoglobin [A1C] values) or periodic laboratory blood glucose tests. Even when SMBG is performed correctly, the results are affected by hematocrit values (anemia falsely elevates glucose values; polycythemia falsely depresses them) and may be unreliable in the hypoglycemic or severe hyperglycemic ranges.

*Accuracy of the blood glucose monitor* is ensured when the manufacturer's directions are followed. The most common source of error is related to the skill of the user and not to errors of the instrument. Common errors involve failure to obtain a sufficient blood drop, poor storage of test strips, using expired strips, and not changing the code number on the meter to match the strip bottle code. Help the patient select a meter based on cost of the meter and strips, ease of use, and availability of repair and servicing. Provide training, explain and demonstrate procedures, assess visual acuity, and check the patient's ability to perform the procedure using “teach-back” strategies. Glucose meters are designed to reduce user error as much as possible. Newer meters have fewer steps, include error signals for inadequate sample size, and can store hundreds of SMBG results. (See the Consumer Guide published yearly in the January edition of Diabetes Forecast [[forecast.diabetes.org](http://forecast.diabetes.org)] for information to help patients determine which blood glucose meter best meets their needs.)

Accuracy and precision vary widely among capillary blood glucose monitoring devices. If the meter requires calibration, teach patients to properly calibrate the machine. Instruct them to recheck the calibration and retest if they obtain a test result that is unusual for them and whenever they are in doubt about test accuracy. Continued retraining of patients performing SMBG helps ensure accurate results because performance accuracy deteriorates over time. Laboratory glucose determinations are more accurate than SMBG.

*Frequency of testing* varies with the drug schedules, the patient's prescribed therapy, and his or her target outcomes. The ADA recommends that patients taking multiple insulin injections or using insulin pump therapy monitor glucose levels three or more times daily. For patients taking less-frequent injections of insulin, noninsulin therapy, or diet therapy alone, SMBG is useful for evaluation of therapy.

*Blood glucose therapy target goals* are set individually for each patient based on duration of disease, age and life expectancy, comorbid conditions, severity of cardiovascular disease, and presence of hypoglycemia unawareness. The health care team works with him or her to reach target blood glucose levels. The ADA recommends that patients with type 1 DM aim for A1C values less than 7%, premeal glucose levels of 70 to 130 mg/dL (3.9 to 7.2 mmol/L), and postmeal glucose levels less than 180 mg/dL (10.0 mmol/L) (ADA, 2017d).

*Infection control measures* are needed for SMBG. The chance of becoming infected from blood glucose monitoring processes is reduced by handwashing before monitoring and by not reusing lancets. *Instruct patients to not share their blood glucose monitoring equipment.* The hepatitis B virus can survive in a dried state for at least 1 week. Infection can be spread by the lancet holder even when the lancet itself has been changed. Small particles of blood can stick to the device and infect multiple users. Regular cleaning of the meter is critical for infection control. Remind health care staff who perform blood glucose testing and family members who help with testing to wear gloves.

Many meters allow data to be downloaded to a computer that has diabetes management software. Some meters allow entry of additional data such as insulin dose, amounts of carbohydrate eaten, or exercise. A radio link to an insulin pump allows automatic transfer of glucose readings to

a calculator that helps the patient decide on an appropriate insulin dose. Some patients use smart phone applications to record and trend or graph serial blood glucose levels, insulin dosages, food intake, and other data. This information can be sent to the primary health care provider electronically or downloaded and printed.

Once the patient learns the technical aspects of meter use, help him or her use the results of SMBG to achieve glycemic control. Postmeal glucose monitoring provides information about the effects of the size and content of their meals. SMBG allows the patient to assess effects of exercise on glucose control and provides critical information to help patients who take insulin to exercise safely. Teach patients how to use SMBG results to adjust the treatment plan. Patients should make agreed-on adjustments in the treatment plan when results are consistently out of range for a 3-day period when no change in meal plan, drugs, or activity has occurred.

*Alternate site testing* uses blood obtained from sites other than the fingertip and is available on many meters. However, use caution when interpreting results obtained from alternate sites. Studies have shown wide variation between fingertip and alternate sites, and variation is most evident during times when glucose levels change rapidly. Teach patients about the lag time for blood glucose levels between the fingertip and other sites when blood glucose levels are changing rapidly and that the fingertip reading is the only safe choice at those times.

## Nursing Safety Priority QSEN

### Action Alert

Teach patients with a history of hypoglycemic unawareness *not* to test at alternative sites.

*Continuous blood glucose monitoring* (CGM) systems monitor glucose levels in interstitial fluid to provide real-time glucose information to the user. The system consists of three parts: a disposable sensor that measures glucose levels, a transmitter that is attached to the sensor, and a receiver that displays and stores glucose information. After an initiation or warm-up period, the sensor gives glucose values every 1 to 5 minutes. Sensors may be used for 3 to 7 days, depending on the manufacturer. CGM provides information about the current blood glucose level, short-term feedback about results of treatment, and warnings when glucose readings become dangerously high or low. Most available sensors require at least two capillary glucose readings per day for calibration of the sensor. Sensor accuracy depends on these calibrations. There may be a lag time between the capillary glucose measurement and the glucose sensor value. If the blood glucose value is changing rapidly, the time between capillary and interstitial glucose values may be as long as 30 minutes. For this reason, capillary glucose readings need to be checked on all extreme values or if symptoms of hypoglycemia are present before any corrective treatment is given. *Continuous glucose monitoring is meant to supplement, not replace, fingerstick tests. Give insulin only after confirming the results of any continuous glucose monitoring system.*

## NCLEX Examination Challenge 64-4

### Health Promotion and Maintenance

Which client does the nurse caution to **avoid** self-monitoring of blood glucose (SMBG) at alternate sites?

- A. 75-year-old client whose blood glucose levels show little variation
- B. 55-year-old client who has hypoglycemic unawareness
- C. 80-year-old client with type 2 diabetes mellitus
- D. 45-year-old client with type 1 diabetes mellitus

### Nutrition Therapy.

Effective self-management of DM requires that NUTRITION, including the meal plan, education, and

counseling programs, be individualized for each patient. A registered dietitian (RD) is a member of the interprofessional team. The nurse, RD, patient, and family work together on all aspects of the meal plan, which must be realistic and as flexible as possible. Plans that consider the patient's cultural background, financial status, and lifestyle are more likely to be successful. The desired outcomes of NUTRITION and diet therapy are listed in [Table 64-9](#).

**TABLE 64-9**  
**Desired Outcomes of Nutrition Therapy for the Patient With Diabetes**

- Achieving and maintaining blood glucose levels in the normal range or as close to normal as is safely possible
- Achieving and maintaining a blood lipid profile that reduces the risk for vascular disease
- Achieving blood pressure levels in the normal range or as close to normal as is safely possible
- Preventing or slowing the rate of development of the chronic complications of diabetes by modifying nutrient intake and lifestyle
- Addressing patient NUTRITION needs, taking into account personal and cultural preferences and willingness to change
- Maintaining the pleasure of eating by limiting food choices only when indicated by scientific evidence
- Meeting the NUTRITION needs of unique times of the life cycle, particularly for pregnant and lactating women and for older adults with diabetes
- Providing self-management training for patients treated with insulin or insulin stimulators (secretagogues) for exercising safely, including the prevention and treatment of hypoglycemia and managing diabetes during acute illness

### Principles of Medical Nutrition Therapy in Diabetes.

Medical Nutrition Management (MNT) is recommended for all adults with DM. For overweight or obese adults with Type 2 DM, even modest weight loss through reduced caloric intake is beneficial. Blood pressure, blood glucose levels, and lipid profiles are improved by weight loss ([ADA, 2017c](#)).

The dietitian develops a meal plan based on the patient's usual food intake, weight-management expectations, and lipid and blood glucose patterns. Consistency in the daily timing and amount of food eaten helps control blood glucose. Patients using insulin therapy need to eat at times that are coordinated with the timed action of insulin. Teach patients using intense insulin therapy to adjust premeal insulin to allow for timing and quantity changes in their meal plan.

Current evidence indicates that no specific percentage of calories from carbohydrates, protein, or fat is ideal for all adults with DM. Recommendations for the distribution of these macronutrients is individualized based on food preferences, eating patterns, and metabolic goals ([ADA, 2017c](#); [Nwankwo & Funnell, 2016](#); [Watts & Howard, 2016](#)).

*Carbohydrate* intake avoids nutrient deficient sources (“empty calories”) and focuses on sources from vegetables, fruits, whole grains, legumes, and dairy products. Adults with diabetes are recommended to consume at least 25 g of fiber daily. Teach those who are at risk for or who have DM to avoid sugar-sweetened beverages (including high fructose corn syrup) and sucrose to prevent weight gain and adverse effects on metabolism ([ADA, 2017c](#); [ADA, 2017j](#)).

*Dietary fat and cholesterol* intake for adults with DM focuses on the quality of fat rather than on the quantity of fat. A Mediterranean-style diet rich in monounsaturated fatty acids (MUFAs) often is beneficial to lower cardiometabolic risk factors. MUFA diets include avocados, nuts and seeds, olives, and dark chocolate. Omega-3 fatty acids, including EPA (eicosapentaenoic acid) and DHA (docosahexaenoic acid) from fish or fish oil supplements are recommended as part of a healthy diet to prevent heart disease, as is ALA (alpha linolenic acid) derived from plant sources. Current recommendations from the ADA to limit trans fats, saturated fats, and cholesterol are the same as for the general population ([ADA, 2017a](#); [ADA 2017c](#)).

*Alcohol* consumption affects blood glucose levels. Levels are not affected by *moderate* use of alcohol when DM is well controlled. Teach patients that two alcoholic beverages for men and one for women can be ingested with, and in addition to, the usual meal plan. (One alcoholic beverage equals 12 ounces of beer, 5 ounces of wine, or 1½ ounces of distilled spirits.) When alcohol is consumed by adults taking insulin or an insulin secretagogue, the risk for delayed hypoglycemia is increased.

## Nursing Safety Priority QSEN

### Action Alert

Because of the potential for alcohol-induced delayed hypoglycemia, instruct the patient with DM to ingest alcohol only with or shortly after meals.

### Patient Education: Prescribed Nutrition Plan.

No one meal plan is right for all patients with DM. Each patient's NUTRITION recommendations are based on blood glucose monitoring results, total blood lipid levels, and A1C levels. These tests help determine whether current meal and exercise patterns need adjustment or whether present habits need reinforcement. A specific nutritional prescription is developed for each patient.

Reinforce NUTRITION information provided by the dietitian. The patient with DM must understand how to adjust food intake during illness, planned exercise, and social occasions and when the usual time of eating is delayed. He or she may be unable to follow the prescribed plan because of an inability to read or understand printed materials. Share dietary information with the person who prepares the meals. The dietitian sees each patient yearly to identify changes in lifestyle and make appropriate diet therapy changes. Some patients, such as those with weight-control problems or low incomes, may need more frequent dietary evaluation and counseling.

### **Meal Planning Strategies.**

Many meal planning approaches for good NUTRITION are available. Each approach emphasizes different aspects of nutrition.

*Carbohydrate (CHO) counting* is a simple approach to NUTRITION and meal planning that uses label information of the nutritional content of packaged food items. Because fat and protein have little effect on after-meal blood glucose levels, CHO counting focuses on the nutrient that has the greatest impact on these levels. It uses total grams of CHO, regardless of the food source. This method is effective in achieving blood glucose control when daily CHO intake is consistent.

Patients using intensive insulin or pump therapies can use CHO counting to determine insulin coverage. After the amount of insulin needed to cover the usual meal is determined, insulin may be added or subtracted for changes in CHO intake. An initial formula of 1 unit of rapid-acting insulin for each 15 g of CHO provides flexibility to meal plans. The patient determines the grams of CHO in a specific meal or snack by reading labels or weighing and measuring each item. The total grams of CHO are used to calculate the bolus dose of insulin based on the prescribed insulin-to-carbohydrate ratio.

*Special considerations for type 1 diabetes* include developing insulin regimens that conform to the patient's preferred meal routines, food preferences, and exercise patterns. Patients using rapid-acting insulin by injection or an insulin pump should adjust insulin doses based on the CHO content of the meals and snacks. Insulin-to-carbohydrate ratios are developed and are used to provide mealtime insulin doses. Blood glucose monitoring before and 2 hours after meals determines whether the insulin-to-carbohydrate ratio is correct. For patients who are on fixed insulin regimens and do not adjust premeal insulin dosages, consistency of timing of meals and the amount of CHO eaten at each meal is important to prevent hypoglycemia.

Exercise can cause hypoglycemia if insulin is not decreased before activity. For planned exercise, reduction in insulin dosage is used for hypoglycemia prevention. For unplanned exercise, intake of additional CHO is usually needed. Moderate exercise increases glucose utilization by 2 to 3 mg/kg/min. A 70-kg adult would need about 10 to 15 g additional CHO per hour of moderate-intensity activity. More CHO is needed for intense activity.

It is important for patients using insulin to avoid weight gain. **Hyperinsulinemia** (chronic high blood insulin levels) can occur with intensive management schedules and may result in weight gain. These patients may need to manage hyperglycemia by restricting calories rather than increasing insulin. Weight gain can be minimized by following the prescribed meal plan, getting regular exercise, and avoiding overtreatment of hypoglycemia.

*Special considerations for type 2 DM* focus on lifestyle changes. Many patients with type 2 DM are overweight and insulin resistant. NUTRITION therapy stresses lifestyle changes that reduce calories eaten and increase calories expended through physical activity. Many patients also have abnormal blood fat levels and hypertension (metabolic syndrome), making reductions of saturated fat, cholesterol, and sodium desirable. A moderate caloric restriction (250 to 500 calories less daily) and an increase in physical activity improve GLUCOSE REGULATION and weight control. Decreases of more than 10% of body weight can significantly improve A1C.

When patients with type 2 DM need insulin, consistency in timing and CHO content of meals is important. Division of the total daily calories into three meals or into smaller meals and snacks is based on patient preference.

## **Considerations for Older Adults**

## Patient-Centered Care QSEN

Older patients are at increased risk for poor NUTRITION, reduced awareness of either hypoglycemia and hyperglycemia, and dehydration, a factor in the development of hyperglycemic-hyperosmolar state (HHS) (Touhy & Jett, 2016). Nutrition needs of the older adult change as his or her taste, smell, and appetite diminish and the ability to obtain and prepare food decreases. Older patients who prepare their own food or have dental issues may not eat enough food. Neuropathy with gastric retention or diarrhea compounds poor food intake. Impaired cognition may disrupt self-care. Older patients may have a marginal food supply because of low income, may have poor understanding of meal-planning needs, or may live alone and not care to prepare or eat proper meals. They may eat in restaurants or live in situations in which they have little control over meal preparation. Visits by home health nurses can help older patients follow a diabetic meal plan.

A realistic approach to NUTRITION therapy is essential for the older patient with DM. Changing the eating habits of 60 to 70 years is very difficult. The nurse, dietitian, and patient assess the patient's usual eating patterns. Teach the older patient taking antidiabetic drugs the importance of eating meals and snacks at the same time every day, eating the same amount of food from day to day, and eating all food allowed on the diet.

### Exercise Therapy.

Regular exercise is an essential part of DM management. It has beneficial effects on carbohydrate metabolism and insulin sensitivity. Programs of increased physical activity and weight loss reduce the risk for type 2 DM in patients with impaired glucose tolerance (AADE, 2015).

Plasma glucose levels remain stable in physically active patients without diabetes because of the balance between glucose use by exercising muscles and glucose production by the liver. The patient with type 1 DM cannot make the hormonal changes needed to maintain stable blood glucose levels during exercise. Without an adequate insulin supply, cells cannot use glucose. Low insulin levels trigger release of glucagon and epinephrine (counterregulatory hormones) to increase liver glucose production, further raising blood glucose levels. In the absence of insulin, free fatty acids become the source of energy. Exercise in the patient with uncontrolled DM results in further hyperglycemia and the formation of ketone bodies. He or she may have prolonged elevated blood glucose levels after vigorous exercise.

Exercise in the adult with DM can cause hypoglycemia because of increased muscle glucose uptake and inhibited glucose release from the liver. It can occur during exercise and for up to 24 hours after exercise. Replacement of muscle and liver glycogen stores, along with increased insulin sensitivity after exercise, causes insulin requirements to drop.

### Benefits of Exercise.

Appropriate exercise results in better blood GLUCOSE REGULATION and reduced insulin requirements for patients with type 1 DM. Exercise also increases insulin sensitivity, which enhances cell uptake of glucose and promotes weight loss.

Regular exercise decreases risk for cardiovascular disease. It decreases most blood lipid levels and increases high-density lipoproteins (HDLs, the “good” cholesterol). Exercise decreases blood pressure and improves cardiovascular function. Regular vigorous physical activity prevents or delays type 2 DM by reducing body weight, insulin resistance, and glucose intolerance.

### Adjustments for Diabetes Complications.

Exercise in the presence of long-term DM complications may require adjustment. Vigorous aerobic or resistance exercise should be avoided in the presence of proliferative diabetic retinopathy or severe nonproliferative diabetic retinopathy. Teach the patient with retinopathy to avoid the *Valsalva maneuver* (breath holding while bearing down) and activities that increase blood pressure. Heavy lifting, rapid head motion, or jarring activities can cause vitreous hemorrhage or retinal detachment. Decreased pain sensation in the extremities increases the risk for skin breakdown and joint damage. Teach patients with peripheral neuropathy to wear proper footwear and examine their feet daily for lesions or injury. Teach anyone with a foot injury or open sore to engage in non-weight-bearing activities such as swimming, bicycling, or arm exercises. Those with autonomic neuropathy are at increased risk for exercise-induced injury from impaired temperature control, postural hypotension, and impaired thirst with risk for dehydration. Physical activity also can

increase urine protein excretion. Encourage high-risk patients to start with short periods of low-intensity exercise and increase the intensity and duration slowly.

### **Safety Assessment.**

Although current ADA guidelines do not recommend routine screening for patients with DM who have no indications of cardiovascular disease, conditions that might predispose to injury or that contraindicate certain types of exercise include:

- Uncontrolled hypertension
- Severe autonomic neuropathy
- Severe peripheral neuropathy or foot lesions
- Unstable proliferative retinopathy

Advise adults with DM to perform at least 150 min/week of moderate-intensity (50% to 70% maximum heart rate) aerobic physical activity divided into 3 days, or 75 min/week of vigorous aerobic physical activity, or an equivalent combination of the two. Teach patients to avoid going more than 2 consecutive days without aerobic physical activity. In the absence of contraindications, patients with type 2 DM are urged to perform resistance exercise at least twice weekly, targeting all major muscle groups.

A 5- to 10-minute warm-up period with stretching and low-intensity exercise before exercise prepares the muscles, heart, and lungs for a progressive increase in exercise intensity. After exercising, a cool-down of at least 5 to 10 minutes is performed to gradually bring the heart rate down to pre-exercise level.

Guidelines for exercise are based on blood glucose levels and urine ketone levels. Recommend that the patient test blood glucose before exercise, at intervals during exercise, and after exercise to determine if it is safe to exercise and to evaluate the effects of exercise. The absence of urine ketones indicates that enough insulin is available for glucose transport. *When urine ketones are present, the patient should **not** exercise.* Ketones indicate that current insulin levels are not adequate and that exercise would elevate blood glucose levels. Carbohydrate foods should be ingested to raise blood glucose levels above 100 mg/dL (5.6 mmol/L) before engaging in exercise. [Chart 64-4](#) lists tips to teach the patient and family about exercise.

### **Chart 64-4**

## **Patient and Family Education: Preparing for Self-Management**

### **Exercise**

- Teach the patient about the relationship between regularly scheduled exercise and blood glucose levels, blood lipid levels, and complications of diabetes.
- Reinforce the level of exercise recommended for the patient based on his or her physical health.
- Instruct the patient to wear appropriate footwear designed for exercise.
- Remind the patient to examine his or her feet daily and after exercising.
- Remind the patient to stay hydrated and not to exercise in extreme heat or cold.
- Warn the patient not to exercise within 1 hour of insulin injection or near the time of peak insulin action.
- Teach patients how to prevent hypoglycemia during exercise:
- **Do not exercise unless blood glucose level is at least 80 and less than 250 mg/dL.**

- Have a carbohydrate snack before exercising if 1 hour has passed since the last meal or if the planned exercise is high intensity.
- Carry a simple sugar to eat during exercise if symptoms of hypoglycemia occur.
- Ensure that identification information about diabetes is carried during exercise.
- Remind the patient to check blood glucose levels more frequently on days in which exercise is performed and that extra carbohydrate and less insulin may be needed during the 24-hour period after extensive exercise.

## Nursing Safety Priority QSEN

### Action Alert

Teach patients with type 1 DM to perform vigorous exercise only when blood glucose levels are 100 to 250 mg/dL (5.6 to 13.8 mmol/L) and no ketones are present in the urine.

## Considerations for Older Adults

### Evidence-Based Practice QSEN

With age, the ability of the heart and lungs to deliver oxygen to tissues and organs declines. Muscle strength and power decline gradually. Connective tissue becomes less elastic, affecting range of motion and flexibility. Limited range of motion can alter gait, increasing risk for falls. Older adults who remain active can limit losses in muscle mass and function.

Emphasize that the focus for any activity program is on changing sedentary behavior to active behavior at any level. Encourage sedentary older adults to begin with low-intensity physical activity. Start low-intensity activities in short sessions (less than 10 minutes); include warm-up and cool-down components with active stretching. Changes in activity levels should be gradual. Formal evaluation by a physical therapist or occupational therapist may be needed. Examples of specific exercise can be found at [www.geri.com](http://www.geri.com).

## Clinical Judgment Challenge 64-1

### Patient-Centered Care; Teamwork and Collaboration; Evidence-Based Practice QSEN

A 33-year-old woman has just returned from a 5-year mission trip to a less affluent country and is having a complete check-up. She is 25 lb (11.3 kg) overweight and had an 11 lb (5 kg) baby 2 years ago while on the mission trip. Her fasting blood glucose level is 119 mg/dL (6.5 mmol/L), and her A1C is 5.8. She reports that her mother, sister, and maternal grandmother all have type 2 DM. She asks what she can do about this possible health problem.

1. Does she have diabetes? Provide a rationale for your response.
2. What risk factors does she have for type 2 DM?
3. What additional assessment information should you obtain?
4. In addition to yourself and the primary health care provider, what other interprofessional health team members would be appropriate to consult at this time?

## 5. What lifestyle recommendations are appropriate for this patient?

### Blood Glucose Control in Hospitalized Patients.

Hyperglycemia in hospitalized patients occurs for many reasons and is associated with poor outcomes. It may result from decline in basic level of GLUCOSE REGULATION and control caused by illness, decreased physical activity, withholding of antidiabetic drugs, use of drugs that cause hyperglycemia such as corticosteroids, and initiation of tube feedings or parenteral NUTRITION.

Hyperglycemia among medical-surgical patients is linked to reduced IMMUNITY, higher infection rates, longer hospital stays, increased need for intensive care, and greater mortality. Admission glucose levels greater than 198 mg/dL (10.9 mmol/L) are associated with greater risk for mortality and complications. Hypoglycemia, defined as blood glucose values lower than 40 mg/dL (2.2 mmol/L), is an independent risk factor for mortality.

Current American Association of Clinical Endocrinologists (AACE) and ADA guidelines recommend treatment protocols that maintain blood glucose levels between 140 and 180 mg/dL (7.8 and 10.0 mmol/L) for critically ill patients. For the majority of non-critically ill patients, premeal glucose targets should be lower than 140 mg/dL (7.8 mmol/L), with random blood glucose values less than 180 mg/dL (10.0 mmol/L). To prevent hypoglycemia, insulin regimens should be reviewed if blood glucose levels fall below 100 mg/dL (5.6 mmol/L) and should be modified when blood glucose levels are less than 70 mg/dL (3.9 mmol/L) (ADA, 2017d).

Continuous IV insulin solutions are the most effective method for achieving glycemic targets in the intensive care setting. Scheduled subcutaneous injection with basal, meal, and correction elements is the preferred method for achieving and maintaining glucose control in non-critically ill patients. Using correction dose or “supplemental insulin” to correct premeal hyperglycemia in addition to scheduled prandial and basal insulin is recommended. The correction dose is determined by the patient’s insulin sensitivity and current blood glucose level.

Prevention of hypoglycemia is also part of managing blood glucose levels. Causes of inpatient hypoglycemia include an inappropriate insulin type, mismatch between insulin type and/or timing of food intake, and altered eating plan without insulin dosage adjustment. Many facilities have protocols for hypoglycemia treatment that direct staff to provide carbohydrate replacement if the patient is alert and able to swallow or to administer 50% dextrose IV or glucagon by subcutaneous injection if the patient cannot swallow.

There is confusion about whether to give or to hold insulin from a patient who is NPO. Administration of rapid-acting or short-acting insulin, as well as amylin and incretin mimetics, will cause hypoglycemia if a patient is not eating. Basal insulin should be administered when the patient is NPO because it controls baseline glucose levels. Insulin mixtures are not administered because they contain some short-acting or rapid-acting insulin and will cause hypoglycemia.

### Surgical Management.

Surgical interventions for DM include a pancreas transplantation or islet cell transplantation. When successful, these procedures eliminate the need for insulin injections, blood glucose monitoring, and many dietary restrictions. They can eliminate the acute complications related to blood GLUCOSE REGULATION but are only partially successful in reversing long-term complications. Pancreatic transplant is successful when the patient no longer needs insulin therapy and all blood measures of glucose are normal.

Transplantation requires lifelong drug therapy to prevent graft rejection. These drug regimens have toxic side effects that restrict their use to patients who have serious progressive complications from DM. Some antirejection drugs increase blood glucose levels. A pancreas-alone transplant is most often considered for patients with severe metabolic complications and for those with consistent failure of insulin-based therapy to prevent acute complications.

Pancreas transplantation is considered in patients with DM and end-stage kidney disease (ESKD) who have had or plan to have a kidney transplant. Normal blood glucose levels after pancreas transplantation improve kidney graft survival. Pancreas graft survival is better when performed at the time of the kidney transplant.

### Whole-Pancreas Transplantation.

The 1-year survival rate for patients in North America is above 95%, with more than 83% of patients remaining free of insulin injection and diet restrictions after 1 year (Kidney Foundation of Canada,

2015; U.S. Department of Health and Human Services [USDHHS], 2015). The degree of HLA tissue-type matching affects the results.

Pancreatic transplantation is performed in one of three ways: pancreas transplant alone (PTA), pancreas after kidney transplant (PAK), and simultaneous pancreas and kidney transplant (SPK). SPK is the ideal procedure for patients with DM and uremia.

### **Operative Procedure.**

Most pancreatic transplants are from cadaver donors using a total pancreas still attached to the exit of the pancreatic duct. The recipient's pancreas is left in place, and the donated pancreas is placed in the pelvis. The insulin released by the pancreas graft is secreted into the bloodstream. The new pancreas also produces about 800 to 1000 mL of fluid daily, which is diverted to either the bladder or the bowel.

Excretion of pancreatic fluids can impair FLUID AND ELECTROLYTE BALANCE, and drainage of these fluids into the urinary bladder causes irritation. When the pancreas is attached to the bladder, the loss of fluid rich in bicarbonate may cause acidosis.

### **Rejection Management.**

A combination of drugs is used to reverse rejection. (See [Chapter 17](#) for a listing of agents used to prevent or manage transplant rejection.) Patients undergoing antirejection therapy first receive drugs to prevent viral, bacterial, and fungal infection because of the risk for opportunistic infections from overall reduced IMMUNITY. Most patients receiving high-dose steroids, as well as those on chronic long-term steroid therapy, will require dosage adjustments in insulin to achieve desired levels of glucose control.

In most episodes of rejections, kidney problems occur before pancreatic problems. An increase in serum creatinine indicates rejection of both the transplanted kidney and the pancreas. In patients with bladder drainage of pancreatic hormones, a decrease in the urine amylase level by 25% is an indication to treat rejection. High blood glucose levels are a later marker of rejection and usually indicate irreversible graft failure.

### **Long-Term Effects.**

Long-term antirejection therapy reduces IMMUNITY even further and increases the risk for infection, cancer, and atherosclerosis. When insulin drains into systemic rather than portal (liver) circulation, blood insulin levels rise (hyperinsulinemia) and increase the risk for hypertension and macrovascular disease.

### **Complications.**

Complications are common in patients taking long-term antirejection therapy. Monitor laboratory values, FLUID AND ELECTROLYTE BALANCE, physical changes, and changes in vital signs to identify possible complications. Early removal of IV and intra-arterial lines, use of sterile technique with dressing changes and catheter irrigations, strict handwashing by all personnel, and good pulmonary hygiene help prevent infection.

Immediate complications include thrombosis, pancreatitis, anastomosis leak with infection, and rejection of the transplanted pancreas. Pancreatic blood vessel thrombosis occurs in about 30% of patients after transplantation. Observe for and report any sudden drop in urine amylase levels, rapid increases in blood glucose, gross **hematuria** (bloody urine), and tenderness or pain in the graft area. Pancreatitis in the transplanted organ occurs to some degree in all patients after surgery. Report elevations in serum amylase that persist after 48 to 96 hours.

The most serious complication of enteric-drained pancreas transplantation is leaking and intra-abdominal abscess. Observe for and report temperature elevation, abdominal discomfort, and elevation in white blood cell (WBC) count. Drainage of bicarbonate-rich fluid with pancreatic enzymes into the urinary bladder can cause urinary tract infections, cystitis, urethritis, and balanitis rather than intra-abdominal abscess. Metabolic acidosis occurs from the loss of large amounts of alkaline pancreatic secretions.

Assess for and document indications of rejection. In acute rejection, decreased kidney function is indicated by increased serum creatinine, decreased urine output, hypertension, weight gain, graft tenderness, and fever. Proteinuria is the first indicator of chronic graft rejection. Check for increased blood amylase, lipase, or glucose; decreased urine amylase; graft tenderness; hyperglycemia; and

fever. It is especially important to assess for infection and start appropriate therapy. Fever can indicate both infection and rejection.

Monitor for side effects of the antirejection drugs. Cyclosporine (Neoral) is toxic to the kidney. Signs of toxicity are elevated creatinine and decreased urine output. Monitor WBC counts daily because azathioprine (Imuran) can suppress bone marrow function. Common side effects of tacrolimus (Prograf) are hypertension, kidney toxicity, neurotoxicity, GI toxicity, and glucose intolerance. Prednisone has many side effects, including elevated blood glucose levels.

### Islet Cell Transplantation.

Islet cell transplantation has had limited success. Wider use of this procedure is hindered by the limited supply of beta cells available for transplantation and by issues related to rejection. Islet cells from tissue-typed (HLA-matched) cadaver pancreas glands are injected into the portal vein. The new cells lodge in the liver and begin to function, secreting insulin and maintaining near-perfect blood GLUCOSE REGULATION.

Currently most patients undergoing this procedure eventually have a progressive loss of islet cell function over time. Very few islet cell transplant recipients have remained insulin free for more than 4 years. The reasons for this gradual loss of function are not known and make this procedure a long-term but temporary intervention.

## Enhancing Surgical Recovery

### Planning: Expected Outcomes.

The patient with DM undergoing a surgical procedure is expected to recover completely without complications. Indicators include:

- Wound healing
- Absence of infection
- Maintenance of blood glucose levels within expected range

### Interventions.

Surgery is a physical and emotional stressor, and the patient with DM is at higher risk for complications. Anesthesia and surgery cause a stress response with release of counterregulatory hormones that elevate blood glucose. Stress hormones suppress insulin action, increasing the risk for ketoacidosis. Hyperglycemic-hyperosmolar state (HHS) is a serious complication after surgery and is associated with increased mortality. Diuresis from hyperglycemia can cause dehydration and increases the risk for acute kidney injury.

Complications of DM increase the risk for surgical problems. Patients with DM are at higher risk for hypertension, ischemic heart disease, cerebrovascular disease, myocardial infarction (MI), and cardiomyopathy. Heart failure is a serious risk factor and must be optimized before surgery. Autonomic neuropathy may result in sudden tachycardia, bradycardia, or postural hypotension. The patient with DM is at risk for acute kidney injury and urinary retention after surgery, especially if he or she has albumin in the urine (indicator of kidney damage). Nerves to the intestinal wall and sphincters can be impaired, leading to delayed gastric emptying and reflux of gastric acid, which increases the risk for aspiration with anesthesia. Autonomic neuropathy may cause paralytic ileus after surgery.

### Preoperative Care.

Before surgery, blood glucose levels are optimized to reduce the risk for complications. Sulfonylureas are discontinued 1 day before surgery. Metformin is stopped at least 24 hours before surgery and restarted only after kidney function is documented as normal. All other oral drugs are stopped the day of surgery. Patients taking long-acting insulin may need to be switched to intermediate-acting insulin forms 1 to 2 days before surgery.

Preoperative blood glucose levels should be less than 200 mg/dL (11.1 mmol/L). Higher levels are associated with increased infection rates and impaired wound healing.

Plan ahead for pain control after surgery. Pain, a stressor, triggers the release of counterregulatory hormones, increasing blood glucose levels and insulin needs. Opioid analgesics slow GI motility and alter blood glucose levels. The older patient who receives opioids is more at risk for confusion, paralytic ileus, hypoventilation, hypotension, and urinary retention. Patient-

controlled analgesia (PCA) systems reduce respiratory complications and confusion. (See [Chapter 3](#) for pain interventions and [Chapter 14](#) for general preoperative care.)

### Intraoperative Care.

IV infusion of insulin, glucose, and potassium is standard therapy for perioperative management of DM. The object is to keep the glucose level between 140 and 180 mg/dL (7.8 and 10.0 mmol/L) during surgery to prevent hypoglycemia and reduce risks from hyperglycemia. Insulin/glucose infusion rates are based on hourly capillary glucose tests. Higher insulin doses may be needed because stress releases glucagon and epinephrine. Patients with DM usually receive about 5 g of glucose per hour during surgery to prevent hypoglycemia, ketosis, and protein breakdown.

Monitor the patient's temperature—it may be lowered deliberately in some surgical procedures and inadvertently in others. Low operating room temperatures and large incisions also lower body temperature. Hypothermia decreases metabolic needs, depresses heart rate and contractility, causes vasoconstriction, and impairs insulin release, resulting in high blood glucose levels. Monitor arterial blood gas values for acidosis.

### Postoperative Care.

Hyperglycemia leads to increased mortality after surgical procedures. AACE and ADA guidelines recommend insulin dosing to maintain blood glucose between 140 and 180 mg/dL (7.8 and 10.0 mmol/L) for critically ill patients ([ADA, 2017d](#)).

Protocols and computer-based programs can be used to determine the insulin infusion rate required to maintain blood glucose levels within a defined target range. Many insulin infusion algorithms are implemented by nursing staff. Continue glucose and insulin infusions as prescribed until the patient is stable and can tolerate oral feedings. Short-term insulin therapy may be needed after surgery for the patient who usually uses oral agents. For those receiving insulin therapy, dosage adjustments may be required until the stress of surgery subsides.

### Monitoring.

Patients with autonomic neuropathy or vascular disease need close monitoring to avoid hypotension or respiratory arrest. Those who take beta blockers for hypertension need close monitoring for hypoglycemia because these drugs mask symptoms of hypoglycemia. Patients with increased blood protein or nitrogens in the blood may have problems with fluid management. Check central venous pressure or pulmonary artery pressure as needed.

Glucose levels are a sensitive marker of counterregulatory hormones, which are often activated before patients become febrile. *Hyperglycemia often occurs before a fever.*

## Nursing Safety Priority QSEN

### Action Alert

When a patient who has had reasonably controlled blood glucose levels in the hospital develops an unexpected rise in blood glucose values, check for wound infection.

**Hyperkalemia** (high blood potassium level) is common in patients with mild to moderate kidney failure and can lead to cardiac dysrhythmia. In other patients, **hypokalemia** (low blood potassium level) may occur and be made worse by insulin and glucose given during surgery. Monitor the cardiac rhythm and serum potassium values.

*Cardiovascular monitoring* by continuous ECG is recommended for older patients with DM, those with long-standing type 1 DM, and those with heart disease. Patients with DM are at higher risk for MI after surgery with a higher mortality rate. Changes in ECG or potassium level may indicate a silent MI.

*Kidney monitoring*, especially observing fluid balance, helps detect acute kidney injury. Diagnosis of kidney impairment may require the use of x-ray studies using contrast medium, which may be nephrotoxic. Management of infections may require the use of nephrotoxic antibiotics. Ensure adequate hydration when these drugs are used. Check for impending kidney failure by assessing

FLUID AND ELECTROLYTE BALANCE.

## Nutrition.

Patients requiring clear or full liquid diets should receive about 200 g of carbohydrate daily in equally divided amounts at meals and snack times. Initial liquids should *not* be sugar free. Most patients require 25 to 35 calories per kilogram of body weight every 24 hours. After surgery, food intake is initiated as quickly as possible, with progression from clear liquids to solid foods occurring as rapidly as tolerated. Returning to a normal meal plan as soon as possible after surgery promotes healing and metabolic balance. When oral foods are tolerated, make sure the patient eats at least 150 to 200 g of carbohydrate daily to prevent hypoglycemia.

If total parenteral NUTRITION (TPN) is used after surgery, severe hyperglycemia may occur. Monitor blood glucose often to determine the need for supplemental insulin.

## Preventing Injury From Peripheral Neuropathy

### Planning: Expected Outcomes.

The patient with DM is expected to identify factors that increase the risk for injury, practice proper foot care, and maintain intact skin on the feet. Indicators include that the patient consistently demonstrates these behaviors:

- Cleanses and inspects the feet daily
- Wears properly fitting shoes
- Avoids walking in bare feet
- Trims toenails properly
- Reports nonhealing breaks in the skin of the feet to the primary health care provider

### Interventions.

Patients with DM need intensive teaching about foot care because foot injury is a common complication. Once a failure of TISSUE INTEGRITY has occurred and an ulcer has developed, there is an increased risk for wound progression that may eventually lead to amputation. Most lower-extremity amputations in adults with DM are preceded by foot ulcers, and the 5-year mortality rate after leg or foot amputation is high ([Centers for Disease Control and Prevention \[CDC\], 2015](#)). Neuropathy is the main factor for development of a diabetic ulcer, and an inadequate vascular supply is the main cause of poor healing.

Motor neuropathy damages the nerves of foot muscles, resulting in foot deformities. These deformities create pressure points that gradually reduce TISSUE INTEGRITY with skin breakdown and ulceration. Thinning or shifting of the fat pad under the metatarsal heads decreases cushioning and increases areas of pressure. In claw toe deformity, toes are hyperextended and increase pressure on the metatarsal heads ("ball" of the foot). These changes predispose the patient to callus formation, ulceration, and infection. The Charcot foot is a type of diabetic foot deformity with many abnormalities, often including a *hallux valgus* (turning inward of the great toe) ([Fig. 64-6](#)). The foot is warm, swollen, and painful. Walking collapses the arch, shortens the foot, and gives the foot a "rocker bottom" shape.

**FIG. 64-6** “Charcot foot” type of diabetic foot deformity. From Frykberg, R.G., Zgonis, T., Armstrong, D.G., Driver, V.R., Giurini, J.M., Kravitz, S.R., et al. (2006). Diabetic foot disorders: A clinical practice guideline—2006 revision. *The Journal of Foot and Ankle Surgery*, 45(5), S1-S66.)

Autonomic neuropathy causes loss of normal sweating and skin temperature regulation, resulting in dry, thinning skin. Skin cracks and fissures increase the infection risk. Sensory neuropathy may cause tingling or burning, but more often it produces numbness and reduced SENSORY PERCEPTION. Without sensation, the patient does not notice injury and loss of TISSUE INTEGRITY in the foot. Peripheral arterial disease reduces blood flow to the foot, increasing the risk for ulcer formation and slowing ulcer healing (McCance et al., 2014).

Foot injuries are caused by walking barefoot, wearing ill-fitting shoes, sustaining thermal injuries from heat (e.g., hot water bottles, heating pads, baths), or chemical burns from over-the-counter corn treatments. These injuries lead to loss of TISSUE INTEGRITY and to amputation.

Ulcers result from continued pressure. Plantar ulcers (on the sole, usually the ball) are from standing or walking. Those on the top or sides of the foot usually are from shoes. The increased pressure causes calluses. Ulcers usually form over or around the great toe, under the metatarsal heads, and on the tops of claw toes.

Loss of TISSUE INTEGRITY with broken skin increases the risk for infection. Skin tends to break in areas of pressure. Infection is common in diabetic foot ulcers and, once present, is difficult to treat. Infection also impairs GLUCOSE REGULATION, leading to higher blood glucose levels and reduced IMMUNITY, which further increases the risk for infection.

### Prevention of High-Risk Conditions.

Neuropathy of the feet and legs can be delayed by keeping blood glucose levels near normal. Poor glucose control increases the risk for neuropathy and amputation. Urge smoking cessation to reduce the risk for vascular complications.

The risk for ulcers or amputation increases with duration of diabetes. Other risk factors are male gender; poor glucose control; and cardiovascular, retinal, or kidney complications. Foot-related risks include poor gait and stepping mechanics, peripheral neuropathy, increased pressure (callus, erythema, hemorrhage under a callus, limited joint mobility, foot deformities, or severe nail pathology), peripheral vascular disease, and a history of ulcers or amputation.

### Peripheral Neuropathy Management.

The feet should be evaluated closely at least annually. [Chart 22-9](#) lists self-management activities for prevention of injury from peripheral neuropathy, and [Table 64-10](#) lists foot risk categories.

**TABLE 64-10**  
**Foot Risk Categories**

RISK CATEGORIES	MANAGEMENT CATEGORIES
<b>Risk Category 0</b> • Has protective sensation • No evidence of peripheral vascular disease • No evidence of foot deformity or loss of TISSUE INTEGRITY	<b>Management Category 0</b> • Comprehensive foot examination once a year • Patient education to include advice on appropriate footwear
<b>Risk Category 1</b> • Does not have protective sensation • May have evidence of foot deformity	<b>Management Category 1</b> • Evaluation every 3-6 months • Consider referral to a specialist to assess need for specialized treatment and follow-up • Patient education
<b>Risk Category 2</b> • Does not have protective sensation • Evidence of peripheral vascular disease	<b>Management Categories 2 &amp; 3</b> • Evaluation every 1-3 months • Referral to a specialist • Prescription footwear
<b>Risk Category 3</b> • History of ulcer or amputation	<b>Management Categories 2 &amp; 3</b> • Consider vascular consultation for combined follow-up • Patient education

Data from American Diabetes Association (ADA). (2017). Classification and diagnosis of diabetes. *Diabetes Care*, 40(Suppl 1), S11-S24.

Complete a full foot assessment as outlined in [Chart 64-5](#). Sensory examination with Semmes-Weinstein monofilaments is a practical measure of the risk for foot ulcers. The nylon monofilament is mounted on a holder standardized to exert a 10-g force. An adult who cannot feel the 10-g pressure at any point is at increased risk for ulcers. To perform the examination:

### Chart 64-5

## Focused Assessment

### The Diabetic Foot

Assess the patient's risk for diabetic foot problems:

- History of previous ulcer
- History of previous amputation

Assess the foot for abnormal skin and nail conditions:

- Dry, cracked, fissured skin
- Ulcers
- Toenails: thickened, long nails; ingrown nails
- Tinea pedis; onychomycosis (mycotic nails)
- Assess the foot for status of circulation:
- Symptoms of claudication
- Presence or absence of dorsalis pedis or posterior tibial pulse
- Prolonged capillary filling time (greater than 25 seconds)
- Presence or absence of hair growth on the top of the foot

Assess the foot for evidence of deformity:

- Calluses, corns
- Prominent metatarsal heads (metatarsal head is easily felt under the skin)
- Toe contractures: clawed toes, hammertoes

- Hallux valgus or bunions
- Charcot foot (“rocker bottom”)

Assess the foot for loss of strength:

- Limited ankle joint range of motion
- Limited motion of great toe

Assess the foot for loss of protective sensation:

- Numbness, burning, tingling
- Semmes-Weinstein monofilament testing at 10 points on each foot

Data from American Diabetes Association (ADA). (2017). Standards of medical care in diabetes—2017: Microvascular complications and foot care. *Diabetes Care*, 40(Suppl. 1), S88-S98.

- Ask the patient to close his or her eyes during the test.
- Test the monofilament on the patient's cheek so he or she knows what to expect.
- Test the sites noted in [Fig. 64-7](#).

**FIG. 64-7** Placement sites of monofilaments for testing of protective sensation.

- Apply the monofilament at a right angle to the skin surface.
- Apply enough force to bend the filament using a smooth, not jabbing, motion ([Fig. 64-8](#)).

**FIG. 64-8** Correct technique for sensation testing with 10-g monofilament. **A**, Apply monofilament to designated areas of the foot sole (intact skin only; see Fig. 64-7). **B**, Apply pressure to the filament either until the patient states that he or she can feel the pressure or until the filament bends (see the [Peripheral Neuropathy Management](#) section). **C**, Quickly remove the filament without sliding it or touching other areas of the foot.

- The approach, contact, and removal of the filament at each site should take 1 to 2 seconds.
- Apply the filament along the perimeter and **not** on an ulcer site, callus, scar, or necrotic tissue. Do not slide the filament across the skin or make repeated contact at the test site.
- Randomize the sequence of applying the filament throughout the examination. Have the patient identify where the filament touched rather than asking, “Do you feel this?”

### Footwear.

Patients with any degree of peripheral neuropathy are at risk for loss of TISSUE INTEGRITY and need to wear protective shoes fitted by an experienced shoe fitter, such as a certified podiatrist. The shoe should be  $\frac{1}{2}$  to  $\frac{5}{8}$  inch longer than the longest toe. Heels should be less than 2 inches high. Tight shoes damage tissue. Instruct the patient to change shoes by midday and again in the evening. Socks must fit properly and be appropriate for the planned activity. Socks should feel soft and have no thick seams, creases, or holes. They should pad the foot and absorb excess moisture. Teach patients to avoid tight stockings or those that have constricting bands. Patients with toe deformities need custom shoes with high, wide toe boxes and extra depth. Those with severely deformed feet need specially molded shoes. New shoes need a long break-in period with frequent foot inspection for irritation or blistering.

### Foot Care.

Teach patients about preventive foot care and the need for examination of the feet and legs at each visit to a primary health care provider. A mirror placed on the floor can help the patient visually examine the plantar surface (sole) of the foot. Identify patients with high-risk foot conditions. Explain problems caused by loss of protective sensation, the importance of monitoring the feet daily, proper care of the feet (including nail and skin care), and how to select appropriate footwear.

Assess the patient's ability to inspect all areas of the foot and to perform foot care. Teach family members how to inspect and care for the patient's feet if the patient cannot. [Chart 64-6](#) lists foot care instructions for self-management.

## Chart 64-6

# Patient and Family Education: Preparing for Self-Management

## Foot Care Instructions

- Inspect your feet daily, especially the area between the toes.
- Wash your feet daily with lukewarm water and soap. Dry thoroughly.
- Apply moisturizing cream to your feet after bathing. Do not apply to the area between your toes.
- Change into clean cotton socks every day.
- Do not wear the same pair of shoes 2 days in a row and wear only shoes made of breathable materials, such as leather or cloth.
- Check your shoes for foreign objects (nails, pebbles) before putting them on. Check inside the shoes for cracks or tears in the lining.
- Purchase shoes that have plenty of room for your toes. Buy shoes later in the day, when feet are normally larger. Break in new shoes gradually.
- Wear socks to keep your feet warm.
- Trim your nails straight across with a nail clipper. Smooth the nails with an emery board.
- See your physician or nurse immediately if you have blisters, sores, or infections. Protect the area with a dry, sterile dressing. Do not use adhesive tape to secure dressing to the skin.
- Do not treat blisters, sores, or infections with home remedies.
- Do not smoke.
- Do not step into the bathtub without checking the temperature of the water with your wrist or thermometer. Optimal temperature is 95° F (35° C). Maximum temperature is 110° F (43° C).
- Do not use very hot or cold water. Never use hot-water bottles, heating pads, or portable heaters to warm your feet.
- Do not treat corns, blisters, bunions, calluses, or ingrown toenails yourself.
- Do not go barefooted.
- Do not wear sandals with open toes or straps between the toes.
- Do not cross your legs or wear garters or tight stockings that constrict blood flow.
- Do not soak your feet.

Data from American Diabetes Association (ADA). (2017). Standards of medical care in diabetes—2017: Microvascular complications and foot care. *Diabetes Care*, 40(Suppl. 1), S88-S98.

### Wound Care.

The standards of care for diabetic ulcers are a moist wound environment, débridement of necrotic tissue, and elimination of pressure (offloading). Proper wound care and débridement are discussed in [Chapter 25](#).

Eliminating pressure on an infected area is essential for wound healing. Teach patients with foot ulcers to not wear a shoe on the affected foot while the ulcer is healing. Those with poor SENSORY PERCEPTION may keep walking on an ulcer because it does not hurt. This results in pressure necrosis that delays healing and increases ulcer size. Pressure is reduced by specialized orthotic devices, custom-molded shoe inserts, or shoe adjustments that redistribute weight.

Offloading redistributes force away from ulcer sites and pressure points to wider areas of the foot. Available products include total-contact casting, half shoes, removable cast walkers, wheelchairs, and crutches. Total-contact casts redistribute pressure over the bottom of the foot. Casting material is molded to the foot and leg to spread pressure along the entire surface of contact,

reducing vertical force. The almost complete elimination of motion of the total-contact cast reduces plantar shear forces. The cast is removed 24 to 48 hours after application to inspect the foot and cast fit. It is replaced and then reapplied weekly until the ulcer is healed. *Teach the patient that foot ulcers will recur unless weight is permanently redistributed.*

## Managing Pain

### Planning: Expected Outcomes.

The patient with neuropathic pain is expected to experience relief of pain. Indicators include these consistent behaviors:

- Uses preventive measures
- Uses available resources to increase comfort
- Reports pain controlled

### Interventions.

Neuropathic pain results from damage anywhere along the nerve. Many patients with DM suffer from the painful neuropathy. Symptoms of diabetic neuropathy include:

- Burning, tingling, numbness, and loss of proprioception in lower extremities
- Muscle cramps
- Piercing, stabbing, or darting pain
- Metatarsalgia (feeling as if you are walking on marbles)
- Hyperalgesia (exaggerated pain response)
- Allodynia (pain in response to normally nonpainful stimuli)

Maintaining normal blood glucose levels and avoiding extreme fluctuations prevent chronic neuropathy and relieve symptoms. Rapid improvement in blood glucose control may actually trigger acute peripheral neuropathy.

Several pharmacologic agents are used to manage neuropathic pain, such as the anticonvulsants gabapentin (Neurontin) and pregabalin (Lyrica) and the serotonin-norepinephrine reuptake inhibitor (SNRI) duloxetine (Cymbalta). Tricyclic antidepressants such as amitriptyline hydrochloride (Elavil, Levate ♣) and nortriptyline (Pamelor) have been used for neuropathic pain but are not approved for this purpose and have significant side effects. Their use is contraindicated for older adults and those with cardiovascular disease.

The burning of neuropathy may respond to capsaicin cream 0.075% (Axsain ♣, Zostrix-HP). Teach the patient to apply it four times daily for several weeks. The pain may worsen for several days after therapy is started before improving.

Unpleasant symptoms are noted with abrupt discontinuation of many of these drugs. A gradual reduction in the dose is recommended to prevent side effects.

Provide support and information on measures to reduce pain. Even having a bed cradle to lift bed clothes off hypersensitive skin can be beneficial. Help the patient maintain stable glucose control. *All patients with neuropathy are at increased risk for foot ulcers and require more frequent assessment and education in routine foot management.*

## Preventing Injury From Reduced Vision

### Planning: Expected Outcomes.

The patient with DM is expected to be free of injury related to reduced SENSORY PERCEPTION for vision and to maintain current level of vision. Indicators include:

- No further reduction of visual fields
- No double vision

### Interventions

#### Blood Glucose Control.

Poor blood glucose control, proteinuria, hypertension, and long duration of DM are risk factors for vision loss among adults with diabetes. Surgical intervention for retinal hemorrhage or new retinal

blood vessel growth can reduce vision loss.

Besides regular eye examinations to evaluate retinopathy, urge the patient with impaired vision to have an optometrist or ophthalmologist assess the remaining vision and prescribe appropriate vision support. A functional vision assessment, performed by a low-vision technician, rehabilitation teacher, or diabetes educator, determines the patient's use of lighting, contrast, nonoptical and low-vision devices, large-print options, and use of central or peripheral vision. Many low-vision reading aids are available as described in [Chapter 47](#). The American Foundation for the Blind (AFB) maintains a list of services for visually impaired people that is organized by type of service and geographic area. More information is available at (800) 232-5463 and [www.afb.org](http://www.afb.org).

### Environmental Management.

Not all visually impaired patients need special devices. Adjustments in lighting, contrast, color, distance, type size of printed materials, and eye movement often improve visual abilities. [Chapter 47](#) describes general methods of enhancing vision. For patients with DM and low vision, coding objects such as vials of insulin with bright colors or felt-tipped markers helps identify the correct bottle. Bringing the blood glucose lancet or insulin syringe close to the eye makes it easier to see.

Prefilled insulin pens are not approved for use by adults with severe visual impairment unless they are assisted by a person with good vision who is trained to use the pen correctly. Adaptive devices can help the patient self-administer insulin independently. Some syringes may have a magnifier attached to the syringe. Other devices include preset dose gauges (which measure the space between the end of the syringe barrel and the plunger) to help the patient draw up the correct amount of insulin by feeling this distance. The blind patient can accurately measure insulin by using products such as the Count-A-Dose Insulin Measuring Device. This device is designed to be used with the BD Lo-Dose syringe. It holds two insulin vials and has a slot to direct the syringe needle into the vials' rubber stoppers. The patient draws insulin into the syringe by turning a thumb-wheel, which clicks for each unit (clicks can be both heard and felt). (See the Consumer Guide published yearly in the January edition of Diabetes Forecast [[forecast.diabetes.org](http://forecast.diabetes.org)] for information to help patients determine which adaptive devices best meet their needs.) When teaching the patient to use an adaptive device, stress:

- Differentiating between bottles of fast-acting and slower-acting insulin by wrapping a rubber band around the fast-acting insulin bottle
- Ensuring proper placement of the device on the syringe
- Holding the insulin bottle upright when measuring insulin
- Avoiding air bubbles in the syringe by pulling a small amount of insulin into the syringe, moving the plunger in and out three times, and measuring insulin on the fourth draw

Help the patient determine how many doses can be drawn from a bottle so he or she does not inject air from an empty bottle instead of insulin.

Specialized adaptive equipment also is available to assist with blood glucose monitoring techniques. Help the patient select a blood glucose monitoring device best suited to his or her level of visual impairment. Some monitors have large display screens and easy-to-use features. Fully audio systems are available for patients who are visually impaired. Assess the ability of the patient to obtain an adequate blood sample and apply it to the test strip. Commercially made blood drop guides can help with this task.

## Reducing the Risk for Kidney Disease

### Planning: Expected Outcomes.

The patient with diabetes is expected to maintain a normal urine elimination pattern. Indicators include:

- Urine protein levels within normal limits
- 24-hour intake and output balance
- Blood urea nitrogen (BUN) and serum creatinine within the normal ranges
- Serum electrolytes within the normal ranges

### Interventions

## Prevention.

Diabetic kidney disease is more likely to develop in patients with poor blood glucose control. Progression to end-stage kidney disease can be delayed or prevented by normalizing blood pressure using drugs from either the angiotensin-converting enzyme inhibitor (ACEI) class or the angiotensin receptor blocker (ARB) class. Once used to “protect” the kidney, neither class of drug is recommended for patients with DM who have normal blood pressure and normal albumin excretion (ADA, 2017c). Hypertension greatly accelerates the progression of diabetic kidney disease.

Stress the need for evaluation of kidney function according to the ADA Standards of Care. An annual test to quantify urine albumin is performed for patients who have had type 1 DM for over 5 years and in all those with type 2 DM starting at diagnosis and during pregnancy (ADA, 2017c). Persistent albuminuria in the range of 30 to 299 mg/24 hours (formerly called *microalbuminuria*) is the earliest stage of nephropathy in type 1 DM and a marker for the development of nephropathy in type 2 DM.

Aggressive control of blood glucose and hypertension in patients without albuminuria can avoid nephropathy. Once albuminuria develops, management focuses on controlling blood pressure and blood glucose and avoiding nephrotoxic agents.

Control of blood pressure and blood glucose levels requires the patient's participation and effort. Prescribed drugs must be taken according to schedules, and dietary restriction must be maintained. Teach patients about the roles of blood pressure and blood glucose levels in kidney disease. Help them maintain normal blood glucose levels and blood pressure levels below 140/80 mm Hg. Stress the need for yearly screening for albuminuria.

Smoking cessation is important in halting the progression of diabetic kidney disease. Teach the patient about the risks of smoking and refer him or her to appropriate resources for assistance in smoking cessation.

Drugs can affect kidney function either through toxic effects on the kidney or by an acute but reversible reduction in function. The most common nephrotoxic drugs are antifungal agents and aminoglycoside antibiotics. Outside the hospital, the leading nephrotoxic agents are NSAIDs such as ibuprofen (Advil) or naproxen (Aleve). Teach the patient to check with his or her primary health care provider or a pharmacist before taking over-the-counter drugs or herbal remedies.

Radiocontrast medium can also affect kidney function, especially in patients with pre-existing kidney problems. Monitor IV hydration before and after a contrast agent is used to prevent contrast-induced nephropathy in patients with DM.

## Drug Therapy.

Use of angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs) is recommended for all patients with persistent albuminuria or advanced stages of nephropathy (ADA, 2017c). ACE inhibitors reduce the level of albuminuria and the rate of progression of kidney disease, although they do not appear to prevent albuminuria. Monitor serum potassium levels for development of hyperkalemia (ADA, 2017c).

Dialysis for patients with DM and kidney failure is the same as for patients without diabetes (see Chapter 68). The dosage of insulin needs to be adjusted when dialysis starts.

## Preventing Hypoglycemia.

Hypoglycemia is a low blood glucose level that induces specific symptoms and resolves when blood glucose concentration is raised. Once plasma glucose levels fall below 70 mg/dL (3.88 mmol/L), a sequence of events begins with release of counterregulatory hormones, stimulation of the autonomic nervous system, and production of *neurogenic* and *neuroglycopenic* symptoms. Peripheral autonomic symptoms, including sweating, irritability, tremors, anxiety, tachycardia, and hunger, serve as an early warning system and occur before the symptoms of confusion, paralysis, seizure, and coma occur from brain glucose deprivation. *Neuroglycopenic symptoms* occur when brain glucose *gradually declines* to a low level. *Neurologic symptoms* result from autonomic nervous activity triggered by a *rapid decline* in blood glucose (Table 64-11).

---

**TABLE 64-11**

### Symptoms of Hypoglycemia

---

NEUROGLYCOPENIC SYMPTOMS	NEUROGENIC SYMPTOMS
--------------------------	---------------------

<ul style="list-style-type: none"> <li>• Weakness</li> <li>• Fatigue</li> <li>• Difficulty thinking</li> <li>• Confusion</li> <li>• Behavior changes</li> <li>• Emotional instability</li> <li>• Seizures</li> <li>• Loss of consciousness</li> <li>• Brain damage</li> <li>• Death</li> </ul>	<ul style="list-style-type: none"> <li>• Adrenergic: <ul style="list-style-type: none"> <li>• Shaky/tremulous</li> <li>• Heart pounding</li> <li>• Nervous/anxious</li> </ul> </li> <li>• Cholinergic: <ul style="list-style-type: none"> <li>• Sweaty</li> <li>• Hungry</li> <li>• Tingling</li> </ul> </li> </ul>
--	---

Central nervous system (CNS) function depends on a continuous supply of glucose in the blood. The brain cannot make glucose and stores only a few minutes' supply as glycogen. This needed supply is not maintained when the blood glucose level falls below critical levels.

The first defense against falling blood glucose levels in the adult without DM is decreased insulin secretion, decreased glucose use, and increased glucose production. Normally, insulin secretion decreases when blood glucose levels drop to about 83 mg/dL (4.5 mmol/L). Counterregulatory hormones are activated at about 67 mg/dL (3.7 mmol/L), a level well above the threshold for symptoms of hypoglycemia. The main counterregulatory hormone is glucagon. Epinephrine also becomes important in patients with DM who are deficient in glucagon. Both glucagon and epinephrine raise blood glucose levels by stimulating liver glycogen breakdown and conversion of protein to glucose. Epinephrine also limits insulin secretion.

Type 1 DM disrupts the body's response to hypoglycemia, usually within 1 to 5 years of diagnosis. Regulation of circulating insulin levels is lost because insulin comes from an injection rather than from the pancreas. As blood glucose levels fall, insulin levels do not decrease. Over time, the pancreas loses its ability to secrete glucagon in response to hypoglycemia. After a few more years of type 1 DM, the response of epinephrine to falling blood glucose levels does not occur until the blood glucose level is very low. These problems greatly increase the risk for severe hypoglycemia.

A second problem with long-standing type 1 DM is *hypoglycemic unawareness*, in which patients no longer have the warning symptoms of impending hypoglycemia that should prompt them to take preventive action. This problem occurs most often in patients who have had type 1 DM for 30 years or longer.

The blood glucose level at which symptoms of hypoglycemia occur varies among patients. Thus clinical criteria used to categorize hypoglycemia are based on symptom severity rather than blood glucose levels. In mild hypoglycemia, the patient remains alert and able to self-manage symptoms. In severe hypoglycemia, neurologic function is so impaired that he or she needs another person's help to increase blood glucose levels.

### Planning: Expected Outcomes.

The patient is expected to have decreased episodes of hypoglycemia and remain oriented to person, place, and time, as indicated by a Glasgow Coma Scale score above 7.

### Interventions.

A blood glucose level below 70 mg/dL (3.9 mmol/L) alerts you to assess for symptoms of hypoglycemia. (see [Table 64-11](#); [Table 64-12](#)).

**TABLE 64-12**  
**Differentiation of Hypoglycemia and Hyperglycemia**

FEATURE	HYPOGLYCEMIA	HYPERGLYCEMIA
Skin	Cool, clammy	Warm, moist
Dehydration	Absent	Present
Respirations	No particular or consistent change	Rapid, deep*; Kussmaul type; acetone odor ("fruity" odor) to breath
Mental status	Anxious, nervous*, irritable, mental confusion*, seizures, coma	Varies from alert to stuporous, obtunded, or frank coma
Symptoms	Weakness*, double vision, blurred vision, hunger, tachycardia, palpitations	None specific for DKA Acidosis; hypercapnia; abdominal cramps, nausea and vomiting Dehydration: decreased neck vein filling, orthostatic hypotension, tachycardia, poor skin turgor
Glucose	<70 mg/dL (3.9 mmol/L)	>250 mg/dL (13.8 mmol/L)
Urine or blood ketones	Negative	Positive

\*Classic symptoms.

DKA, Diabetic ketoacidosis.

### Blood Glucose Management.

Monitor blood glucose levels before giving antidiabetic drugs, before meals, before bedtime, and

when the patient is symptomatic. All patients who take insulin, those taking long-acting insulin secretagogues (glyburide [glibenclamide], and those taking metformin in combination with glyburide (Glucovance) are at risk for hypoglycemia. This risk is increased if they are older, have liver or kidney impairment, or are taking drugs that enhance the effects of antidiabetic drugs. Proper patient selection, drug dosage, and instructions are important factors in avoiding severe hypoglycemia. In the hospital setting it is important that mealtime insulin be coordinated with delivery of food for patient consumption to avoid episodes of hypoglycemia (see the [Quality Improvement box](#)).

## Quality Improvement QSEN

### Increasing “Perfect Blood Glucose Control” Improved Insulin-Mealtime Match Among Inpatients With Diabetes

Engle, M., Fergusin, A., & Fields, W. (2016). A journey to improved inpatient glycemic control by redesigning meal delivery and insulin administration. *Clinical Nurse Specialist, 30*(2), 117–124.

Hypoglycemia is a common preventable occurrence in the acute care setting, most often caused by a lack of coordination between blood glucose testing, insulin administration, and meal delivery. This “never” event has the potential for serious adverse health outcomes and death and is the focus of the development of strategies for “perfect blood glucose (BG) control” in which BG does not fall below 70 mg/dL (3.68 mmol/L) nor elevates beyond 180 mg/dL (10 mmol/L).

The incidence of hyperglycemia and hypoglycemia in one large (540-bed) acute care community hospital was examined for a calendar year among all inpatients receiving insulin for diabetes. The rate of perfect blood glucose control was only 45%. This less-than-desirable rate was attributed primarily to issues relating to timing of premeal blood glucose checks, meal delivery, and administration of insulin. A major problem with inconsistent meal tray delivery through the dietary department was uncovered. This obstacle to perfect blood glucose control often resulted in patients having their point-of-care premeal blood glucose testing and insulin administration after, rather than before, consumption of a meal. The percentage of patients receiving mealtime insulin within 30 minutes of accurate blood glucose checks was only 35%.

A plan was developed in cooperation with the dietary department in which trays for patients receiving mealtime insulin were identified from a computer-generated list and were ticketed by dietary staff with a colored stamp stating “INSULIN” to differentiate them from trays for patients with diabetes who were not receiving insulin. Once the trays were prepared and ready to deliver to the nursing unit, dietary called the unit to inform nurses that a specific tray was en route. At that time, the nurse would perform point-of-care blood glucose testing. On arrival of the tray to the unit, the tray was delivered by the nurse who then administered the prescribed mealtime and correction insulin dose (based on the blood glucose level and the assessment by the nurse of the amount of carbohydrate the patient was expected to eat).

Examination of data after this policy was implemented hospital-wide revealed an increase of perfect blood glucose control rate to 53% and an improvement of the percentage of patients receiving mealtime insulin within 30 minutes of the blood glucose check from 35% to 73%. The incidence of both hyperglycemia and hypoglycemia decreased.

#### Commentary: Implications for Practice and Research

This quality improvement project demonstrated that barriers to best practice can be overcome for patient safety when interprofessional coordination is successful. The work flow for both nursing and dietary personnel required modification and coordination. Although improvement was significant, more research, especially in prevention of hypoglycemic episodes, is needed to achieve “perfect blood glucose control” in large acute care settings.

Hypoglycemia may be difficult to recognize in those who take beta-blocking drugs. Symptoms are less intense and less obvious. Symptoms of hypoglycemia in older patients may be mistaken for other conditions.

The most common causes of hypoglycemia are:

- Too much insulin compared with food intake and physical activity
- Insulin injected at the wrong time relative to food intake and physical activity

- The wrong type of insulin injected at the wrong time
- Decreased food intake resulting from missed or delayed meals
- Delayed gastric emptying from gastroparesis
- Decreased liver glucose production after alcohol ingestion
- Increased insulin sensitivity as a result of regular exercise and weight loss
- Decreased insulin clearance from progressive kidney failure

### Nutrition Therapy.

When the patient is hypoglycemic, start prescribed carbohydrate (CHO) replacement, usually ingestion of 15 to 20 g of glucose. If the patient can swallow, give a liquid form of CHO, although any CHO source can be used. Ingestion of 15 to 20 g of glucose is the preferred management for blood glucose levels less than 70 mg/dL (3.9 mmol/L), repeated in about 15 minutes if symptoms have not improved or if blood glucose levels are still less than 70. The amount of CHO is increased to 30 g for glucose levels less than 50 mg/dL (2.8 mmol/L).

A 10-g amount of oral glucose raises plasma glucose levels by about 40 mg/dL over 30 minutes, and 20 g of oral glucose raises plasma glucose levels by about 60 mg/dL over 45 minutes. Specific recommendations are listed in [Chart 64-7](#).

### Chart 64-7

## Patient and Family Education: Preparing for Self-Management

### Management of Hypoglycemia at Home

For *mild* hypoglycemia (hungry, irritable, shaky, weak, headache, fully conscious; blood glucose usually less than 60 mg/dL [3.4 mmol/L]):

- Treat the symptoms of hypoglycemia with 10 to 15 g of carbohydrate. You may use one of these:
- Glucose tablets or glucose gel (dosage is printed on the package)
- $\frac{1}{2}$  cup (120 mL) of fruit juice
- $\frac{1}{2}$  cup (120 mL) of regular (nondiet) soft drink
- 8 ounces (240 mL) of skim milk
- 6 to 10 hard candies
- 4 cubes of sugar
- 4 teaspoons of sugar
- 6 saltines
- 3 graham crackers
- 1 tablespoon (15 mL) of honey or syrup

- Retest blood glucose in 15 minutes.
- Repeat this treatment if glucose remains less than 60 mg/dL (3 mmol/L). Symptoms may persist after blood glucose has normalized.
- Eat a small snack of carbohydrate and protein if your next meal is more than an hour away.

For **moderate** hypoglycemia (*cold, clammy skin; pale; rapid pulse; rapid, shallow respirations; marked change in mood; drowsiness; blood glucose usually less than 40 mg/dL [2.2 mmol/L]*):

- Treat the symptoms of hypoglycemia with 15 to 30 g of rapidly absorbed carbohydrate.
- Retest glucose in 15 minutes.
- Repeat treatment if glucose is less than 60 mg/dL (3 mmol/L).
- Eat additional food, such as low-fat milk or cheese, after 10 to 15 minutes.

For **severe** hypoglycemia (*unable to swallow; unconsciousness or convulsions; blood glucose usually less than 20 mg/dL [1.0 mmol/L]*):

- Treatment administered by family members:
- Give 1 mg of glucagon as intramuscular or subcutaneous injection.
- Give a second dose in 10 minutes if the person remains unconscious.
- Notify the primary health care provider immediately and follow instructions.
- If still unconscious, transport the person to the emergency department.
- Give a small meal when the person wakes up and is no longer nauseated.

The blood glucose level determines the form and amount of glucose used. The response should be apparent in 10 to 20 minutes; however, test plasma glucose again in about 60 minutes because additional management may be needed. Fluid is absorbed much more quickly from the GI tract than are solids. Concentrated sweet fluids, such as juice with sugar added or a soft drink, may slow absorption.

Management of hypoglycemia requires ingestion of glucose or glucose-containing foods. The blood glucose response correlates better with the glucose content rather than the carbohydrate content of the food. Adding protein to CHO does not improve blood glucose response and does not prevent subsequent hypoglycemia. Adding fat may retard and then prolong the blood glucose response, resulting in post-treatment hyperglycemia. Commercially available products provide predictable glucose absorption.

### Drug Therapy.

Subcutaneous or IM glucagon and 50% IV dextrose are administered to patients who cannot swallow. Glucagon is the main counterregulatory hormone to insulin and is used as first-line therapy for severe hypoglycemia in DM. It converts liver glycogen to glucose but is not effective in severely starved patients. Take care to prevent aspiration in patients receiving glucagon, because it often causes vomiting. Give 50% dextrose carefully to avoid extravasation because it is hyperosmolar and can damage tissue. The effects of glucagon and dextrose are temporary. After the patient responds and is no longer nauseated, give a simple sugar followed by a small snack or meal. IV glucose is used to maintain mild hyperglycemia. Diazoxide (Proglycem) or octreotide (Sandostatin) may be required to treat sulfonylurea-induced hypoglycemia. Evaluate response by monitoring blood glucose levels for several hours because symptoms may persist. A target blood glucose level is 70 to 110 mg/dL (3.9 to 6.2 mmol/L).

## Critical Rescue

Assess patients to recognize the presence and severity of hypoglycemia. For the patient with *severe* hypoglycemia (unable to swallow, unconscious or convulsing, blood glucose usually less than 20 mg/dL [1.0 mmol/L]), respond by:

1. Giving glucagon 1 mg subcutaneously or IM
2. Repeating the dose in 10 minutes if the patient remains unconscious
3. Notifying the primary health care provider immediately and following instructions

## Prevention Strategies.

Teach the patient how to prevent hypoglycemia by avoiding its four common causes: (1) excess insulin, (2) deficient intake or absorption of food, (3) exercise when insulin action is peaking, and (4) alcohol intake.

*Insulin excess* from variable absorption of insulin can cause hypoglycemia even when insulin is injected correctly. Increased insulin sensitivity can occur with weight loss, exercise programs, and resolution of an infection. Differences in insulin formulation can result in hypoglycemia. Teach the patient to not change insulin brands without medical supervision.

*Deficient food intake* from inadequate or incorrectly timed meals can result in hypoglycemia. Changes in gastric absorption may cause hypoglycemia in patients with delayed gastric emptying, which is more severe with solid meals and is made worse by illness or poor glucose control. Teach the patient the importance of regularity in timing and quantity of food eaten.

*Exercise* often causes blood glucose levels to fall in a patient with type 1 DM. Prolonged exercise increases muscle glucose uptake for several hours after exercise. Teach the patient about blood glucose monitoring and carbohydrate consumption before and during exercise. Also teach him or her to exercise at times when insulin activity is not peaking.

*Alcohol* inhibits liver glucose production and leads to hypoglycemia. It interferes with the counterregulatory response to hypoglycemia and impairs glycogen breakdown, making exercise-induced hypoglycemia more severe. Teach the patient to ingest alcohol only with or shortly *after* eating a meal with enough carbohydrate to prevent hypoglycemia. Warn patients to avoid excess alcohol at bedtime to prevent nighttime hypoglycemia.

## Patient and Family Education.

The cause of hypoglycemia may be subtle. At the onset of menses, a fall in hormone levels decreases insulin needs and contributes to hypoglycemia. When patients switch to a new bottle of insulin, hypoglycemia may occur because the fresh insulin has greater potency. Some patients have hypoglycemia when they change injection sites. Beta-blocking drugs mask warning signs and thus predispose patients to severe hypoglycemia. Some episodes of hypoglycemia occur without an obvious cause.

Many patients who have been treated in the emergency department for hypoglycemia do not receive adequate prevention instructions and are at continuing risk. Help each patient develop a personal treatment plan for hypoglycemia. The exact glucose rise from a set amount of carbohydrate (CHO) varies; however, using the estimate that each 5 g of CHO raises blood glucose about 20 mg/dL is a good starting plan. For example, the patient may be directed to take:

- 20 to 30 g of CHO if the blood glucose level is 50 mg/dL (2.8 mmol/L) or less
- 10 to 15 g of CHO if the blood glucose level is 51 to 70 mg/dL (2.9 to 3.9 mmol/L)

Use blood glucose monitoring results to revise or reinforce this plan.

Encourage the patient to wear a medical alert bracelet and help him or her obtain one. This bracelet is helpful if the patient becomes hypoglycemic and is unable to provide self-care.

Teach the patient and family about the symptoms of hypoglycemia. Stress that delaying a meal for more than 30 minutes raises the risk for hypoglycemia when using some insulin regimens. Instruct him or her to keep a CHO source nearby at all times. Teach the patient and family how to inject glucagon.

Hypoglycemia is a major risk for patients receiving intensive insulin protocols who engage in exercise programs. Explain that nightmares or headaches on days after prolonged or severe exercise

may indicate hypoglycemia.

### Establishing Treatment Plans.

Blood glucose monitoring directs hypoglycemia management. Treatment continues until blood glucose levels reach and stay in the target range. Once blood glucose control is regained, the patient should identify the specific cause of the episode and take specific measures to prevent recurrence.

## Considerations for Older Adults

### Patient-Centered Care QSEN

Older patients are especially vulnerable to hypoglycemia. Age-related declines in kidney function and liver enzyme activity may interfere with the metabolism of sulfonylureas and insulin, thereby potentiating their hypoglycemic effects. Older adults with DM have impaired epinephrine release and a reduced glucagon response to low blood glucose levels and often have hypoglycemic unawareness. Confusion and impairment in psychomotor skill when glucose is low prevent the older adult from taking steps to return glucose levels to normal.

Instruct the older patient's family to check blood glucose values when symptoms such as unsteadiness, light-headedness, poor concentration, trembling, or sweating occur (Touhy & Jett, 2016). Assess eating patterns to make sure that sufficient foods are eaten at appropriate times. Encourage a patient with a poor appetite to eat a small snack at bedtime to prevent hypoglycemia during the night.

The highest rates of severe and fatal episodes of hypoglycemia are associated with the use of glyburide in patients older than 70. Drug regimens that require that meals be eaten on time increase the potential for hypoglycemic reactions. Complex regimens that require multiple decision points should be simplified, especially for patients with decreased functional status (ADA, 2017h).

## Clinical Judgment Challenge 64-2

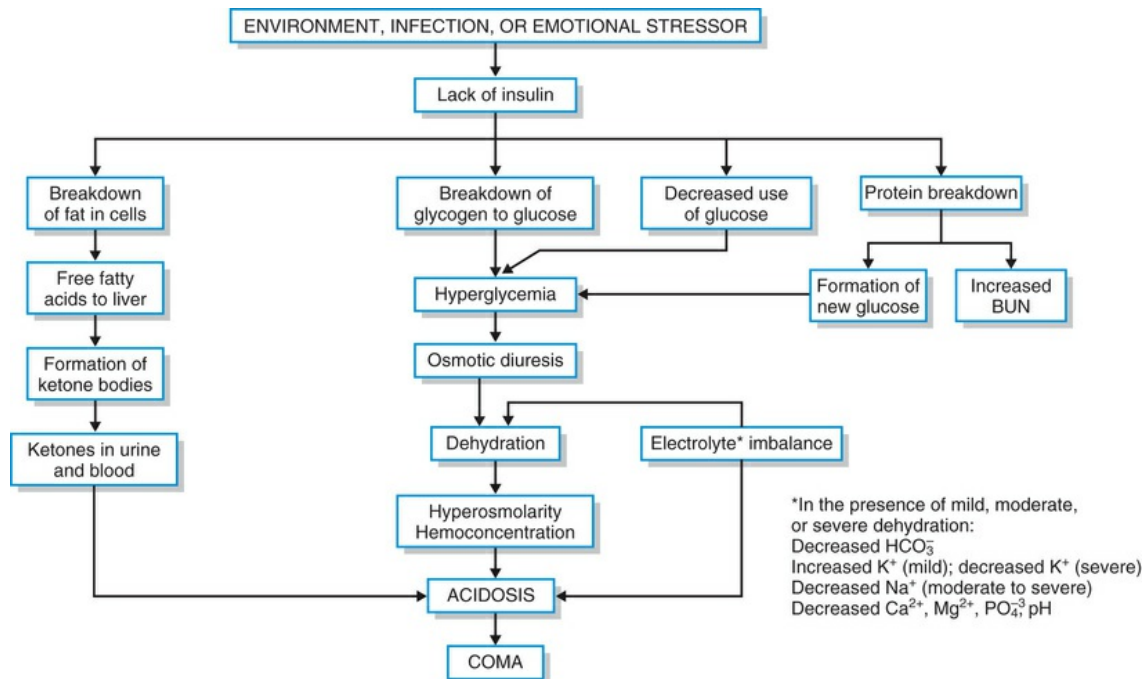

### Safety; Quality Improvement; Patient-Centered Care QSEN

The patient is a 67-year-old man with type 1 diabetes who is 2 days postoperative from a below-the-knee amputation. He is scheduled for an x-ray in an hour. His lunch has just arrived; and, after you check his blood glucose level, you administer the prescribed short-acting insulin. After updating the nurse who is covering for you, you go to lunch. When you return to the unit 45 minutes later, you receive a call from the radiology department that the patient is unconscious and his skin is cold and clammy. You check his room and find his lunch tray cold and untouched. It appears that transport services came early and did not notify anyone on the unit.

1. What is your first action? Provide a rationale.
2. What is the most likely cause leading to this problem?
3. What could be done to prevent such an incident from happening again?

### Preventing Diabetic Ketoacidosis.

Diabetic ketoacidosis (DKA) is characterized by uncontrolled hyperglycemia, metabolic acidosis, and increased production of ketones. This condition results from the combination of insulin deficiency and an increase in hormone release that leads to increased liver and kidney glucose production and decreased glucose use in peripheral tissues (Fig. 64-9). Laboratory diagnosis of DKA is shown in Table 64-13. All of these changes increase ketoacid production with resultant ketonemia and metabolic acidosis.

**FIG. 64-9** Pathophysiologic mechanism of diabetic ketoacidosis (DKA). *BUN*, Blood urea nitrogen;  $\text{Ca}^{2+}$ , calcium;  $\text{HCO}_3^-$ , bicarbonate;  $\text{K}^+$ , potassium;  $\text{Mg}^{2+}$ , magnesium;  $\text{Na}^+$ , sodium;  $\text{PO}_4^{3-}$ , phosphate.

**TABLE 64-13**

**Differences Between Diabetic Ketoacidosis and Hyperglycemic-Hyperosmolar State**

	DIABETIC KETOACIDOSIS (DKA)	HYPERGLYCEMIC-HYPEROSMOLAR STATE (HHS)
Onset	Sudden	Gradual
Precipitating factors	Infection Other stressors Inadequate insulin dose	Infection Other stressors Poor fluid intake
Symptoms	Ketosis: Kussmaul respiration, "rotting fruit" breath, nausea, abdominal pain Dehydration or electrolyte loss: polyuria, polydipsia, weight loss, dry skin, sunken eyes, soft eyeballs, lethargy, coma	Altered central nervous system function with neurologic symptoms Dehydration or electrolyte loss: same as for DKA
<b>Laboratory Findings</b>		
Serum glucose	>300 mg/dL (16.7 mmol/L)	>600 mg/dL (33.3 mmol/L)
Osmolarity/Osmolality	Variable	>320 mOsm/L (mOsm/kg)
Serum ketones	Positive at 1 : 2 dilutions	Negative
Serum pH	<7.35	>7.4
Serum $\text{HCO}_3^-$	<15 mEq/L (mmol/L)	>20 mEq/L (mmol/L)
Serum $\text{Na}^+$	Low, normal, or high	Normal or low
<i>BUN</i>	>30 mg/dL (10 mmol/L); elevated because of dehydration	Elevated
Creatinine	>1.5 mg/dL (60 $\mu\text{mol/L}$ ); elevated because of dehydration	Elevated
Urine ketones	Positive	Negative

*BUN*, Blood urea nitrogen;  $\text{HCO}_3^-$ , bicarbonate;  $\text{Na}^+$ , sodium.

DKA occurs most often in patients with type 1 DM but also can occur in those with type 2 DM who are under severe stress (e.g., trauma, surgery, infection). Some adults with type 2 DM have a syndrome known as ketosis-prone diabetes or KPD. Regardless of whether the patient with DKA has type 1 or type 2 DM, management of the acute episode is the same. The most common precipitating factor for DKA is infection. *Death occurs in up to 10% of these cases even with appropriate treatment.*

Hyperglycemia leads to osmotic diuresis with dehydration and electrolyte loss. Classic symptoms of DKA include polyuria, polydipsia, polyphagia, a rotting citrus fruit odor to the breath, vomiting, abdominal pain, dehydration, weakness, confusion, shock, and coma. Mental status can vary from total alertness to profound coma. As ketone levels rise, the pH of the blood decreases, and acidosis occurs. **Kussmaul respirations** (very deep and rapid respirations) cause respiratory alkalosis in an attempt to correct metabolic acidosis by exhaling carbon dioxide. Initial serum sodium levels may be low or normal. Initial potassium levels depend on how long DKA lasts before treatment. After therapy starts, serum potassium levels drop quickly.

### Planning: Expected Outcomes.

The patient is expected to have few episodes of hyperglycemia and avoid diabetic ketoacidosis. Indicators include that the patient consistently demonstrates these behaviors:

- Maintains blood glucose levels within the prescribed target range
- Adjusts insulin doses to match eating patterns and blood glucose levels during illness
- Maintains easily digestible liquid diet containing carbohydrate and salt when nauseated
- Describes correct procedure for urine ketone testing
- Describes when to seek help from health care professional

### Interventions

#### Blood Glucose Management.

Monitor for symptoms of DKA (see [Table 64-13](#) and [Fig. 64-9](#)). Document and use these findings to determine therapy effectiveness. *First assess the airway, level of consciousness, hydration status, electrolytes, and blood glucose level.* Check the patient's blood pressure, pulse, and respirations every 15 minutes until stable. Record urine output, temperature, and mental status every hour. When a central venous catheter is present, assess central venous pressure every 30 minutes or as prescribed. After treatment starts and these values are stable, monitor and record vital signs every 4 hours. Use blood glucose values to assess therapy and determine when to switch from saline to dextrose-containing solutions.

#### Fluid and Electrolyte Management.

*Closely assess the patient's FLUID AND ELECTROLYTE BALANCE.* Assess for acute weight loss, thirst, decreased skin turgor, dry mucous membranes, and oliguria with a high specific gravity. Assess for weak and rapid pulse; flat neck veins; increased temperature; decreased central venous pressure; muscle weakness; postural hypotension; and cool, clammy, and pale skin to determine if the patient is at risk for dehydration.

The first outcome of fluid therapy is to restore volume and maintain PERFUSION to vital organs. Typically initial infusion rates are 15 to 20 mL/kg/hr during the first hour.

The second outcome of replacing total body fluid losses is achieved more slowly. The choice for fluid replacement depends on blood pressure, hydration, serum electrolyte levels, and urinary output. In general, hypotonic fluids are infused at 4 to 14 mL/kg/hr after the initial fluid bolus. When blood glucose levels reach 250 mg/dL (13.8 mmol/L), give 5% dextrose in 0.45% saline. This solution helps prevent hypoglycemia and cerebral edema, which can occur when serum osmolality declines too rapidly.

During the first 24 hours of treatment, the patient needs enough fluids to replace the actual volume lost and any ongoing losses. This may be as much as 6 to 10 L. Assess cardiac, kidney, and mental status to avoid fluid overload. Watch for symptoms of congestive heart failure and pulmonary edema. Central venous pressure may be monitored for older patients and those with cardiac disease. Assess the status of fluid replacement by monitoring blood pressure, intake and output, and changes in daily weight.

#### Drug Therapy.

Insulin therapy is used to lower serum glucose by about 50 to 75 mg/dL/hr (2.8 to 4.2 mmol/L/hr) ([Sanuth et al., 2014](#)). Unless the episode of DKA is mild, regular insulin by continuous IV infusion is the usual management. Effective blood insulin levels are reached quickly when an IV bolus dose is given at the start of the infusion. An initial IV bolus dose of 0.1 unit/kg is followed by an IV infusion of 0.1 unit/kg/hr. Continuous insulin infusion is used because insulin half-life is short and subcutaneous insulin has a delayed onset of action. Subcutaneous insulin is started when the patient can take oral fluids and ketosis has stopped. DKA is considered resolved when blood glucose is less than 200 mg/mL (11.2 mmol/L) along with a serum bicarbonate level higher than 18 mEq/L (mmol/L), venous pH is higher than 7.3, and a calculated anion gap is less than 12 mEq/L (mmol/L). Assess therapy effectiveness by monitoring blood glucose levels and serial electrolyte levels.

#### Acidosis Management.

The key feature of DKA is elevation in blood ketone concentration (measured as serum  $\beta$ -hydroxybutyrate). Accumulation of ketoacids results in an increased anion gap metabolic acidosis. A normal anion gap is between 7 and 9 mEq/L (mmol/L); an anion gap greater than 10 to 12 mEq/L (mmol/L) indicates metabolic acidosis.

Mild-to-moderate hyperkalemia is common in patients with hyperglycemia. Insulin therapy, correction of acidosis, and volume expansion decrease serum potassium concentration. To prevent hypokalemia, potassium replacement is initiated after serum levels fall below normal (5.0 mEq/L [mmol/L]). *Assess for signs of hypokalemia, including fatigue, malaise, confusion, muscle weakness, shallow respirations, abdominal distention or paralytic ileus, hypotension, and weak pulse.* An ECG shows conduction changes related to alterations in potassium. Hypokalemia is a common cause of death in the treatment of DKA.

## Nursing Safety Priority QSEN

### Action Alert

Before giving IV potassium-containing solutions, make sure that the urine output is at least 30 mL/hr.

Bicarbonate is used only for severe acidosis (Sanuth et al., 2014). Sodium bicarbonate, given by slow IV infusion over several hours, is indicated when the arterial pH is 7.0 or less or the serum bicarbonate level is less than 5 mEq/L (5 mmol/L).

### Patient and Family Education.

Exploring the factors leading to DKA helps in planning specific educational efforts. Teach the patient and family to check blood glucose levels every 4 to 6 hours as long as symptoms such as anorexia, nausea, and vomiting are present and as long as glucose levels exceed 250 mg/dL (13.8 mmol/L). Teach them to check urine ketone levels when blood glucose levels exceed 300 mg/dL (16.7 mmol/L).

Teach the patient to prevent dehydration by maintaining food and fluid intake. Unless another health problem is present that requires fluid restriction, suggest that he or she drink at least 2 L of fluid daily and increase this amount when infection is present. When nausea is present, instruct the patient to take liquids containing both glucose and electrolytes (e.g., regular sugar-sweetened soda pop, diluted fruit juice, and sports drinks [Gatorade]). Small amounts of fluid may be tolerated even when vomiting is present. When the blood glucose level is normal or elevated, the patient should take 8 to 12 ounces (240 to 360 mL) of calorie-free and caffeine-free liquids every hour while awake to prevent dehydration.

Liquids containing carbohydrate (CHO) can be taken if the patient cannot eat solid food. Ingesting at least 150 g of CHO daily reduces the risk for starvation ketosis. After consulting the primary health care provider, urge the patient to take additional rapid-acting (lispro) or short-acting (regular) insulin based on blood glucose levels.

Instruct the patient and family to consult the primary health care provider when these problems occur:

- Blood glucose exceeds 250 mg/dL (13.8 mmol/L) that does not respond to therapy.
- Ketonuria lasts for more than 24 hours.
- The patient cannot take food or fluids.
- Illness lasts more than 1 to 2 days.

Also instruct them to detect hyperglycemia by monitoring blood glucose whenever the patient is ill. Illness can result in dehydration with DKA, hyperglycemic-hyperosmolar state, or both. The sooner the patient seeks treatment, the less severe is the metabolic alteration. He or she should not omit insulin therapy during illness. [Chart 64-8](#) lists guidelines for the ill patient.

### Chart 64-8

## Patient and Family Education: Preparing for Self-

## Management

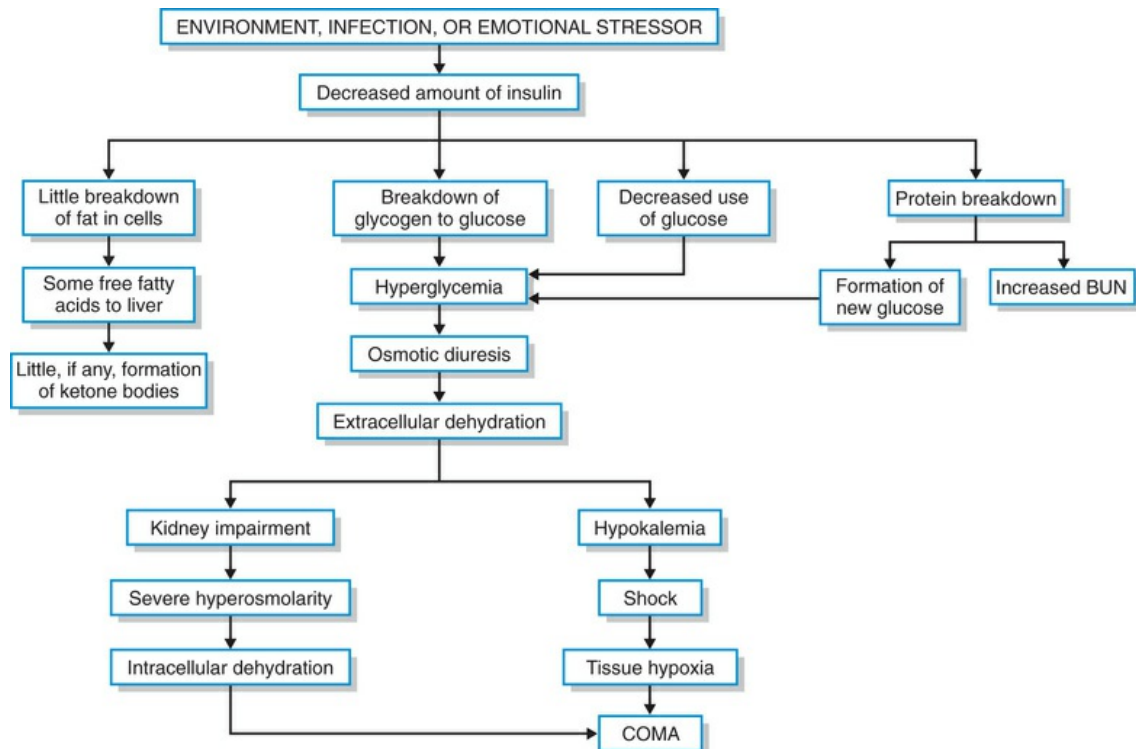

### Sick-Day Rules

- Notify your primary health care provider that you are ill.
- Monitor your blood glucose at least every 4 hours.
- Test your urine for ketones when your blood glucose level is greater than 240 mg/dL (13.8 mmol/L).
- Continue to take insulin or other antidiabetic agents.
- To prevent dehydration, drink 8 to 12 ounces (240 to 360 mL) of sugar-free liquids every hour that you are awake. If your blood glucose level is below your target range, drink fluids that contain sugar.
- Continue to eat meals at regular times.
- If unable to tolerate solid food because of nausea, consume more easily tolerated foods or liquids equal to the carbohydrate content of your usual meal.
- Call your primary health care provider for any of these danger signals:
  - Persistent nausea and vomiting
  - Moderate or large ketones
  - Blood glucose elevation after two supplemental doses of insulin
  - High (101.5° F [38.6° C]) temperature or increasing fever; fever for more than 24 hours
- Treat symptoms (e.g., diarrhea, nausea, vomiting, fever) as directed by your primary health care provider.
- Get plenty of rest.

### Preventing Hyperglycemic-Hyperosmolar State (HHS).

Hyperglycemic-hyperosmolar state (HHS) is a hyperosmolar (increased blood osmolarity) state caused by hyperglycemia. The processes of HHS are outlined in [Fig. 64-10](#). Both HHS and diabetic ketoacidosis (DKA) are caused by hyperglycemia and dehydration. HHS differs from DKA in that ketone levels are absent or low and blood glucose levels are much higher. Blood glucose levels may exceed 600 mg/dL (33.3 mmol/L), and blood osmolarity may exceed 320 mOsm/L. [Table 64-13](#) lists the differences between DKA and HHS.

**FIG. 64-10** Pathophysiologic mechanism of hyperglycemic-hyperosmolar state (HHS). *BUN*, Blood urea nitrogen.

HHS results from a sustained osmotic diuresis. Kidney impairment in HHS allows for extremely high blood glucose levels. As serum concentrations of glucose exceed the renal threshold, the kidney's capacity to reabsorb glucose is exceeded.

Decreased blood volume, caused by osmotic diuresis, or underlying kidney disease, common in many older patients with DM, results in further reduction of kidney function. The decreased volume further reduces glomerular filtration rate, causing the glucose level to increase. Decreased kidney PERFUSION from hypovolemia further impairs kidney function.

## Considerations for Older Adults

### Patient-Centered Care QSEN

HHS occurs most often in older patients with type 2 DM, many of whom are unaware they have the disease (Touhy & Jett, 2016). Mortality rates in older patients are high. The onset of HHS is slow and may not be recognized. The older patient often seeks medical attention later and is sicker than the younger patient. HHS does not occur in well-hydrated patients. Older patients are at greater risk for dehydration and HHS because of age-related changes in thirst perception, poor urine-concentrating abilities, and use of diuretics. Assess all older adults for dehydration, regardless of whether they are known to have DM.

Myocardial infarction, sepsis, pancreatitis, stroke, and some drugs (glucocorticoids, diuretics, phenytoin [Dilantin], beta blockers, and calcium channel blockers) also may cause or contribute to HHS. Central nervous system (CNS) changes range from confusion to complete coma. Unlike DKA, patients with HHS may have seizures and reversible paralysis. The degree of neurologic impairment is related to serum osmolarity, with coma occurring once serum osmolarity is greater than 350 mOsm/L (350 mmol/L).

The development of HHS rather than DKA is related to residual insulin secretion. In HHS, the patient secretes just enough insulin to prevent ketosis but not enough to prevent hyperglycemia. The hyperglycemia of HHS is more severe than that of DKA, greatly increasing blood osmolarity, leading to extreme diuresis with severe dehydration and electrolyte loss.

### Planning: Expected Outcomes.

The patient with DM is expected to have few episodes of hyperglycemia and avoid HHS. Indicators include that the patient consistently demonstrates these behaviors:

- Maintains blood glucose levels within the target range
- Uses antidiabetic drugs appropriately
- Remains well hydrated
- Describes when to seek help from health care professionals

### Interventions

#### Monitoring.

Assess for indications of HHS. (See [Tables 64-11](#) and [64-12](#) for symptoms of hyperglycemia.) Continually assess fluid status.

#### Fluid Therapy.

The expected outcomes of therapy are to rehydrate the patient and restore normal blood glucose levels within 36 to 72 hours. The choice of fluid replacement and the rate of infusion are critical in managing HHS. The severity of the CNS problems is related to the level of blood hyperosmolarity and cellular dehydration. Re-establishing fluid balance in brain cells is a difficult and slow process, and many patients do not recover baseline CNS function until hours after blood glucose levels have returned to normal.

The *first* priority for fluid replacement in HHS is to increase blood volume. In shock or severe hypotension, normal saline is used. Otherwise half-normal saline is used. Infuse fluids at 1 L/hr until central venous pressure or pulmonary capillary wedge pressure begins to rise or until blood pressure and urine output are adequate. The rate is then reduced to 100 to 200 mL/hr. Half of the estimated fluid deficit is replaced in the first 12 hours, and the rest is given over the next 36 hours. Body weight, urine output, kidney function, and the presence or absence of pulmonary congestion and jugular venous distention determine the rate of fluid infusion. In patients with heart failure, kidney disease, or acute kidney injury, monitor central venous pressure. *Assess the patient hourly for signs of cerebral edema (i.e., abrupt changes in mental status, abnormal neurologic signs, and coma).* Lack of improvement in level of consciousness may indicate inadequate rates of fluid replacement or reduction in plasma osmolarity. Regression after initial improvement may indicate a too-rapid reduction in plasma osmolarity. A slow but steady improvement in CNS function is the best evidence that fluid management is satisfactory.

## Nursing Safety Priority QSEN

### Critical Rescue

Continually monitor the patient being managed for hyperglycemic-hyperosmolar state to recognize status changes. When you notice changes in the level of consciousness; changes in pupil size, shape, or reaction; or seizures, respond by immediately notifying the primary health care provider.

### Continuing Therapy.

IV insulin is administered after adequate fluids have been replaced. The typical intervention is an initial bolus dose of 0.15 unit/kg IV followed by an infusion of 0.1 unit/kg/hr until blood glucose levels fall to 250 mg/dL (13.9 mmol/L). A reduction of blood glucose of 50 to 70 mg/dL (2.8 to 4.0 mmol/L) per hour is the expected outcome. Monitor the patient closely for hypokalemia. Total body potassium depletion is often unrecognized because the blood potassium level may be normal or high. The potassium level may drop quickly when insulin therapy is started. Potassium replacement is initiated once urine output is adequate. Serum electrolytes are checked every 1 to 2 hours until stable, and the cardiac rhythm is monitored continuously for signs of hypokalemia or hyperkalemia. Patient education and interventions to minimize dehydration are similar to those for ketoacidosis.

### Care Coordination and Transition Management

## Self-Management Education.

DM is a self-managed chronic disease requiring those affected to be actively involved in their own care. Diabetes self-management is the patient's daily responsibility for almost all tasks involved in diabetes care. Education about blood glucose control for those with or at risk for DM occurs in a variety of health care settings. The interprofessional team of certified diabetes educators, physicians, nurses, registered dietitians, pharmacists, social workers, and psychologists all participate in the education. Adults are best able to learn through educational efforts tailored to their individual needs.

### Assessing Learning Needs and Readiness to Learn.

First assess the patient's learning needs and readiness to learn. This assessment establishes what the patient already knows and what he or she needs to know. It also helps you determine the patient's ability and desire to learn. Assess the needs of both the patient and family before teaching. [Table 64-14](#) lists areas to include in this assessment.

**TABLE 64-14**

### Assessment of Learning Needs for the Patient With Diabetes

- Health and medical history
- Nutrition history and practices
- Physical activity and exercise behaviors
- Prescription and over-the-counter medications and complementary and integrative therapies and practices
- Factors that influence learning such as education and literacy levels, perceived learning needs, motivation to learn, and health beliefs
- Diabetes self-management behaviors, including experience with self-adjusting the treatment plan
- Previous diabetes self-management training, actual knowledge, and skills
- Physical factors, including age, mobility, visual acuity, hearing, manual dexterity, alertness, attention span, and ability to concentrate or special needs or limitations requiring adaptive support and use of alternative skills
- Psychosocial concerns, factors, or issues, including family and social support
- Current mental health status
- History of substance use, including alcohol, tobacco, and recreational drugs
- Occupation, vocation, education level, financial status, and social, cultural, and religious practices
- Access to and use of health care resources

Patients want information that applies directly to them. Find out what concerns the patient most about having DM, and ask what he or she wants to learn. Start with what the patient already knows and build on that base. Make sure that his or her knowledge is current and applies to his or her type of DM.

Your assessment may indicate that the patient is not ready to learn needed self-management behaviors. With the patient's permission, you would then teach a family member or someone close to him or her about DM management. Provide written materials on DM management and telephone numbers for the patient to call when he or she is ready to learn.

### Assessing Physical, Cognitive, and Emotional Limitations.

Assessing the patient's literacy is essential in developing a plan of care and providing self-management education ([Watts et al., 2017](#)). It is important to measure the patient's ability to read and understand written materials and perform math calculations. Assess the patient's education and reading level to determine what level of information to present. Match the literacy level of materials to the literacy level of the patient. Simplify the information you present by using plain language to replace technical terms with words adults use in everyday conversation.

Assess the patient's ability to read printed information, insulin labels, and markings on syringes and equipment. Many patients with DM have age-related visual problems made worse by blurred vision caused by changing blood glucose levels. Determine whether the patient has the math skills needed to interpret a food label or to make adjustments in insulin doses based on glucose readings.

Assess manual dexterity for any physical limitations that may alter the teaching plan. A hand injury, tremors, or severe arthritis often leads to dosing errors with a standard syringe and may require a change in insulin preparation.

Individual learning styles vary. Visual learners think in terms of pictures and remember things best by seeing something written or by seeing visual aids. Auditory learners learn best through hearing. Kinesthetic or tactile learners learn best through touching, feeling, and experiencing what they are trying to learn. Tactile learners remember best by writing or physically manipulating the equipment. Successful self-management education provides written handouts, discusses steps involved in a procedure such as insulin administration or self-monitoring of blood glucose (SMBG), and encourages the learner to touch and manipulate equipment. Confirm that the patient understands your instructions by using "teach-back" techniques.

Tailor educational sessions to the time available and to the condition of the patient. Hospitalized adults require only basic education when they are acutely ill. In these situations, it is appropriate to teach basic survival skills or focused problem-solving skills while reserving more detailed education for follow-up sessions.

### **Survival Skills Information.**

The initial phase of education involves teaching information necessary for the survival of any adult diagnosed with DM. Survival information includes:

- Simple information on pathophysiology of DM
- Learning how to prepare and administer insulin or how to take other antidiabetic drugs
- Recognition, treatment, and prevention of hypoglycemia and hyperglycemia
- Basic diet information
- Monitoring of blood glucose and urine ketones
- Sick-day management rules
- Where to buy DM supplies and how to store them
- When and how to notify the primary health care provider

### **In-Depth Education.**

In-depth education and counseling involve teaching more detailed information about survival skills and actions for avoiding long-term complications. Educational sessions with patient and family are needed to “patientize” the DM regimen for their needs and abilities.

The adult with DM needs to understand the disease pathology. He or she must be able to discuss the action of insulin and the effects of insulin deficiency and to explain the effects of diet, drugs, and activity on blood glucose. The patient should be able to relate maintaining normal blood glucose levels to preventing complications. This includes relating changes in glucose level to the possible need for a change in insulin dosage.

Provide education about the symptoms of hypoglycemia along with the prescribed treatment options if the patient takes any drugs that will lower blood glucose levels. Educate patients and their families about common causes of hypoglycemia such as changes in drug regimen, increase in physical activity, and delayed or missed meals. Review indications of hypoglycemia at each visit. Advise patients to check their blood glucose levels before driving and to make sure they have easy-to-reach snacks and/or fast-acting sugars with them at all times. Encourage them to always wear a medical ID tag or bracelet and to contact their primary health care provider if they experience low blood glucose levels more than twice a week.

Many patients require combination drug therapy to achieve glucose control in addition to aspirin and drugs for lowering lipids and blood pressure. If the patient takes an antidiabetic drug, ask him or her to identify the drug and describe the prescribed schedule. Determine if the patient is able to administer insulin or other injectable antidiabetic drugs accurately by having him or her demonstrate injection techniques. Ask the patient to discuss the onset, peak, and duration of the insulin used. The patient must be able to state when insulin is to be injected, where it is injected, and how it is stored. Review formulas for self-adjustment in insulin (when supported by the primary health care provider), and explain blood glucose monitoring requirements needed to evaluate the effects of additional insulin. Stress the dangers of skipping doses. Review drug interactions, especially with older patients taking oral antidiabetic drugs.

Teach patients receiving diet therapy alone, glucose-lowering drugs, or fixed insulin doses to eat the consistent amounts of carbohydrate (CHO) at meals and snacks. Patients who adjust mealtime doses of insulin or those on insulin pump therapy can be taught to match their insulin dose to the CHO content of their diet. The patient needs to understand what to eat, how much to eat, and when to eat. Stress the importance of eating on time, the dangers of skipping meals, and how to maintain food intake during illness. Ask the patient to describe the meal plan and explain the adjustments needed to meet diabetic diet requirements. Include the family member usually responsible for buying groceries and preparing meals in this teaching.

Regular physical activity is important for physical fitness, weight management, and blood glucose control. Help all patients identify activities they can do to achieve the goal of moderate-intensity activity 3 or more days a week. For patients taking insulin and/or insulin secretagogues, physical activity can cause hypoglycemia if carbohydrate intake isn't increased. Review how to

perform physical activities safely. Instruct the patient on blood glucose levels that are safe for exercise, the frequency of glucose monitoring during exercise, drug adjustments before exercise, food required before exercise, and what food to have available during exercise. He or she should be aware of the risk for injury during exercise and be able to explain the importance of protective footwear.

Self-monitoring of blood glucose (SMBG) provides immediate information on a patient's blood glucose level and provides feedback on the effects of recent activity, drugs, and meals. The nurse's role includes teaching skills of performing the test, educating how to interpret results, and problem solving to adjust behaviors and therapy based on the information. Teach patients how to recognize when blood glucose levels are out of range, how to adjust therapy and behaviors based on SMBG results, and how to verify the effects of these adjustments by performing subsequent glucose testing. In addition, show patients who use insulin how to use SMBG to adjust dosages to achieve glucose control while avoiding episodes of hypoglycemia.

Teach patients sick-day procedures when initially diagnosed with DM. Hyperglycemia often develops before infection symptoms and can serve as a warning sign that infection is developing. Provide guidelines for the frequency of glucose testing, ketone testing, and insulin adjustment for those patients able to self-adjust insulin doses.

### **Psychosocial Preparation.**

The diagnosis of DM may represent a loss of control and flexibility. Life becomes ordered, and routines must be followed. Some events surrounding DM are predictable. Injecting insulin and not eating for several hours causes hypoglycemia. Poorly controlled DM leads to complications and premature death. Tight control of blood glucose prevents complications.

The stress of DM is in addition to the demands of normal daily life. The patient must be able to integrate the demands of DM into daily schedules while keeping blood glucose stable.

Patients are more likely to adhere to disease management activities when the strategies make sense and seem effective. Other factors promoting adherence include the patient's belief that the activity is important, having confidence in himself or herself, and having support. Assist in healthy psychological adaptation to DM by providing successful educational experiences. Mastery of blood glucose monitoring helps the patient feel control over the disease. Knowing the effects of extra activities, extra food, or extra insulin is helpful in learning to adjust the regimen.

Feeling a sense of control over the condition promotes a positive attitude about DM. Success in injecting insulin provides concrete evidence that he or she can master the disease. Teach by breaking a task into small, achievable units to ensure mastery. For example, a patient may begin learning how to inject insulin by first obtaining an accurate dose.

Devote as much teaching time as possible to insulin injection and blood glucose monitoring. Patients with newly diagnosed DM may fear giving themselves injections. After this technique is mastered, he or she may be less anxious and more able to attend to other tasks.

Recognize that not everyone will adapt to DM. Some patients are unable to progress beyond the survival level. Major depression affects many patients, having an impact on quality of life and all aspects of functioning, including self-management behaviors. Refer those who have significant problems coping with the day-to-day demands of DM to mental health counseling for appropriate treatment.

### **Home Care Management.**

Patients with DM self-manage their disease. Each day they decide what to eat, whether to exercise, and whether to take prescribed drugs. Maintaining blood glucose control depends on the accuracy of self-management skills. The role of the nurse is to provide support and education and to empower the patient to make informed decisions. Self-management education allows patients to identify their problems and provides techniques to help them make decisions, take appropriate actions, and alter these actions as needed.

Provide information about resources. The patient must know whom to contact in case of emergency. Older adults who live alone need to have daily telephone contact with a friend or neighbor. The patient may also need help shopping and preparing meals. He or she may have limited access to transportation and may not have sufficient supplies of food, particularly in bad weather. Because of the likelihood of visual problems in older patients, they may need help in preparing insulin syringes for injection or in monitoring blood glucose. Make referrals to home care

or public health agencies as needed. [Chart 64-9](#) identifies areas for assessment during a home or clinic visit.

### **Chart 64-9**

## **Focused Assessment**

### **The Insulin-Dependent Patient With Diabetes During a Home or Clinic Visit**

- Assess overall mental status, wakefulness, ability to converse.
- Take vital signs and weight:
- Fever could indicate infection.
- Are blood pressure and weight within target range? If not, why?
- Question patient regarding any change in visual acuity; check current visual acuity.
- Inspect oral mucous membranes, gums, and teeth.
- Question patient about injection areas used; inspect areas being used; assess whether patient is using areas and sites appropriately.
- Inspect skin for intactness, wounds that have not healed, new sores, ulcers, bruises, or burns; assess any previously known wounds for infection, progression of healing.
- Question patient regarding foot care.
- Assess lower extremities and feet for peripheral pulses, lack of or decreased sensation, abnormal sensations, breaks in skin integrity, condition of toes and nails.
- Question patient regarding color and consistency of stools and frequency of bowel movements; assess abdomen for bowel sounds.
- Review patient's home health diary:
- Is blood glucose within targeted range? If not, why?
- Is glucose monitoring being recorded often enough?
- Is the patient's food intake adequate and appropriate? If not, why?
- Is exercise occurring regularly? If not, why?
- Assess patient's ability to perform self-monitoring of blood glucose.
- Assess patient's procedures for obtaining and storing insulin and syringes, cleaning equipment, disposing of syringes and needles.
- Assess patient's insulin preparation and injection technique.
- Assess patient's knowledge of antidiabetic drug regimen and for which side effects to look.

### **Evaluation: Reflection**

Evaluate the care of the patient with DM based on the identified priority patient problems. Outcome success for diabetes education is the ability of the patient to maintain blood glucose levels within their established target range. General outcome criteria are listed below and in [Table 64-15](#). The expected outcomes include that the patient should:

---

**TABLE 64-15**

**Outcome Criteria for Diabetes Teaching**

---

<p>Before self-management begins to home, the patient with diabetes or the significant other should be able to:</p> <ul style="list-style-type: none"><li>• Tell why insulin or a noninsulin antidiabetic drug is being prescribed</li><li>• Name which insulin or noninsulin antidiabetic drug is being prescribed, and name the dosage and frequency of administration</li><li>• Discuss the relationship between mealtime and the action of insulin or the other antidiabetic agent</li><li>• Discuss plans to follow diabetic diet instructions</li><li>• Prepare and administer insulin accurately</li><li>• Test blood for glucose or state plans for having blood glucose levels monitored</li><li>• Test urine for ketones and state when this test should be done</li><li>• Describe how to store insulin</li><li>• List symptoms that indicate a hypoglycemic reaction</li><li>• Tell which carbohydrate sources are used to treat hypoglycemic reactions</li><li>• Tell which symptoms indicate hyperglycemia</li><li>• Tell which dietary changes are needed during illness</li><li>• State when to call the primary health care provider or the nurse (frequent episodes of hypoglycemia, symptoms of hyperglycemia)</li><li>• Describe the procedures for proper foot care</li></ul>
--

- Achieve blood glucose control
- Avoid acute and chronic complications of diabetes
- Avoid injury
- Experience relief of pain
- Maintain optimal vision
- Maintain a urine output in the expected range
- Have an optimal level of mental status functioning
- Have decreased episodes of hypoglycemia
- Have decreased episodes of hyperglycemia

# Get Ready for the NCLEX® Examination!

## Key Points

Review these key points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Use aseptic technique during any invasive procedure when caring for a patient with diabetes. **QSEN: Safety**
- Administer antidiabetic drugs and insulin in a safe manner. **QSEN: Safety**
- Ensure that meals are available with or immediately after the patient receives an antidiabetic drug or insulin. **QSEN: Safety**
- Use good handwashing techniques before providing any care to a patient with diabetes. **QSEN: Safety**
- Collaborate with the primary health care provider, diabetes nurse educator, registered dietitian, pharmacist, social worker, and case manager to individualize patient care for the adult with diabetes in any care setting. **QSEN: Patient-Centered Care**
- Never dilute or mix insulin glargine with any other insulin or solution. **QSEN: Safety**
- Avoid injecting insulin within a 2-inch radius of the umbilicus. **QSEN: Evidence-Based Practice**
- Reinforce to all patients with diabetes that tight control over blood glucose levels reduces the risk for the vascular complications of diabetes. **QSEN: Evidence-Based Practice**
- Instruct the patient and family about complications and when to seek assistance. **QSEN: Safety**
- Assess patients' visual acuity and peripheral tactile sensation to determine needed adjustments in teaching self-medication and self-monitoring of blood glucose levels. **QSEN: Safety**
- Teach patients with peripheral neuropathy to use a bath thermometer to test water for bathing, to avoid walking barefoot, and to inspect their feet daily. **QSEN: Safety**
- Teach the patient and family about the symptoms of infection and when to seek medical advice. **QSEN: Safety**
- Instruct patients with diabetes to wear a medical alert bracelet. **QSEN: Safety**
- Instruct patients to not share blood glucose monitoring equipment. **QSEN: Safety**
- Teach patients to rotate insulin injection sites within one area rather than to other areas, to prevent changes in absorption. **QSEN: Evidence-Based Practice**
- Teach patients who experience Somogyi phenomenon (early morning hyperglycemia) to ensure an adequate dietary intake at bedtime. **QSEN: Evidence-Based Practice**
- Instruct patients to always carry a glucose source. **QSEN: Safety**
- Teach patients who exercise to test urine for ketone bodies if blood glucose levels are greater than 250 mg/dL before engaging in strenuous exercise. **QSEN: Safety**

### Health Promotion and Maintenance

- Encourage all patients to maintain weight within an appropriate range. **QSEN: Patient-Centered Care**
- Encourage patients with diabetes, to participate regularly in exercise or physical activity appropriate to their health status. **QSEN: Evidence-Based Practice**
- Instruct all patients with diabetes to avoid becoming dehydrated and to drink at least 2 L of water each day unless another medical condition requires fluid restriction. **QSEN: Patient-Centered Care**
- Refer patients newly diagnosed with diabetes to local resources and support groups. **QSEN:**

### **Patient-Centered Care**

- Remind patients with diabetes to have yearly eye examinations by an ophthalmologist. **QSEN: Evidence-Based Practice**
- Instruct patients in foot care as outlined in [Chart 64-6](#).

### **Psychosocial Integrity**

- Explore with the patient what the diagnosis of diabetes means to him or her. **QSEN: Patient-Centered Care**
- Allow the patient the opportunity to express concerns about the diagnosis of diabetes or the treatment regimen. **QSEN: Patient-Centered Care**
- Pace your education sessions to match the learning needs and style of the patient. **QSEN: Patient-Centered Care**
- Urge patients newly diagnosed with DM to attend diabetes education classes to become a fully engaged partner in management of the disease. **QSEN: Patient-Centered Care**

### **Physiological Integrity**

- Help patients who have pain from peripheral neuropathy determine which pain-relieving drugs and techniques work best for them. **QSEN: Patient-Centered Care**
- Assess the patient's hemoglobin A1C for indications of adherence to prescribed regimens and their effectiveness. **QSEN: Evidence-Based Practice**
- Explain all procedures, restrictions, drugs, and follow-up care to the patient and family. **QSEN: Patient-Centered Care**
- Use return demonstration with “teach-back” strategies when teaching the patient about drug regimen, insulin injection, blood glucose monitoring, and foot assessment. **QSEN: Patient-Centered Care**
- Teach patients to administer an accurate dose of insulin using a prefilled or disposable insulin pen. **QSEN: Patient-Centered Care**
- Instruct patients who are taking sulfonylurea drugs about an increased risk for hypoglycemic reactions. **QSEN: Patient-Centered Care**
- Teach patients who are taking metformin the symptoms of lactic acidosis (fatigue, dizziness, difficulty breathing, stomach discomfort, irregular heartbeat). **QSEN: Patient-Centered Care**
- Warn patients to not take over-the-counter drugs with their oral antidiabetic drugs without consulting their primary care provider. **QSEN: Patient-Centered Care**
- Start carbohydrate replacement per the primary health care provider's prescription or standing protocols immediately on identifying a patient with hypoglycemia. **QSEN: Evidence-Based Practice**
- Give glucagon subcutaneously or IM and 50% dextrose IV to patients identified with hypoglycemia who cannot swallow. **QSEN: Evidence-Based Practice**
- First assess the airway, level of consciousness, hydration status, electrolytes, and blood glucose level of any patient with diabetic ketoacidosis. **QSEN: Evidence-Based Practice**
- Use blood glucose values to assess therapy effectiveness and determine when to switch from saline to dextrose-containing solutions in a patient with diabetic ketoacidosis. **QSEN: Evidence-Based Practice**
- Continually assess fluid status and level of consciousness in a patient with hyperglycemic-hyperosmolar state (HHS) during the resuscitation period. **QSEN: Evidence-Based Practice**
- Immediately report indications of cerebral edema (abrupt changes in mental status; changes in level of consciousness; changes in pupil size, shape, or reaction; seizures) in a patient with HHS to the primary health care provider. **QSEN: Patient-Centered Care**

## UNIT XV

# Interprofessional Collaboration for Patients With Problems of the Renal/Urinary System

### OUTLINE

---

Chapter 65 Assessment of the Renal/Urinary System

Chapter 66 Care of Patients With Urinary Problems

Chapter 67 Care of Patients With Kidney Disorders

Chapter 68 Care of Patients With Acute Kidney Injury and Chronic Kidney Disease

## CHAPTER 65

# Assessment of the Renal/Urinary System

Chris Winkelman

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is ELIMINATION.**

**The interrelated concepts for this chapter are:**

- FLUID AND ELECTROLYTE BALANCE
- ACID-BASE BALANCE

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to perform a complete urinary and renal system assessment, including ELIMINATION, FLUID AND ELECTROLYTE BALANCE, and ACID-BASE BALANCE.
2. Protect the patient, yourself, and others from injury and infection during assessment of the renal and urinary systems.

### Health Promotion and Maintenance

3. Explain how physiologic changes of the urinary/renal system affect ELIMINATION and the associated care of older adults.

### Psychosocial Integrity

4. Implement patient-centered nursing interventions to help patients and families cope with the psychosocial impact caused by a urinary ELIMINATION health problem.

### Physiological Integrity

5. Apply knowledge of anatomy and physiology to perform an evidence-based assessment for the patient with a urinary ELIMINATION health problem.
6. Interpret assessment findings for the patient with a urinary or renal system health problem.
7. Teach the patient and caregivers about diagnostic procedures associated with assessment of kidney and urinary health problems.

The kidneys and urinary tract together make up the renal system, which is responsible for urine elimination. The concept of **ELIMINATION** is the excretion of waste from the body by the GI tract (as feces) and by the kidneys (as urine). See [Chapter 2](#) for a summary overview of the concept of elimination and how it relates to the concepts of FLUID AND ELECTROLYTE BALANCE and ACID-BASE BALANCE.

The urinary tract includes the ureters, bladder, and urethra. It is the drainage route for the excretion of urine. The kidneys filter fluids and small compounds from the blood for elimination of waste. Structural or functional problems in the kidneys or urinary tract may alter FLUID AND ELECTROLYTE BALANCE and ACID-BASE BALANCE.

The kidneys help maintain health in many ways. *Most important, they maintain body fluid volume and composition and create urine for waste ELIMINATION.* The kidneys also help adjust blood pressure, regulate ACID-BASE BALANCE, produce erythropoietin for red blood cell (RBC) synthesis, and convert vitamin D to an active form.

Assessment of the patient at risk for or with actual problems of the kidneys or urinary system

begins with a history and physical assessment. Understanding the anatomy, physiology, and diagnostic tests of the renal system helps you problem solve about kidney and urinary tract function in the clinical setting. It also helps you teach the patient about the purpose of procedures and physically and emotionally prepare the patient for assessment.

# Anatomy and Physiology Review

## Kidneys

### Structure

#### Gross Anatomy.

The two kidneys are located behind the peritoneum, not in the abdominal cavity, one on either side of the spine (Fig. 65-1). The adult kidney is 4 to 5 inches (10 to 13 cm) long, 2 to 3 inches (5 to 7 cm) wide, and about 1 inch (2.5 to 3 cm) thick. The left kidney is slightly longer and narrower than the right kidney. Larger-than-usual kidneys may indicate obstruction or polycystic disease. Smaller-than-usual kidneys may indicate chronic kidney disease (CKD).

**FIG. 65-1** Anatomic location of the kidneys and structures of the urinary system.

Variation in kidney shape and number is relatively common and does not always indicate a problem in kidney function. Some adults have more than two kidneys or may have only one large, horseshoe-shaped kidney. As long as tests of kidney function are normal, these variations are of no significance (Brenner, 2016).

Several layers of tissue surround the kidney, providing protection and support. The outer surface of the kidney is a layer of fibrous tissue called the *capsule* (Fig. 65-2). It covers most of the kidney except the *hilum*, which is the indented area where the kidney blood vessels and nerves enter and exit. It is also where the ureter exits. The capsule is surrounded by layers of fat and connective tissue.

**FIG. 65-2** Bisected view of the kidney showing the major structures of the kidney.

Lying beneath the capsule are the two layers of functional kidney tissue: the cortex and the medulla. The *renal cortex* is the outer tissue layer. The *medulla* is the medullary tissue lying below the cortex in the shape of many fans. Each “fan” is called a pyramid. The *renal columns* are cortical tissue that dips down into the interior of the kidney and separates the pyramids.

The tip of each pyramid is called a *papilla*. The papillae drain urine into the collecting system. A cuplike structure called a *calyx* collects the urine at the end of each papilla. The calices join together to form the *renal pelvis*, which narrows to become the ureter.

The kidneys have a rich blood supply and receive a blood flow from 600 to 1300 mL/min. The blood supply to each kidney comes from the renal artery, which branches from the abdominal aorta. The renal artery divides into progressively smaller arteries, supplying all blood to areas of the kidney tissue and the nephrons. The smallest arteries (*afferent arterioles*) feed the nephrons directly to form urine.

Venous blood from the kidneys starts with the capillaries surrounding each nephron. These capillaries drain into progressively larger veins, with blood eventually returned to the inferior vena cava through the renal vein.

### Microscopic Anatomy.

The **nephron** is the functional unit of the kidney and forms urine by filtering waste products and water from the blood. There are about 1 million nephrons per kidney, and each nephron separately performs filtration and makes urine from blood.

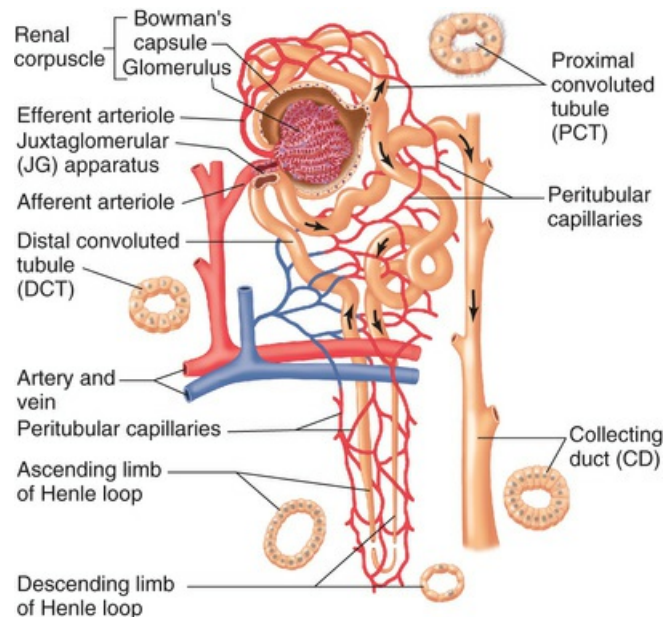

There are two types of nephrons: *cortical nephrons* and *juxtamedullary nephrons*. The cortical nephrons are short and lie totally within the renal cortex. The juxtamedullary nephrons (about 20% of all nephrons) are longer, and their tubes and blood vessels dip deeply into the medulla. The purpose of these nephrons is to concentrate urine during times of low fluid intake to allow continued excretion of body waste with less fluid loss (McCance et al., 2014).

Blood supply to the nephron is delivered through the *afferent arteriole* (i.e., the smallest, most distal portion of the renal arterial system). From the afferent arteriole, blood flows into the *glomerulus*, which is a series of specialized capillary loops. It is through these capillaries that water and small particles are filtered from the blood to make urine. The remaining blood leaves the glomerulus through the *efferent arteriole*, which is the first vessel in the kidney's venous system. From the efferent arteriole, blood exits into either the *peritubular capillaries* around the tube of the cortical nephrons or the *vasa recta* around the tube of juxtamedullary nephrons.

Each nephron is a tubelike structure with distinct parts (Fig. 65-3). The tube begins with Bowman's capsule, a saclike structure that surrounds the glomerulus. The tubular tissue of Bowman's capsule narrows into the *proximal convoluted tubule* (PCT). The PCT twists and turns,

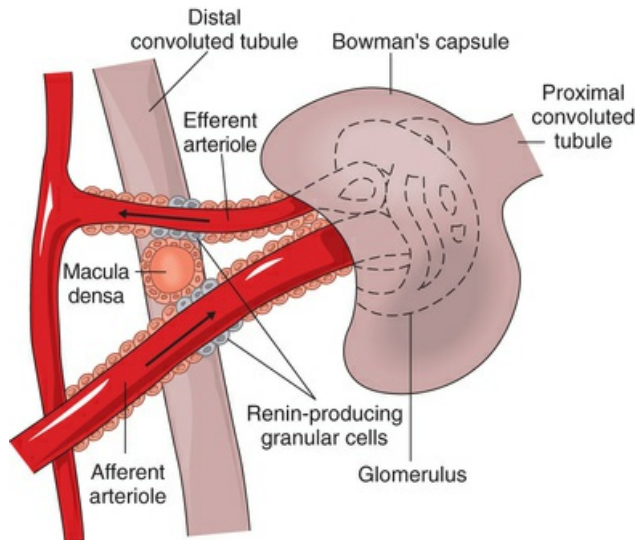

finally straightening into the descending limb of the *loop of Henle*. The descending loop of Henle dips in the direction of the medulla but forms a hairpin loop and comes back up into the cortex as the ascending loop of Henle.

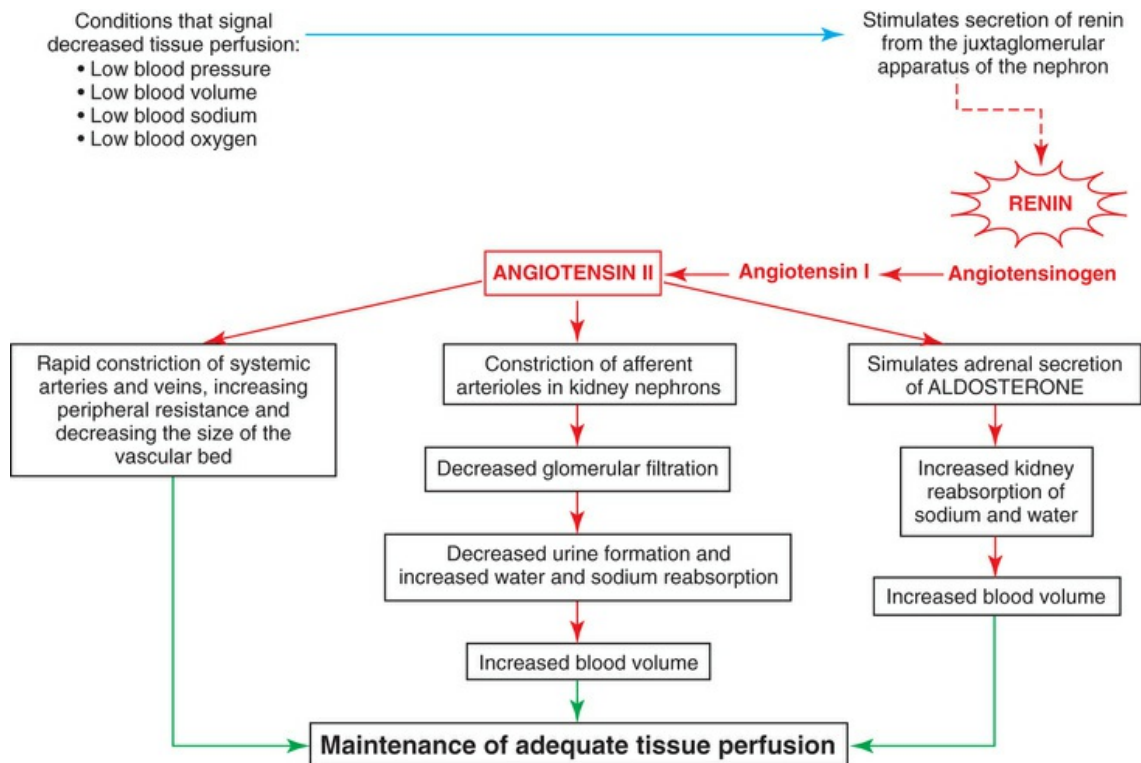

**FIG. 65-3** Anatomy of the nephron—the functional unit of the kidney. The differences in appearance in tubular cells seen in a cross section reflect the differing functions of each nephron segment. Note that the particular nephron labeled here is a juxtamedullary nephron. (From Patton, K.T., & Thibodeau, G.A. [2018]. *The human body in health & disease* [7th ed.]. St. Louis: Mosby.)

The two segments of the ascending limb of the loop of Henle are the thin segment and the thick segment. The *distal convoluted tubule (DCT)* forms from the thick segment of the ascending limb of the loop of Henle. The DCT ends in one of many collecting ducts located in the kidney tissue. The urine in the collecting ducts passes through the papillae and empties into the renal pelvis.

Special cells in the afferent arteriole, efferent arteriole, and DCT are known as the *juxtaglomerular complex* (Fig. 65-4). These cells produce *renin*, which is a hormone that helps regulate blood flow, glomerular filtration rate (GFR), and blood pressure. Renin is secreted when sensing cells in the DCT (called the *macula densa*) sense changes in blood volume and pressure. The macula densa touches the renin-producing cells. Renin is produced when the macula densa cells sense that blood volume, blood pressure, or blood sodium level is low. Renin then converts renin substrate (angiotensinogen) into angiotensin I. This leads to a series of reactions that cause secretion of the hormone aldosterone (Fig. 65-5). Aldosterone increases kidney reabsorption of sodium and water, restoring blood pressure, blood volume, and blood sodium levels (McCance et al., 2014). It also promotes excretion of potassium (see Chapter 11).

**FIG. 65-4** Juxtaglomerular complex showing juxtaglomerular cells and the macula densa.

**FIG. 65-5** Role of aldosterone, renin substrate (angiotensinogen), angiotensin I, and angiotensin II in the renal regulation of water and sodium.

The glomerular capillary wall has three layers (Fig. 65-6): the endothelium, the basement membrane, and the epithelium. The endothelial and epithelial cells lining these capillaries are separated by pores that filter water and small particles from the blood into Bowman's capsule. This fluid is called the *filtrate*.

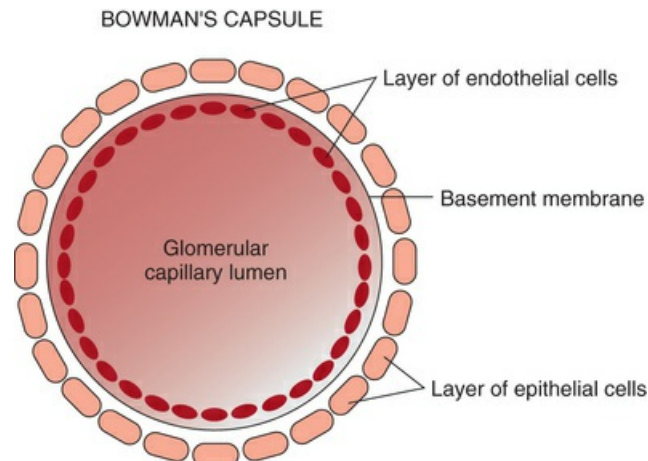

FIG. 65-6 Glomerular capillary wall.

## Function

The kidneys have both regulatory and hormonal functions. The regulatory functions control FLUID AND ELECTROLYTE BALANCE and ACID-BASE BALANCE. The hormonal functions control red blood cell (RBC) formation, blood pressure, and vitamin D activation.

## Regulatory Functions.

The kidney processes that maintain FLUID AND ELECTROLYTE BALANCE and ACID-BASE BALANCE through urine ELIMINATION are glomerular filtration, tubular reabsorption, and tubular secretion. These processes use filtration, diffusion, active transport, and osmosis. (See Chapter 11 for a review of these actions.) Table 65-1 lists the functions of nephron tubules and blood vessels.

TABLE 65-1

### Vascular and Tubular Components of the Nephron

STRUCTURE	ANATOMIC FEATURES	PHYSIOLOGIC ASPECTS
<b>Vascular Components</b>		
Afferent arteriole	Delivers arterial blood from the branches of the renal artery into the glomerulus	Autoregulation of renal blood flow via vasoconstriction or vasodilation Renin-producing granular cells
Glomerulus	Capillary loops with thin, semipermeable membrane	Site of glomerular filtration Glomerular filtration occurs when hydrostatic pressure (blood pressure) is greater than opposing forces (tubular filtrate and oncotic pressure)
Efferent arteriole	Delivers arterial blood from the glomerulus into the peritubular capillaries or the vasa recta	Autoregulation of renal blood flow via vasoconstriction or vasodilation Renin-producing granular cells
Peritubular capillaries (PTCs) and vasa recta (VR)	PTCs: surround tubular components of cortical nephrons VR: surround tubular components of juxtamedullary nephrons	Tubular reabsorption and tubular secretion allow movement of water and solutes to or from the tubules, interstitium, and blood
<b>Tubular Components</b>		
Bowman's capsule (BC)	Thin membranous sac surrounding $\frac{2}{3}$ of the glomerulus	Collects glomerular filtrate (GF) and funnels it into the tubule
Proximal convoluted tubule (PCT)	Evolves from and is continuous with Bowman's capsule Specialized cellular lining facilitates tubular reabsorption	Site for reabsorption of sodium, chloride, water, glucose, amino acids, potassium, calcium, bicarbonate, phosphate, and urea
Loop of Henle	Continues from PTC Juxtamedullary nephrons dip deep into the medulla Permeable to water, urea, and sodium chloride	Regulation of water balance
Descending limb (DL)	Continues from the loop of Henle Permeable to water, urea, and sodium chloride	Regulation of water balance
Ascending limb (AL)	Emerges from DL as it turns and is redirected up toward the renal cortex	Potassium and magnesium reabsorption in the thick segment Thin segment is impermeable to water
Distal convoluted tubule (DCT)	Evolves from AL and twists so the macula densa cells lie adjacent to the juxtaglomerular cells of afferent arteriole	Site of additional water and electrolyte reabsorption, including bicarbonate Potassium and hydrogen secretion
Collecting ducts	Collect formed urine from several tubules and deliver it into the renal pelvis	Receptor sites for antidiuretic hormone regulation of water balance

*Glomerular filtration* is the first process in urine formation. As blood passes from the afferent arteriole into the glomerulus, water, electrolytes, and other small particles (e.g., creatinine, urea nitrogen, glucose) are filtered across the glomerular membrane into the Bowman's capsule to form *glomerular filtrate*. As the filtrate enters the proximal convoluted tubule (PCT), it is called *tubular filtrate* or *early urine*.

Large particles, such as blood cells, albumin, and other proteins, are too large to filter through the glomerular capillary walls. *Therefore these substances are not normally present in the excreted final urine.*

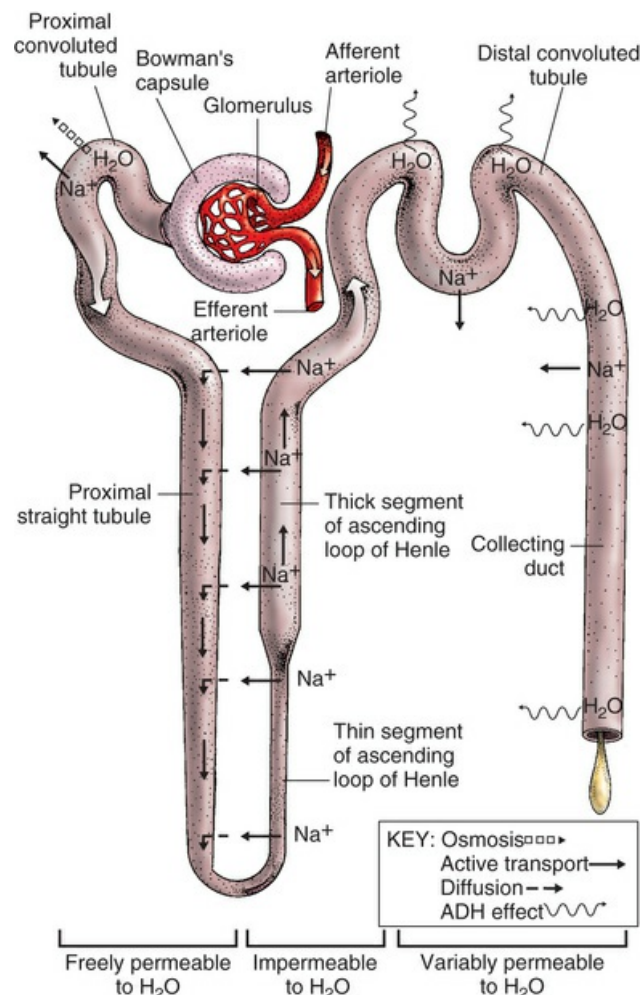

Filtration rate is expressed in milliliters per minute. Normal glomerular filtration rate (GFR) averages 125 mL/min, totaling about 180 L daily. If the entire amount of filtrate were excreted as urine, death would occur from dehydration. Actually, only about 1 to 3 L is excreted each day as

urine. The rest is reabsorbed back into the blood (McCance et al., 2014).

GFR is controlled by blood pressure and blood flow. The kidneys self-regulate their own blood pressure and blood flow, which keeps GFR constant. GFR is controlled by selectively constricting and dilating the afferent and efferent arterioles. When the afferent arteriole is constricted or the efferent arteriole is dilated, pressure in the glomerular capillaries falls, and filtration decreases. When the afferent arteriole is dilated or the efferent arteriole is constricted, pressure in the glomerular capillaries rises, and filtration increases. This way the kidney maintains a constant GFR, even when systemic blood pressure changes. When systolic pressure drops below 65 to 70 mm Hg, these self-regulation processes do not maintain GFR.

*Tubular reabsorption* is the second process in urine formation. Tubular reabsorption of most of the filtrate (early urine) keeps normal urine output at 1 to 3 L/day and prevents dehydration. As the filtrate passes through the tubular parts of the nephron, water and electrolytes are reabsorbed from the tubular lumen of the nephron and into the peritubular capillaries. This process returns much of the water, electrolytes, and other particles to the blood.

The tubules return about 99% of filtered water back into the body (Fig. 65-7). Most water reabsorption occurs in the proximal convoluted tubule (PCT). Water reabsorption continues as the filtrate flows down the descending loop of Henle. The thin and thick segments of the ascending loop of Henle are *not* permeable to water, and no water reabsorption occurs here.

**FIG. 65-7** Sodium and water reabsorption by the tubules of a cortical nephron. ADH, Antidiuretic hormone;  $\text{Na}^+$ , sodium.

The distal convoluted tubule (DCT) can be permeable to water, and some water reabsorption occurs as the filtrate continues to flow through the tubule. The membrane of the DCT may be made more permeable to water when *vasopressin* (antidiuretic hormone [ADH]), and aldosterone are

present. Vasopressin increases tubular permeability to water, allowing water to leave the tube and be reabsorbed into the capillaries. Vasopressin also increases arteriole constriction. Arteriole constriction alters blood pressure, which then affects the amounts of fluid and particles that exit glomerular capillaries. Aldosterone promotes the reabsorption of sodium in the DCT. Water reabsorption occurs as a result of the movement of sodium (where sodium goes, water follows).

The ability of the kidneys to vary the volume or concentration of urine helps regulate water balance regardless of fluid intake. In this way, the healthy kidney can prevent dehydration when fluid intake is low and can prevent circulatory overload when fluid intake is high.

In addition to water, electrolytes are reabsorbed as needed to maintain FLUID AND ELECTROLYTE BALANCE in the blood. Most sodium, chloride, and water reabsorption occurs in the proximal convoluted tubule (PCT). The collecting ducts are the other site of sodium, chloride, and water reabsorption. Here reabsorption is caused by aldosterone. Potassium is mostly reabsorbed in the PCT and in the thick segment of the loop of Henle.

Bicarbonate, calcium, and phosphate are mostly reabsorbed in the PCT. Bicarbonate reabsorption helps ACID-BASE BALANCE and maintains a normal blood pH. Blood levels of calcitonin and parathyroid hormone (PTH) (see Chapters 11 and 63) control calcium balance.

Some types of particles in the tubular filtrate also are returned to the blood by *tubular reabsorption*. About 50% of all urea in the filtrate is reabsorbed; creatinine is not reabsorbed.

The kidney reabsorbs some of the glucose filtered from the blood. However, there is a limit to how much glucose the kidney can reabsorb. This limit is called the **renal threshold** or **transport maximum (tm)** for glucose reabsorption. The usual renal threshold for glucose is about 220 mg/dL (12 mmol/L). This means that at a blood glucose level of 220 mg/dL (12 mmol/L) or less, all glucose is reabsorbed and returned to the blood, with no glucose present in final urine. When blood glucose levels are greater than 220 mg/dL (12 mmol/L), some glucose stays in the filtrate and is present in the urine. Normally, almost all glucose and most proteins are reabsorbed and thus are not present in the urine.

## Nursing Safety Priority QSEN

### Action Alert

Report the presence of glucose or proteins in the urine of a patient undergoing a screening examination to the primary health care provider because this is an abnormal finding and requires further assessment.

*Tubular secretion* is the third process of urine formation. It allows substances to move from the blood into the urine. During tubular secretion, substances move from the peritubular capillaries in reverse, across capillary membranes, and into the cells that line the tubules. From the cells, these substances are moved into the urine and excreted from the body. Potassium (K<sup>+</sup>) and hydrogen (H<sup>+</sup>) ions are some of the substances moved in this way to maintain FLUID AND ELECTROLYTE BALANCE and ACID-BASE BALANCE (pH).

### Hormonal Functions.

The kidneys produce renin, prostaglandins, erythropoietin, and activated vitamin D (Table 65-2). Other kidney products, such as the kinins, change kidney blood flow, regulate blood pressure, and influence capillary permeability. The kidneys also help break down and excrete insulin and many other drugs.

**TABLE 65-2**

**Kidney Hormones and Hormones Influencing Kidney Function**

	SITE	ACTION
<b>Kidney Hormones</b>		
Renin	Renin-producing granular cells	Raises blood pressure as result of angiotensin (local vasoconstriction) and aldosterone (volume expansion) secretion
Prostaglandins	Kidney tissues	Regulate intrarenal blood flow by vasodilation or vasoconstriction
Bradykinins	Juxtaglomerular cells of the arterioles	Increase blood flow (vasodilation) and vascular permeability
Erythropoietin	Kidney parenchyma	Stimulates bone marrow to make red blood cells
Activated vitamin D (1,25-dihydrocholecalciferol)	Kidney parenchyma	Promotes absorption of calcium in the GI tract

Hormones Influencing Kidney Function		
Vasopressin (Antidiuretic hormone [ADH])	Released from posterior pituitary	Makes DCT and CD permeable to water to maximize reabsorption and produce a concentrated urine
Aldosterone	Released from adrenal cortex	Promotes sodium reabsorption and potassium secretion in DCT and CD; water and chloride follow sodium movement
Natriuretic hormones	Cardiac atria, cardiac ventricles, brain	Cause tubular secretion of sodium

CD, Collecting duct; DCT, distal convoluted tubule.

*Renin*, as discussed in the Microscopic Anatomy section, assists in blood pressure control. It is formed and released when there is a decrease in blood flow, blood volume, or blood pressure through the renal arterioles or when too little sodium is present in kidney blood. These conditions are detected through the receptors of the juxtaglomerular complex.

Renin release causes the production of *angiotensin II* through a series of steps (see Fig. 65-5). Angiotensin II increases systemic blood pressure with powerful blood vessel constricting effects and triggers the release of aldosterone from the adrenal glands. Aldosterone increases the reabsorption of sodium in the distal tubule of the nephron. Therefore more water is reabsorbed, which increases blood volume and blood pressure. When blood flow to the kidney is reduced, this system also prevents fluid loss and maintains circulating blood volume (see Chapter 11).

*Prostaglandins* are produced in the kidney and many other tissues. Those produced specifically in the kidney help regulate glomerular filtration, kidney vascular resistance, and renin production. They also increase sodium and water excretion.

*Erythropoietin* is produced and released in response to decreased oxygen tension in the kidney's blood supply. It triggers red blood cell (RBC) production in the bone marrow. When kidney function is poor, erythropoietin production decreases, and anemia results.

*Vitamin D activation* occurs through a series of steps. Some of these steps take place in the skin when it is exposed to sunlight, and then more processing occurs in the liver. From there, vitamin D is converted to its active form in the kidney. Activated vitamin D is needed to absorb calcium in the intestinal tract and regulate calcium balance (McCance et al., 2014).

## Ureters

Each kidney usually has a single ureter, which is a hollow tube that connects the renal pelvis with the urinary bladder. The ureter is about  $\frac{1}{2}$  inch (1.25 cm) in diameter and about 12 to 18 inches (30 to 45 cm) in length. The diameter of the ureter narrows in three areas:

- In the upper third of the ureter, at the point at which the renal pelvis becomes the ureter, is a narrowing known as the **ureteropelvic junction (UPJ)**.
- The ureter also narrows as it bends toward the abdominal wall (aortoiliac bend).
- Each ureter narrows at the point at which it enters the bladder; this point is called the **ureterovesical junction (UVJ)**.

The ureter tunnels through bladder tissue for a short distance and then opens into the bladder at the trigone (Fig. 65-8).

**FIG. 65-8** Gross anatomy of the urinary bladder. (Modified from Patton, K.T., & Thibodeau, G.A. [2013]. *Anatomy & physiology* (8th ed.). St. Louis: Mosby.)

The ureter has three layers: an inner lining of mucous membrane (*urothelium*), a middle layer of smooth muscle fibers, and an outer layer of fibrous tissue. The middle layer of muscle fibers is controlled by several nerve pathways from the lower spinal cord.

Contractions of the smooth muscle in the ureter move urine from the kidney pelvis to the bladder. Stretch receptors in the kidney pelvis regulate this movement. For example, a large volume of urine in the kidney pelvis triggers the stretch receptors, which respond by increasing ureteral contractions and ureter peristalsis.

## Urinary Bladder

### Structure

The urinary bladder is a muscular sac (see Fig. 65-8) that lies directly behind the pubic bone. In men, the bladder is in front of the rectum. In women, it is in front of the vagina.

The bladder is composed of the *body* (the rounded sac portion) and the *bladder neck* (posterior urethra), which connects to the bladder body. The bladder has three linings: an inner lining of epithelial cells (*urothelium*), middle layers of smooth muscle (*detrusor muscle*), and an outer lining. The *trigone* is an area on the posterior wall between the points of ureteral entry (ureterovesical junctions [UVJs]) and the urethra.

The **internal urethral sphincter** is the smooth detrusor muscle of the bladder neck and elastic tissue. The **external urethral sphincter** is skeletal muscle that surrounds the urethra. In men, the external sphincter surrounds the urethra at the base of the prostate gland. In women, the external sphincter is at the base of the bladder. The pudendal nerve from the spinal cord controls the external sphincter.

### Function

The bladder stores urine, provides continence, and enables voiding. The secretions of the urothelium lining the bladder resist bacteria.

**Continence** is the ability to voluntarily control bladder emptying. It occurs during bladder filling through the combination of detrusor muscle relaxation, internal sphincter muscle tone, and external sphincter contraction. As the bladder fills with urine, stretch sensations are transmitted to spinal sacral nerves.

*Maintaining continence* occurs by the interaction of the nerves that control the muscles of the bladder, bladder neck, urethra, and pelvic floor, as well as by factors that close the urethra. In the continent person, the smooth muscle of the detrusor remains relaxed during a period of urine filling

and storage. Sympathetic nervous system fibers prevent detrusor muscle contraction. These control centers for voiding are located in the cerebral cortex, the brainstem, and the lower spinal cord. For urethral closure to be adequate for continence, the mucosal surfaces must be in contact and must be adhesive. Contact depends on the presence and proper function of the involved nerves and muscles. Adhesion depends on the secretion of mucuslike substances.

*Micturition* (voiding, urination) is a reflex of autonomic control that triggers contraction of the detrusor muscle (closing the ureter at the UVJ to prevent backflow) at the same time as relaxation of the external sphincter and the muscles of the pelvic floor. Voluntary urine ELIMINATION (voiding) occurs as a learned response and is controlled by the cerebral cortex and the brainstem. Contraction of the external sphincter inhibits the micturition reflex and prevents voiding.

## Urethra

The urethra is a narrow tube lined with mucous membranes. Its purpose is to allow urine ELIMINATION from the bladder. The **urethral meatus**, or opening, is the endpoint of the urethra. In men, the urethra is about 6 to 8 inches (15 to 20 cm) long, with the meatus located at the tip of the penis. The male urethra has three sections:

- The prostatic urethra, which extends from the bladder through the prostate gland
- The membranous urethra, which extends from the prostate to the wall of the pelvic floor
- The cavernous urethra, which is external and extends through the length of the penis

In women, the urethra is 1 to 1.5 inches (2.5 to 3.75 cm) long and exits through the pelvic floor. The meatus lies slightly below the clitoris and directly in front of the vagina and rectum.

## Kidney and Urinary Changes Associated With Aging

### Kidney Changes

Changes occur in the kidney as a result of the aging process that can affect urine ELIMINATION and health ([Chart 65-1](#)). The kidney loses cortical tissue and nephrons and gets smaller with age as a result of reduced blood flow to the kidney ([Touhy & Jett, 2016](#)). The medulla is not affected by aging, and the juxtamedullary nephron functions are preserved. The glomerular and tubular linings thicken. Both the number of glomeruli and their surface areas decrease with aging. Tubule length decreases. The changes reduce the older adult's ability to filter blood and excrete waste products.

### Chart 65-1

## Nursing Focus on the Older Adult

### Changes in the Renal System Related to Aging

PHYSIOLOGIC CHANGE	NURSING INTERVENTIONS	RATIONALES
Decreased glomerular filtration rate (GFR)	Monitor hydration status.	The ability of the kidneys to regulate water balance decreases with age.
	Ensure adequate fluid intake.	The kidneys are less able to conserve water when necessary.
	Administer potentially nephrotoxic agents or drugs carefully.	Dehydration reduces kidney blood flow and increases the nephrotoxic potential of many agents. Acute or chronic kidney failure may result.
Nocturia	Ensure adequate nighttime lighting and a hazard-free environment.	Falls and injuries are common among older patients seeking bathroom facilities.
	Ensure the availability of a bedside toilet, bedpan, or urinal.	Using these items instead of getting up to go the bathroom can help prevent falls.
	Discourage excessive fluid intake for 2-4 hr before the patient goes to bed.	Excessive fluid intake at night may increase nocturia.
	Evaluate drugs and timing.	Some drugs increase urine output and increase the risk for falling when toileting.
Decreased bladder capacity	Encourage the patient to use the toilet, bedpan, or urinal at least every 2 hr.	Emptying the bladder on a regular basis may avoid overflow urinary incontinence.
	Respond as soon as possible to the patient's indication of the need to void.	A quick response may alleviate episodes of urinary stress incontinence.
Weakened urinary sphincters and shortened urethra in women	Provide thorough perineal care after each voiding.	The shortened urethra increases the potential for bladder infections. Good perineal hygiene may prevent skin irritations and urinary tract infection (UTI).
Tendency to retain urine	Observe the patient for urinary retention (e.g., bladder distention) or urinary tract infection (e.g., dysuria, foul odor, confusion).	Urinary stasis may result in a UTI, which may lead to bloodstream infections, urosepsis, or septic shock.
	Provide privacy, assistance, and voiding stimulants such as warm water over the perineum as needed.	Nursing interventions can help initiate voiding.
	Evaluate drugs for possible contribution to retention.	Anticholinergic drugs promote urinary retention.

Blood flow to the kidney declines by about 10% per decade as blood vessels thicken. This means that blood flow to the kidney is not as adaptive in older adults, leaving nephrons more vulnerable

to damage during episodes of either hypotension or hypertension.

Glomerular filtration rate (GFR) decreases with age. By age 65 years, the GFR is about 65 mL/min (half the rate of a young adult) and increases the risk for fluid overload. This decline is more rapid in patients with diabetes, hypertension, or heart failure. The combination of reduced kidney mass, reduced blood flow, and decreased GFR contributes to reduced drug clearance and a greater risk for drug reactions and kidney damage from drugs and contrast media in older adults.

Tubular changes with aging decrease the ability to concentrate urine, resulting in **urgency** (a sense of a nearly uncontrollable need to urinate) and **nocturnal polyuria** (increased urination at night). The regulation of sodium, acids, and bicarbonate is less efficient. Along with an age-related impairment in the thirst mechanism, these changes increase the risk for disturbances of FLUID AND ELECTROLYTE BALANCE, such as dehydration and **hypermnatremia** (increased blood sodium levels) in the older adult. Hormonal changes include a decrease in renin secretion, aldosterone levels, and activation of vitamin D.

## Urinary Changes

Changes in detrusor muscle elasticity lead to decreased bladder capacity and reduced ability to retain urine (Touhy & Jett, 2016). The urge to void may cause immediate bladder emptying because the urinary sphincters lose tone and often become weaker with age. In women, weakened muscles in the pelvic floor shorten the urethra and promote incontinence. In men, an enlarged prostate gland makes starting the urine stream difficult and may cause urinary retention.

## Cultural/Spiritual Considerations

### Patient-Centered Care QSEN

African Americans have more rapid age-related decreases in GFR than do white adults. Kidney excretion of sodium is less effective in hypertensive African Americans who have high sodium intake, and the kidneys have about 20% less blood flow as a result of anatomic changes in small blood vessels and intrarenal responses to renin. Thus African-American patients are at greater risk for kidney failure than are white patients (Jarvis, 2016). Yearly health examinations should include urinalysis, checking for the presence of microalbuminuria, and evaluating serum creatinine.

## Assessment: Noticing and Interpreting

### Patient History

*Demographic information*, such as age, gender, race, and ethnicity, is important to consider as nonmodifiable risk factors in the patient with any kidney or urinary ELIMINATION problem. A sudden onset of hypertension in patients older than 50 years suggests possible kidney disease. Clinical changes in polycystic kidney disease typically occur in patients in their 40s or 50s. In men older than 50 years, altered urine patterns accompany prostate disease.

Anatomic gender differences make some disorders worse or more common. For example, men rarely have ascending urinary tract infections. Women have a shorter urethra and more commonly develop **cystitis** (bladder inflammation, most often with infection) because bacteria pass more readily into the bladder.

Ask the patient about any previous kidney or urologic problems, including tumors, infections, stones, or urologic surgery. A history of any chronic health problems, especially diabetes mellitus or hypertension, increases the risk for development of kidney disease because these disorders damage kidney blood vessels.

Exposure to certain contrast media during imaging can harm the kidneys. Iodinated contrast medium used for CT scans is associated with both acute and chronic kidney injury (Lambert et al., 2017). High-osmolarity contrast agents can also contribute to kidney function impairment. Exposure to gadolinium-enhanced MRI can result in nephrogenic systemic fibrosis.

Ask the patient about chemical exposures at the work place or with hobbies. Exposure to hydrocarbons (e.g., gasoline, oil), heavy metals (especially mercury and lead), and some gases (e.g., chlorine, toluene) can impair kidney function. Use this opportunity to teach patients who come into contact with chemicals at work or during leisure-time activities to avoid direct skin or mucous membrane contact with these chemicals. Use of heroin, cocaine, methamphetamine, ecstasy, and volatile solvents (inhalants) has also been associated with kidney damage.

Specifically ask the patient whether he or she has ever been told about the presence of protein or albumin in the urine. The question, "Have you ever been told that your blood pressure is high?" may prompt a response different from the one to the question, "Do you have high blood pressure?" Ask women about health problems during pregnancy (e.g., proteinuria, high blood pressure, gestational diabetes, urinary tract infections). Obtain information about:

- Chemical or environmental toxin exposure in occupational, diagnostic, or other settings
- Recent travel to geographic regions that pose infectious disease risks
- Recent trauma or injury, particularly to the abdomen or pelvic or genital areas
- A history of altered patterns of urinary ELIMINATION

*Socioeconomic status* may influence health care practices. Prevention, early detection, and treatment of kidney or urinary problems may be limited by lack of insurance or access to health care, lack of transportation, and reduced income. Low income may also result in difficulty following medical advice, having prescriptions filled, adhering to dietary instructions, and keeping follow-up appointments.

Educational level may affect health-seeking practices and the patient's understanding of a disease or its symptoms. Recurring urinary tract infections can result from not completing a course of antibiotic therapy or from not following up to ensure that the infection is cleared.

The patient's health beliefs affect the approach to health and illness. Cultural background or religious affiliation may influence the belief system, as well as comfort when discussing issues about ELIMINATION (Jackson et al., 2013).

The language used by patients may be different from that used by the health care professional. When obtaining a history, listen to and explore the terms used by the patient. By using the patient's own terms, you may help him or her provide a more complete description of the problem and may decrease the patient's discomfort when discussing bodily functions.

### Nutrition History

Ask the patient with known or suspected kidney or urologic disorders about his or her usual diet and any recent changes in the diet. Note any excessive intake or omission of certain food categories.

Ask about food and fluid intake. Assess how much and which types of fluids the patient drinks daily, especially fluids with a high calorie or caffeine content. Use this opportunity to teach the patient the importance of drinking sufficient fluid to cause urine to be dilute (clear or very light yellow). If another medical problem does not require fluid restriction, ingestion of about 2 liters of fluid daily is recommended to prevent dehydration and cystitis. If the patient has followed a diet for weight reduction, the details of the diet plan are important, and collaboration with a dietitian may be needed. A high-protein intake can result in temporary kidney problems. For example, a patient at risk for **calculi** (stone) formation who ingests large amounts of protein or has a poor fluid intake may form new stones.

Ask about any change in appetite or taste. These symptoms can occur with the buildup of nitrogenous waste products from kidney failure. Changes in thirst or fluid intake may also cause changes in the volume of urine ELIMINATION. Endocrine disorders may also cause changes in thirst, fluid intake, and urine output. (See [Chapter 61](#) for a discussion of endocrine influences on fluid balance.)

### Medication History

Identify all of the patient's prescription drugs because many can impair kidney function ([Burchum & Rosenthal, 2016](#)). Ask about the duration of drug use and whether there have been any recent changes in prescribed drugs. Drugs for diabetes mellitus, hypertension, cardiac disorders, hormonal disorders, cancer, arthritis, and psychiatric disorders are potential causes of kidney problems. Antibiotics, such as gentamicin (Garamycin, Cidomycin ♣), may also cause acute kidney injury. Drug-drug interactions and drug–contrast media interactions also may lead to kidney dysfunction ([Lambert et al., 2017](#)).

Explore the past and current use of over-the-counter (OTC) drugs or agents, including dietary supplements, vitamins and minerals, herbal agents, laxatives, analgesics, acetaminophen, and NSAIDs. Many of these agents affect kidney function and urine ELIMINATION. For example, dietary supplementation with synthetic creatine, used to increase muscle mass, has been associated with compromised kidney function. High-dose or long-term use of NSAIDs or acetaminophen can seriously reduce kidney function. Some agents are associated with hypertension, hematuria, or proteinuria, which may occur before kidney dysfunction.

### Family History and Genetic Risk

The family history of the patient with a suspected kidney or urologic problem is important because some disorders have a familial pattern. Ask whether siblings, parents, or grandparents have had kidney problems. Past terms used for kidney disease include *Bright's disease*, *nephritis*, and *nephrosis*. Although nephritis is a current term for an inflammatory process in the kidney and nephrosis is a current term for a degenerative process in the kidney, these terms have been used by lay adults for years to describe any type of kidney problem. Polycystic kidney disease, which is a genetic disorder, can occur in either gender.

### Current Health Problem

The effects of kidney failure are seen in all body systems. Document all of the patient's current health problems. Ask him or her to describe all health concerns, because some kidney disorders cause problems in other body systems. Recent upper respiratory problems, achy muscles or joints, heart disease, or GI conditions may be related to problems of kidney function.

Assess the kidney and urologic system by asking about any changes in the appearance (color, odor, clarity) of the urine, pattern of urine ELIMINATION, ability to initiate or control voiding, and other unusual symptoms. For example, urine that is reddish, rust-colored, brown or black, greenish, or different from the usual yellowish color may prompt the patient to seek health care assistance. Urine typically has a mild but distinct odor of ammonia. An increase in the intensity of color, a change in odor quality, or a decrease in urine clarity may suggest infection.

Ask about changes in urination patterns, such as **incontinence** (involuntary bladder emptying), **nocturia** (urination at night), **urgency** (unstoppable urge to urinate), frequency, or an increase or decrease in the amount of urine. The normal urine output for adults is about 1500 to 2000 mL/day or within 500 mL of the volume of fluid ingested daily. Ask about how closely the urine output is to the volume of fluid ingested. A bladder diary may be useful. Ask whether:

- Initiating urine flow is difficult

- A burning sensation or other discomfort occurs with urination
- The force of the urine stream is decreased (in men)
- Persistent dribbling of urine is present

The onset of pain in the flank, in the lower abdomen or pelvic region, or in the perineal area triggers concern and usually prompts the patient to seek assistance. Ask about the onset, intensity, and duration of the pain; its location; and its association with any activity or event.

Pain associated with kidney or ureteral irritation is often severe and spasmodic. Pain that radiates into the perineal area, groin, scrotum, or labia is described as *renal colic*. This pain occurs with distention or spasm of the ureter, such as in an obstruction or the passing of a stone. Renal colic pain may be intermittent or continuous and may occur with pallor, diaphoresis, and hypotension. These general symptoms occur because of the location of the nerve tracts near or in the kidneys and ureters (Brenner, 2016).

Because the kidneys are close to the GI organs and the nerve pathways are similar, GI symptoms may occur with kidney problems. These renointestinal reflexes often complicate the description of the kidney problem.

**Uremia** is the buildup of nitrogenous waste products in the blood from inadequate ELIMINATION as a result of kidney failure. Symptoms include anorexia, nausea and vomiting, muscle cramps, *pruritus* (itching), fatigue, and lethargy.

## Physical Assessment

The physical assessment of the patient with a known or suspected kidney or urologic disorder includes general appearance, a review of body systems, and specific structure and functions of the kidney and urinary system.

Assess the patient's general appearance and check the skin for the presence of any rashes, bruising, or yellowish discoloration. The skin and tissues may show edema associated with kidney disease, especially in the *pedal* (foot), *pretibial* (shin), and sacral tissues and around the eyes. Use a stethoscope to listen to the lungs to determine whether fluid is present. Weigh the patient and measure blood pressure as a baseline for later comparisons.

Assess the levels of consciousness and alertness. Record any deficits in memory, concentration, or thought processes. Family members may report subtle changes. Cognitive changes may be the result of the buildup of waste products when kidney disease is present.

### Assessment of the Kidneys, Ureters, and Bladder

Assess the kidneys, ureters, and bladder during an abdominal assessment (Jarvis, 2016). Auscultate before percussion and palpation because these activities can enhance bowel sounds and obscure abdominal vascular sounds.

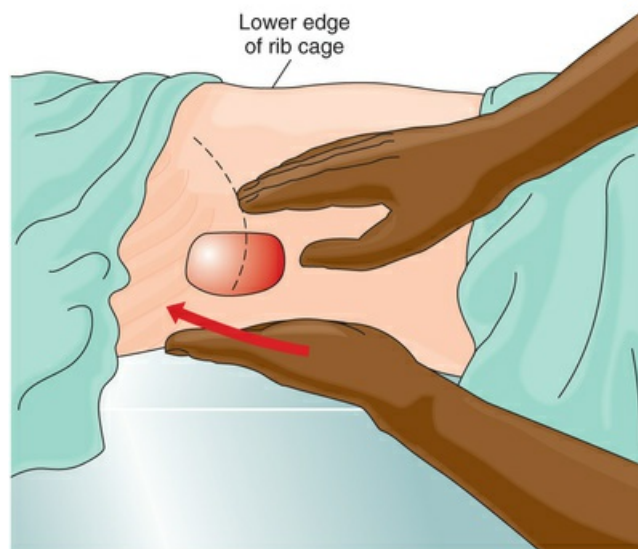

Inspect the abdomen and the flank regions with the patient in both the supine and the sitting positions. Observe the patient for asymmetry (e.g., swelling) or discoloration (e.g., bruising or redness) in the flank region, especially in the area of the costovertebral angle (CVA). The CVA is located between the lower portion of the twelfth rib and the vertebral column.

Listen for a bruit by placing a stethoscope over each renal artery on the midclavicular line. A **bruit** is an audible swishing sound produced when the volume of blood or the diameter of the blood vessel changes. It often occurs with blood flow through a narrowed vessel, as in renal artery stenosis.

Kidney palpation is usually performed by a primary health care provider. It can help locate masses and areas of tenderness in or around the kidney. Lightly palpate the abdomen in all quadrants. Ask about areas of tenderness or pain, and examine nontender areas first. The outline of the bladder may be seen as high as the umbilicus in patients with severe bladder distention. *If tumor or aneurysm is suspected, palpation may harm the patient.*

Because the kidneys are located deep and posterior, palpation is easier in thin patients who have little abdominal musculature. For palpation of the right kidney, the patient is in a supine position while the examiner places one hand under the right flank and the other hand over the abdomen below the lower right part of the rib cage. The lower hand is used to raise the flank, and the upper hand depresses the abdomen as the patient takes a deep breath (Fig. 65-9). The left kidney is deeper and often cannot be palpated. A transplanted kidney is readily palpated in either the lower right or left abdominal quadrant. The normal kidney is smooth, firm, and nontender.

**FIG. 65-9** Advanced technique for palpation of the kidney.

A distended bladder sounds dull when percussed. After gently palpating to determine the outline of the distended bladder, begin percussion on the lower abdomen and continue in the direction of the umbilicus until dull sounds are no longer produced. If you suspect bladder distention, use a portable bladder scanner to determine the amount of retained urine.

If the patient reports flank pain or tenderness, percuss the nontender flank first. Have the patient assume a sitting, side-lying, or supine position, and then form one of your hands into a clenched fist. Place your other hand flat over the CVA of the patient. Quickly deliver a firm thump to your hand over the CVA area (Jarvis, 2016). Costovertebral tenderness often occurs with kidney infection or inflammation. Patients with inflammation or infection in the kidney or nearby structures may describe their pain as severe or as a constant, dull ache.

### Assessment of the Urethra

Using a good light source and wearing gloves, inspect the urethra by examining the meatus and the tissues around it. Record any unusual discharge such as blood, mucus, or pus. Inspect the skin and mucous membranes of surrounding tissues. Record the presence of lesions, rashes, or other abnormalities of the penis or scrotum or of the labia or vaginal opening. Urethral irritation is suspected when the patient reports discomfort with urination. Use this opportunity to remind women to clean the perineum by wiping from front to back, never from back to front. Teach them that the front-to-back technique keeps organisms in stool from coming close to the urethra and decreases the risk for infection.

## Cultural/Spiritual Considerations

### Patient-Centered Care QSEN

Women from some cultures or religions may have undergone female circumcision. This procedure alters the appearance of the vulvar-perineal area and increases the risk for urinary tract infections. It also makes urethral inspection or catheterization difficult. Document any noted anatomic changes and ask the patient to describe her hygiene practices for this area.

### Psychosocial Assessment

Concerns about the urologic system may evoke fear, anger, embarrassment, anxiety, guilt, or sadness in the patient. Childhood learning often includes the idea that toileting should take place in private and not be discussed with other people. Urologic disorders may bring up forgotten memories of difficult toilet training and bedwetting or of childhood experiences of exploring one's body. The patient may ignore symptoms or delay seeking health care because of emotional

responses or cultural taboos about the urogenital area.

## NCLEX Examination Challenge 65-1

### Physiological Integrity

When obtaining a health history from a 22-year-old female client who has new-onset urinary incontinence, which findings or factors does the nurse consider significant? **Select all that apply.**

- A. Chemical exposure in the workplace
- B. A burning sensation occurring on urination
- C. Urinating 10 times daily although fluid intake remains unchanged
- D. A recent change in the client's oral contraceptive prescription
- E. A new inability to hold urine (urgency)
- F. A "stinky" odor from the urine

## Diagnostic Assessment

### Laboratory Assessment

#### Blood Tests.

*Serum creatinine* is produced when muscle and other proteins are broken down. Because protein breakdown is usually constant, the serum creatinine level is a good indicator of kidney function. Serum creatinine levels are slightly higher in men than in women because men tend to have a larger muscle mass than do women. Similarly, adults with greater muscle mass or muscle mass turnover (e.g., athletes) may have a slightly higher-than-average serum creatinine level. Muscle mass and the amount of creatinine produced decrease with age. However, because of decreased rates of creatinine clearance, the serum creatinine level remains relatively constant in older adults unless kidney disease is present.

*No common pathologic condition other than kidney disease increases the serum creatinine level.* The serum creatinine level does not increase until at least 50% of the kidney function is lost; therefore *any* elevation of serum creatinine values is important and should be assessed further. Creatinine is excreted by the kidneys.

## Nursing Safety Priority QSEN

### Action Alert

A serum creatinine of 1.5 mg/dL (110 μmol/L) or greater places a patient at risk for acute kidney injury (AKI) from iodinated contrast media and some drugs (Lambert et al., 2017). Monitor both baseline and trend values to recognize risk for and actual kidney damage, especially among patients exposed to agents that can cause kidney dysfunction. If indicated, respond by promptly informing the primary health care provider of increases in serum creatinine greater than 1.5 times the baseline and urine output values of less than 0.5 mL/kg/hr for 6 or more hours.

*Blood urea nitrogen (BUN)* measures the effectiveness of kidney excretion of urea nitrogen, a by-product of protein breakdown in the liver. Urea nitrogen is produced mostly from liver metabolism of food sources of protein. The kidneys filter urea nitrogen from the blood and excrete the waste as part of urine **ELIMINATION**.

Other factors influence the BUN level, and an elevation does not always mean that kidney disease is present (**Chart 65-2**). For example, rapid cell destruction from infection, cancer treatment, or steroid therapy may elevate BUN level. In addition, blood is a protein. Blood in the tissues rather

than in the blood vessels is reabsorbed as if it were a general protein. Thus reabsorbed blood protein is processed by the liver and increases BUN levels. This means that injured tissues can result in increased BUN levels even when kidney function is normal. In addition, BUN is increased by protein turnover in exercising muscle and is elevated as a result of concentration during dehydration.

### Chart 65-2

## Laboratory Profile

### Kidney Function Blood Studies

TEST	NORMAL RANGE FOR ADULTS	CANADIAN NORMAL RANGE	SIGNIFICANCE OF ABNORMAL FINDINGS
Serum creatinine	Males: 0.6-1.2 mg/dL Females: 0.5-1.1 mg/dL Older adults: May be decreased	Males: 53-106 μmol/L Females: 44-97 μmol/L	An increased level indicates kidney impairment. A decreased level may be caused by a decreased muscle mass.
Blood urea nitrogen (BUN)	10-20 mg/dL Older adults: Slightly higher	3.6-7.1 mmol/L	An increased level may indicate liver or kidney disease, dehydration or decreased kidney perfusion, a high-protein diet, infection, stress, steroid use, GI bleeding, or other situations in which blood is in body tissues. A decreased level may indicate malnutrition, fluid volume excess, or severe hepatic damage.
BUN/creatinine ratio (BUN divided by creatinine)	6-25	6-25	An increased ratio may indicate fluid volume deficit, obstructive uropathy, catabolic state, or a high-protein diet. A decreased ratio may indicate fluid volume excess.

Data from Pagana, K., Pagana, T., & Pagana, T. (2017). *Mosby's diagnostic & laboratory test reference* (13th ed.). St. Louis: Mosby; and Pagana, K., Pagana, T., & Pike-McDonald, S. (2013). *Mosby's Canadian manual of diagnostic and laboratory tests*. St. Louis: Elsevier.

The liver must function properly to produce urea nitrogen. When liver and kidney dysfunction are present, urea nitrogen levels are actually *decreased* because the liver failure limits urea production. The BUN level is not always elevated with kidney disease and is not the best indicator of kidney function. However, an elevated BUN level suggests kidney dysfunction.

*Blood urea nitrogen to serum creatinine ratio* can help determine whether non-kidney-related factors, such as low cardiac output or red blood cell destruction, are causing the elevated BUN level. When blood volume is deficient (e.g., dehydration) or cardiac output is low, the BUN level rises more rapidly than the serum creatinine level. As a result, the ratio of BUN to creatinine is *increased*.

When both the BUN and serum creatinine levels increase at the same rate, the BUN/creatinine ratio remains normal. However, elevations of *both* serum creatinine and BUN levels suggest kidney dysfunction that is not related to dehydration or poor perfusion.

*Blood osmolarity* is a measure of the overall concentration of particles in the blood and is a good indicator of hydration status. The kidneys excrete or reabsorb water to keep blood osmolarity in the range of 280 to 300 mOsm/kg (mmol/kg). Osmolarity is slightly higher in older adults. When blood osmolarity is decreased, vasopressin (antidiuretic hormone [ADH]) release is inhibited. Without vasopressin, the distal tubule and collecting ducts are *not* permeable to water. As a result, water is *excreted*, not reabsorbed, and blood osmolarity increases. When blood osmolarity increases, vasopressin is released. Vasopressin increases the permeability of the distal tubule to water. Then water is reabsorbed, and blood osmolarity decreases.

## Urine Tests

### Urinalysis.

Urinalysis is a part of any complete physical examination and is especially useful for patients with suspected kidney or urologic disorders (Chart 65-3). Ideally, the urine specimen is collected at the morning's first voiding. Specimens obtained at other times may be too dilute. The specimen may be collected by several techniques (Table 65-3).

### Chart 65-3

## Laboratory Profile

### Urinalysis

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Color	Yellow	<i>Dark amber</i> indicates concentrated urine. <i>Very pale yellow</i> indicates dilute urine. <i>Dark red or brown</i> indicates blood in the urine. Brown may indicate increased bilirubin level. Red also may indicate the presence of myoglobin. <i>Other color changes</i> may result from diet or drugs.
Odor	Specific aroma, similar to ammonia	<i>Foul smell</i> indicates possible infection, dehydration, or ingestion of certain foods or drugs.
Turbidity	Clear	<i>Cloudy urine</i> indicates infection, sediment, or high levels of urine protein.
Specific gravity	Usually 1.005-1.030; possible range 1.000-1.040 <i>Older adult</i> : Decreased	<i>Increased</i> in decreased kidney perfusion, inappropriate ADH secretion, or heart failure. <i>Decreased</i> in chronic kidney disease, diabetes insipidus, malignant hypertension, diuretic administration, and lithium toxicity.
pH	Average: 6; possible range: 4.6-8	<i>Changes</i> are caused by diet, drugs, infection, age of specimen, acid-base imbalance, and kidney disease.
Glucose	Fresh specimen, negative 50-300 mg/day in a 24-hour specimen (<2.78 mmol/day in a 24-hour specimen)	<i>Presence</i> reflects hyperglycemia or a decrease in the kidney threshold for glucose.
Ketones	None	<i>Presence</i> occurs with diabetic ketoacidosis, prolonged fasting, anorexia nervosa.
Protein	0-0.8 mg/dL (0-0.08 g/L) 50-80 mg in a 24-hour specimen at rest <250 mg in a 24-hour specimen with exercise	<i>Increased</i> amounts may indicate stress, infection, recent strenuous exercise, or glomerular disorders.
Bilirubin (urobilinogen)	None	<i>Presence</i> suggests liver or biliary disease or obstruction.
Red blood cells (RBCs)	0-2 per high-power field	<i>Increased</i> is normal with catheterization or menses but may reflect tumor, stones, trauma, glomerular disorders, cystitis, or bleeding disorders.
White blood cells (WBCs)	0-4 per low-power field	<i>Increased</i> may indicate an infection or inflammation in the kidney and urinary tract, kidney transplant rejection, or exercise.
Casts	None	<i>Increased</i> indicates bacteria, protein, or urinary calculi.
Crystals	None	<i>Presence</i> may indicate that the specimen has been allowed to stand.
Bacteria	<1000 colonies/mL	<i>Increased</i> indicates the need for urine culture to determine the presence of urinary tract infection.
Parasites	None	<i>Presence of Trichomonas vaginalis</i> indicates infection, usually of the urethra, prostate, or vagina.
Leukocyte esterase	None	<i>Presence</i> suggests urinary tract infection.
Nitrites	None	<i>Presence</i> suggests urinary <i>Escherichia coli</i> .

ADH, Antidiuretic hormone.

Data from Pagana, K., Pagana, T., & Pagana, T. (2017). *Mosby's diagnostic & laboratory test reference* (13th ed.). St. Louis: Mosby; and Pagana, K., Pagana, T., & Pike-McDonald, S. (2013). *Mosby's Canadian manual of diagnostic and laboratory tests*. St. Louis: Elsevier.

**TABLE 65-3**

### Collection of Urine Specimens

NURSING INTERVENTIONS	RATIONALES
<b>Voided Urine</b>	
Collect the first specimen voided in the morning.	Urine is more concentrated in the early morning.
Send the specimen to the laboratory as soon as possible.	After urine is collected, cellular breakdown results in more alkaline urine.
Refrigerate the specimen if a delay is unavoidable.	Refrigeration delays the alkalization of urine. Bacteria are more likely to multiply in an alkaline environment.
<b>Clean-Catch Specimen</b>	
Explain the purpose of the procedure to the patient.	Correct technique is needed to obtain a valid specimen.
Instruct the patient to self-clean before voiding: Instruct the female patient to separate the labia and use the sponges and solution provided to wipe with three strokes over the urethra. The first two wiping strokes are over each side of the urethra; the third wiping stroke is centered over the urethra (from front to back). Instruct the male patient to retract the foreskin of the penis and to similarly clean the urethra, using three wiping strokes with the sponge and solution provided (from the head of the penis downward).	Surface cleaning is necessary to remove secretions or bacteria from the urethral meatus.
Instruct the patient to initiate voiding after cleaning. The patient then stops and resumes voiding into the container. At no time should any part of the patient's anatomy touch the lip or inner aspect of the container. Only 1 ounce (30 mL) is needed; the remainder of the urine may be discarded into the commode.	A midstream collection further removes secretions and bacteria because urine flushes the distal portion of the internal urethra.
Ensure that the patient understands the procedure.	An improperly collected specimen may result in inappropriate or incomplete treatment.
Help the patient as needed.	The patient's understanding and the nurse's assistance ensure proper collection.
<b>Catheterized Specimen</b>	
For non-indwelling (straight) catheters:	The one-time passage of a urinary catheter may be necessary to obtain an uncontaminated specimen for analysis or to measure the volume of residual urine.
Follow facility procedures for urinary catheterization.	These procedures minimize bacterial entry.
For indwelling catheters:	Urine is collected from an indwelling catheter or tubing when patients have catheters for continence or long-term urinary drainage.
• Apply a clamp to the drainage tubing, distal to the injection port.	Clamping allows urine to collect in the tubing at the location where the specimen is obtained.
• Clean the injection port cap of the catheter drainage tubing with an appropriate antiseptic and allow to dry. Povidone-iodine solution or alcohol is acceptable.	Surface contamination is prevented by following the cleaning procedures.
• Attach a sterile 5-mL syringe into the port and aspirate the quantity of urine required.	A minimum of 5 mL is needed for culture and sensitivity (C&S) testing.
• Inject the urine sample into a sterile specimen container.	A sterile container is used for C&S specimens.
• Remove the clamp to resume drainage.	
• Properly dispose of the syringe.	
<b>24-Hour Urine Collection</b>	
Instruct the patient thoroughly.	A 24-hr collection of urine is necessary to quantify or calculate the rate of clearance of a particular substance.
Provide written materials to assist in instruction. Place signs appropriately. Inform all personnel or family caregivers of test in progress.	Instructional materials for patients, signs, etc. remind patients and staff to ensure that the total collection is completed.
Check laboratory or procedure manual on proper technique for maintaining the collection (e.g., on ice, in a refrigerator, or with a preservative).	Proper technique prevents breakdown of elements to be measured.
On initiation of the collection, ask the patient to void, discard the urine, and note the time. If a Foley catheter is in use, empty the tubing and drainage bag at the start time and discard the urine. Collect all urine of the next 24 hr. Twenty-four hours after initiation, ask the patient to empty the bladder and add that urine to the container.	Proper techniques ensure that <i>all</i> urine formed within the 24-hr period is collected.
Do not remove urine from the collection container for other specimens.	Urine in the container is not considered a "fresh" specimen and may be mixed with preservative.

*Urine color* comes from trichrome pigment. Color variations may result from increased levels of trichrome or other pigments, changes in the concentration or dilution of the urine, and the presence of drug metabolites in the urine. Urine smells faintly like ammonia and is normally clear without

*turbidity* (cloudiness) or haziness.

*Specific gravity* is the concentration of particles (i.e., electrolytes, wastes) in urine. A high specific gravity indicates concentrated urine from dehydration, decreased kidney blood flow, or excess vasopressin associated with stress, surgery, anesthetic agents, and certain drugs (e.g., morphine, some oral antidiabetic drugs) or syndrome of inappropriate antidiuretic hormone (SIADH) (see [Chapter 62](#)). Low specific gravity indicates dilute urine that may occur from high fluid intake, diuretic drugs, or diabetes insipidus (DI) (see [Chapter 62](#)).

Specific gravity of urine is compared with distilled water, which has a specific gravity of 1.000. The normal specific gravity of urine ranges from 1.005 to about 1.030. Kidney disease diminishes the concentrating ability of the kidney, and chronic kidney disease may be associated with a low (dilute) specific gravity.

*pH* is a measure of urine acidity or alkalinity. A pH value less than 7 is acidic, and a value greater than 7 is alkaline. Urine pH is affected by diet, drugs, systemic disturbances of ACID-BASE BALANCE, and kidney tubular function. For example, a high-protein diet produces acidic urine, whereas a high intake of citrus fruit produces alkaline urine.

Urine specimens become more alkaline when left standing unrefrigerated for more than 1 hour, when bacteria are present, or when a specimen is left uncovered. Alkaline urine increases cell breakdown; thus the presence of red blood cells may be missed on analysis. Ensure that urine specimens are covered and delivered to the laboratory promptly or refrigerated ([McGoldrick, 2015](#)). During systemic acidosis or alkalosis, the kidneys, along with blood buffers and the lungs, normally respond to keep serum pH normal. [Chapter 12](#) discusses ACID-BASE BALANCE and imbalance.

*Protein* is not normally present in the urine. Microalbumin levels greater than 80 mcg/24 hr (0.08 g/24 hr), are abnormal. Protein molecules are too large to pass through intact glomerular membranes. When glomerular membranes are not intact, protein molecules pass through and are excreted with urine ELIMINATION. Increased membrane permeability is caused by infection, inflammation, or immunologic problems. Some systemic problems cause production of abnormal proteins, such as globulin. Detection of abnormal protein types requires electrophoresis.

A random finding of **proteinuria** (usually albumin in the urine) followed by a series of negative (normal) findings does not imply kidney disease. If infection is the cause of the proteinuria, urinalyses after resolution of the infection should be negative for protein. Persistent proteinuria needs further investigation.

**Microalbuminuria** is the presence of albumin in the urine that is not measurable by a urine dipstick or usual urinalysis procedures. Specialized assays are used to quickly analyze a freshly voided urine specimen for microscopic levels of albumin. The normal microalbumin levels in a freshly voided specimen should be less than 2.0 mg/dL. Higher levels indicate microalbuminuria and could mean mild or early kidney disease, especially in patients with diabetes mellitus. In 24-hour urine specimens, levels greater than 80 mcg/24 hr (0.08 g/24 hr) indicate microalbuminuria.

*Glucose* in the urine may indicate a high level of glucose in the blood, typically greater than 220 mg/dL (12 mmol/L). Changes in the renal threshold for glucose may occur temporarily in patients who have infection or severe stress.

*Ketone bodies* are formed from the incomplete metabolism of fatty acids. Three types of ketone bodies are acetone, acetoacetic acid, and beta-hydroxybutyric acid. *Normally there are no ketones in urine.* Ketone bodies are produced when fat is used instead of glucose for cellular energy. Ketones present in the blood are partially excreted in the urine.

*Leukoesterase* is an enzyme found in some white blood cells, especially neutrophils. When the number of these cells increases in the urine or they are damaged (lysed), the urine then contains leukoesterase. A normal reading is no leukoesterase in the urine. A positive test (+ sign) is an indication of a urinary tract infection.

*Nitrites* are not usually present in urine. Many types of bacteria, when present in the urine, convert nitrates (normally found in urine) into nitrites. A positive test enhances the sensitivity of the leukoesterase test to detect urinary tract infection.

*Sediment* is precipitated particles in the urine. These particles include cells, casts, crystals, and bacteria. Normally, urine contains few, if any, cells. Types of cells abnormally present in the urine include tubular cells (from the tubule of the nephron), epithelial cells (from the lining of the urinary tract), red blood cells (RBCs), and white blood cells (WBCs). WBCs may indicate a urinary tract or kidney infection. RBCs may indicate *glomerulonephritis*, *acute tubular necrosis*, *pyelonephritis*, kidney trauma, or kidney cancer.

Casts are clumps of materials or cells. When cells, bacteria, or proteins are present in the urine,

minerals and sticky materials clump around them and form a cast of the distal renal tubule and collecting duct. Casts are described by the type of particle they have surrounded (e.g., hyaline [protein-based] or cellular [from RBCs, WBCs, or epithelial cells]) or the stage of cast breakdown (whole cell or granular from cell breakdown). Although an isolated urinalysis with sediment from casts may be the result of strenuous exercise, repeated findings with sediment are more likely to be associated with disease.

Urine crystals come from mineral salts as a result of diet, drugs, or disease. Common salt crystals are formed from calcium, oxalate, urea, phosphate, magnesium, or other substances. Some drugs, such as the sulfates, can also form crystals.

Bacteria multiply quickly, so the urine specimen must be analyzed promptly to avoid falsely elevated counts of bacterial colonization. Normally urine is sterile, but it can be easily contaminated by perineal bacteria during collection.

Recent advances in technology and molecular biology have led to new diagnostic tests using urine, including identification of biomarkers of disease and profiling for specific proteins. For example, cystatin-C, produced by all nucleated cells, is formed at a constant rate and freely filtered by the kidneys. It is used to estimate glomerular filtration rate (GFR) and may predict progression of chronic kidney disease. Markers such as cystatin-C are being investigated to identify early-onset kidney dysfunction, target therapy, and predict responsiveness to intervention. Other markers for angiogenesis and kidney cell adhesion, regulation, and apoptosis (i.e., connective tissue growth factor [CTGF], neutrophil gelatinase-associated lipocalin [NGAL]) will likely contribute to clinical diagnostics in the future.

### Urine for Culture and Sensitivity.

Urine is analyzed for the number and types of organisms present. Symptoms of infection and unexplained bacteria in a urine specimen are indications for urine culture and sensitivity testing. Bacteria from urine are placed in a medium with different antibiotics. In this way we can know which antibiotics are effective in killing or stopping the growth of the organisms (organisms are “sensitive”) and which are not effective (organisms are “resistant”). A clean-catch or catheter-derived specimen is best for culture and sensitivity testing.

### Composite Urine Collections.

Some urine collections are made for a specified number of hours (e.g., 24 hours) for precise analysis of urine levels of substances such as creatinine or urea nitrogen, sodium, chloride, calcium, catecholamines, or other components (Chart 65-4). For a composite urine specimen, *all* urine within the designated time frame must be collected (see Table 65-3). If other urine must be obtained while the collection is in progress, measure and record the amount collected but not added to the timed collection.

## Chart 65-4

### Laboratory Profile

#### 24-Hour Urine Collections

COMPONENT	NORMAL RANGE FOR ADULTS	CANADIAN RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Creatinine	Males: 1-2 g/24 hr or 14-26 mg/kg/24 hr Females: 0.6-1.8 g/24 hr Older adults: slightly lower	Males: 124-230 μmol/kg/24 hr Females: 97-177 μmol/kg/24 hr	Decreased amounts indicate deterioration in function caused by kidney disease. Increased amounts occur with infections, exercise, diabetes mellitus, and meat meals.
Urea nitrogen	12-20 g/24 hr	0.43-0.71 mmol/24 hr	Decreased amounts occur when kidney damage or liver disease is present. Increased amounts commonly result from a high-protein diet, dehydration, trauma, or sepsis.
Sodium	40-250 mEq/24 hr	40-250 mmol/day	Decreased in hemorrhage, shock, hyperaldosteronism, and prerenal acute kidney injury. Increased with diuretic therapy, excessive salt intake, hypokalemia, and acute tubular necrosis.
Chloride	110-250 mEq/24 hr Older adults: Lower	110-250 mmol/24 hr	Decreased in certain kidney diseases, malnutrition, pyloric obstruction, prolonged nasogastric tube drainage, diarrhea, diaphoresis, heart failure, and emphysema. Increased with hypokalemia, adrenal insufficiency, and massive diuresis.
Calcium	100-400 mg/24 hr	2.50-7.50 mmol/kg/24 hr	Decreased with hypocalcemia, hypoparathyroidism, nephrosis, and nephritis. Increased with calcium kidney stones, hyperparathyroidism, sarcoidosis, certain cancers, immobilization, and hypercalcemia.
*Total catecholamines	<100 mcg/24 hr	<591 mmol/24 hr	Increased with pheochromocytoma, neuroblastomas, stress, or heavy exercise.
Protein	<80 mg/24 hr	10-150 mg/24 hr	Increased in glomerular disease, nephrotic syndrome, diabetic nephropathy, urinary tract malignancies, and irritations.

\*Epinephrine and norepinephrine only; dopamine is not measured.

Data from Pagana, K., Pagana, T., & Pagana, T. (2017). *Mosby's diagnostic & laboratory test reference* (13th ed.). St. Louis: Mosby; Pagana, K., Pagana, T., & Pike-McDonald, S. (2013). *Mosby's Canadian manual of diagnostic and laboratory tests*. St.

The urine collection may need to be refrigerated or stored on ice to prevent changes in the urine during the collection time. Follow the procedure from the laboratory for urine storage, including whether a preservative is to be added. The urine collection must be free from fecal contamination. Menstrual blood and toilet tissue also contaminate the specimen and can invalidate the results.

The collection of all urine for a 24-hour period is often challenging. With hospitalized patients, the cooperation of staff personnel, the patient, family members, and visitors is essential. Placing signs in the bathroom, instructing the patient and family, and emphasizing the need to save the urine are helpful.

### **Creatinine Clearance.**

Creatinine clearance is a measure of glomerular filtration rate (GFR) and kidney function. The patient's age, gender, height, weight, diet, and activity level influence the expected amount of excreted creatinine. Thus these factors are considered when interpreting creatinine clearance test results. Decreases in the creatinine clearance rate may require reducing drug doses and often signifies the need to further explore the cause of kidney deterioration.

Commonly, creatinine clearance is calculated from serum creatinine, age, weight, urine creatinine, gender, and race. Creatinine clearance can be based on the excretion of injected inulin or other substances that are not reabsorbed into the blood. Creatinine clearance to estimate GFR can also be based on a 24-hour urine collection, although urine can be collected for shorter periods (e.g., 8 or 12 hours). The analysis compares the urine creatinine level with the blood creatinine level; therefore a blood specimen for creatinine must also be collected. The range for normal creatinine clearance is 107 to 139 mL/minute for men (1.78-2.32 mL/sec) and 87 to 107 mL/minute (1.45-1.78 mL/sec) for women tested with a 24-hour urine collection. Values decrease progressively per decade of life for adults older than 40 years because of age-related decline in GFR. However, these expensive and time-consuming methods are usually reserved for when a decision for starting renal replacement therapy (dialysis) is needed.

Current guidelines suggest that clinical laboratories report an estimate of GFR whenever a serum creatinine is ordered, based on the modified diet in renal disease (MDRD) study equation. The MDRD equation does not require urine to estimate GFR. The estimated GFR (eGFR) for the MDRD equation is  $>60$  mL/min/1.73 m<sup>2</sup> (Pagana et al., 2017). An alternate approach for calculation is the Cockcroft-Gault equation, which has traditionally been used to determine drug dose adjustment when the eGFR is  $<50$  mL/min/1.73 m<sup>2</sup>.

### **Urine Electrolytes.**

Urine samples can be analyzed for electrolyte levels (e.g., sodium, chloride). Normally the amount of sodium excreted in the urine is nearly equal to that consumed. Urine sodium levels of less than 10 mEq/L (mmol/L) indicate that the tubules are able to conserve (reabsorb) sodium.

### **Urine Osmolarity.**

Osmolarity measures the concentration of particles in solution. The particles in urine contributing to osmolarity include electrolytes, glucose, urea, and creatinine. Urine osmolarity can vary from 50 to 1200 mOsm/kg or L (mmol/kg or L), depending on the patient's hydration status and kidney function. With average fluid intake, the range for urine osmolarity is 300 to 900 mOsm/kg or L (mmol/kg or L). Electrolytes, acids, and other normal metabolic wastes are continually produced. These particles are the solute load that must be excreted in the urine on a regular basis. This is referred to as *obligatory solute excretion*. If the patient loses excessive fluids, the kidney response is to save water while excreting wastes by excreting small amounts of highly concentrated urine. Diet, drugs, and activity can change urine osmolarity. Urine with an increased osmolarity is concentrated urine with less water and more solutes. Urine with a decreased osmolarity is dilute urine with more water and fewer solutes.

## **NCLEX Examination Challenge 65-2**

### **Safe and Effective Care Environment**

Which client being managed for dehydration does the nurse consider at **greatest** risk for possible reduced kidney function?

- A. An 80-year-old man who has benign prostatic hyperplasia
- B. A 62-year-old woman with a known allergy to contrast media
- C. A 48-year-old woman with established urinary incontinence
- D. A 45-year-old man receiving oral and IV fluid therapy

### Bedside Sonography/Bladder Scanners.

The use of portable ultrasound scanners in the hospital and rehabilitation setting by nurses is a noninvasive method of estimating bladder volume (Fig. 65-10). Bladder scanners are used to screen for post-void residual volumes and determine the need for intermittent catheterization based on the amount of urine in the bladder rather than the time between catheterizations. There is no discomfort with the scan, and no patient preparation beyond an explanation of what to expect is required.

**FIG. 65-10** “BladderScan” BVI 9400, a handheld portable bladder scanner. (Courtesy Verathon Corporation, Bothell, WA.)

Explain the reason the procedure is being done and what sensations the patient might experience during it. For example, “This test will measure the amount of urine in your bladder. I will place a gel pad just above your pubic area and then place the probe, which is a little bigger and heavier than a stethoscope, on the gel.”

Before scanning, select the male or female icon on the bladder scanner. Using the female icon allows the scanner software to subtract the volume of the uterus from any measurement. Use the male icon on all men and on women who have undergone a hysterectomy.

Place an ultrasound gel pad right above the pubic bone or moisten the round dome of the scan head area with 5 mL of conducting gel to improve ultrasound conduction. Use gel on the scanner head for obese patients and those with heavy body hair in the area to be scanned. Place the probe midline over the abdomen about 1.5 inches (4 cm) above the pubic bone. Aim the scan head so the ultrasound is projected toward the expected location of the bladder, typically toward the patient's coccyx. Press and release the scan button. The scan is complete with the sound of a beep, and a

volume is displayed. Two readings are recommended for best accuracy. An aiming icon on the portable bladder scanner indicates whether the bladder image is centered on the crosshairs of the scan head. If the crosshairs on the aiming icon are not centered on the bladder, the measured volume may not be accurate.

## Imaging Assessment

Many imaging procedures are used to diagnose abnormalities within the renal-urinary system (Table 65-4). Explain the procedures to the patient, prepare him or her, and provide follow-up care. Patient education materials for many urologic tests have been developed by organizations such as the Society for Urologic Nurses and Associates and are freely available.

**TABLE 65-4**  
**Radiologic and Special Diagnostic Tests for Patients With Disorders of the Kidney and Urinary System**

TEST	PURPOSE
Radiography of kidneys, ureters, and bladder (KUB) (plain film of abdomen)	To screen for the presence of two kidneys To measure kidney size To detect gross obstruction in kidneys or urinary tract
Computed tomography (CT) with contrast, CT-arteriography or angiography	To measure kidney size To evaluate contour to assess for injury, masses, or obstruction in kidneys or the urinary tract To assess renal blood flow
Magnetic resonance imaging (MRI)	Similar to CT Useful for staging of cancers
Ultrasonography (US) Can be used with contrast media	To identify the urine volume in the bladder, size of the kidneys or obstruction (e.g., tumors, stones) in the kidneys or lower urinary tract Can also assess blood flow to and from the kidney
(Nuclear) renal scan	To evaluate renal perfusion To estimate glomerular filtration rate To provide functional information without exposing the patient to iodinated contrast medium
Cystoscopy	To identify abnormalities of the bladder wall and urethral and ureteral occlusions To treat small obstructions or lesions via fulguration, lithotripsy, or removal with a stone basket
Cystography and cystourethrography	To outline bladder's contour when full and examine structure during voiding To examine the structure of the urethra To detect backward urine flow
Metabolic imaging with positron emission tomography (PET)	To evaluate cysts, tumors, and other lesions, eliminating the need for biopsy in some patients

## Kidney, Ureter, and Bladder X-rays.

An x-ray of the kidneys, ureters, and bladder (KUB) is a plain film of the abdomen obtained without any specific patient preparation. The KUB study shows gross anatomic features and obvious stones, strictures, calcifications, or obstructions in the urinary tract. This test identifies the shape, size, and position of the organs in relation to other parts of the urinary tract. Other tests are needed to diagnose functional or structural problems.

There is no discomfort or risk from this procedure. Tell the patient that the x-ray will be taken while he or she is in a supine position. No specific follow-up care is needed.

## Computed Tomography.

Inform the patient that a CT scan provides three-dimensional information about the kidneys, ureters, bladder, and surrounding tissues. The CT scan is performed in a special room, usually in the radiology department. It can provide information about tumors, cysts, abscesses, other masses, and obstruction. CT can also be used to image the kidney's vascular system (i.e., CT angiography). Some hospitals require patients having CT scans to be NPO for some period before the scan, although there is no specific evidence guiding this practice.

Determine whether the scan requires contrast medium (often called *dye*). The most common contrast agents used for imaging of the kidney are radiopaque, contain iodine, are nonionic, and have varying osmolarity. These include lohexol (Omnipaque), loplomide (Ultravist), and lodixanol (Visiopaque). Oral or injected contrast medium is usually given before starting the imaging procedure. Dye use may be omitted in patients at risk for contrast-induced acute kidney injury, but the images produced are less distinct.

When contrast is used, ensure that there is sufficient oral or IV intake to dilute and excrete the contrast media. Typically, the radiologist will specify a total fluid intake of 1 liter or a variable rate to maintain urine output at 1 to 2 mL/kg/hr for up to 6 hours. When no contrast is used, there is no special postprocedure care.

Contrast medium is potentially kidney-damaging (nephrotoxic). *Contrast-induced nephropathy* is the onset of *acute kidney failure* within 48 hours after the administration of iodinated contrast medium (Lambert et al., 2017; Wichmann et al., 2015). The risk for *contrast-induced nephropathy* is

greatest in patients who are older or dehydrated, have pre-existing chronic kidney disease (CKD), or have comorbidities of diabetes, heart failure, or current hypotension (Silva et al., 2015). Patients who take nephrotoxic drugs also are at risk (Davenport et al., 2014). Chart 65-5 lists assessment questions to ask before a patient undergoes testing with contrast material.

### Chart 65-5

## Best Practice for Patient Safety & Quality Care QSEN

### Assessing the Patient About to Undergo a Kidney Test or Procedure Using Contrast Medium

Before the procedure:

- Ask the patient if he or she has ever had a reaction to contrast media. (Such a patient has the highest risk for having another reaction.)
- Ask the patient about a history of asthma. (Patients with asthma have been shown to be at greater risk for contrast reactions than the general public. When reactions do occur, they are more likely to be severe.)
- Ask the patient about known hay fever or food or drug allergies, especially to seafood, eggs, milk, or chocolate. (Contrast reactions have been reported to be as high as 15% in these patients.)
- Ask the patient to describe any specific allergic reactions (e.g., hives, facial edema, difficulty breathing, bronchospasm).
- Assess for a history of renal impairment and for conditions that have been implicated in increasing the chance of developing kidney injury or impairment after contrast media (e.g., diabetic nephropathy, class IV heart failure, dehydration, concomitant use of potentially nephrotoxic drugs such as the aminoglycosides or NSAIDs, and cirrhosis).
- Ask the patient if he or she is taking metformin (Glucophage). (Metformin must be discontinued at least 24 hours before any study using contrast media because the life-threatening complication of lactic acidosis, although rare, could occur.)
- Assess hydration status by checking blood pressure, heart and respiratory rates, mucous membranes, skin turgor, and urine concentration.
- Ask the patient when he or she last ate or drank anything.

In addition, patients taking metformin are at risk for lactic acidosis when they receive iodinated contrast media. Metformin should be discontinued at least 24 hours before the time of a procedure and for at least 48 hours after the procedure. Kidney function should be re-evaluated before the patient resumes metformin therapy.

## Nursing Safety Priority QSEN

### Drug Alert

Ensure that the patient who is prescribed metformin does not receive the drug after a procedure requiring IV contrast material until adequate kidney function has been determined.

All patients at risk for contrast-induced nephrotoxicity need regular assessment and collaboration with the primary health care provider to maintain hydration and decrease the risk for kidney injury following a CT scan with IV contrast administration. Sodium bicarbonate in a liter of IV fluid or oral acetylcysteine (an antioxidant) may be used before the procedure to prevent contrast-induced nephrotoxic effects in radiologic procedures; however, protection provided to the kidneys is not

consistent in clinical trials (Lameire & Kellum, 2013). Diuretics may be given immediately after the contrast is injected to enhance excretion in patients who are well hydrated.

### **Magnetic Resonance Imaging.**

MRI provides improved imaging between normal and abnormal tissue in the renal system compared with a CT scan. As with all MRIs, the patient with metal implants (pins, pacemaker, joint replacement, aneurysmal clips, or other cosmetic or medical devices) is not eligible for this test because the magnet can move the metal implant. Gadolinium-based contrast agents have been linked with nephrogenic systemic fibrosis (Pagana et al., 2017) and should not be used in patients with renal impairment, usually defined as a serum creatinine above 1.5 mg/dL (110  $\mu\text{mol/L}$ ) or an estimated GFR less than 45 mL/minute. Adults older than 60 years should be carefully evaluated for renal impairment (see the [Kidney and Urinary System Changes Associated with Aging](#) section).

### **Kidney Ultrasonography.**

Inform the patient that ultrasonography does not cause discomfort and is without risk. This test usually requires a full bladder. Ask the patient to drink 500 to 1000 mL of water, if needed, about 2 to 3 hours before the test to help fill the bladder. The patient should not void after drinking the water until the test is complete. This test applies sound waves to structures of different densities to produce images of the kidneys, ureters, and bladder and surrounding tissues. Ultrasonography allows assessment of kidney size, cortical thickness, and status of the calices. The test can identify obstruction in the urinary tract, tumors, cysts, and other masses without the use of contrast. In addition, it can determine blood flow into and out from the kidney using Doppler color flow imaging.

The patient undergoing kidney ultrasound is usually placed in the prone position. Sonographic gel is applied to the skin over the back and flank areas to enhance sound wave conduction. A transducer in contact with and moving across the skin delivers sound waves and measures the echoes. Images of the internal structures are produced. Skin care to remove the gel is all that is needed after ultrasonography.

### **Renal Scan.**

This imaging test is used to examine the perfusion, function, and structure of the kidneys by the IV administration of a radioisotope. It does not use an iodinated contrast agent and thus may be used in preference to a CT scan when the patient is allergic to iodine or has impaired kidney function that places him or her at risk for kidney injury from IV contrast.

No fasting or sedation is used. A peripheral IV catheter is inserted to give the radioisotope contrast agent. While the patient lies in a prone or sitting position, a camera is passed over the kidney area and records the isotope uptake on film, minutes after the radioisotope is given. After initial images, the patient may be given furosemide or captopril to better visualize kidney function and blood flow. The isotope is eliminated 6 to 24 hours after the procedure. Encourage the patient to drink fluids to aid in excretion of the isotope. Because only tracer doses of radioisotopes are used, no precautions are needed related to radioactive exposure.

### **Renal Arteriography (Angiography).**

Renal arteriography allows the radiopaque contrast medium to enter the renal blood vessels and generates images to determine blood vessel size and abnormalities. This test has largely been replaced by other imaging techniques (e.g., nuclear renal scans, ultrasonography, computed tomography) and is seldom used as a stand-alone diagnostic procedure. The most common use of renal arteriography is at the time of a renal angioplasty or other intervention.

### **Cystoscopy and Cystourethroscopy**

#### **Patient Preparation.**

Cystoscopy and cystourethroscopy are endoscopic procedures and require completion of a preoperative checklist and a signed informed consent statement. The urologist provides a complete description of and reasons for the procedure, and the nurse reinforces this information. Cystoscopy may be performed for diagnosis or treatment. This test is used to examine for bladder trauma

(cystoscopy) or urethral trauma (cystourethroscopy) and to identify causes of urinary tract obstruction. Cystoscopy also may be used to remove bladder tumors or plant radium seeds into a tumor, dilate the urethra and ureters with or without stent placement, stop areas of bleeding, or resect an enlarged prostate gland.

Cystoscopy may be performed under general anesthesia or under local anesthesia with sedation. The patient's age and general health and the expected duration of the procedure are considered in the decision about anesthesia. A light evening meal may be eaten. Usually the patient is NPO after midnight on the night before the cystoscopy. A bowel preparation with laxatives or enemas is performed the evening before the procedure so bowel contents do not interfere with the procedure.

#### **Procedure.**

The cystoscopy is performed in a designated cystoscopic examination room. If the procedure is performed in a surgical suite under general anesthesia, the usual surgical support personnel are present (see [Chapter 15](#)). This procedure is often performed in clinics, ambulatory surgery or short-procedure units, or a urologist's office.

Assist the patient onto a table and, after sedation, place him or her in the lithotomy position. After the anesthesia is given and the area cleansed and draped, the urologist inserts a cystoscope through the urethra into the urinary bladder. This examination commonly includes the use of both the cystoscope and the urethroscope.

#### **Follow-up Care.**

After this procedure with general anesthesia, the patient is returned to a postanesthesia care unit (PACU) or area. If local anesthesia and sedation were used, he or she may be returned directly to the hospital room. Patients undergoing cystoscopic examinations as outpatients are transferred to an area for monitoring before discharge to home. Monitor for airway patency and breathing, changes in vital signs (including temperature), and changes in urine output. Also observe for the complications of bladder puncture, excessive bleeding, and infection. Bladder puncture is accompanied by severe pain, including abdominal pain, nausea, and vomiting.

A catheter may or may not be present after cystoscopy. The patient without a catheter has urinary frequency as a result of irritation from the procedure. The urine may be pink tinged, but gross bleeding is not expected. Bleeding or the presence of clots may obstruct the catheter and decrease urine output. Monitor urine output and notify the urologist of obvious blood clots or a decreased or absent urine output. Irrigate the Foley catheter with sterile saline, if prescribed. Notify the urologist if the patient has a fever (with or without chills) or an elevated white blood cell (WBC) count, which suggests infection. Urge the patient to take oral fluids to increase urine output (which helps prevent clotting) and reduce the burning sensation on urination.

#### **Cystography and Cystourethrography.**

These tests are a series of x-rays or a continuous radiographic visualization by fluoroscopy. During the imaging, radiopaque contrast medium fills the bladder, and the bladder is emptied. Images show structure and function of the bladder and urethra. Tumors, rupture or perforation of the bladder and urethra, abnormal backflow of urine, and distortion from trauma or other pelvic masses can be seen.

#### **Patient Preparation and Procedure.**

Explain the procedure to the patient. A urinary catheter is temporarily needed to instill contrast medium directly into the bladder for both procedures. The contrast medium enhances x-ray visibility of the lower urinary tract and is not absorbed into the bloodstream, reducing the risk for contrast-induced kidney injury.

After bladder filling, x-rays are taken from the front, back, and side positions. For the voiding cystourethrogram (VCUG), the patient is requested to void, and x-rays are taken during the voiding. A VCUG can determine whether urine refluxes (flow backward) into the ureter. The cystogram is used in cases of trauma when urethral or bladder injury is suspected or for patients with recurrent *pyelonephritis* (kidney infection).

#### **Follow-up Care.**

Monitor for infection as a result of catheter placement. In this test, the contrast medium is not

nephrotoxic because it does not enter the bloodstream and does not reach the kidney. Encourage fluid intake to dilute the urine and reduce the burning sensation from catheter irritation after removal. Monitor for changes in urine output because pelvic or urethral trauma may be present.

### Retrograde Procedures.

**Retrograde** means going against the normal flow of urine. A retrograde examination of the ureters and pelvis (*pyelogram*), the bladder (*cystogram*), and the urethra (*urethrograph*) involves instilling radiopaque contrast medium into the lower urinary tract. Because the contrast agent is instilled directly to obtain an outline of the structures desired, the agent does not enter the bloodstream. Therefore the patient is not at risk for contrast-induced kidney injury.

The patient is prepared for retrograde procedures (retrograde pyelography, retrograde cystography, and retrograde urethrography) in the same way as for cystoscopy. Retrograde x-rays are obtained during the cystoscopy. After placement of the cystoscope by the urologist, catheters are placed into each ureter, and contrast is instilled into each ureter and renal pelvis. The catheters are removed by the urologist, and x-rays are taken to outline these structures as the agent is excreted. The procedure identifies obstruction or structural abnormalities.

For patients undergoing retrograde cystoscopy or urethrography, radiopaque contrast medium is instilled similarly into the bladder or urethra. Cystography and urethrography identify structural problems, such as fistulas, diverticula, and tumors.

After retrograde procedures, monitor the patient for infection caused by placing instruments in the urinary tract. Because these procedures are performed during cystoscopic examination, follow-up care is the same as that for cystoscopy, including monitoring for bladder puncture or perforation.

### Other Diagnostic Assessments

#### Urodynamic Studies.

Urodynamic studies examine the processes of voiding and include:

- Tests of bladder capacity, pressure, and tone
- Studies of urethral pressure and urine flow
- Tests of perineal voluntary muscle function

These tests are often used along with voiding urographic or cystoscopic procedures to evaluate problems with urine flow and disorders of the lower urinary tract.

*Cystometrography (CMG)* can determine how well the bladder wall (detrusor) muscle functions and how sensitive it is to stretching as the bladder fills. This test provides information about bladder capacity, bladder pressure, and voiding reflexes.

Explain the procedure and inform the patient that a urinary catheter will be needed temporarily during the procedure. Ask the patient to void normally. Record the amount and time of voiding. Insert a urinary catheter to measure the residual urine volume. The cystometer is attached to the catheter, and fluid is instilled via the catheter into the bladder. The point at which the patient first notes a feeling of the urge to void and the point at which he or she notes a strong urge to void are recorded. Bladder capacity and bladder pressure readings are recorded graphically. The patient is asked to void when the bladder instillation is complete (about 500 mL). The residual urine after voiding is recorded, and the catheter is removed. Electromyography of the perineal muscles may be performed during this examination.

For any procedure that involves inserting instruments into the urinary tract, monitor for infection. Record the patient's temperature, the character of the urine, and urine output volume.

*Urethral pressure profile* (also called a *urethral pressure profilometry [UPP]*) can provide information about the nature of urinary incontinence or urinary retention.

Explain the procedure and inform the patient that a urinary catheter will be needed temporarily during the procedure. A special catheter with pressure-sensing capabilities is inserted into the bladder. Variations in the pressure of the smooth muscle of the urethra are recorded as the catheter is slowly withdrawn.

As with any study involving inserting instruments into the urinary tract, monitor the patient for symptoms of infection.

*Urine stream testing* is used to evaluate pelvic muscle strength and the effectiveness of pelvic

muscles in stopping the flow of urine. It is useful in assessing urinary incontinence.

Explain the procedure and reassure the patient that efforts will be made to ensure privacy. The patient is asked to begin urinating. Three to five seconds after urination begins, the examiner gives the patient a signal to stop urine flow. The length of time required to stop the flow of urine is recorded.

Cleaning the perineal area, as after any voiding, is all that is necessary after the urine stream test.

*Electromyography (EMG)* of the perineal muscles tests the strength of the muscles used in voiding. This information may help identify methods of improving continence. Inform the patient that some mild, temporary discomfort may accompany placement of the electrodes.

In EMG of the perineal muscles, electrodes are placed in either the rectum or the urethra to measure muscle contraction and relaxation. After the completion of EMG, administer analgesics as prescribed to promote the patient's comfort.

## NCLEX Examination Challenge 65-3

### Safe and Effective Care Environment

The nurse is admitting a client who has type 2 diabetes (T2D) and is scheduled for surgery. Which laboratory findings from this client's admission panel does the nurse report as indicating possible abnormal kidney function? **Select all that apply.**

- A. Presence of ammonia in the urine
- B. Urine microalbumin 240 mcg/24 hour (0.240 g/ 24 hour)
- C. Urine specific gravity of 1.028
- D. Blood urea nitrogen of 38 mg/dL (13.5 mmol/L)
- E. Serum creatinine 2.2 mg/dL (294.3 mcmol/L)
- F. Blood osmolarity 290 mOsm/kg (290 mmol/kg)

### Kidney Biopsy

#### Patient Preparation.

Explain that a kidney biopsy can help determine a cause of unexplained kidney problems and help direct or change therapy. Most kidney biopsies are performed **percutaneously** (through skin and other tissues) using ultrasound or CT guidance. The patient signs an informed consent. Patients are NPO for 4 to 6 hours before the procedure.

Because of the risk for bleeding after the biopsy, coagulation studies such as platelet count, activated partial thromboplastin time (aPTT), prothrombin time (PT), and bleeding time are performed before surgery. Hypertension is aggressively managed before and after the procedure because high blood pressure can make stopping the bleeding after the biopsy more difficult. Uremia also increases the risk for bleeding, and dialysis may be prescribed before a biopsy. A blood transfusion may be needed to correct anemia before biopsy.

#### Procedure.

In a percutaneous biopsy, the nephrologist or radiologist obtains tissue samples without an incision. Patients receive sedation and are monitored throughout the procedure. The patient is placed in the prone position on the procedure table. The entry site is selected after taking preliminary images. The area is prepped and sterilely draped. A local anesthetic is injected, and the physician then inserts the biopsy device into the tissues toward the kidney. Needle depth and placement are confirmed by ultrasound or CT. While the patient holds his or her breath, the needle is advanced into the renal cortex. Samples are then taken with a spring-loaded coring biopsy needle and sent for pathologic study.

#### Follow-up Care.

After a percutaneous biopsy, the major risk is bleeding into the kidney or into the tissues external from the kidney at the biopsy site. For 24 hours after the biopsy, monitor the dressing site, vital signs (especially fluctuations in blood pressure), urine output, hemoglobin level, and hematocrit. Even if the dressing is dry and there is no hematoma, the patient could be bleeding from the site. An internal bleed is not readily visible but is suspected with flank pain, decreasing blood pressure, decreasing urine output, or other signs of hypovolemia or shock. With severe bleeding, some patients develop bruising along the flank and back accompanied by pain.

The patient follows a plan of strict bedrest, lying in a supine position with a back roll for additional support for 2 to 6 hours after the biopsy. The head of the bed may be elevated, and the patient may resume oral intake of food and fluids. After bedrest, the patient may have limited bathroom privileges if there is no evidence of bleeding.

Monitor for hematuria, the most common complication of kidney biopsy. Hematuria occurs microscopically in most patients, but 5% to 9% have gross hematuria. This problem usually resolves without treatment 48 to 72 hours after the biopsy but can persist for 2 to 3 weeks. In rare cases, transfusions and surgery are required. There should be no obvious blood clots in the urine.

The patient may have some local pain after the biopsy. If aching originates at the biopsy site and begins to radiate to the flank, back, and around the front of the abdomen, bleeding may have started, or a hematoma is forming around the kidney. This pattern of pain with bleeding occurs because blood in the tissues around the kidney increases pressure on local nerve tracts.

If bleeding occurs, IV fluid, packed red blood cells, or both may be needed to prevent shock. In general, a small amount of bleeding creates enough pressure to compress bleeding sites. This is called a *tamponade effect*. If tamponade does not occur and bleeding is extensive, surgery for hemostasis or even nephrectomy may be needed. A hematoma in, on, or around the kidney may become infected, requiring treatment with antibiotics and surgical drainage.

If no bleeding occurs, the patient can resume general activities after 24 hours. Instruct him or her to avoid lifting heavy objects, exercising, or performing other strenuous activities for 1 to 2 weeks after the biopsy procedure. Driving may also be restricted. Refer to [Chapter 16](#) for general postoperative care for the patient who has undergone an open kidney biopsy.

## NCLEX Examination Challenge 65-4

### Safe and Effective Care Environment

Which symptom(s) in a client during the first 12 hours after a kidney biopsy indicate(s) to the nurse a possible complication from the procedure?

- A. The client experiences nausea and vomiting after drinking juice.
- B. The biopsy site is tender to light palpation.
- C. The abdomen is distended, and the client reports abdominal discomfort.
- D. The heart rate is 118, blood pressure is 108/50, and peripheral pulses are thready.

## Clinical Judgment Challenge 65-1

### Safety; Patient-Centered Care QSEN

You are assessing a 66-year-old patient who is scheduled for surgical repair of a hip fracture from a car crash 4 hours ago. The patient hit a telephone pole while traveling at 45-50 miles per hour and was wearing a seat belt at the time of the accident. When the patient voids, you notice that the urine is rust-colored. The patient reports a sensation of burning during this voiding but no other subjective urinary symptoms.

1. What assessment information will you document?
2. What additional information should you get from the patient and what else should you consider?

3. Organize your thoughts into a SBAR communication (see Chapter 1).

4. Which member(s) of the interprofessional team will you notify and why?

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Use Contact Precautions with any patient who has drainage from the genitourinary tract. **QSEN: Safety**
- Wear gloves when testing or handling urine. **QSEN: Safety**
- Evaluate risk for injury from diagnostic testing by asking about adverse or allergic reactions to radiopaque contrast agents, iodine, or gadolinium. **QSEN: Safety**
- Ask the patient about the use of prescribed and over-the-counter drugs that increase risk for kidney dysfunction. **QSEN: Safety**
- Verify that informed consent has been obtained and that the patient has a clear understanding of the potential risks before he or she undergoes invasive procedures to assess the kidneys and urinary function. **QSEN: Safety**
- Assess the patient for bleeding, increased pain, and symptoms of perforation or infection after any invasive test of kidney/urinary function. **QSEN: Safety**
- Inform primary health care providers about any symptoms of complications following invasive or noninvasive tests of urinary and kidney structure or function. **QSEN: Safety**

### Health Promotion and Maintenance

- Teach patients to clean the perineal area after voiding, after having a bowel movement, and after sexual intercourse. **QSEN: Evidence-Based Practice**
- Urge all patients to maintain an adequate fluid intake (sufficient to dilute urine to a light yellow color). A minimum of 2 L/day may be recommended unless another health problem requires fluid restriction. **QSEN: Evidence-Based Practice**
- Teach patients who come into contact with chemicals in their workplaces or for leisure-time activities to avoid direct skin or mucous membrane contact with these chemicals. **QSEN: Safety**

### Psychosocial Integrity

- Allow the patient the opportunity to express fear or anxiety about tests of the kidneys and urinary tract or about a potential change in kidney function. **QSEN: Patient-Centered Care**
- Assess the patient's level of comfort in discussing issues related to ELIMINATION and the urogenital area. **QSEN: Patient-Centered Care**
- Provide as much privacy as possible for patients undergoing examination or testing of the kidney/urinary tract. **QSEN: Patient-Centered Care**
- Use language and terminology that the patient can understand during discussions of kidney/urinary assessment. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Use sterile technique when inserting a urinary catheter. **QSEN: Evidence-Based Practice**
- Ask the patient about kidney problems in any other members of the family, because some problems have a genetic component. **QSEN: Patient-Centered Care**
- Ask the patient about current and past drug use (prescribed, over-the-counter, and illicit) and evaluate drug use for potential nephrotoxicity. **QSEN: Patient-Centered Care**
- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for tests. **QSEN: Patient-Centered Care**

- Interpret laboratory data to distinguish between dehydration and kidney impairment. **QSEN: Evidence-Based Practice**
- Describe how to obtain a sterile urine specimen from a urinary catheter. **QSEN: Evidence-Based Practice**
- Describe which information regarding the urinary and renal system assessment should be documented in the patient's electronic health record. **QSEN: Patient-Centered Care**
- Assess urine output (compared with fluid intake) and serum tests of kidney function closely after any procedure in which IV radiopaque contrast agents are used. **QSEN: Evidence-Based Practice**

## CHAPTER 66

# Care of Patients With Urinary Problems

Chris Winkelman

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is ELIMINATION.**

✚ The ELIMINATION concept exemplar for this chapter is Urinary Incontinence, below.

**The interrelated concepts for this chapter are:**

- COMFORT
- IMMUNITY
- TISSUE INTEGRITY

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to coordinate high-quality care and promote urinary ELIMINATION in patients who have problems in the urinary tract.
2. Teach the patient and caregiver(s) how home safety is affected by impaired ELIMINATION resulting from problems in the urinary tract.

### Health Promotion and Maintenance

3. Identify community resources for patients requiring assistance with incontinence or any chronic urinary tract problem.
4. Teach adults how to decrease the risk for urinary tract infections.

### Psychosocial Integrity

5. Implement nursing interventions to help patients and families cope with the psychosocial impact caused by urinary incontinence or any other chronic problem of the urinary tract.

### Physiological Integrity

6. Apply knowledge of anatomy and physiology to assess patients with urinary problems affecting ELIMINATION.
7. Teach the patient and caregiver(s) about common drugs used for urinary tract problems, including pain control.

The urinary tract includes the ureters, bladder, and urethra. Although these structures play no role in the making of urine, their functions are essential for the urine made by the kidneys to be eliminated from the body. Both infectious and noninfectious problems in the urinary tract can disrupt urinary ELIMINATION and affect control of fluids, electrolytes, nitrogenous wastes, and blood pressure.

Any urinary problem can affect the storage or ELIMINATION of urine. Both acute and chronic urinary problems are common and costly. More than 20 million people in the United States are treated annually for urinary tract infections, cystitis, kidney and ureter stones, or urinary incontinence ([U.S. Renal Data Systems, 2015](#)). Although life-threatening complications are rare with urinary problems, patients may have functional, physical, and psychosocial changes that reduce quality of life. Nursing interventions are directed toward prevention, detection, and management of urologic disorders.

# Elimination Concept Exemplar Urinary Incontinence

## Pathophysiology

**Continence** is the control over the time and place of urine ELIMINATION and is unique to humans and some domestic animals. It is a learned behavior in which a person can suppress the urge to urinate until a socially appropriate location is available (e.g., a toilet). Efficient bladder emptying (i.e., coordination between bladder contraction and urethral relaxation) is needed for continence.

**Incontinence** is an involuntary loss of urine severe enough to cause social or hygienic problems. It is *not* a normal consequence of aging or childbirth and often is a stigmatizing and an underreported health problem. Many adults suffer in silence, are socially isolated, and may be unaware that treatment is available. In addition, the cost of incontinence can be enormous.

Continence occurs when pressure in the urethra is greater than pressure in the bladder. For normal voiding to occur, the urethra must relax, and the bladder must contract with enough pressure and duration to empty completely. Voiding should occur in a smooth and coordinated manner under conscious control. Incontinence has several possible causes and can be either temporary or chronic (Table 66-1). Except for infection, temporary causes of incontinence usually do not involve a disorder of the urinary tract. The most common types of adult urinary incontinence are stress incontinence, urge incontinence, overflow incontinence, functional incontinence, and a mixed form.

**TABLE 66-1**  
**Types of Urinary Incontinence**

TYPE	DEFINITION/DESCRIPTION	CAUSE	SYMPTOMS
Stress incontinence	The involuntary loss of urine during activities that increase abdominal and detrusor pressure. Patients cannot tighten the urethra sufficiently to overcome the increased detrusor pressure; leakage of urine results.	Weakening of bladder neck supports; associated with childbirth. Intrinsic sphincter deficiency caused by such congenital conditions as epispadias (abnormal location of the urethra on the dorsum of the penis) or myelomeningocele. Acquired anatomic damage to the urethral sphincter (from repeated incontinence surgeries, prostatectomy, radiation therapy, and trauma). Vaginal prolapse from vaginal birth or aging.	Urine loss with physical exertion, cough, sneeze, or exercise. Usually only small amounts of urine are lost with each exertion. Normal voiding habits (<8 times per day, <2 times per night). Post-void residual usually <50 mL. Pelvic examination shows hypermobility of the urethra or bladder neck with Valsalva maneuvers.
Urge incontinence	The involuntary loss of urine associated with a strong desire to urinate. Patients cannot suppress the signal from the bladder muscle to the brain that it is time to urinate.	Idiopathic. Brain and nerve disorders. Bladder inflammation or infection. Bladder cancer.	An abrupt and strong urge to void. May have loss of large amounts of urine with each occurrence.
Detrusor hyperreflexia (reflex incontinence)	The abnormal detrusor contractions result from neurologic abnormalities.	Central nervous system (CNS) lesions from stroke, multiple sclerosis, and parasacral spinal cord lesions. Local irritating factors such as caffeine, drugs, or bladder tumor.	Post-void residual <50 mL.
Overflow incontinence	The involuntary loss of urine associated with overdistention of the bladder when the bladder's capacity has reached its maximum. The urethra is obstructed, so it fails to relax sufficiently to allow urine to flow, resulting in incomplete bladder emptying or complete urinary retention, causing overflow incontinence.	Diabetic neuropathy; side effects of drugs; after radical pelvic surgery or spinal cord damage; outlet obstruction. Causes external to the mechanism of the urethra: an enlarged prostate (male patients) and large genital prolapse (female patients). When the cause is intrinsic to the urethra, abnormal contraction of the skeletal muscle occurs, causing obstruction. This condition, called <i>detrusor dyssynergia</i> , is seen in patients with spinal cord injuries and multiple sclerosis.	Bladder distention, often up to the level of the umbilicus. Constant dribbling of urine.
Mixed incontinence	A combination of stress, urge, and overflow incontinence.	As with each separate disorder.	As with each separate disorder.
Functional incontinence	Leakage of urine caused by factors other than disease of the lower urinary tract.	Decreased cognition such as with dementia, some central nervous system disorders; inability to walk to the toilet.	Quantity and timing of urine leakage vary; patterns are difficult to discern.
Transient causes	Transient causes improve with treatment of the underlying condition.	Reversible loss of cognitive functioning. Loss of awareness that urination is to occur in a socially acceptable place.	Altered mental state, as in sedation, delirium, confusion, depression, sepsis, mental illness, or severe psychological stress.
		Abnormal openings in the urinary tract, such as a fistula or diverticulum.	Urinary drainage noted from areas other than the urinary meatus.
		Drugs such as sedatives, hypnotics, diuretics, anticholinergics, decongestants, antihypertensives, and calcium channel blockers.	Some drugs cause altered mental state; others cause increased urine production.
		Diabetes insipidus or psychogenic polydipsia.	Increased urine output.
		Inability to get to toileting facilities.	Restraints, restricted mobility.
Permanent causes	Permanent causes are organic but may be improved with treatment.	Direct bladder pressure or urethral obstruction.	Constipation or fecal impaction.
		Cognitive impairment. Traumatic or surgical effects. Factors contributing to stress incontinence, urge incontinence, and overflow incontinence. Structural or functional defects of the bladder or the sphincters. Injuries or diseases of the spinal cord, brainstem, or cerebral cortex (neurogenic bladder). Congenital defects, including exstrophy of the bladder (bladder turned "inside out") and spina bifida.	Symptoms depend on the cause.

*Stress incontinence* is the most common type. Its main feature is the inability to retain urine when laughing, coughing, sneezing, jogging, or lifting. In the continent adult, the urethra can be relaxed and tightened under conscious control because skeletal muscles of the pelvic floor surround it. When an adult feels the urge to urinate, the conscious contraction of the urethra can override a

bladder contraction if the urethral contraction is strong enough.

Patients with *stress incontinence* cannot tighten the urethra enough to overcome the increased bladder pressure caused by contraction of the detrusor muscle. This is common after childbirth, when the pelvic muscles are stretched and weakened. The weakened pelvic floor allows the urethra to move during exertion. If the pelvic muscles are not strengthened, this condition continues. Low estrogen levels after menopause also contribute to stress incontinence. Vaginal, urethral, and pelvic floor muscles become thin and weak without estrogen.

*Urge incontinence* is the loss of urine for no apparent reason after suddenly feeling the need or urge to urinate. Normally when the bladder is full, contraction of the smooth muscle fibers of the bladder detrusor muscle signals the brain that it is time to urinate. Continent adults override that signal and relax the detrusor muscle for the time it takes to locate a toilet. Those who suffer from urge incontinence cannot suppress the signal and have a sudden strong urge to void and can leak large amounts of urine at this time. Urge incontinence is also known as an *overactive bladder (OAB)*. Overactivity may have no known cause or may be the result of abnormal detrusor contractions related to other problems. Such problems include stroke and other neurologic problems; other urinary tract problems; and irritation from concentrated urine, artificial sweeteners, caffeine, alcohol, and citric intake. Drugs, such as diuretics, and nicotine can also irritate the bladder. Often urine loss is related to both stress and urge incontinence, and symptoms mimic more than one subtype. This category is more common in older women.

*Overflow incontinence* occurs when the detrusor muscle fails to contract and the bladder becomes overdistended. This type of incontinence (*reflex incontinence* or *underactive bladder*) occurs when the bladder has reached its maximum capacity and some urine must leak out to prevent bladder rupture. Causes may include an underactive bladder muscle or a urethral obstruction. Causes for the underactive (acontractile) bladder may or may not be determined. A partially obstructed urethra can fail to relax enough to allow urine flow. Incomplete bladder emptying or urinary retention from urethral obstruction results in overflow incontinence.

*Functional incontinence* is incontinence occurring as a result of factors other than the abnormal function of the bladder and urethra. A common factor is the loss of cognitive function in patients affected by dementia. To maintain continence, an adult must be aware that urination occurs in a socially acceptable place. Patients with dementia may not have that awareness.

## Etiology

Incontinence may have temporary or permanent causes. Evaluation of the incontinent patient means considering all possible causes, beginning with those that are temporary and correctable. Surgical and traumatic causes of urinary incontinence are related to procedures or surgery in the lower pelvic structures, which are areas that contain complex nerve pathways. Radical urologic, prostatic, and gynecologic procedures for treatment of pelvic cancers may result in urinary incontinence. Injury to segments S2 to S4 of the spinal cord may cause incontinence from impairment of normal nerve pathways.

Inappropriate bladder contraction may result from disorders of the brain and nervous system or from bladder irritation due to chronic infection, stones, chemotherapy, or radiation therapy. Other causes of bladder contraction failure include the neuropathies associated with diabetes mellitus, syphilis, and previous treatment with neurotoxic anticancer drugs. Constipation can lead to temporary urinary incontinence. Some drugs or drug-drug interactions from polypharmacy, such as anticholinergics, calcium channel blockers, diuretics, and sedatives, can cause or worsen urinary incontinence.

## Considerations for Older Adults

### Patient-Centered Care QSEN

Many factors contribute to urinary incontinence in older adults (Chart 66-1). An older adult may have decreased mobility from many causes. In inpatient settings, mobility is limited when the older patient is placed on bedrest. Vision and hearing impairments may also prevent the patient from locating a call light to notify the nurse or assistive personnel of the need to void. Assess for these factors and minimize them to prevent urinary incontinence. Getting out of bed to urinate is a common cause of falls among older adults in the home and other settings (Touhy & Jett, 2016).

## Chart 66-1

# Nursing Focus on the Older Adult

## Factors Contributing to Urinary Incontinence\*

### Drugs

- Central nervous system depressants, such as opioid analgesics, decrease the patient's level of consciousness and the urge to void and contribute to constipation.
- Diuretics cause frequent voiding, often of large amounts of urine.
- Multiple drugs can contribute to changes in mental status or mobility, and they can irritate the bladder.
- Anticholinergic drugs or drugs with anticholinergic side effects are especially challenging because they affect both cognition and the ability to void. Monitor patient responses to these drugs early in treatment.

### Disease

- Stroke, Parkinson disease, dementia, and other neurologic disorders decrease mobility, sensation, or cognition.
- Arthritis decreases mobility and causes pain.

### Depression

- Depression decreases the energy necessary to maintain continence.
- Decreased self-esteem and feelings of self-worth decrease the importance to the patient of maintaining continence.

### Inadequate Resources

- Patients who need assistive devices (e.g., eyeglasses, cane, walker) may be afraid to ambulate without them or without personal assistance.
- Products that help patients manage incontinence of urine ELIMINATION are often costly.
- No one may be available to assist the patient to the bathroom or help with incontinence products.

\*These factors are in addition to the physiologic changes of aging given in Chapter 3.

## Incidence and Prevalence

Incontinence is a major health problem. As many as 45% of woman over 65 years report some degree of urinary incontinence, with roughly half as many men reporting this condition (Gorina et al., 2014). As many as 75% of residents in long-term care facilities have urinary incontinence (Gorina et al., 2014).

Risk for urinary incontinence increases with chronic conditions such as diabetes mellitus, stroke, cognitive impairment, and impaired mobility. Urinary incontinence occurs not only with older age but with a history of vaginal delivery, particularly if the first child was delivered after age 30. Conditions of pelvic prolapse in women, prostate problems in men, diabetes, heart failure, spinal cord or nerve injury, and obesity also increase the risk for urinary incontinence (Cerruto et al., 2015; McCance et al., 2014). Both central nervous system diseases (i.e., dementia, multiple sclerosis, Parkinson disease) and musculoskeletal disorders (i.e., osteoporosis, osteoarthritis, paresthesia, pain or paralysis) contribute to cognitive and mobility impairment, resulting in the onset and severity of

urinary incontinence (McCance et al., 2014). Many adults admitted to the hospital develop urinary incontinence. Because the problem is common among older adults, all adults older than 65 years are recommended to be screened for incontinence (Touhy & Jett, 2016).

## ❖ Interprofessional Collaborative Care

Incontinence can occur in any setting and is very common in the community. Usually the adult with incontinence is treated using self-management strategies. Even when surgical intervention is used, hospitalization for incontinence is rare. Because urinary incontinence carries a burden of impaired COMFORT, activity disruption, shame or embarrassment, and loss of TISSUE INTEGRITY, it has a great impact on quality of life for most adults.

### Assessment: Noticing

#### History.

Incontinence may be underreported because health care professionals do not ask patients about urine loss. *Do not assume that patients will volunteer the information without specifically being asked* (Testa, 2015). Effective screening includes asking patients to respond “always,” “sometimes,” or “never” to these questions:

- Do you ever leak urine or water when you don't want to?
- Do you ever leak urine or water when you cough, sneeze, laugh, or exercise?
- Do you ever leak urine or water on the way to the bathroom?
- Do you ever use pads, tissue, or cloth in your underwear to catch urine?

If any answer is “always” or “sometimes,” perform a focused assessment (Chart 66-2).

### Chart 66-2

## Focused Assessment

### The Patient With Urinary Incontinence

Note the presence of risk factors for urinary incontinence:

- Age
- If female, menopausal status
- Central or peripheral neurologic disease with associated impairment in cognition or mobility
- Diabetes mellitus
- History of vaginal delivery; vaginal prolapse
- Urologic procedures
- Prescribed and over-the-counter drugs that affect cognition or mobility
- Bowel patterns; fecal impaction

- Stress/anxiety level

Detail the symptoms of urinary incontinence:

- Leakage
- Frequency
- Urgency
- Nocturia
- Sensation of full bladder before leakage

Obtain a 24-hour intake-and-output record or a voiding diary:

- Time and amount of oral intake and continent voiding
- Time and estimated amount of incontinent leakages
- Activity around the time of leakage

Assess the patient's:

- Mobility
- Self-care ability
- Cognitive ability
- Communication patterns

Assess the environment for barriers to toileting:

- Privacy
- Restrictive clothing
- Access to toilet

### **Physical Assessment/Signs and Symptoms.**

Assess the abdomen to estimate bladder fullness, rule out palpable hard stool, and evaluate bowel sounds. Urinary incontinence is confirmed by evaluating the force and character of the urine stream during voiding. Ask the patient to cough while wearing a perineal pad to assess for stress incontinence; a wet pad on forceful coughing indicates stress incontinence.

For women, inspect the external genitalia to determine whether there is apparent urethral or uterine prolapse, **cystocele** (herniation of the bladder into the vagina), or rectocele. These conditions

occur with pelvic floor muscle weakness. A primary health care provider puts on an examination glove and inserts two fingers into the vagina to assess the strength of these muscles. Strength is described as *weak*, *adequate*, or *strong* based on the amount of pressure felt by the primary health care provider as the patient tightens her vaginal muscles. Describe and document the color, consistency, and odor of any secretions from the genitourinary orifices. The urine stream interruption test (i.e., asking a patient to voluntarily start and stop urine flow during a void at least twice) is another method of determining pelvic muscle strength. For men, inspect the urethral meatus for any discharge.

A digital rectal examination (DRE) is performed by the primary health care provider on both male and female patients. It provides information about the nerve integrity to the bladder. The examiner determines whether there is tactile sensation in the anal area by observing whether the rectal sphincter is relaxed or contracted on digital insertion. Because nerve supply to the bladder is similar to nerve supply to the rectum, the presence of tactile sensation and a rectal sphincter that contracts suggest that the nerve supply to the bladder is intact. Impaction of stool is a cause of transient urinary incontinence and can be detected during a rectal examination. The primary health care provider assesses for prostate enlargement in men as a possible cause of incontinence.

### **Laboratory Assessment.**

A urinalysis is useful to rule out urinary tract infection. This test is the first step in the assessment of incontinent patients of any age. The presence of red blood cells (RBCs), white blood cells (WBCs), leukocyte esterase, or nitrites is an indication for culturing the urine. Any infection is treated before further assessment of incontinence.

### **Imaging Assessment.**

Determine the amount of post-void residual urine (urine remaining in the bladder right after voiding) by portable ultrasound (bladder scanner). If prescribed, catheterizing the patient immediately after voiding can also be used to assess residual volume. Additional imaging is needed when surgery is being considered. CT is most useful for locating abnormalities in kidneys and ureters. A voiding cystourethrogram (VCUG) or urodynamic testing may be performed to assess the size, shape, support, and function of the urinary tract system. Urodynamic testing (see [Chapter 65](#)) may take several hours and more than one visit. Electromyography (EMG) of the pelvic muscles may be a part of the urodynamic studies.

### **◆Analysis: Interpreting**

The priority collaborative problems for patients with urinary incontinence include:

1. Stress incontinence due to weak pelvic muscles and structural supports
2. Urge incontinence due to decreased bladder capacity, bladder spasms, diet, and neurologic impairment
3. Reflex incontinence due to neurologic impairment
4. Functional incontinence due to impaired cognition or neuromuscular limitations
5. Total urinary incontinence (mixed) due to many causes

### **◆Planning and Implementation: Responding**

Several interventions are useful for each type of incontinence in addition to drugs, surgical repair, and nutrition therapy.

### **Reducing Stress Incontinence**

#### **Planning: Expected Outcomes.**

With appropriate therapy, the patient with stress incontinence is expected to develop continence of urine ELIMINATION. Indicators include that the patient rarely or never demonstrates these actions:

- Urine leakage between voidings

- Urine leakage with increased abdominal pressure (e.g., sneezing, laughing, lifting)

### Interventions.

Initial interventions for patients with stress incontinence include keeping a diary and pelvic muscle exercises (Kegel exercises) (Qaseem et al., 2014). Surgery also may be an option if other interventions are not effective (Testa, 2015). Explain the purpose of a detailed diary in which the patient records times of urine leakage, activities, and food eaten. The diary is then used by the primary health care provider to plan and evaluate interventions. Collection devices, absorbent pads, and undergarments may be used during the often lengthy process of assessment and treatment and by patients who elect not to pursue further interventions.

### Nonsurgical Management.

Changes to diet and regularly performing pelvic muscle exercises require the patient's active participation for success. Nursing interventions focus on teaching patients about the drugs and behavioral strategies and on providing ongoing encouragement, clarification, and support to maximize intervention effects.

*Pelvic muscle (Kegel) exercise therapy* for women with stress incontinence strengthens the muscles of the pelvic floor (circumvaginal muscles). These muscles become strengthened, as any other skeletal muscle does, by frequent, systematic, and repeated contractions. Pelvic floor muscle training improves not only continence but also quality of life in women with urinary incontinence (Wilde et al., 2014).

The most important step in teaching pelvic muscle exercises is to help the patient learn which muscles to exercise. During the pelvic examination in women and the rectal examination in men or women, instruct the patient to tighten the pelvic muscles around your fingers. Then provide feedback about the strength of the contraction. Starting and stopping the urine stream or stopping the passage of flatus indicates that the patient has correctly identified the pelvic muscles. Biofeedback devices, such as electromyography or perineometers, measure the strength of contraction. A perineometer is a tampon-shaped instrument inserted into the vagina to measure the strength of pelvic muscle contractions. The graph shows the amplitude of muscle contraction to the patient for biofeedback. Alternatively, retention of a vaginal weight also shows that the patient has identified the proper muscle (see discussion on vaginal cone therapy that follows).

Instructions for pelvic muscle exercises are given in Chart 66-3. Although improvement may take several months, most patients notice a positive change after 6 weeks. Teach patients to continue the exercises 10 times daily to improve and maintain pelvic muscle strength.

### Chart 66-3

## Patient and Family Education: Preparing for Self-Management

### Pelvic Muscle Exercises

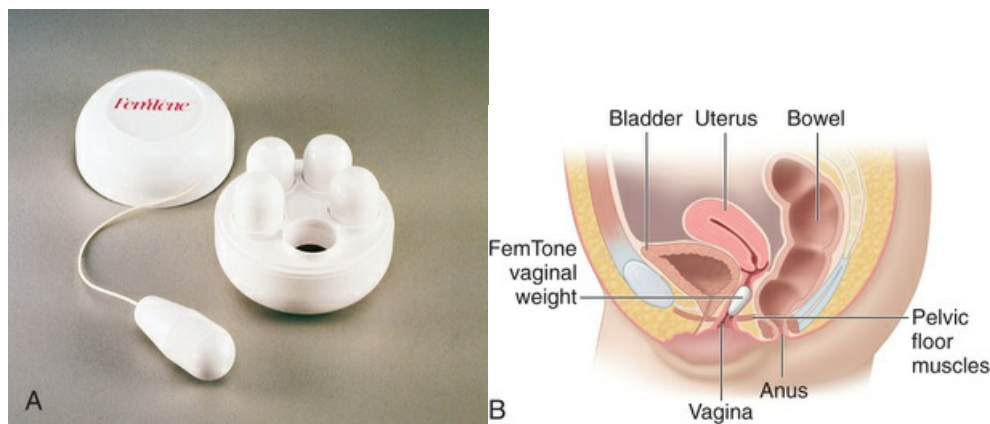

- The pelvic muscles are composed of a sling of muscles that support your bladder, urethra, and vagina. Like any other muscles in your body, you can make your pelvic muscles stronger by alternately contracting (tightening) and relaxing them in regular exercise periods. By strengthening these muscles, you will be able to stop your urine flow more effectively.
- To identify your pelvic muscles, sit on the toilet with your feet flat on the floor about 12 inches apart. Begin to urinate, and then try to stop the urine flow. Do not strain down, lift your bottom off the seat, or squeeze your legs together. When you start and stop your urine stream, you are using your pelvic muscles.
- To perform pelvic muscle exercises, tighten your pelvic muscles for a slow count of 10 and then relax for a slow count of 10. Do this exercise 15 times while you are lying down, sitting up, and standing (a total of 45 exercises). Repeat—and this time rapidly contract and relax the pelvic muscles 10 times. This should take no more than 10 to 12 minutes for all three positions, or 3 to 4 minutes for each set of 15 exercises.

- Begin with 45 exercises a day in three sets of 15 exercises each. You will notice faster improvement if you can do this twice a day, or a total of 20 minutes each day. Remember to exercise in all three positions so your muscles learn to squeeze effectively despite your position. At first, it is helpful to have a designated time and place to do these exercises because you will have to concentrate to do them correctly. After you have been doing them for several weeks, you will notice improvement in your control of urine. However, many people report that improvement may take as long as 3 months.

*Nutrition therapy* with weight reduction is helpful for obese patients because stress incontinence is made worse by increased abdominal pressure from obesity (Wilde et al., 2014). Teach the patient to avoid bladder irritants in the diet, such as caffeine, that can contribute to urgency and frequency. Stress the importance of maintaining an adequate fluid intake, especially water. Refer the patient to a registered dietitian as needed.

*Drug therapy* with topical estrogen to the perineal and vaginal orifice is used to treat postmenopausal women with stress incontinence. Estrogen may increase the blood flow and tone of the muscles around the vagina and urethra, thus improving the patient's ability to contract those muscles during times of increased intra-abdominal stress.

*Vaginal cone weight therapy* involves using a set of five small, cone-shaped weights (Touhy & Jett, 2016). They are of equal size but of varying weights and are used together with pelvic muscle exercise. The woman inserts the lightest cone, labeled 1, into her vagina (Fig. 66-1A), with the string to the outside, for a 1-minute test period. If she can hold the first cone in place without its slipping out while she walks around, she proceeds to the second cone, labeled 2, and repeats the procedure. The patient begins her treatment with the heaviest cone she can comfortably hold in her vagina for the 1-minute test period. Treatment periods are 15 minutes twice a day. When the patient can comfortably hold the cone in her vagina for 15-minutes, she progresses to the next heaviest weight. Treatment is completed with the cone labeled 5.

**FIG. 66-1** A, FemTone vaginal weights, or cones. The number on the top of each cone represents increasing weight up to the heaviest cone, a 5. B, Diagram showing the correct positioning of a vaginal weight, or cone, in place. (A Courtesy ConvaTec, A Bristol-Meyers Squibb Company, a Division of E.R. Squibb & Sons, Inc., Princeton, NJ.)

Weighted vaginal cones can help strengthen the pelvic muscles and decrease stress incontinence but may not help pelvic prolapse. Vaginal cones do not require a prescription.

*Other interventions* for stress incontinence include behavior modification, psychotherapy, and electrical stimulation devices to strengthen urethral contraction. Intravaginal and intrarectal electrical stimulation devices have been used with varying degrees of success.

A *pessary* (plastic device, often ring shaped, that helps hold internal organs in place) inserted into the vagina may help with a prolapsed uterus or bladder when this condition is contributing to urinary incontinence. A prolapse occurs when the supportive tissue in the vagina weakens and stretches, allowing pelvic organs to protrude into the vaginal lumen. The pessary presses against the wall of the vagina to reposition pelvic organs. Generally, a pessary is removed and cleaned with soap and water on a monthly basis by the patient, but the nurse can do it for adults with cognitive or musculoskeletal impairment.

Urethral occlusion devices (urethral plugs) can be helpful for activity-induced incontinence. One device, the Reliance insert, is like a tiny tampon that the patient inserts into the urethra. After insertion, the patient inflates a tiny balloon, which rests at the bladder neck and prevents the flow of urine. To void, the patient pulls a string to deflate the balloon and removes the device. The applicator is reusable, although the tampon part is disposed of after each void.

*Electrical stimulation* with either an intravaginal or intrarectal electrical stimulation device is available to treat both urge and stress incontinence. Treatment consists of stimulating sensory nerves to decrease the sensation of urgency. It is done as an office-based procedure one to three times weekly for 6 to 8 weeks.

*Magnetic resonance therapy* involves targeted urinary tract nerves and muscles for depolarization. The patient sits on a chair containing a magnetic device that induces depolarization and helps reduce stress-induced incontinence similar to drug-induced relaxation of muscle and nerves.

### Surgical Management.

Stress incontinence may be treated by a surgical sling or bladder suspension procedure (Table 66-2). A sling procedure creates a sling around the bladder neck and urethra using strips of body tissue or synthetic mesh. Mid-urethral sling procedures are particularly effective for stress urinary incontinence (Cerruto et al., 2015). Bladder suspension procedures are more extensive than sling procedures, and the surgeon sutures tissue near the bladder neck to a pubic bone ligament to provide support and prevent sagging. A third surgical procedure is the injection of bulking agents into the urethral wall to provide resistance to urine outflow. Bulking agents include collagen, carbon-coated zirconium beads, and silicone implants.

**TABLE 66-2**  
**Surgical Procedures for Stress Incontinence**

PROCEDURE	PURPOSE	NURSING CONSIDERATIONS
Anterior vaginal repair (colporrhaphy)	Elevates the urethral position and repairs any cystocele.	Because the operation is performed by vaginal incision, it is often done in conjunction with a vaginal hysterectomy. Recovery is usually rapid, and a urethral catheter is in place for 24-48 hr.
Retropubic suspension (Marshall-Marchetti-Krantz or Burch colposuspension)	Elevates the urethral position and provides longer-lasting results.	The operation requires a low abdominal incision and a urethral or suprapubic catheter for several days after. Recovery takes longer, and urinary retention and detrusor instability are the most frequent complications.
Needle bladder neck suspension (Pereyra or Slamey procedure)	Elevates the urethral position and provides longer-lasting results without a long operative time.	The combined vaginal approach with a needle and a small suprapubic skin incision does not allow direct vision of the operative site; however, the high complication rates may be due to the selection of patients who, because of their medical condition, are not good candidates for longer retropubic procedures.
Pubovaginal sling procedures	A sling made of synthetic or fascial material is placed under the urethrovesical junction to elevate the bladder neck.	The operation uses an abdominal, vaginal, or combined approach to treat intrinsic sphincter deficiencies. Temporary or permanent urinary retention is common after surgery.
Midurethral sling procedures	A tensionless vaginal sling is made from polypropylene mesh (or other materials) and placed near the urethrovesical junction to increase the angle, which inhibits movement of urine into the urethra with lower intravesicular pressures.	This ambulatory surgery procedure uses a vaginal approach to improve symptoms of stress incontinence. Temporary or permanent urinary retention is common after surgery.
Artificial sphincters	A mechanical device to open and close the urethra is placed around the anatomic urethra.	The operation is done more frequently in men. The most common complications include mechanical failure of the device, erosion of tissue, and infection.
Periurethral injection of collagen or Siloxane	Implantation of small amounts of an inert substance through several small injections provides support around the bladder neck.	The procedure can be done in an ambulatory care setting and can be repeated as often as necessary. Certain compounds may migrate after injection; an allergy test to bovine collagen must be performed before implantation.

### Preoperative Care.

Teach the patient about the procedure, and clarify the surgeon's explanation of events surrounding the surgery. Extensive urodynamic testing (see Chapter 65) has not been shown to be useful before surgical interventions for stress urinary incontinence (Cerruto et al., 2015).

### Postoperative Care.

After surgery, assess for and intervene to prevent or detect complications. For prevention of movement or traction on the bladder neck, secure the urethral catheter with tape or a tube holder. If a suprapubic catheter is used instead of a urethral catheter, monitor the dressing for urine leakage and other drainage. Catheters are usually in place until the patient can urinate easily and has residual urine volume of less than 50 mL after voiding. (See Chapters 14 and 16 for a discussion of general care before and after surgery.)

### Reducing Urge Incontinence

Planning: Expected Outcomes.

The patient with urge urinary incontinence is expected to use techniques to prevent or manage uncontrolled urine ELIMINATION. Indicators include that the patient often or consistently demonstrates these behaviors:

- Responds to urge in a timely manner
- Gets to toilet between urge and passage of urine
- Avoids substances that stimulate the bladder (e.g., caffeine, alcohol)

### Interventions.

Interventions for patients with urge incontinence or overactive bladder (OAB) are nonsurgical. These include bladder training and drug therapy if bladder training is not successful (Qaseem et al., 2014). Neuromodulation therapy, which involves stimulation of the nerves to the bladder, can be used to manage urge incontinence. Minor surgery is required to place the device. Most types of surgery are not the recommended treatment of this condition.

### Drug Therapy.

Because the hypertonic bladder contracts involuntarily in patients with urge incontinence, drugs that relax the smooth muscle and increase the bladder's capacity are prescribed (Chart 66-4). The most commonly prescribed drugs are anticholinergics (also known as antimuscarinics because they target specific receptors in the cholinergic family of receptors), which include darifenacin (Enablex), fesoterodine (Toviaz), oxybutynin (Ditropan and Ditropan XL), propiverdine (Detrunorm), solifenacin (VESIcare), tolterodine (Detrol and Detrol LA), and trospium (Sanctura). Some of these drugs are available over-the-counter. This class of drugs has serious side effects, particularly for older adults, and is used along with behavioral interventions. These drugs inhibit the nerve fibers that stimulate bladder contraction. Tricyclic antidepressants with anticholinergic and alpha-adrenergic agonist activity, such as imipramine (Tofranil, Novopramine), have been used successfully in younger patients.

### Chart 66-4

## Common Examples of Drug Therapy

### Urinary Incontinence

DRUG CATEGORY	NURSING IMPLICATIONS
<b>Hormones</b> —Thought to enhance nerve conduction to the urinary tract, improve blood flow, and reduce tissue deterioration of the urinary tract	
Estrogen vaginal cream daily or an estrogen-containing ring inserted monthly	Teach patients to use only a thin application of the cream to minimize excessive absorption and distribution and avoid systemic side effects. Teach patients that it takes 4-6 weeks to achieve continence benefits and that benefits disappear after about 4 weeks after discontinuing regular use because knowing the drug responses increases the likelihood of its correct use.
<b>Anticholinergics</b> —Suppress involuntary bladder contraction and increase bladder capacity	
Darifenacin (Enablex) Fesoterodine (Toviaz) Oxybutynin (Ditropan) Propiverdine (Detrunorm) Solifenacin (VESIcare) Tolterodine (Detrol) Trospium (Sanctura)	Ask whether the patient has glaucoma before starting any drugs from this class because anticholinergics can increase intraocular pressure and make glaucoma worse. Suggest that patients increase fluid intake and use hard candy to moisten the mouth to reduce the dry mouth side effect. Teach patients to increase fluid intake and the amount of dietary fiber to prevent constipation associated with this drug category. Teach patients to monitor urine output and to report an output significantly lower than intake to the primary health care provider because all of these drugs can cause urinary retention, especially for men with an enlarged prostate. Instruct patients taking the extended-release forms of these drugs not to chew or crush the tablet/capsule to avoid both ruining the time-release feature and increasing the risk for a bolus dose with more side effects.
<b>Alpha-Adrenergic Agonists</b> —Increase contractile force of the urethral sphincter, increasing resistance to urine outflow	
Midorine (ProAmatine, Orvaten)*	Teach the patient to monitor his or her blood pressure periodically when starting the drug because these drugs can cause severe supine hypertension and should not be used in patients with severe cardiac disease.
<b>Beta<sub>3</sub> Blockers</b> —Relax the detrusor smooth muscle to increase bladder capacity and urine storage	
Mirabegron (Myrbetriq)	Teach the patient to periodically obtain a blood pressure and to inform the health care provider if the systolic or diastolic values increase more than 10 mm Hg or above 180/110 because this drug has the potential to increase blood pressure. If the patient is taking warfarin, avoid this drug or schedule additional blood testing for potential increased risk for bleeding because this drug uses the same metabolic pathway as warfarin and can potentiate warfarin's effects, leading to a prolonged international normalized ratio (INR) and increase the risk for bleeding.
<b>Antidepressants: Tricyclics and Serotonin-Norepinephrine Reuptake Inhibitors (SNRIs)</b> —Increase norepinephrine and serotonin levels, which are thought to strengthen the urinary sphincters; also have anticholinergic actions	
Tricyclics Imipramine (Tofranil, Novo-Pramine) Amitriptyline (Elavil, Levate) SNRI Duloxetine (Cymbalta)*	Warn patients not to combine these drugs with other antidepressant drugs to avoid a drug-drug interaction that can lead to a hypertensive crisis. Instruct patients to inform their primary health care provider if they take drugs to manage hypertension. Teach patients to change positions slowly, especially in the morning to avoid dizziness from orthostatic hypotension, which increases the risk for falls. Teach patients the same interventions as for anticholinergic agents because these drugs have anticholinergic activity and can produce the same side effects.

\*These drugs are used off label and do not have United States Food and Drug Administration (FDA) approval for use. However, they are commonly used to manage incontinence syndromes.

A beta-adrenergic agonist, mirabegron (Myrbetriq) has demonstrated effectiveness in reducing urge incontinence. The evidence comparing different drug categories for effectiveness in managing incontinence is limited, and no single drug or class is recommended over another.

Another drug therapy for urge incontinence is onabotulinumtoxinA (Botox). This drug is injected

during cystoscopy into multiple areas of the detrusor muscle of the bladder. Usually 10 to 30 different sites are injected during one treatment session. This treatment relaxes the detrusor muscle and relieves the urge to urinate (Felicilda-Reynaldo & Backes, 2014). Some patients have had relief of incontinence for as long as 6 to 9 months after injection. Side effects may include urinary retention, painful urination, and an increased incidence of urinary tract infections. For most patients who experience urinary retention, the condition is temporary but does require intermittent self-catheterization.

## Nursing Safety Priority QSEN

### Drug Alert

Teach patients taking the extended-release forms of anticholinergic drugs to swallow the tablet or capsule whole without chewing or crushing it. Chewing or crushing the tablet/capsule ruins the extended-release feature, allowing the entire dose to be absorbed quickly, which increases adverse drug side effects.

## NCLEX Examination Challenge 66-1

### Safe and Effective Care Environment

For which adverse drug effects does the nurse assess in a client who is hospitalized for an acute problem and is also prescribed an anticholinergic drug to manage incontinence? **Select all that apply.**

- A. Insomnia
- B. Blurred vision
- C. Constipation
- D. Dry mouth
- E. Loss of sphincter control
- F. Increased sweating
- G. Worsening mental function
- H. Hypotension

### Nutrition Therapy.

Teach the patient to avoid foods that irritate the bladder such as caffeine and alcohol. Spacing fluids at regular intervals throughout the day (e.g., 120 mL every hour or 240 mL every 2 hours) and limiting fluids after the dinner hour (e.g., only 120 mL at bedtime) help avoid fluid overload on the bladder and allow urine to collect at a steady pace. Remind patients that maintaining an ideal body weight helps avoid the pressure that abdominal fat places on pelvic organs, thus reducing incontinence.

### Bladder Training.

Bladder training, sometimes called *behavioral training* for incontinence, includes the interventions listed in [Chart 66-5](#) and electrical stimulation. Bladder training involves a great deal of patient participation. Provide ongoing encouragement, clarification, and support to increase the effectiveness of all interventions. This intervention may be combined with drug and diet therapy for weight loss.

## Chart 66-5

# Best Practice for Patient Safety & Quality Care OSEN

## Bladder Training and Habit Training to Reduce Urinary Incontinence

### Bladder Training

- Assess the patient's awareness of bladder fullness and ability to cooperate with training regimen.
- Assess the patient's 24-hour urine ELIMINATION pattern for 2 to 3 consecutive days (bladder diary).
- Base the initial interval of toileting on the voiding pattern (e.g., 45 minutes).
- Teach the patient to void every 45 minutes on the first day and to ignore or suppress the urge to urinate between the 45-minute intervals.
- Take the patient to the toilet or remind him or her to urinate at the 45-minute intervals.
- Provide privacy for toileting and run water in the sink to promote the urge to urinate at this time.
- If the patient is not consistently able to resist the urge to urinate between the intervals, reduce the intervals by 15 minutes.
- Continue this regimen for at least 24 hours or for as many days as it takes for the patient to be comfortable with this schedule and not urinate between the intervals.
- When the patient remains continent between the intervals, increase the intervals by 15 minutes daily until a 3- to 4-hour interval is comfortable for the patient.
- Praise successes. If incontinence occurs, work with the patient to re-establish an acceptable toileting interval.

### Habit Training

- Assess the patient's 24-hour voiding pattern for 2 to 3 days.
- Base the initial interval of toileting on the voiding pattern (e.g., 2 hours).
- Help the patient to the toilet or provide a bedpan/urinal every 2 hours (or whatever has been determined to be an appropriate toileting interval for the individual patient).
- During the toileting, remind the patient to void and provide cues such as running water.
- If the patient is incontinent between scheduled toileting, reduce the time interval by 30 minutes until the patient is continent between voidings.
- Help the patient to toilet and prompt to void at prescribed intervals.
- Do not leave the patient on the toilet or bedpan for longer than 5 minutes.
- Ensure that all nursing staff members comply with the established toileting schedule and do not apply briefs or encourage the patient to "just wet the bed."
- Reduce toileting interval by 30 minutes if there are more than two incontinence episodes in 24 hours.
- If the patient remains continent at the toileting interval, attempt to increase the interval by 30 minutes until a 3- to 4-hour continence interval is reached.
- Praise the patient for successes and spend extra time socializing with the patient.

- When incontinence occurs, ensure that the patient and bed are cleaned appropriately but do not spend extra time socializing with the patient.
- Discuss daily record of continence with staff to provide reinforcement and encourage compliance with toileting schedule.
- Include unlicensed assistive personnel in all aspects of the habit training.

Bladder training is an education program for the patient that begins with a thorough explanation of the problem of urge incontinence. Instead of the bladder being in control of the patient, the patient learns to control the bladder. For the program to succeed, he or she must be alert, aware, and able to resist the urge to urinate (Wilde et al., 2014).

Start a schedule for voiding, beginning with the longest interval that is comfortable for the patient, even if the interval is only 30 minutes. Instruct the patient to void every 30 minutes and to ignore any urge to urinate between the set intervals. Once he or she is comfortable with the starting schedule, increase the interval by 15 to 30 minutes. Instruct the patient to follow the new schedule until he or she achieves success again. As the interval increases, the bladder gradually tolerates more volume. Teach him or her relaxation and distraction techniques to maximize success in the retraining. Provide positive reinforcement for maintaining the prescribed schedule.

Habit training (scheduled toileting) is a type of bladder training that is successful in reducing incontinence in cognitively impaired patients. To use habit training, caregivers help the patient void at specific times (e.g., every 2 hours on the even hours). The goal is to get the patient to the toilet before incontinence occurs. The focus is on reducing incontinence. When that has been achieved, the focus may change to increasing bladder capacity by gradually lengthening the voiding intervals, but this is only secondary.

## Nursing Safety Priority QSEN

### Action Alert

Habit training is undermined when absorbent briefs are used in place of timed toileting. Do not tell patients to “just wet the bed.” A common cause of falls in health care facilities is related to patient efforts to get out of bed unassisted to use the toilet. Work with all staff members, including unlicensed assistive personnel (UAP), to implement consistently the toileting schedule for habit training.

Prompted voiding, a supplement to habit training, attempts to increase the patient's awareness of the need to void and to prompt him or her to ask for toileting assistance. Habit training otherwise relies completely on a time schedule.

Pelvic muscle exercises for urge incontinence is helpful and is taught in the same way as for stress incontinence (see [Chart 66-3](#)). Improved urethral resistance helps the patient overcome abnormal detrusor contractions long enough to get to the toilet.

### Surgical Management for Urge Incontinence.

In contrast to stress urinary incontinence, urge urinary incontinence requires extensive preoperative testing for diagnosis and selection of surgery. The patient may need emotional support during this extensive diagnostic work-up. Surgical procedures and preoperative and postoperative management are the same as those described for stress urinary incontinence and in [Table 66-2](#).

## Reducing Reflex Incontinence

### Planning: Expected Outcomes.

With appropriate intervention, the patient with reflex incontinence is expected to achieve continence. Indicators include that the patient often or consistently demonstrates these behaviors:

- Recognizes the urge to void
- Maintains a predictable pattern of voiding

- Responds to urge in a timely manner
- Empties bladder completely
- Keeps urine volume in the bladder under 300 mL

#### Interventions.

Interventions for the patient with reflex (overflow) incontinence caused by obstruction of the bladder outlet may include surgery to relieve the obstruction. The most common procedures are prostate removal (see [Chapter 72](#)) and repair of uterine prolapse (see [Chapter 71](#)).

#### Drug Therapy.

Drugs are prescribed for short-term management of urinary retention, often after surgery. They are not used in long-term management of overflow incontinence caused by a hypotonic bladder. The most commonly used drug is bethanechol chloride (Urecholine), an agent that increases bladder pressure.

#### Behavioral Interventions.

The most effective common behavioral interventions are bladder compression and intermittent self-catheterization.

*Bladder compression* uses techniques that promote bladder emptying and include the Credé method, the Valsalva maneuver, double-voiding, and splinting.

For the Credé method, teach the patient how to press over the bladder area, increasing the pressure, or to trigger nerve stimulation by tugging at pubic hair or massaging the genital area. These techniques manually help the bladder empty. In the Valsalva maneuver, breathing techniques increase chest and abdominal pressure. This increased pressure is then directed toward the bladder during exhalation. (The Valsalva maneuver is contraindicated in patients who have some cardiac problems because it can trigger a vagal response and cause bradycardia.) With the technique of double-voiding, the patient empties the bladder and then, within a few minutes, attempts a second bladder emptying.

For women who have a large *cystocele* (prolapse of the bladder into the vagina), a technique called *splinting* both compresses the bladder and moves it into a better position. The woman inserts her fingers into her vagina, gently lifts the cystocele, and begins to urinate. A *pessary*, described earlier, can also provide relief from cystocele-related incontinence.

*Intermittent self-catheterization* is often used to help patients with long-term problems of incomplete bladder emptying. It is effective, can be learned fairly easily, and remains the preferred method of bladder emptying in patients who have incontinence as a result of a neurogenic bladder ([Prieto et al., 2015](#)). These points are important in teaching the technique:

- Proper handwashing and cleaning of the catheter reduce the risk for infection.
- A small lumen and good lubrication of the catheter prevent urethral trauma.
- A regular schedule for bladder emptying prevents distention and mucosal trauma.

Patients must be able to understand instructions and have the manual dexterity to manipulate the catheter. Caregivers or family members in the home can also be taught to perform intermittent catheterization using clean (rather than sterile) technique with good outcomes ([Bickhaus et al., 2015](#)).

### Reducing Functional Incontinence

#### Planning: Expected Outcomes.

The patient with functional urinary incontinence is expected to remain dry and maintain skin TISSUE INTEGRITY. Indicators include that the patient often or consistently demonstrates these behaviors:

- Uses urine containment or collection measures to ensure dryness
- Manages clothing independently

#### Interventions.

Causes of functional (or chronic intractable) incontinence vary greatly. Some are reversible, and others are not. The focus of intervention is treatment of reversible causes. When incontinence is not reversible, urinary habit training (see [Chart 66-5](#)) is used to establish a predictable pattern of

bladder emptying to prevent incontinence. A final strategy focuses on containment of the urine and protection of the patient's skin. Nonsurgical interventions include applied devices, containment, and catheterization.

*Applied devices* include intravaginal pessaries for women and penile clamps for men. The intravaginal pessary supports the uterus and vagina and helps maintain the correct position of the bladder. (See [Chapter 71](#) for further discussion of pessaries.) The penile clamp is applied around the outside of the penis to compress the urethra and prevent urine leakage.

Adverse outcomes from pessaries and penile clamps include reduced TISSUE INTEGRITY with tissue damage from pressure and infection from colonization of damaged tissues. Both devices require that the patient have either manual dexterity or a caregiver to apply and remove the device. Instruct the patient or caregivers in the use of these devices. Male patients may use an external collecting device, such as a condom catheter. Design of an effective external collecting device for women has not been as successful.

*Containment* is achieved with absorbent pads and briefs designed to collect urine and keep the patient's skin and clothing dry. Many types and sizes of pads are available:

- Shields or liners inserted inside a panty
- Undergarments that are full-size pads with waist straps
- Plastic-lined protective underpants
- Combination pad and pant systems
- Absorbent bed pads

A major concern with the use of wearable protective pads is the risk for skin breakdown (loss of TISSUE INTEGRITY). Some patients develop incontinence-associated dermatitis (IAD) even when the skin is kept free of contact with urine ([Gray et al., 2016](#)). The wearable pads generate heat and sweat in the area that can cause dermatitis. Materials and costs of protective pads vary. Some are reusable; others are disposable. The disposal of these products raises ecologic concerns. Avoid use of the word “diaper” when discussing these adult pants, because of the association of diapers with a baby. More acceptable terms are “briefs” and “pads.” See [Chapter 25](#) for more information about IAD.

*Catheterization* for control of functional incontinence may be intermittent or involve a long-term catheter. Intermittent catheterization is preferred to a long-term catheter because of the reduced risk for infection. A long-term urinary catheter is appropriate for patients with disrupted TISSUE INTEGRITY who need a dry environment for healing, for those who are terminally ill and need COMFORT, and for those who are critically ill and require precise measurement of urine output.

### Managing Total or Mixed Urinary Incontinence.

Mixed or total urinary incontinence is a combination of two or more types of involuntary urine loss syndromes. For example, stress incontinence and urge incontinence often occur together in women during and after menopause. For the patient with mixed or total incontinence, combinations of assessment techniques (as discussed under each syndrome) are used. Interventions are also combined to promote continence. The problems and interventions for mixed incontinence are the same as for each specific type of incontinence separately. After identifying the specific types of incontinence that an individual patient has, apply the appropriate priority patient problems, interventions, and expected outcomes discussed earlier with each incontinence type.

## Cultural/Spiritual Considerations

### Patient-Centered Care QSEN

Lower income is associated with fewer discussions between clinicians and patients about incontinence among women who have at least one episode of incontinence weekly (Duralde et al., 2016). Some evidence indicates that African-American women are less knowledgeable about risk factors associated with incontinence and its treatment options (Mandimika et al., 2015). Perform systematic screening of all women, including minority women, to overcome barriers to discussions and evaluation of incontinence and its treatment.

## Clinical Judgment Challenge 66-1

## Patient-Centered Care; Evidence-Based Practice QSEN

The patient is a 72-year-old woman who reports loss of a large volume of urine just as she enters the bathroom both at home and away from home. The problem started only recently and occurred about four times during the past week. She is an active church volunteer, lives independently with her husband, and recently passed a safe driving course to assure her that she is still safe to drive around town. The patient wants to continue to participate in her active lifestyle and wants to discuss options for preventing/managing this embarrassing condition.

1. What other information will you obtain from this patient?
2. What type or types of incontinence is she most likely to have from the information she has provided thus far?
3. What will you tell her regarding options for care?
4. She asks if there is anything she can do now to stop this problem of involuntary loss of urine. How do you respond?

### Care Coordination and Transition Management

Community-based care for the patient with incontinence of urine **ELIMINATION** considers his or her personal, physical, emotional, and social resources. Important personal resources for self-care include mobility and manual dexterity. When planning care, consider who will be the primary caregiver and which factors may influence the effectiveness of the plan. A comparative effectiveness review from the Agency for Healthcare Research and Quality ([AHRQ, 2013](#)) reports that drugs for urinary incontinence can provide benefit but that adverse drug events, overall, lead to poor adherence. This report also provides information that nonpharmacologic and nonsurgical treatments provide significant clinical benefit with low risk for adverse effects but that these interventions are also associated with poor adherence. Ongoing relationships with primary health care providers may improve adherence.

### Home Care Management.

Assess the home environment for barriers that limit access to the bathroom. Eliminate hazards that might slow walking or lead to a fall. Such hazards include throw rugs, furniture with legs that extend into the walking area, slippery waxed or polished floors, and poor lighting.

If the patient must climb stairs to reach a bathroom, handrails should be installed and stairs kept free of obstacles. Toilet seat extenders may help provide the right level and height of seating so maximal abdominal pressure may be applied for voiding. Portable commodes may be obtained when ambulatory access to toilets is impractical. Physical and occupational therapists are valuable resources for assisting with home care management.

### Self-Management Education.

Teach the patient and family about the cause of the specific type of incontinence and discuss available treatment options for its management. The teaching plan addresses the prescribed drugs (purpose, dosage, method and route of administration, and expected and potential side effects). Instruct the patient and family about the importance of weight reduction and dietary modification to help control incontinence of urine **ELIMINATION**. Remind the patient who smokes that nicotine can contribute to bladder irritation and that coughing can cause urine leakage.

When external devices or protective pads are needed, describe the possible options and help the patient make a selection best for his or her lifestyle and resources. For patients who will use intermittent catheterization or those with artificial urinary sphincters, demonstrate the correct technique to the patient or caregiver. Evaluate return demonstrations for correct technique. [Chart 66-6](#) also addresses teaching.

### Chart 66-6

## Patient and Family Education: Preparing for Self-

## Management

### Urinary Incontinence

- Maintain a normal body weight to reduce the pressure on your bladder.
- Do not try to control your incontinence by limiting your fluid intake. Adequate fluid intake is necessary for kidney function and health maintenance.
- If you have a catheter in your bladder, follow the instructions given to you about maintaining the sterile drainage system.
- If you are discharged with a suprapubic catheter in your bladder, inspect the entry site for the tube daily, clean the skin around the opening gently with warm soap and water, and place a sterile gauze dressing on the skin around the tube. Report any redness, swelling, drainage, or fever to your primary health care provider.
- Do not put anything into your vagina, such as tampons, drugs, hygiene products, or exercise weights, until you check with your primary health care provider at your 6-week checkup after surgery.
- Do not have sexual intercourse until after your 6-week postoperative checkup.
- Do not lift or carry anything heavier than 5 lb or participate in any strenuous exercise until your primary health care provider gives you postoperative clearance. In some cases, this could be as long as 3 months.
- Avoid exercises, such as running, jogging, step or dance aerobic classes, rowing, cross-country ski or stair-climber machines, and mountain biking. Brisk walking without any additional hand, leg, or body weights is allowed. Swimming is allowed after all drains and catheters have been removed and your incision is completely healed.
- If Kegel exercises are recommended, ask your nurse for specific instructions.

### Psychosocial Preparation.

The embarrassment of incontinence can be devastating to self-esteem, body image, and relationships. Sexual intimacy is adversely affected by it. Its unpredictable nature creates anxiety. Patients may be embarrassed to seek help and, even when resources are identified, they may need help to feel comfortable in using them. Buying supplies at a local store may threaten privacy.

Acknowledge the personal concerns of the patient and caregiver. Never make their concerns seem trivial. As he or she learns the specifics of the plan that will allow control of urinary incontinence, the confidence to resume social interactions should return. Many continence supplies can be purchased online and delivered to the home to maintain privacy.

### Health Care Resources.

Referral to home care agencies for help with personal care and to continence clinics that specialize in evaluation and treatment may be helpful. In many continence clinics, nurses collaborate with physicians and other health care professionals to evaluate and manage patients. The treatment plan is specific for each patient; supplies and products are custom selected.

Patients may benefit from education and from the support of others who experience similar concerns. The National Association for Continence (NAFC) ([www.nafc.org](http://www.nafc.org)), Access to Continence Care and Treatment ([www.wellweb.com/INCONT/acct/contents.htm](http://www.wellweb.com/INCONT/acct/contents.htm)), and the Wound, Ostomy, and Continence Nurses ([www.wocn.org](http://www.wocn.org)) publish newsletters and educational materials written with easy-to-understand explanations. The American Foundation for Urologic Disease ([www.afud.com](http://www.afud.com)) provides information on many areas of bladder dysfunction. Local hospitals often have local NAFC-approved support groups.

## NCLEX Examination Challenge 66-2

### Safe and Effective Care Environment

For which hospitalized client does the nurse recommend the ongoing use of a urinary catheter?

- A. 35-year-old woman who was admitted with a splenic laceration and femur fracture (closed repair completed) following a car crash
- B. 48-year-old man who has established paraplegia and is admitted for pneumonia
- C. 61-year-old woman who is admitted following a fall at home and has new-onset dysrhythmia
- D. 74-year-old man who has lung cancer with brain metastasis and is being transitioned to hospice for end-of-life care

### ◆ Evaluation: Reflecting

Evaluate the care of the patient with urinary incontinence based on the identified priority patient problems. The expected outcomes are that the patient will:

- Describe the type of urinary incontinence experienced
- Demonstrate knowledge of proper use of drugs and correct procedures for self-catheterization, use of the artificial sphincter, or care of an indwelling urinary catheter
- Demonstrate effective use of the selected exercise or bladder-training program
- Select and use incontinence interventions, devices, and products
- Have a reduction in the number of incontinence episodes
- Maintain TISSUE INTEGRITY of the skin and mucous membranes in the perineal area

# Cystitis

## ❖ Pathophysiology

**Cystitis** is an inflammatory condition of the bladder. Commonly, it refers to inflammation from an infection of the bladder. However, cystitis can be caused by inflammation without infection. For example, drugs, chemicals, or local radiation therapy cause bladder inflammation without an infecting organism. Irritants, such as feminine hygiene spray, spermicidal jellies, or long-term use of a catheter can cause cystitis without infection. Cystitis may sometimes occur as a complication of other disorders, such as gynecologic cancers, pelvic inflammatory disorders, endometriosis, Crohn's disease, diverticulitis, lupus, or tuberculosis. **Interstitial cystitis** is a painful inflammatory bladder condition.

An infection can occur in any area of the urinary tract and the kidney. Such infections are known as *urinary tract infections* or *UTIs*. Risk factors associated with cystitis and other UTIs are listed in **Table 66-3**. An acute UTI is the invasion of a normal urinary tract by an infectious organism. A recurrent UTI occurs as more than two infections in 6 months or more than three infections in 1 year. These distinctions in UTIs are important because they have different approaches to management.

**TABLE 66-3**  
**Factors Contributing to Urinary Tract Infections**

FACTOR	MECHANISM
Obstruction	Incomplete bladder emptying creates a continuous pool of urine in which bacteria can grow, prevents flushing out of bacteria, and allows bacteria to ascend more easily to higher structures. Bacteria have a greater chance of multiplying the longer they remain in residual urine. Overdistention of the bladder damages the mucosa and allows bacteria to invade the bladder wall.
Stones (calculi)	Large stones can obstruct urine flow. The rough surface of a stone irritates mucosal surfaces and creates a spot where bacteria can establish and grow. Bacteria can live within stones and cause re-infection.
Vesicoureteral reflux	The urethra is colonized with bacteria. These bacteria are noninfectious until they move to upstream anatomy (bladder, ureters, kidneys) and colonize or form an infection with reflux (backward-flowing urine). Reflux of sterile urine can cause kidney scarring, which may promote kidney dysfunction.
Diabetes mellitus	Excess glucose in urine provides a rich medium for bacterial growth. Peripheral neuropathy affects bladder innervation and leads to a flaccid bladder and incomplete bladder emptying.
Characteristics of urine	Urine pH can promote different species of bacterial growth. Concentrated urine allows bacterial growth and adhesion to urinary tract anatomy.
Gender	<b>Women</b> Susceptibility to urethral colonization with coliform or pathogenic bacteria is increased, especially as estrogen levels fall during menopause. Use of douches, perfumed pads or toilet tissue, diaphragms, or spermicide (including spermicide-coated condoms) in women can inflame periurethral tissue and contribute to colonization. Bladder displacement during pregnancy predisposes women to cystitis and the development of pyelonephritis. A diaphragm or pessary that is too large can obstruct urine flow or traumatize the urethra. <b>Men</b> With increased age, the prostate enlarges and may obstruct the normal flow of urine, producing stasis. With increased age, prostatic secretions lose their antibacterial characteristics and predispose to bacterial proliferation in the urine. Sexually transmitted diseases may cause urethral strictures that obstruct the flow of urine and predispose to urinary stasis.
Age	Urinary stasis may be caused by incomplete bladder emptying as a result of an enlarged prostate in men and cystocele and vaginal prolapse in women. Neuromuscular conditions that cause incomplete bladder emptying, such as Parkinson disease and stroke, affect older adults more frequently. The use of drugs with intentional or unintentional anticholinergic properties in older adults contributes to delayed bladder emptying. Fecal incontinence contributes to urethral contamination. Low estrogen in menopausal women adversely affects the cells of the vagina and urethra, making them more susceptible to infections. Overall IMMUNITY declines with age, increasing the risk for uncomplicated infections to become complicated.
Sexual activity	Sexual intercourse is the strongest risk factor for uncomplicated cystitis, particularly in young women. Irritation of the perineum and urethra during intercourse can promote migration of bacteria from the perineal area to the urinary tract in some women. Inadequate vaginal lubrication may exacerbate potential urethral irritation. Bacteria may be introduced into the man's urethra during anal intercourse or during vaginal intercourse with a woman who has a bacterial vaginitis.
Recent use of antibiotics	Antibiotics change IMMUNITY and normal protective flora, providing opportunity for pathogenic bacterial overgrowth and colonization.

## Gender Health Considerations

### Patient-Centered Care QSEN

About 10% of young, sexually active women experience a UTI each year, and 60% of all women have one or more UTIs in their lifetime. Most UTIs are acute and uncomplicated in women. Acute, uncomplicated UTIs rarely occur in men.

A UTI is further categorized as *uncomplicated* or *complicated*. With an uncomplicated UTI, there is no anatomic or functional abnormality of the urinary tract or condition that increases the risk for infection or possibility of treatment failing to resolve the infection (such as the presence of a multi-drug-resistant organism or urologic dysfunction). Some factors and conditions that contribute to a diagnosis of complicated UTI are pregnancy, male gender, obstruction, diabetes, neurogenic

bladder, chronic kidney disease, and reduced IMMUNITY (Nicolle, 2016). In men, a UTI is generally considered complicated even with normal structure and function because most UTIs occur in older men or in association with anal intercourse (resulting in exposure to potentially virulent pathogens). Complicated cystitis or other UTI requires greater vigilance to avoid or detect adverse events from the infection and a longer course of antimicrobial treatment. A diagnosis of complicated UTI may require additional testing to identify and manage other related health problems (comorbidities).

The presence of bacteria in the urine is **bacteriuria** and may occur with cystitis or any UTI. When the patient has bacteriuria but no symptoms of infection, it is called *colonization*, or *asymptomatic bacterial urinary tract infection* or *ABUTI*, and is more common in older adults. This problem may progress to acute infection or renal insufficiency when the patient has other conditions, and only then does it require treatment.

The urinary and genitourinary tracts are normally sterile, apart from the distal urethra. Several host defenses help protect against infection in the urinary tract. Mucin produced by cells lining the bladder helps maintain mucosal integrity and prevents cellular damage. Mucin prevents bacteria from adhering to urothelial cells. Urine pH and the concentration of organic acids also contribute to sustaining sterile urine. Polymorphonuclear (PMN) leukocytes (white blood cells [WBCs]) in the urinary tract are the IMMUNITY cells that engulf and destroy pathogens. Urine proteins, such as secreted antibodies, also are protective. In men, the prostate gland secretes additional protective proteins. Frequent voiding is another defense against bacterial growth and adherence by preventing urine stasis.

### Etiology and Genetic Risk

UTIs, like other infections, result from interactions between a pathogen and the host. Usually a high bacterial *virulence* (ability to invade and infect) is needed to overcome normal host defenses and IMMUNITY. However, an adult with reduced immunity is more likely to become infected even with bacteria that have low virulence. With UTI, bacteria (and, infrequently, fungi), move up the urinary tract from the external urethra to the bladder to cause infectious cystitis. Less commonly, spread of infection through the blood and lymph fluid can occur, although this cause of UTI is not common. Invading bacteria with special adhesions are more likely to cause ascending UTIs that start in the urethra or bladder and move up into the ureter and kidney.

*Infectious cystitis* typically is caused by pathogens from the bowel or, in some cases, the vagina. About 90% of UTIs are caused by *Escherichia coli*. Less common organisms include *Staphylococcus saprophyticus*, *Klebsiella pneumoniae*, and organisms from the *Proteus* and *Enterobacter* species (Nicolle, 2016). Other infecting microbes causing infectious cystitis are viruses, mycobacteria, parasites, and yeast (fungus), especially *Candida* species. Reflux from the colonized distal urethra can also contribute to UTI in vulnerable patients. Irritation, trauma, or instrumentation of the urinary tract decreases host defenses and contributes to UTIs through the ascending migration of uropathogens.

Catheters are the most common factor associated with new-onset UTIs in the hospital and long-term care settings (Conway et al., 2017; Corley, 2015; Panchisin, 2016). Within 48 hours of catheter insertion, bacterial colonization along the urethra and the catheter itself begins. About half of patients with indwelling catheters become infected within 1 week of catheter insertion.

How a catheter-associated infection occurs varies between genders. Bacteria from a woman's perineal area are more likely to ascend to the bladder by moving along the urethra. The shorter urethra in women aids in the ascending organisms' migration. In men, bacteria tend to gain access to the bladder from the catheter itself (Conway et al., 2017). Any break in the closed urinary drainage system allows bacteria to move through the lumen of the catheter. The external catheter surface also provides route for migration. Best practices to reduce the risk for catheter contamination and catheter-associated UTIs are listed in [Chart 66-7](#).

#### Chart 66-7

### Best Practice for Patient Safety & Quality Care QSEN

#### Minimizing Catheter-Associated Urinary Tract Infections (CAUTI)

- Maintain good hand hygiene during insertion and manipulation of the catheter system to avoid contamination.
- Insert urinary catheters for appropriate use only, including:
  - Acute urinary retention or bladder obstruction
  - Accurate measurement of urine volume in critically ill patients
  - Perioperative situations that involve urologic surgery, prolonged surgery, large-volume infusions or diuretics during surgery, or the need for monitoring intraoperative urine output
  - To assist in healing of open sacral or perineal wounds in incontinent patients
  - Potentially unstable spine conditions or multiple traumatic injuries, such as pelvic fractures, for which patient requires immobilization
  - To provide COMFORT at end of life
- Ensure that only properly trained personnel insert and maintain catheters.
- Use routine hygiene to clean periurethral area; antiseptic cleaning solutions are NOT recommended.
- Leave catheters in place only as long as needed. The strongest predictor of a CAUTI is the length of time the catheter dwells in a patient.
- Assess need for urinary catheter daily and document patient needs or indications.
- For example, remove catheters in postanesthesia care or as soon as possible after surgery when intraoperative indications have resolved.
- Use aseptic technique and sterile equipment in the acute care setting when inserting a urinary catheter.
- Maintain a closed system by ensuring that catheter tubing connections are sealed securely; disconnections can introduce pathogens into the urinary tract.
- Obtain urine samples aseptically.
- If breaks in the system occur, replace the catheter and entire collecting system.
- Maintain unobstructed urine flow:
  - Keep the catheter and collecting tube free from kinking.
  - Keep the urine collection bag below the level of the bladder and do

## not rest the bag on the floor

- Empty the bag regularly, using a separate, clean container for each patient.
- Ensure that the drainage spigot does not come into contact with nonsterile surfaces.
- Secure the catheter to the patient's thigh (women) or lower abdomen (men); catheter movement can cause urethral friction and irritation.
- Consider the use of antiseptic or antimicrobial catheters for patients requiring urinary catheters for more than 3 to 5 days. These catheters reduce bacterial colonization (i.e., biofilm) along the catheter.
- Consider appropriate alternatives to an indwelling catheter:
  - External (condom) devices in cooperative men without obstruction or urinary retention
  - Intermittent catheterization in patients requiring drainage for neurogenic bladder or postoperative urinary retention
- Use portable ultrasound devices to assess urine volume to reduce unnecessary catheterization.
- Implement best practices in quality improvement to ensure that core recommendations for use, insertion, and maintenance are implemented. Examples of projects that improve patient care and reduce CAUTI include:
  - Nurse-initiated protocols for urinary catheter removal
  - Compliance with hand hygiene
  - Impact of educational programs on CAUTI occurrence
  - Compliance with documentation for catheter placement or maintenance
  - Number of CAUTI per 1000 catheter days or patient days on unit
  - Track number of catheters inserted

Adapted from [www.cdc.gov/CAUTItoolkits](http://www.cdc.gov/CAUTItoolkits); [www.ihl.org/preventCAUTI](http://www.ihl.org/preventCAUTI).

Organisms other than bacteria cause cystitis. Fungal infections, such as those caused by *Candida*, can occur during long-term antibiotic therapy, because antibiotics change normal protective flora that reduce the adherence and volume of pathogenic bacteria. Patients with reduced IMMUNITY (those who are severely immunosuppressed, are receiving corticosteroids or other immunosuppressive agents, or have diabetes mellitus or acquired immune deficiency syndrome) are at higher risk for fungal UTIs.

Viral and parasitic infections are rare and usually are transferred to the urinary tract from an infection at another body site. For example, *Trichomonas*, a parasite found in the vagina, can also be found in the urine. Treatment of the vaginal infection also resolves the UTI.

*Noninfectious cystitis* may result from chemical exposure, such as to drugs (e.g., cyclophosphamide [Cytosan, Procytox]); from radiation therapy; and from IMMUNITY problems, as with systemic lupus erythematosus (SLE).

*Interstitial cystitis* is a rare, chronic inflammation of the entire lower urinary tract (bladder, urethra, and adjacent pelvic muscles) that is related to genetic and IMMUNITY dysfunction rather than infection (Martin et al., 2015). The condition affects women six to seven times more often than men, and the diagnosis is difficult to make. Symptoms are pain associated with bladder filling or voiding, usually accompanied by frequency, urgency, and nocturia (McCance et al., 2014). Pain occurs in suprapubic or pelvic areas, sometimes radiating to the groin, vulva, or rectum.

Although cystitis is not life threatening, infection of the urinary tract can lead to life-threatening complications, including pyelonephritis and sepsis. Severe kidney damage from an ascending UTI is a rare complication. Patients with predisposing factors, such as anatomic abnormalities, pregnancy, obstruction, reflux, calculi, or diabetes, are at greater risk for complications.

The urinary tract is the infection source of severe sepsis or septic shock in about 10% to 30% of cases (Wagenlehner et al., 2013). The spread of the infection from the urinary tract to the bloodstream is termed *bacteremia* or **urosepsis**. Urosepsis is associated with a mortality rate of 30% (Conway et al., 2015). Sepsis, regardless of the source, is a systemic reaction to infection that prolongs hospitalization and can lead to shock, multiple organ failure, and other profound complications (see Chapter 37).

## Incidence and Prevalence

The incidence of UTI is second only to upper respiratory infections in primary care. Patients who have **frequency** (an urge to urinate frequently in small amounts), **dysuria** (pain or burning with urination), and **urgency** (feeling that urination will occur immediately) account for more than 8 million health care visits annually. Total direct and indirect costs for adult UTIs are estimated at \$1.6 billion annually. In addition to a high prevalence in primary care, UTIs are the most common health care–associated infection (Conway et al., 2015).

## Considerations for Older Adults

### Patient-Centered Care QSEN

In men, the incidence of UTI greatly increases after 73 years of age. In women, the prevalence of UTIs increases from 20% among all women to 50% among those older than 80 years (U.S. Renal Data Systems, 2015). Skin and mucous membrane changes from a lack of estrogen appear to account for much of the increased risk in older women, together with overall decreased IMMUNITY. Prostate disease increases risk for UTIs in men. Often the older adult does not have the typical symptoms of UTI (i.e., flank pain, dysuria, fever). More common symptoms are grossly bloody, foul-smelling urine with increasing frequency of urination (Touhy & Jett, 2016). When UTI leads to urosepsis, mental status changes occur. Ask about these additional symptoms of UTI whenever you are assessing an older adult.

## Health Promotion and Maintenance

Although infectious cystitis is common, in many cases it is preventable. **In the health care setting, using guidelines to prevent UTIs that are associated with catheter use is a National Patient Safety Goal (www.jointcommission.org, 2016).** When catheters must be used in institutional settings, strict attention to sterile technique during insertion is essential to reduce the risk for UTIs (see Chart 66-7). Long-term placement of urinary catheters requires aseptic technique for insertion. When *intermittent catheterization* was used in rehabilitation and other chronic settings, use of clean technique resulted in a similar rate of UTI compared with sterile technique as reported in a recent meta-analysis (Prieto et al., 2015). Clean technique for catheter insertion is used in home settings where multiple resistant organisms are less likely to be present.

## Nursing Safety Priority QSEN

## Action Alert

Ensuring that urinary catheters are used appropriately and discontinued as early as possible is everyone's responsibility (Panchisin, 2016). Do not allow catheters to remain in place for staff convenience.

Certain changes in fluid intake patterns, urinary ELIMINATION patterns, and hygiene patterns can help prevent or reduce cystitis in the general population. For example, a liberal water intake of 2.2 L for women and 3 L for men can promote general health. Another strategy to promote health is to have sufficient fluid intake to cause 1.5 L of clear or light yellow urine daily. Strategies to prevent cystitis and other UTIs are listed in [Chart 66-8](#). Although these strategies do not have consistent or high-quality evidence to support a reduced risk for UTI when followed, they are low risk and reasonable.

## Chart 66-8

### Patient and Family Education: Preparing for Self-Management

#### Preventing a Urinary Tract Infection

- Drink fluid liberally, as much as 2 to 3 liters daily if not contraindicated by health conditions.
- Be sure to get enough sleep, rest, and nutrition daily to maintain immunologic health.
- If spermicides are used, consider changing to another method of contraception.
- *[For women]* Clean your perineum (the area between your legs) from front to back.
- *[For women]* Avoid using or wearing irritating substances such as douches, scented lubricants for intercourse, bubble bath, tight-fitting underwear, and scented toilet tissue. Wear loose-fitting cotton underwear.
- *[For women]* Empty your bladder before and after intercourse.
- *[For both women and men]* Gently wash the perineal area before intercourse.
- Do not routinely delay urination because the flow of urine can help remove bacteria that may be colonizing the urethra or bladder.
- If you experience burning when you urinate, if you have to urinate frequently, or if you find it difficult to begin urinating, notify your primary health care provider right away, especially if you have a chronic medical condition (e.g., diabetes) or are pregnant.
- Consider using one or more of these therapies to reduce the risk for developing a urinary tract infection:
  - Taking cranberry substances (juice, capsules, or tablets) daily. Avoid high fructose cranberry juice to minimize calories and high-glucose urine favorable to bacterial reproduction.
  - Applying topical estrogen to the perineal area, if postmenopausal. Topical estrogen normalizes vaginal flora. Oral estrogens are not effective.

## ❖ Interprofessional Collaborative Care

Cystitis and UTIs can occur in any setting and are very common in the community. Usually the adult with cystitis is treated at home using self-management strategies.

### ◆ Assessment: Noticing

#### Physical Assessment/Signs and Symptoms.

Frequency, urgency, and dysuria are the common symptoms of a urinary tract infection (UTI), but other symptoms may be present (Chart 66-9). Urine may be cloudy, foul smelling, or blood tinged. Ask the patient about risk factors for UTI during the assessment (see Table 66-3). For noninfectious cystitis, the Pelvic Pain and Urgency/Frequency Patient Symptom Scale (PUF, 2011) can identify patients with interstitial cystitis.

### ▶ Chart 66-9

## Key Features

### Urinary Tract Infection

#### Common Symptoms

- Frequency
- Urgency
- Dysuria
- Hesitancy or difficulty in initiating urine stream
- Low back pain
- Nocturia
- Incontinence
- Hematuria
- Pyuria
- Bacteriuria
- Retention
- Suprapubic tenderness or fullness
- Feeling of incomplete bladder emptying

#### Rare Symptoms

- Fever
- Chills
- Nausea or vomiting
- Malaise
- Flank pain

## Symptoms That May Occur in the Older Adult

- The only symptom may be something as vague as increasing mental confusion or frequent, unexplained falls.
- A sudden onset of incontinence or a worsening of incontinence may be the only symptom of an early urinary tract infection (UTI).
- Fever, tachycardia, tachypnea, and hypotension, even without any urinary symptoms, may be signs of urosepsis.
- Loss of appetite, nocturia, and dysuria are common indications.

For patients with a urinary catheter, in addition to common signs of UTI (e.g., fever with or without chills; leukocytosis; suprapubic or flank pain; urine with sediment, blood, or foul odor), new onset of hypotension or changes in mental status can indicate a UTI (Nelson & Good, 2015). If a catheter has been in place for more than 2 weeks, it may be necessary to first replace the catheter before obtaining a urine specimen for culture (McGoldrick, 2016).

Before performing the physical assessment, ask the patient to void so the urine can be examined and the bladder emptied before palpation. Assess vital signs to help identify the presence of infection (e.g., fever, tachycardia, and tachypnea). Inspect the lower abdomen and palpate the bladder. Distention after voiding indicates incomplete bladder emptying.

Using Standard Precautions, record any lesions around the urethral meatus and vaginal opening. To help differentiate between a vaginal and a urinary tract infection, note whether there is any vaginal discharge or irritation. Vaginal discharge and irritation are more indicative of vaginal infection. Women often report burning with urination when urine touches labial tissues that are inflamed or have lost TISSUE INTEGRITY with ulcerations by vaginal infections or sexually transmitted infections (STIs). Maintain privacy with drapes during the examination.

The prostate is palpated by digital rectal examination (DRE) by the primary health care provider for size, change in shape or consistency, and tenderness. A large prostate gland can obstruct urine outflow and contribute to uroastasis and bacterial colonization of the urinary tract, contributing to the risk for a complicated UTI.

### Laboratory Assessment.

Laboratory assessment for a UTI begins with a clean-catch urine specimen that is divided into two containers. If the patient cannot produce a clean-catch specimen, you may need to obtain the specimen with a small-diameter (6 Fr) catheter. For a routine urinalysis, 10 mL of urine is needed; smaller quantities are sufficient for culture.

One container is used for a urinalysis. The combination of a positive leukocyte esterase and nitrate from a urinalysis is 68% to 88% sensitive in the diagnosis of a UTI. The presence of white blood cells (WBCs) (**pyuria**), red blood cells (RBCs) (**hematuria**), or casts (clumps of material or cells) also may indicate UTI. The presence of more than 20 epithelial cells/high-power field (HPF) suggests contamination, and a new specimen should be collected for culture and sensitivity (if needed).

If the urinalysis suggests a UTI and there are no risk factors or conditions for complicated UTI in a woman, treatment can be started. If the UTI is complicated (described previously), the second specimen is analyzed as a urine culture. A culture also may be performed when a patient with a UTI does not respond to usual therapy, when the diagnosis is uncertain, to assess for sensitivity, or to determine resolution of UTI. Urinalysis is less specific in diagnosing a UTI in an older adult, especially one who has a urinary catheter (Nelson & Good, 2015).

A urine culture confirms the type of organism and the number of colonies. Urine culture is expensive, and initial results take at least 24 hours. A UTI is confirmed when more than  $10^5$  colony-forming units/mL are in the urine from any patient. In noncatheterized patients who have symptoms of UTI (e.g., fever, dysuria, new-onset frequency or urgency, suprapubic or flank pain, or hematuria), as few as  $10^3$  colony-forming units/mL in a voided specimen can confirm the infection. For patients with a catheter who are symptomatic,  $10^2$  colony-forming units/mL are diagnostic of a complicated UTI. The presence of many different types of organisms in low colony counts usually indicates that the specimen is contaminated. Sensitivity testing follows culture results when

complicating factors are present (e.g., stones or recurrent infection), when the patient is older, or to ensure that appropriate antibiotics are prescribed.

Occasionally the serum WBC count may be elevated, with the differential WBC count showing a “left shift” (see [Chapter 17](#)). This shift indicates that the number of immature WBCs is increasing and the number of mature WBCs is decreasing in response to continued infection. Thus the number of “bands” or immature WBCs, is elevated, which indicates reduced IMMUNITY. Left shift most often occurs with urosepsis and rarely occurs with uncomplicated cystitis, because cystitis is a local rather than a systemic infection.

### Other Diagnostic Assessment.

The diagnosis of UTI and cystitis is based on history, physical examination, and laboratory data. If urinary retention and obstruction of urine outflow are suspected, pelvic ultrasound or CT may be needed to locate the site of obstruction or the presence of calculi. Voiding cystourethrography (see [Chapter 65](#)) is needed when urine reflux is suspected.

Cystoscopy (see [Chapter 65](#)) may be performed when the patient has recurrent UTIs (more than three or four a year). A urine culture is performed first to ensure that no infection is present. If infection is present, the urine is sterilized with antibiotic therapy before the procedure to reduce the risk for sepsis. Cystoscopy identifies abnormalities that increase the risk for cystitis. Such abnormalities include bladder calculi, bladder diverticula, urethral strictures, foreign bodies (e.g., sutures from previous surgery), and **trabeculation** (an abnormal thickening of the bladder wall caused by urinary retention and obstruction). Retrograde pyelography, along with the cystoscopic examination, shows outlines and images of the drainage tract.

Cystoscopy is needed to accurately diagnose interstitial (noninfectious) cystitis. A urinalysis usually shows WBCs and RBCs but no bacteria. Common findings in interstitial cystitis are a small-capacity bladder, the presence of Hunner's ulcers (a type of bladder lesion), and small hemorrhages after bladder distention.

### ◆Interventions: Responding

#### Nonsurgical Management.

The expected outcome is to maintain an optimal urine ELIMINATION pattern. Nursing interventions for the management of cystitis focus on COMFORT and teaching about drug therapy, fluid intake, and prevention measures. In a hospital setting, timely administration of antibiotics can prevent or reduce complications from urosepsis.

#### Drug Therapy.

Drugs used to treat bacteriuria and promote patient COMFORT include urinary antiseptics or antibiotics, analgesics, and antispasmodics. Cure of a UTI depends on the antimicrobial levels achieved in the urine. Fluconazole is the drug of choice for treatment of *Candida* (fungal) infections. Antispasmodic drugs decrease bladder spasms and promote complete bladder emptying.

Antibiotic therapy is used for bacterial UTIs ([Chart 66-10](#)). Guidelines for uncomplicated cystitis recommend nitrofurantoin, trimethoprim/sulfamethoxazole, or fosfomycin as first-line therapy ([Infectious Disease Society of America, 2013; Hopkins et al., 2014](#)). Longer antibiotic treatment (7 to 21 days) and sometimes different agents are required for hospitalized patients and those with complicated UTIs (e.g., men, pregnant women, and patients with anatomic, functional or metabolic derangements that affect the urinary tract).

### Chart 66-10

## Common Examples of Drug Therapy

### Urinary Tract Infections

DRUG	NURSING IMPLICATIONS
Trimethoprim*/sulfamethoxazole (Bactrim DS, Septra DS, trimethoprim/sulfamethoxazole orally)	<p>Ask patients about drug allergies, especially to sulfa drugs, before beginning drug therapy <i>because allergies to sulfa drugs are common and require changing drug therapy.</i></p> <p>Teach patients to drink a full glass of water with each dose and to have an overall fluid intake of 3 L daily <i>because these drugs can form crystals that precipitate in the kidney tubules. Fluids can prevent this complication.</i></p> <p>Teach patients to keep out of the sun or to wear protective clothing outdoors and use a sunscreen <i>because these drugs increase sun sensitivity and can lead to severe sunburn.</i></p> <p>Caution patients to complete the drug regimen even if the symptoms improve or disappear sooner <i>to prevent bacterial resistance and</i></p>

Ciprofloxacin (Cipro, ProQuin) Levofloxacin (Levaquin) Ofloxacin (Floxin)	<i>infection recurrence.</i> Teach patients taking the extended-release drugs to swallow them whole and not to crush or chew the tablets <i>because this action ruins the extended effect.</i> Warn patients not to take the drug within 2 hours of taking an antacid to <i>prevent interference with drug absorption.</i> Teach patients how to take their pulse, to monitor it twice daily while on this drug, and to notify the primary health care provider if new-onset irregular heartbeats occur to <i>identify serious drug-induced dysrhythmias.</i> Teach patients to keep out of the sun or to wear protective clothing outdoors and use a sunscreen to <i>avoid serious sunburns from increased sun sensitivity.</i> Caution patients to complete the drug regimen even if the symptoms improve or disappear sooner to <i>reduce bacterial resistance and infection recurrence.</i>
Amoxicillin (Amoxil) Amoxicillin/clavulanate (Augmentin, Clavulin)	Ask patients about drug allergies to penicillin before beginning drug therapy <i>because allergies to this drug category are common.</i> Teach patients to take the drug with food to <i>reduce the risk for GI upset.</i> Instruct patients to call the primary health care provider if severe or watery diarrhea develops to <i>recognize the complication of pseudomembranous colitis, which may require discontinuing the drug.</i> Suggest that women who take oral contraceptives use an additional method of birth control while taking this drug <i>because these drugs may reduce the effectiveness of estrogen-containing contraceptives.</i> Caution patients to complete the drug regimen even if the symptoms improve or disappear sooner to <i>prevent bacterial resistance and infection recurrence.</i>
Cefdinir, cefaclor, or cefpodoxime	Ask about drug allergies to penicillin or cephalosporins before beginning drug therapy <i>because these drugs are structurally similar to penicillin and anyone with allergies to penicillin is likely to be allergic to the cephalosporins.</i> Instruct patients to call the prescriber if severe or watery diarrhea develops to <i>recognize the complication of pseudomembranous colitis, which may require discontinuing the drug.</i> Caution patients to complete the drug regimen even if the symptoms improve or disappear sooner to <i>prevent bacterial resistance and infection recurrence.</i>  Instruct patients to mix the contents of a package in about $\frac{1}{2}$ cup of cold water, stir well, and drink all the liquid to <i>ensure that all granules are dissolved and the correct dose is taken.</i> Avoid taking this drug when also taking metoclopramide or any other drug that increases GI motility to <i>prevent interference with drug absorption.</i> Teach patients to shake the bottle well before measuring the drug to <i>thoroughly mix the suspension.</i> Suggest that patients obtain a calibrated spoon for liquid drugs and not to use household spoons to <i>ensure accurate dosing.</i> Teach patients to drink a full glass of water with each dose and to have an overall fluid intake of at least 3 L daily to <i>avoid having the drug precipitate in the kidneys and cause kidney damage.</i> Caution patients to complete the drug regimen even if the symptoms improve or disappear sooner to <i>prevent bacterial resistance and infection recurrence.</i>
Phenazopyridine (Azo-Dine, Prodiem, Pyridiate, Pyridium, Uristat, Phenazo)	Remind patients that this drug will not treat an infection, only the symptoms <i>because these drugs have no antibacterial activity.</i> Teach patients to take the drug with or immediately after a meal to <i>reduce the risk for GI upset.</i> Warn patients that urine will turn red or orange to <i>reduce anxiety about this change.</i>
Hyoscyamine (Anaspaz, Cystospaz, many others)	Teach patients to notify the primary health care provider if blurred vision or other eye problems, confusion, dizziness or fainting spells, fast heartbeat, fever, or difficulty passing urine occurs <i>because these symptoms indicate drug toxicity.</i> Teach patients to wear dark glasses in sunlight or other bright-light areas <i>because these drugs dilate the pupil and increase eye sensitivity to light.</i>

Trimethoprim can be given alone to patients with a sulfa allergy.

## Nursing Safety Priority QSEN

### Drug Alert

Sulfamethoxazole/trimethoprim (Bactrim DS, Septra DS) should be stopped at the first appearance of a skin rash. A rash may indicate the onset of Stevens-Johnson syndrome (aching joints and muscles; bilateral blistering skin) or toxic epidermal necrolysis (redness, blistering, and peeling skin and mucous membranes).

Antibiotics are one of the drug categories most frequently involved in the error of administration to patients who have documented allergies to these drugs.

Low-dose antibiotic therapy over 6 to 12 months is sometimes used for chronic, recurring infection caused by structural abnormalities or stones. Trimethoprim 100 mg daily may be used for long-term management of the older patient with frequent UTIs. For women who have recurrent UTIs after intercourse, antibiotics may be prescribed to be taken after intercourse. The three most common drug treatment regimens are (1) one low-dose tablet of trimethoprim (Proloprim, Trimpex), (2) sulfamethoxazole/trimethoprim (single-strength Bactrim, Cotrim), or (3) nitrofurantoin (Macrochantin, Nephronex , Novo Furantoin ).

## Gender Health Considerations

### Patient-Centered Care QSEN

Pregnant women with a bacterial UTI require prompt and aggressive treatment because a UTI can lead to acute pyelonephritis during pregnancy. Pyelonephritis in pregnancy can cause preterm labor and adversely affect the fetus. Remind pregnant patients to contact their health care provider whenever symptoms of UTI are present.

#### Fluid Intake.

Urge patients to drink enough fluid to maintain dilute urine throughout the day and night unless fluid restriction is needed for another health problem. Some urologists recommend sufficient fluid

intake to result in at least 1.5 L of urine output or 7 to 12 voidings daily. Food can provide 20% or more of fluid intake, particularly the intake of fruits and vegetables.

Cranberry-containing products taken daily appear to decrease the ability of bacteria to adhere to the epithelial cells lining the urinary tract. In some patients, this may result in preventing UIT or decreasing the incidence of recurrent symptomatic UTIs, but the evidence is not high quality (Allan & Nicole, 2013). Cranberry juice, tablets, or capsules must be consumed for more than 4 weeks to affect the ability of *E. coli* to adhere to the urinary tract (Foxman et al., 2015). Cranberry juice can be an irritant to the bladder with interstitial cystitis and should be avoided by patients with this condition. Avoiding caffeine, carbonated beverages, and tomato products may decrease bladder irritation and promote COMFORT during cystitis.

### Comfort Measures.

A warm sitz bath two or three times a day for 20 minutes may provide COMFORT and some relief of local symptoms. If burning with urination is severe or urinary retention occurs, teach the patient to sit in the sitz bath and urinate into the warm water. Urinary tract analgesics or antispasmodics may also provide comfort (see Chart 66-10).

### Surgical Management.

Surgery for cystitis treats the conditions that increase the risk for recurrent UTIs (e.g., removal of obstructions and repair of vesicoureteral reflux). Procedures may include cystoscopy (see Chapter 65) to identify and remove calculi or obstructions.

### Care Coordination and Transition Management

Assess the patient's level of understanding of the problem. Her or his knowledge about factors that promote the development of cystitis determines the teaching interventions planned.

Teach the patient how to take prescribed drugs. Stress the need for correct spacing of doses throughout the day and the need to complete all of the prescribed antibiotics. If the drug will change the color of the urine, as it does with phenazopyridine (Pyridium, Urogesic, Phenazo), inform the patient to expect this change.

Patients may associate discomfort with sexual activities and have feelings of guilt and embarrassment. Open and sensitive discussions with a woman who has recurrences of UTI after sexual intercourse can help her find techniques to handle the problem (see Chart 66-8). Explore with her the factors that contribute to her infections, such as sexual penetration when the bladder is full, diaphragm use, and her general IMMUNITY responses against infection. Some positions during intercourse may reduce urethral irritation and subsequent cystitis. Remind the patient that vigorous cleaning of the perineum with harsh soaps and vaginal douching may irritate the perineal tissues and *increase* the risk for UTI. At the patient's request, discuss the problem with her and her partner to help them find ways of maintaining their intimate relationship.

## NCLEX Examination Challenge 66-3

### Health Promotion and Maintenance

A 25-year-old sexually active female client diagnosed with cystitis tells the nurse that she doesn't understand why she has these infections yearly because she tries to avoid them by drinking very little at work so she doesn't have to use the "dirty" public toilet. Which suggestions or actions by the nurse are **most** likely to help this client reduce her risk for cystitis? **Select all that apply.**

- A. Reinforce her choice to avoid using a public toilet.
- B. Teach her to shower immediately after having sexual intercourse.
- C. Suggest that she drink at least 2-3 L of fluid throughout the day.
- D. Urge her to change her method of birth control from oral contraceptives to a barrier method.
- E. Instruct her to always wipe her perineum from front to back after each toilet use.

F. Reinforce that she should complete the entire course of antibiotics as prescribed.

G. Instruct her to empty her bladder immediately before having intercourse.

# Urethritis

## ❖ Pathophysiology

**Urethritis** is an inflammation of the urethra and can result from infectious and noninfectious conditions. The incidence is highest among adults ages 20 to 24 years. The most common cause of infectious urethritis is sexually transmitted infections (STIs). These include gonorrhea or nonspecific urethritis caused by *Ureaplasma* (a gram-negative bacterium), *Chlamydia* (a sexually transmitted gram-negative bacterium), or *Trichomonas vaginalis* (a protozoan found in both the male and female genital tract). Urethritis is also known as *pyuria-dysuria syndrome*, *frequency-dysuria syndrome*, *trigonitis syndrome*, and *urethral syndrome*.

Many women with urethritis have symptoms similar to cystitis, vaginitis, or cervicitis. Men with urethritis may report symptoms of cystitis, as well as heaviness in the genitals (*orchalgia*). Noninfectious urethritis in postmenopausal women may be related to uretero-genital tissue changes resulting from low estrogen levels.

Symptoms of urethritis include discharge of mucopurulent or purulent material, dysuria, and itching or discomfort of the area (urethral pruritus). The discharge can be any color, depending on the infecting organism or source of irritation. Additional symptoms may include fever (with or without chills) and urgent or frequent urination.

## ❖ Interprofessional Collaborative Care

Ask the patient about a history of STI, painful or difficult urination, discharge from the penis or vagina, and discomfort in the lower abdomen. Urinalysis may show **pyuria** (white blood cells [WBCs] in the urine) without a large number of bacteria. Similarly, a urethral smear may show WBCs. All patients with urethritis should be tested for *N. gonorrhoeae* and *C. trachoma* with an endourethral (in men) or endocervical (women) smear. Testing for *Chlamydia* may be done with the same sample. STI testing for VDRL serology and HIV is suggested by the Centers for Disease Control and Prevention (CDC, 2016a). A pregnancy test is performed for women who have had unprotected intercourse. In women, a pelvic examination may reveal tissue changes from low estrogen levels in the vagina. Urethroscopy may show low estrogen changes with inflammation of urethral tissues.

Noninfectious urethritis symptoms usually resolve spontaneously over time, regardless of treatment. Postmenopausal women often have improvement in urethral symptoms with the use of estrogen vaginal cream. Estrogen cream applied locally to the vagina increases the amount of estrogen in the urethra as well, reducing irritating symptoms. Urethritis from STIs is treated with antibiotic therapy. More information on STIs can be found in [Chapter 74](#).

# Urolithiasis

## ❖ Pathophysiology

**Urolithiasis** is the presence of *calculi* (stones) in the urinary tract. Stones often do not cause symptoms until they pass into the lower urinary tract, where they can cause excruciating pain.

**Nephrolithiasis** is the formation of stones in the kidney; formation of stones in the ureter is **ureterolithiasis**. Stones are particles in the urine that occur in amounts too high to stay dissolved (become supersaturated) in urine. As a result of supersaturation, the particles precipitate and collect to form calculi.

The most common condition associated with stone formation is dehydration. Everyone excretes crystals in the urine at some time, but fewer than 10% of adults form stones. Most stones contain calcium as one part of the stone complex. Struvite (15%), uric acid (8%), and cystine (3%) are more rare compositions of stones. Formation of stones involves two conditions:

1. Supersaturation of the urine with the particular element (e.g., calcium, uric acid) that first becomes crystallized and later becomes the stone
2. Formation of a *nidus* (deposit of crystals that can be the point of infection) along the lining of the kidney and urinary tract

In addition, some patients may have decreased amounts of inhibitor substances in the urine that would otherwise prevent supersaturation with crystal aggregation. This type of metabolic risk factor can be inherited.

In addition to low urine volume, high urine acidity (as with uric acid and cystine stones) or alkalinity (as with calcium phosphate and struvite stones), as well as drugs (e.g., topiramate, corticosteroids, indinavir, acetazolamide), contribute to stone formation.

One example of a metabolic problem causing stone formation begins when excessive amounts of calcium are absorbed through the intestinal tract, leading to hypercalciuria. As blood circulates through the kidneys, the excess calcium is filtered into the urine, causing supersaturation of calcium in the urine. If fluid intake is poor, such as when a patient is dehydrated, supersaturation is more likely to occur.

Any stone may result in obstruction within the urinary tract, which can threaten both glomerular filtration rate (GFR) and kidney perfusion. When the stone occludes the ureter and blocks the flow of urine, the ureter dilates. Enlargement of the ureter is called **hydroureter**.

The pain associated with ureteral spasm is excruciating and may cause the patient to go into shock from stimulation of nearby nerves. **Hematuria** (bloody urine) may result from damage to the urothelial lining. If the obstruction is not removed, urinary stasis can lead to infection and impair kidney function on the side of the blockage. As the blockage persists, **hydronephrosis** (enlargement of the kidney caused by blockage of urine lower in the tract and filling of the kidney with urine) and permanent kidney damage may develop.

## Etiology and Genetic Risk

The vast majority of adults who form stones have a metabolic risk factor. The cause of stone formation in a susceptible adult (e.g., one who has a metabolic risk factor) is dehydration. [Table 66-4](#) lists some metabolic problems that cause stone formation. Patients who are white, are obese, or have diabetes or gout (hyperuricemia) have increased risk for initial stone formation ([Rodgers, 2013](#)). Other conditions associated with stone formation and recurrence are hyperparathyroidism, urinary tract obstruction, inflammatory bowel diseases, and a history of GI problems ([Fink et al., 2013](#)). Because a metabolic problem is so strongly associated with stone formation and is a nonmodifiable risk factor, an adult of any age who develops a stone is always at high risk for future stone development.

---

**TABLE 66-4**  
**Metabolic Defects That Commonly Cause Kidney Stones**

---

METABOLIC

DEFICIT	
Hypercalcemia	
Primary	Absorptive: Increased intestinal calcium absorption Renal: Decreased kidney tubular excretion of calcium
Secondary	Resorptive: Hyperparathyroidism, vitamin D intoxication, kidney tubular acidosis, prolonged immobilization
Hyperoxaluria	
Primary	Genetic: Autosomal-recessive trait resulting in high oxalate production
Secondary	Dietary: Excess oxalate from foods such as spinach, rhubarb, Swiss chard, cocoa, beets, wheat germ, pecans, peanuts, okra, chocolate, and lime peel
Hyperuricemia	
Primary	Gout is an inherited disorder of purine metabolism (20% of patients with gout have uric acid calculi)
Secondary	Increased production or decreased clearance of purine from myeloproliferative disorders, thiazide diuretics, carcinoma
Struvite	Made of magnesium ammonium phosphate and carbonate apatite; formed by urea splitting by bacteria, most commonly, <i>Proteus mirabilis</i> ; needs an alkaline urine to form
Cystinuria	Autosomal-recessive defect of amino acid metabolism that precipitates insoluble cystine crystals in the urine

Diet is not considered a risk for stone formation. However, calcium (greater than 1000 mg daily) and vitamin D supplementation (greater than 800 IU daily) and high-dose ascorbic acid (vitamin C) intake have been implicated in stone formation (Fletcher, 2013). Conversely, high intake of fluid, fruits, and vegetables; low consumption of protein; and a balanced intake of fats and carbohydrates are prescribed to prevent and treat recurrent urolithiasis (Fink et al., 2013).

## Genetic/Genomic Considerations

### Patient-Centered Care QSEN

Family history has a strong association with stone formation and recurrence because of inherited metabolic variations. More than 30 genetic variations are associated with the formation of kidney stones, although single gene disorders are rare. More commonly, nephrolithiasis is a complex disease, with genetic variation in intestinal calcium absorption, kidney calcium transport, or kidney phosphate transport all associated with stone formation (Online Mendelian Inheritance in Man [OMIM], 2016). Always ask a patient with a renal stone whether other family members also have this problem.

### Incidence and Prevalence

The incidence of stone disease is high and varies with geographic location, race, and family history. About 12% of adults will have at least one episode of renal stone disease (McCance et al., 2014). The incidence of most stone types is higher in men, although struvite stones are twice as common in women. This difference in struvite stone formation incidence is thought to be related to the fact that women have more UTIs and struvite stones are associated with UTI. Recurrence rates vary depending on the type of treatment, although any adult who has had a stone is much more likely to have recurrence. Recurrence of stones occurs in patients with a family history of stone disease and in those who had their first occurrence by age 25 years.

## Cultural/Spiritual Considerations

### Patient-Centered Care QSEN

The incidence of stone disease is most common in the southeastern United States, Japan, and western Europe. Calcium stone disease is more common in men than in women and tends to occur in young adults or during early middle adulthood. Initial onset of stone disease occurs more often in younger adults than older adults and more commonly among white adults (Rodgers, 2013). For patients in these higher-risk groups, nursing care includes teaching family members, as well as patients, to avoid dehydration. Collaborate with the interprofessional health care team about referring patients with recurrent stone formation to evaluate metabolic risk factors.

## Interprofessional Collaborative Care

### Assessment: Noticing

Ask the patient about a personal or family history of urologic stones. Obtain a diet history, focusing on fluid intake patterns and supplemental vitamin or mineral intake. If he or she has a history of stone formation, ask about past treatment, whether chemical analysis of the stone was performed, and which preventive measures are followed.

The major symptom of stones is severe pain, commonly called **renal colic**. Flank pain suggests

The major symptom of stones is severe pain, commonly called **renal colic**. Flank pain suggests that the stone is in the kidney or upper ureter. Flank pain that extends toward the abdomen or to the scrotum and testes or the vulva suggests that stones are in the ureters or bladder. Pain is most intense when the stone is moving or the ureter is obstructed.

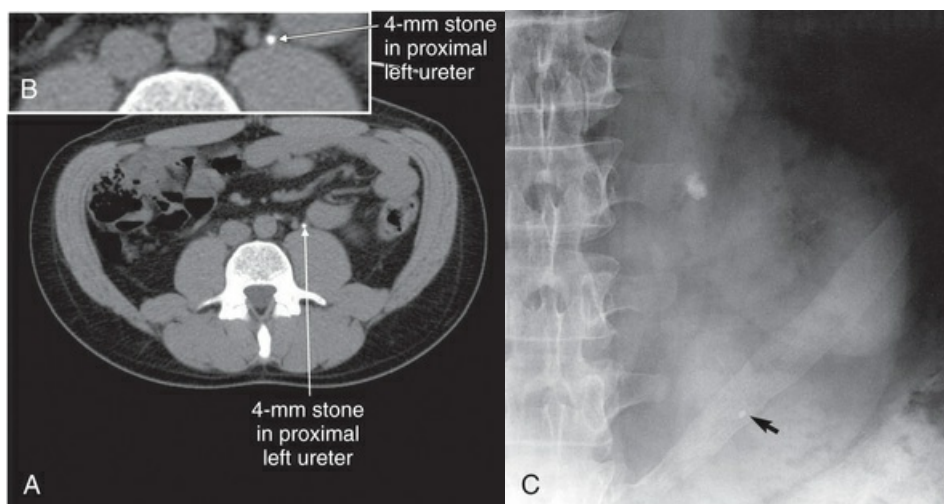

Renal colic begins suddenly and is often described as “unbearable.” Nausea, vomiting, pallor, and diaphoresis often accompany the pain. However, a large stationary stone in the kidney (staghorn calculus) rarely causes much pain because it is not moving. Frequency and dysuria occur when a stone reaches the bladder. **Oliguria** (scant urine output) or **anuria** (absence of urine output) suggests obstruction, possibly at the bladder neck or urethra. *Urinary tract obstruction is an emergency and must be treated immediately to preserve kidney function.*

Assess the patient for bladder distention. He or she may appear pale, ashen, and diaphoretic and may have excruciating pain. Vital signs may be elevated with pain; body temperature and pulse are elevated with infection. Blood pressure may decrease if the severe pain causes shock.

Urinalysis is performed in patients with suspected stones. Measurement of urine specific gravity and osmolarity can provide a clue about the adequacy of fluid intake. Urine pH can help in the determination of stone type. (High urine acidity [low urine pH] is associated with uric acid and cystine stones; high urine alkalinity [high urine pH] is associated with calcium phosphate and struvite stones.) A 24-hour urine analysis can determine whether supersaturation of common stone particles is present. Hematuria during renal colic is common, and blood may make the urine appear smoky or rusty. RBCs are usually caused by stone-induced trauma to the lining of the ureter, bladder, or urethra. WBCs and bacteria may be present as a result of urinary stasis. Increased *turbidity* (cloudiness) and odor indicate that infection may also be present. Microscopic examination of the urine may identify possible stone-forming crystals.

The serum WBC count is elevated with infection. Increases in the serum levels of calcium, phosphate, or uric acid levels indicate that excess minerals are present that may contribute to stone formation.

The current standard for confirming urinary stones is an unenhanced helical CT scan of the abdomen and pelvis. Most stones are radiopaque; and the size, location, and surrounding anatomic structures are easily seen. In settings where a CT is not available, a plain abdominal x-ray (KUB) is useful (Fig. 66-2). Ultrasound may be used in pregnant women suspected to have stones, but it is not sensitive for ureteral stones and is not used for general screening.

**FIG. 66-2** A and B, Urinary stones on CT scan. C, Urinary stones on x-ray of the kidneys, ureters, and bladder (KUB). (A and B from Broder, J. K. [2011]. *Diagnostic imaging for the emergency physician*. Philadelphia: Saunders. C from Pollack, H.M. [2000]. *Clinical urography* [2nd ed.]. Philadelphia: Saunders.)

### ◆ Interventions: Responding

Nursing interventions focus on promoting COMFORT and preventing infection and urinary obstruction. Most patients expel the stone without invasive procedures. Size (i.e., less than 5 mm) is the most important factor for whether a stone will pass on its own; its composition and location are

pass. When the stone is passed, it should be captured and sent to the laboratory for analysis. Other interventions are needed when the stone does not pass spontaneously (Fig. 66-3).

**FIG. 66-3** Treatment options for ureteral stones. ESWL, Extracorporeal shock wave lithotripsy. (Modified from Singal, R.K., & Denstedt, J.D. [1997]. Contemporary management of ureteral stones. *The Urologic Clinics of North America*, 24[1], 59-70.)

## Managing Pain.

Nonsurgical and surgical approaches are used to help the patient with a kidney stone achieve an acceptable degree of pain relief and COMFORT.

### Nonsurgical Management.

Nonsurgical measures to relieve pain include strategies to enhance stone passing, as well as direct pain management.

*Drug therapy* is needed in the first 24 to 36 hours when pain is most severe. Opioid analgesics are used to control the severe pain caused by stones in the urinary tract and may be given IV for rapid pain relief. NSAIDs such as ketorolac (Toradol) or ketoprofen (Nexcede) in the acute phase may be quite effective. When NSAIDs are used, there is an increased risk for kidney impairment from reduced perfusion. NSAIDs interfere with renal autoregulation, and the risk for impairment is greater among patients with pre-existing kidney dysfunction. Risk for bleeding also is increased from platelet inhibition when NSAIDs are used. Bleeding risk is particularly concerning when surgical intervention for stones is needed.

Control of pain and promotion of COMFORT are more effective when drugs are given at regularly scheduled intervals or by a constant delivery system (e.g., skin patch) instead of PRN. Spasmolytic drugs, such as oxybutynin chloride (Ditropan) and propantheline bromide (Pro-Banthine, Propanthel), are important for control of pain (see Chart 66-8). Give the drugs and assess the response by asking the patient to rate the discomfort on a pain-rating scale.

*Other management techniques* include avoiding overhydration and underhydration in the acute phase to help make the passage of a stone less painful. Strain the urine and teach the patient to strain it to monitor for stone passage. Send any stone passed to the laboratory for analysis because preventive therapy is based on stone composition.

Antibiotics may be used to manage struvite stones, because these are associated with urinary infections from urease-producing organisms such as *Proteus mirabilis*, *Klebsiella*, *Enterobacter*, or *Pseudomonas*. (*E. coli* does not produce urease.) When urease-producing bacteria remain in the urine and within the stone, urine becomes alkaline, causing phosphate to precipitate and allowing staghorn-shaped struvite stones to rapidly form.

Two drugs may be used to aid in stone expulsion: a thiazide diuretic and allopurinol. These

drugs, combined with a high fluid intake, increase urine volume or decrease urine pH and help increase the excretion of stones or stone fragments. Alpha-adrenergic blockers and calcium channel blockers can shorten the time to stone passage by relaxing the smooth muscle within the ureters. Citrate may be used to alkalinize urine pH and dissolve uric acid stones. Implementing oral citrate treatment cannot be done until stone composition is known. It is typically reserved for prevention and treatment of recurrent stone formation.

A stone that has not passed within 1 to 2 months is unlikely to pass spontaneously. Other options for stone intervention are considered when infection occurs, when pain cannot be well managed, or when there is an actual or increased risk for reduced kidney function. An observation period of 1 to 2 weeks may be reasonable if the patient is comfortable or has few symptoms and stones are smaller than 5 mm.

**Lithotripsy** or extracorporeal *shock wave lithotripsy (SWL)* is the use of sound, laser, or dry shock waves to break the stone into small fragments. The patient receives moderate sedation and lies on a flat table with the lithotripter aimed at the stone, which is located by fluoroscopy. A local anesthetic cream is applied to the skin site over the stone 45 minutes before the procedure. During the procedure, cardiac rhythm is monitored by ECG, and the shock waves are delivered in synchrony with the R wave. Shock waves at the rate of 60 to 120/min are applied over 30 to 45 minutes (Li et al., 2013). Continuous ECG monitoring for dysrhythmia and fluoroscopic observation for stone destruction are maintained.

After lithotripsy, strain the urine to monitor the passage of stone fragments. Bruising may occur on the flank of the affected side. Occasionally a stent is placed in the ureter before SWL to ease passage of the stone fragments.

### **Surgical Management.**

Minimally invasive surgical and open surgical procedures are used if urinary obstruction occurs or if the stone is too large to be passed.

### **Minimally Invasive Surgical Procedures.**

Minimally invasive surgical (MIS) procedures include stenting, ureteroscopy, percutaneous ureterolithotomy, and percutaneous nephrolithotomy.

*Stenting* is performed with a **stent**, a small tube that is placed in the ureter by ureteroscopy. The stent dilates the ureter and enlarges the passageway for the stone or stone fragments. This totally internal procedure prevents the passing stone from coming in contact with the ureteral mucosa, thereby reducing pain, bleeding, and infection risk, all of which could block the ureter. A Foley catheter may facilitate passage of the stone through the urethra.

*Ureteroscopy* is an endoscopic procedure. The ureteroscope is passed through the urethra and bladder into the ureter. Once the stone is seen, it is removed with grasping baskets, forceps, or loops. Lithotripsy also can be performed through the ureteroscope. A Foley catheter may be placed to facilitate passage of the stone fragments through the urethra.

*Percutaneous ureterolithotomy or nephrolithotomy* is the removal of a stone in the ureter or kidney through the skin. The patient lies prone or on the side and receives local or general anesthesia. The urologist or radiologist identifies the ideal entry point with fluoroscopy and passes a needle into the collecting system of the kidney. Once a tract has been made in the kidney, other equipment, such as an **intracorporeal** (inside the body) ultrasonic or laser lithotripter, can be used to break up and remove the stone. An endoscope with a special attachment to grasp and extract the stone can be used. Often a nephrostomy tube is left in place at first to prevent the stone fragments from passing through the urinary tract.

Monitor the patient for complications after the procedure. Complications include bleeding at the site or through the tube, pneumothorax, and infection. Monitor nephrostomy tube drainage for volume and the presence of blood in the urine, which is normal for the first 24 to 48 hours after tube placement. Provide routine nephrostomy tube care, with sterile dressing changes and tube flushing (if ordered).

### **Open Surgical Procedures.**

When other stone removal attempts have failed or when risk for a lasting injury to the ureter or kidney is possible, an *open ureterolithotomy* (into the ureter), *pyelolithotomy* (into the kidney pelvis), or *nephrolithotomy* (into the kidney) procedure may be performed. These procedures are used for a

or *nephrolithotomy* (into the kidney) procedure may be performed. These procedures are used for a large or impacted stone.

### Preoperative Care.

Explain to the patient how, when, and where the procedure will be performed. Describe what he or she can expect to see, hear, and feel before and after the procedure. The patient is given nothing by mouth and also receives a bowel preparation before the procedure. (See [Chapter 14](#) for routine care before surgery.)

### Operative Procedures.

The retroperitoneal area is entered through a large flank incision, as for nephrectomy (see [Chapter 67](#)), pyelolithotomy, or nephrolithotomy and through a lower abdominal incision for ureterolithotomy. The urinary tract is entered surgically, and the stone is removed. Before closure, tubes and drains may be placed (e.g., nephrostomy tube, ureteral stent, Penrose or other wound drainage device, and Foley catheter).

### Postoperative Care.

Follow routine procedures for assessment of the patient who has received anesthesia. (See [Chapter 16](#) for routine care after surgery.) Monitor the amount of bleeding from incisions and in the urine. Maintain adequate fluid intake. Strain the urine to monitor passage of stone fragments. Teach the patient how to prevent future stones with dietary changes, including consistent daily fluid intake to avoid dehydration and supersaturation.

## NCLEX Examination Challenge 66-4

### Safe and Effective Care Environment

A client with diabetes has all of the following changes after a percutaneous nephrolithotomy procedure. Which change is **most important** for the nurse need to immediately report to the health care provider?

- A. Difficulty breathing and an oxygen saturation of 88% on 2 L of oxygen by nasal cannula
- B. A point-of-care blood glucose of 150 mg/dL and client report of thirst
- C. A decreased hematocrit by 1% (compared with preoperative values and hematuria)
- D. An oral temperature of 38° C (101° F) and cloudiness of urine draining from the nephrostomy tube right after IV administration of a broad-spectrum antibiotic

### Preventing Infection.

Infection control before invasive procedures is critical for preventing urosepsis. Interventions include giving antibiotics, either to eliminate an existing infection or to prevent new infections, and maintaining nutrition and fluid intake. Because infection always occurs with struvite stone formation, the health care team plans for long-term infection prevention.

*Drug therapy* involves the use of quinolones, ampicillin, or other broad-spectrum antibiotics. When urine culture and sensitivity (C&S) results are known, more specific antibiotics may be prescribed. C&S studies are often repeated 48 hours after completion of antibiotic therapy to evaluate whether urine sterility has returned.

Urine levels of antibiotics may be measured to ensure that adequate levels have been reached. If the antibiotic is not sufficiently concentrated in urine, organisms may not be completely eliminated. Evidence of a new infection (e.g., chills, fever, and altered mental status) warrants the collection of urine sample for new C&S tests.

For the patient with struvite stones, periodic and long-term monitoring of the urine for infection is needed. Urine cultures are checked monthly for as long as 1 year. Long-term use of antibiotics, while recommended, makes the development of resistant organisms more likely and antibiotic therapy less effective. Drugs that prevent bacteria from splitting urea, such as acetohydroxamic acid

stones. Serum creatinine levels are monitored in patients receiving acetohydroxamic acid, and the drug is stopped if creatinine levels are above 2 mg/dL. Review interventions aimed at preventing urinary tract infection (UTI). (See the Health Promotion discussion in the [Cystitis](#) section.)

*Nutrition therapy* ideally includes adequate calorie intake with a balance of all food groups. Encourage a fluid intake sufficient to dilute urine to a light color throughout the 24-hour day (typically 2 to 3 L/day) unless another health problem requires fluid restriction.

### Preventing Obstruction.

Measures to prevent urinary obstruction by stones include a high intake of fluids (3 L/day or more) and accurate measures of intake and output. Fluid intake sufficient to provide diluted urine helps prevent dehydration, promotes urine flow, and decreases the chance of crystals forming a stone. Interventions also depend on the type of stone the patient has formed. Drugs, diet modification, and fluid intake are the major strategies used to prevent future stones.

*Drug therapy* to prevent obstruction depends on what is causing stone formation and the type of stone formed. Teach the patient the reason for the drug and assess for side effects or adverse drug reactions. Some drugs may need to be avoided because they may contribute to stone formation.

Drugs to treat *hypercalciuria* (high levels of calcium in the urine) include thiazide diuretics (e.g., chlorothiazide [Diuril] or hydrochlorothiazide [HydroDIURIL, Urozide ♣]). These drugs promote calcium reabsorption from the renal tubules back into the body, thereby reducing urine calcium loads. For patients with *hyperoxaluria* (high levels of oxalic acid in the urine), allopurinol (Zyloprim) or febuxostat (Uloric) is used.

For patients with hyperuricemia or chronic gout, both allopurinol and febuxostat help prevent the formation of urate (uric acid) stones. To alkalinize the urine, drugs such as potassium citrate, 50% sodium citrate, and sodium bicarbonate are used. Lemon or orange juice may also be ingested as a daily source of citrate. The desired urine pH is 6.0 to 6.5. Because the normal urine pH averages 5.0 to 6.0, the desired values are termed *alkaline*.

For patients with *cystinuria* (high levels of cystine in the urine), both alpha-mercaptopyrionylglycine (AMPG) and captopril (Capoten) lower urine cystine levels. They are used when hydration and urine alkalization have not been successful.

Statins (i.e., drugs used to manage hypercholesterolemia) have also been found to reduce the incidence of stone recurrence in some patients ([Sur et al., 2013](#)). Usually patients with one stone are advised to increase fluid intake. With two or more stones, drug therapy is advised based on the type of stone as described previously ([Fink et al., 2013](#)).

*Nutrition therapy* depends on the type of stone formed ([Table 66-5](#)). Collaborate with the dietitian to plan for and teach the appropriate diet to the patient.

**TABLE 66-5**  
**Dietary Treatment for Kidney and Urinary Stones**

STONE TYPE	DIETARY INTERVENTIONS	RATIONALES
Calcium oxalate	Avoid oxalate sources, such as spinach, black tea, and rhubarb.	Reduction of urinary oxalate content may help prevent these stones from forming. Urinary pH is not a factor.
	Decrease sodium intake.	High sodium intake reduces kidney tubular calcium reabsorption.
Calcium phosphate	Limit intake of foods high in animal protein to 5-7 servings per week and never more than 2 per day.	Reduction of protein intake reduces acidic urine and prevents calcium precipitation.
	Some patients may benefit from a reduced calcium intake (milk, other dairy products).	Reduction of urine calcium concentration may prevent calcium precipitation and crystallization.
	Decrease sodium intake.	High sodium intake reduces kidney tubular calcium reabsorption.
Struvite (magnesium ammonium phosphate)	Limit high-phosphate foods, such as dairy products, organ meats, and whole grains.	Reduction of urinary phosphate content may help prevent these stones from forming.
Uric acid (urate)	Decrease intake of purine sources, such as organ meats, poultry, fish, gravies, red wines, and sardines.	Reduction of urinary purine content may help prevent these stones from forming.
Cystine	Limit animal protein intake (as above).	Reduces urinary uric acid.
	Encourage oral fluid intake (500 mL every 4 hours while awake and 750 mL at night).	Increased fluid helps dilute the urine and prevents the cystine crystals from forming.

*Other measures* can help the stone pass more quickly. Urge the patient to walk as often as possible. Walking promotes passage of stones and reduces bone calcium resorption. Check the urine pH daily and strain all urine with filter paper or a special urine sieve/strainer to collect passed stones and fragments.

*Self-management education* includes the key points listed in [Chart 66-11](#). Follow-up care to evaluate effects of intervention includes a 24-hour urine collection and serum chemical analysis. The patient often has great anxiety and fear that a stone and its pain may recur. In addition to anxiety about the pain, the risk for repeated surgical interventions or permanent and serious kidney damage may be present. Psychosocial preparation is enhanced when patients know what to expect and which

actions to take if problems develop. Reassure the patient that preventive and health promotion activities help prevent recurrence.

#### **Chart 66-11**

## **Patient and Family Education: Preparing for Self-Management**

### **Urinary Calculi**

- Finish your entire prescription of antibiotics to ensure that you will not get a urinary tract infection.
- You may resume your usual daily activities.
- Remember to balance regular exercise with sleep and rest.
- You may return to work 2 days to 6 weeks after surgery, depending on the type of intervention, your personal tolerance, and your primary health care provider's directives.
- Depending on the type of stone you had, you may be advised to take medications or adjust your diet may to reduce the risk for further stone formation.
- Remember to drink at least 3 L of fluid a day to dilute potential stone-forming crystals, prevent dehydration, and promote urine flow.
- Monitor urine pH as directed (possibly up to three times per day).
- Expect bruising after lithotripsy. The bruising may be quite extensive and may take several weeks to resolve.
- Your urine may be bloody for several days after surgery.
- Pain in the region of the kidneys or bladder may signal the beginning of an infection or the formation of another stone. Report any pain, fever, chills, or difficulty with urination immediately to your primary health care provider or nurse.
- Keep follow-up appointments to check on infection and have repeat cultures done.

# Urothelial Cancer

## ❖Pathophysiology

Urothelial cancers are malignant tumors of the *urothelium*, which is the lining of transitional cells in the kidney, renal pelvis, ureters, urinary bladder, and urethra. Most urothelial cancers occur in the bladder, and the term *bladder cancer* describes this condition.

In North America, most urinary tract cancers are transitional cell carcinomas of the bladder (American Cancer Society [ACS], 2017; Canadian Cancer Society, 2016). The second most common site of urinary tract cancer is the kidney and renal pelvis. Urothelial cancers are usually low grade, have multiple points of origin (*multifocal*), and are recurrent. Once the cancer spreads beyond the transitional cell layer, it is highly invasive and can spread beyond the bladder. Because of the nature of this cancer, patients may have recurrence up to 10 years after being cancer free (ACS, 2017).

Tumors confined to the bladder mucosa are treated by simple excision, whereas those that are deeper but not into the muscle layer are treated with excision plus **intravesical** (inside the bladder) chemotherapy. Cancer that has spread deeper into the bladder muscle layer is treated with more extensive surgery, often a **radical cystectomy** (removal of the bladder and surrounding tissue) with urinary diversion. Chemotherapy and radiation therapy are used in addition to surgery. If untreated, the tumor invades surrounding tissues, spreads to distant sites (liver, lung, and bone), and ultimately leads to death.

Exposure to toxins such as gasoline and diesel fuel, as well as to chemicals used in hair dyes and in the rubber, paint, electric cable, and textile industries, increases the risk for bladder cancer. The greatest risk factor for bladder cancer is tobacco use. Other risks include *Schistosoma haematobium* (a parasite) infection, excessive use of drugs containing phenacetin, and long-term use of cyclophosphamide (Cytoxan, Procytox).

In the United States and Canada, about 87,730 new cases of bladder cancer are diagnosed each year, and about 19,190 deaths occur each year from the disease (ACS, 2017; Canadian Cancer Society, 2016). This cancer is rare in adults younger than 40 years and is most common after 60 years of age.

As with many urologic conditions, sexual health is commonly affected by this diagnosis and treatment (Dunn, 2015). To manage sexual health concerns, encourage patients to discuss sexual health and ensure that the proper interprofessional care team member provides education to patients and their partners about:

- Potential implications of treatment on sexuality
- Treatment options
- Referrals to providers who specialize in sexual dysfunction

## Health Promotion and Maintenance

Many adults believe that tobacco use is associated with cancers only of organs that come into direct contact with it, such as the lungs. However, many compounds in tobacco enter the bloodstream and affect other organs, such as the bladder. Therefore encourage everyone who smokes to quit and nonsmokers not to start (see the Health Promotion and Maintenance section of [Chapter 27](#)). Just as important, encourage anyone who comes in contact with dry, liquid, or gaseous chemicals to take precautions. Some adults work with chemicals, and others may come into contact with them while engaging in hobbies. Many chemicals and fumes can enter the body through contact with skin and with mucous membranes in the respiratory tract. Use of personal protective equipment, such as gloves and masks, can reduce this contact. Also encourage anyone who works with chemicals to shower or bathe and change clothing as soon as contact is completed.

## ❖NCLEX Examination Challenge 66-5

### Physiological Integrity

A 70-year-old client is seeing his primary care provider for an annual examination. Which

assessment finding alerts the nurse to an increased risk for bladder cancer?

- A. A five-pack year history of smoking 45 years ago
- B. Difficulty starting and stopping the urine stream
- C. A 30-year occupation as a long-distance truck driver
- D. A recent colon cancer diagnosis in his 72-year-old brother

## ❖ Interprofessional Collaborative Care

### ◆ Assessment: Noticing

#### Physical Assessment/Signs and Symptoms.

Ask about the patient's perception of his or her general health. Document the gender and age of the patient. Ask about active and passive exposure to cigarette smoke. To detect exposure to harmful environmental agents, ask the patient to describe his or her occupation and hobbies in detail. Also ask the patient to describe any change in the color, frequency, or volume of urine ELIMINATION and any abdominal discomfort.

Observe the patient's overall appearance, especially skin color and nutrition status. Inspect, percuss, and palpate the abdomen for asymmetry, tenderness, and bladder distention.

Examine the urine for color and clarity. Blood in the urine is often the first indication of bladder cancer. It may be gross or microscopic and is usually painless and intermittent. Dysuria, frequency, and urgency occur when infection or obstruction is also present.

#### Psychosocial Assessment.

Assess the patient's emotions, including his or her response to a tentative diagnosis of bladder cancer, and note anxiety, fear, sadness, anger, or guilt. Early symptoms are painless, and many patients ignore the blood in the urine because it is intermittent. They also may be reluctant to seek treatment if they suspect a sexually transmitted infection (STI). As a result, they may have guilt or anger about their own delays in seeking medical attention.

Assess the patient's coping methods and available support from family members. Social support may provide motivation and improve coping during recovery from treatment.

#### Diagnostic Assessment.

The only significant finding on a routine urinalysis is gross or microscopic hematuria. Cytologic testing on voided urine specimens usually is not helpful. Bladder-wash specimens and bladder biopsies are the most specific tests for cancer.

Cystoscopy is usually performed to evaluate painless hematuria. A biopsy of a visible bladder tumor can be performed during cystoscopy. This is essential for staging and is usually performed in an ambulatory care surgery center. Cystoureterography may be used to identify obstructions, especially where the ureter joins the bladder. CT scans show tumor invasion of surrounding tissues. Ultrasonography shows masses but is less valuable for tumor staging. MRI may help assess deep, invasive tumors.

### ◆ Interventions: Responding

Therapy for the patient with bladder cancer usually begins with surgical removal of the tumor for diagnosis and staging of disease. For tumors extending beyond the mucosa, surgery is followed by intravesical chemotherapy or immunotherapy. High-grade or recurrent tumors are treated with more radical surgery plus intravesical chemotherapy, radiotherapy, or both. Systemic chemotherapy is reserved for patients with distant metastases. (See [Chapter 22](#) for general care of the patient receiving chemotherapy or radiation therapy.)

#### Nonsurgical Management.

Prophylactic immunotherapy with intravesical instillation of bacille Calmette-Guérin (BCG), a live virus compound, is used to prevent tumor recurrence of superficial cancers. This procedure is more

effective than single-agent chemotherapy. Usually the agent is instilled in an outpatient cancer clinic and allowed to dwell in the bladder for a specified length of time, usually 2 hours. When the patient urinates, live virus is excreted with the urine.

Teach patients receiving this treatment to prevent contact of the live virus with other members of the household by not sharing a toilet with others for at least 24 hours after instillation. Instruct men to urinate while sitting down to avoid splashing the urine. After 24 hours, the toilet should be completely cleaned using a solution of 10% liquid bleach. If only one toilet is available in the household, teach the patient to flush the toilet after use and follow this by adding one cup of undiluted bleach to the bowl water. The bowl is then flushed after 15 minutes, and the seat and flat surfaces of the toilet wiped with a cloth containing a solution of 10% liquid bleach. Instruct the patient to wear gloves during the cleaning and to dispose of the cloth after sealing it in a plastic bag.

Underwear or other clothing that has come in contact with the urine during the immediate 24 hours after instillation should be washed separately from other clothing in a solution of 10% liquid bleach. Sexual intercourse is avoided for 24 hours after the instillation.

Multi-agent chemotherapy is successful in prolonging life after distant metastasis has occurred but rarely results in a cure. Radiation therapy is also useful in prolonging life.

### **Surgical Management.**

The type of surgery for bladder cancer depends on the type and stage of the cancer and the patient's general health. Complete bladder removal (*cystectomy*) with additional removal of surrounding muscle and tissue offers the best chance of a cure for large, invasive bladder cancers. Four alternatives for urine ELIMINATION are used after cystectomy: ileal conduit; continent pouch; bladder reconstruction, also known as *neobladder*; and ureterosigmoidostomy.

#### **Preoperative Care.**

Specific patient education depends on the type and extent of the planned surgical procedure. Coordinate education before surgery with the patient, surgeon, and enterostomal therapist (ET) or wound, ostomy, and continence nurse. Discuss the type of planned urinary diversion and the selection of a site for the stoma. Including the patient in this planning improves the chances for the patient to have a positive attitude about body image and a positive self-image. Use educational counseling to ensure understanding about self-care practices, methods of pouching, control of urine drainage, and management of odor.

The site selected for the stoma should be visible to the patient and avoid folds of skin, bones, and scar tissue. When possible, the waistline or belt area is avoided to reduce the risk for reducing TISSUE INTEGRITY. Prepare the patient for the number and type of drains that will be present after surgery. General care before surgery is discussed in [Chapter 14](#).

#### **Operative Procedures.**

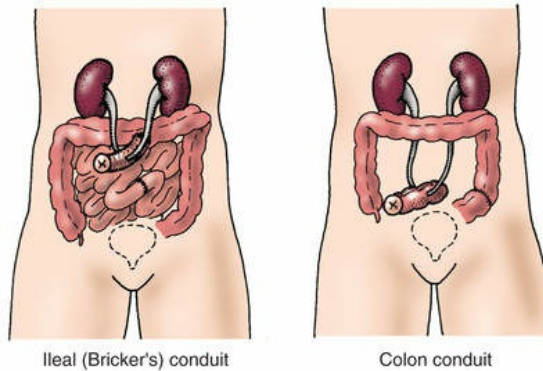

Transurethral resection of the bladder tumor (TURBT) or partial cystectomy is performed for small, early, superficial tumors. In a partial (segmental) cystectomy, a portion of the bladder is removed when there is only a single isolated bladder tumor.

When the entire bladder must be removed (complete cystectomy), the ureters are diverted into a collecting reservoir. Techniques for urinary diversion are shown in [Fig. 66-4](#). With an ileal conduit, the ureters are surgically placed in the ileum, and urine is collected in a pouch on the skin around the stoma. More often, a continent reservoir known as a "neobladder" is created from an intestinal graft to store urine and replace the surgically removed bladder. With cutaneous ureterostomy or ureteroureterostomy, the ureter opening is brought out onto the skin. The cutaneous ureterostomies may be located on either side of the abdomen or side by side.

**Ureterostomies** divert urine directly to the skin surface through a ureteral skin opening (stoma). After ureterostomy, the patient must wear a pouch.

**Conduits** collect urine in a portion of the intestine, which is then opened onto the skin surface as a stoma. After the creation of a conduit, the patient must wear a pouch.

**Ileal reservoirs** divert urine into a surgically created pouch, or pocket, that functions as a bladder. The stoma is continent, and the patient removes urine by regular self-catheterization.

**Sigmoidostomies** divert urine to the large intestine, so no stoma is required. The patient excretes urine with bowel movements, and bowel incontinence may result.

Continent internal ileal reservoir (Kock's pouch)

**FIG. 66-4** Urinary diversion procedures used in the treatment of bladder cancer.

### Postoperative Care.

After cutaneous ureterostomy, an external pouch covers the ostomy to collect urine and maintain **TISSUE INTEGRITY**. Work with the ET to focus care on the wound, the skin, and urinary drainage. (See [Chapter 56](#) for ostomy care.)

The patient with a Kock's pouch, a continent reservoir, may have a Penrose drain and a plastic Medena catheter in the stoma. The drain removes lymphatic fluid or other secretions; the catheter ensures urine drainage so incisions can heal. The patient with a neobladder usually requires 2 to 4 days in the ICU and will have a drain at first in the event the neobladder requires irrigation. Later, irrigation can be performed with intermittent catheterization. Irrigation is performed to ensure patency. There is no sensation of bladder fullness with a neobladder because sensory nerves are not attached. As a result, the patient will need to learn new cues to void, such as prescribed times or noticing a feeling of neobladder pressure. General care after surgery is discussed in [Chapter 16](#).

Different types of drains and nephrostomy catheters are used, sometimes on a temporary basis, to drain urine from the kidney. Some are totally internal, with no drainage to the outside. Others may drain exclusively to the outside, and urine is collected in a pouch or bag. For this type of drainage system, urine output remains constant. Decreased or no drainage is cause for concern and must be reported to the surgeon or nephrologist, as is leakage around the catheter. Some nephrostomy tubes

are connected both to the new bladder (internal drainage) and to an external drainage system. With this type of system, urine output from the external portion of the catheter varies. With any drainage system, intervention is needed if the external catheter is partially or completely pulled out accidentally. Immediately notify the surgeon or nephrologist. If the catheter remains partially in place, secure it from further movement. This action may result in a reinsertion process rather than a total replacement.

## Care Coordination and Transition Management

### Self-Management Education.

Teach the patient and family about drugs, diet and fluid therapy, the use of external pouching systems, and the technique for catheterizing a continent reservoir.

With some procedures, the patient may need electrolyte replacement to prevent long-term deficits. Teach him or her to avoid foods that are known to produce gas if the urinary diversion uses the intestinal tract. When intestinal production of gas is excessive, flatus can induce incontinence.

Patients who have a neobladder created often have extreme weight loss during the first few weeks after surgery. Collaborate with a dietitian to develop a diet plan specific to the patient to meet his or her caloric needs.

## Nursing Safety Priority QSEN

### Action Alert

Infection is common in patients who have a neobladder. Teach patients and family members the symptoms of infection and the importance of reporting them immediately to the surgeon.

Instruct the patient and family about any changes in self-care activities related to the urinary diversion. In collaboration with the enterostomal therapist, demonstrate external pouch application, local skin care, pouch care, methods of adhesion, and drainage mechanisms. If a Kock's pouch has been created, teach the patient how to use a catheter to drain the pouch. For all instruction, observe at least one return demonstration or "teach-back" session by the patient or the caregiver. Ideally the patient assumes responsibility for self-care before discharge.

Help the patient prepare for the impact of urinary diversion on self-image, body image, sexual functioning, and self-esteem. Counseling provides information and support to reduce feelings of powerlessness.

Through discussions with the patient about common social situations, help him or her gain control over new toileting practices. Men with a urinary diversion into the sigmoid colon need to learn the habit of sitting to urinate. For patients of either gender, promote confidence in social situations by encouraging frequent emptying of urinary collection devices before traveling or attending social functions. Resumption of sexual activity is a major concern for many, regardless of age. Address this topic openly and with sensitivity. Cystectomy causes impotence in men, but treatment is available (see [Chapter 72](#)).

### Health Care Resources.

The United Ostomy Association and the ACS have educational materials that may be useful to patients. Refer patients and family members to local chapters or units of these organizations. In some areas, local support groups have meetings to help others and to send visitors to provide peer counseling and support. Home care personnel may help with follow-up, easing the transition from hospital to home. The Wound, Ostomy, and Continence Nurses Society has educational programs and a journal for the care of patients with ostomies.

## Bladder Trauma

### ❖ Pathophysiology

Bladder trauma can be caused by penetrating or blunt injury to the lower abdomen. Penetrating injury may occur by stabbing, gunshot wound, or other trauma in which objects pierce the abdominal wall. A fractured pelvis with puncture of the bladder by bone fragments is the most common cause of bladder trauma. It also may result from sexual assault.

Blunt trauma compresses the abdominal wall and the bladder. A seat belt may compress the bladder hard enough to cause injury, especially when the bladder is full or distended.

### ❖ Interprofessional Collaborative Care

Patients with a penetrating bladder wound often have anuria or hematuria. In the emergency department, initial assessment includes inspection of the urinary meatus for blood.

Bladder trauma, other than a simple contusion, requires surgical intervention. When bone fractures are present, they are stabilized before bladder repair to prevent further bladder damage. Surgical interventions include repairing the bladder wall and peritoneal membrane. Usually repairs of the bladder are procedures to close the abnormal opening(s) caused by the trauma.

Patients with an anterior bladder wall injury usually have a Penrose drain and a Foley catheter in place after surgery. Those with a posterior bladder wall injury have a Penrose drain and Foley or suprapubic catheter after surgery. In some instances, vaginal or rectal fistulas may also require repair.

Psychosocial support is critical for patients who have sustained traumatic injuries. Refer them to counseling resources to help them deal with psychosocial issues.

# Get Ready for the NCLEX<sup>®</sup> Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Use sterile technique when inserting a catheter or any other instrument into the urinary system. **QSEN: Safety**
- Use Contact Precautions with any drainage from the genitourinary tract. **QSEN: Safety**
- Assess daily to determine whether there is an ongoing need for an indwelling catheter. **QSEN: Evidence-Based Practice**
- Teach patients and families of patients with urge or stress incontinence to keep pathways to the bathroom well lighted and clear of obstacles to help prevent falls. **QSEN: Safety**

### Health Promotion and Maintenance

- Teach patients to clean the perineal area daily, after voiding, after having a bowel movement, and after sexual intercourse. **QSEN: Patient-Centered Care**
- Encourage all patients to maintain an adequate fluid intake. **QSEN: Evidence-Based Practice**
- Teach women who have stress incontinence the proper way to perform pelvic floor–strengthening exercises. **QSEN: Patient-Centered Care**
- Urge adults who smoke to stop smoking. **QSEN: Evidence-Based Practice**
- Teach patients who come into contact with chemicals in their workplaces or with leisure-time activities to avoid direct skin and mucous membrane contact with these chemicals. **QSEN: Safety**

### Psychosocial Integrity

- Allow the patient the opportunity to express feelings or concerns regarding a potential chronic urinary tract disorder or a cancer diagnosis. **QSEN: Patient-Centered Care**
- Use a nonjudgmental approach in caring for patients with urinary incontinence. **QSEN: Patient-Centered Care**
- Avoid referring to protective pads, briefs, or pants as “diapers.” **QSEN: Patient-Centered Care**
- Recognize the need for the patient undergoing cystectomy and urinary diversion to grieve about the body image change. **QSEN: Patient-Centered Care**
- Assess the patient's level of COMFORT in discussing issues related to ELIMINATION and the urogenital area. **QSEN: Patient-Centered Care**
- Use language and terminology during kidney/urinary assessment that the patient is comfortable using. **QSEN: Patient-Centered Care**
- Refer patients to community resources and support groups. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Identify hospitalized patients at risk for bacteriuria and urosepsis. **QSEN: Evidence-Based Practice.**
- Report immediately any condition that obstructs urine flow. **QSEN: Safety**
- Instruct patients with UTI to complete all prescribed antibiotic therapy even when symptoms of infection are absent. **QSEN: Patient-Centered Care**
- Evaluate daily the indications for maintaining urinary catheters and discontinue their use as soon as possible. **QSEN: Evidence-Based Practice**

- Teach patients the expected side effects and any adverse reactions to prescribed drugs. **QSEN: Patient-Centered Care**
- Assess the patient's manual dexterity and cognitive awareness before teaching a regimen of intermittent self-catheterization. **QSEN: Patient-Centered Care**

## CHAPTER 67

# Care of Patients With Kidney Disorders

Chris Winkelman

## PRIORITY CONCEPTS AND INTERRELATED CONCEPTS

**The priority concept in this chapter is ELIMINATION.**

✚ The ELIMINATION concept exemplar for this chapter is Pyelonephritis, below.

**The interrelated concepts for this chapter are:**

- FLUID AND ELECTROLYTE BALANCE
- ACID-BASE BALANCE
- IMMUNITY
- CELLULAR REGULATION

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to coordinate high-quality care and promote urinary ELIMINATION in patients who have kidney disorders.
2. Teach the patient and caregiver(s) about home safety issues affected by impaired ELIMINATION and impairment of FLUID AND ELECTROLYTE BALANCE OR ACID-BASE BALANCE resulting from kidney problems.
3. Prioritize evidence-based care for patients with kidney disorders that impair urinary ELIMINATION.

### Health Promotion and Maintenance

4. Identify community resources for patients requiring assistance with any acute or chronic kidney problem.
5. Teach adults how to decrease the risk for kidney damage or kidney disease.

### Psychosocial Integrity

6. Implement nursing interventions to help the patient and family cope with the psychosocial impact caused by acute or chronic kidney disorders.

### Physiological Integrity

7. Apply knowledge of anatomy, physiology, pathophysiology, and genetics to assess patients with impaired kidney function affecting ELIMINATION, FLUID AND ELECTROLYTE BALANCE, OR ACID-BASE BALANCE.
8. Teach the patient and caregiver(s) about common drugs and other management strategies used for kidney disease, including pain control.
9. Implement evidence-based nursing interventions to prevent complications of kidney disorders and their therapies.

Healthy kidneys are the major controllers of urinary ELIMINATION. They perform this function by filtering wastes from the blood and selectively determining which substances remain in the body and which are eliminated. Thus the kidneys maintain homeostasis by contributing to FLUID AND ELECTROLYTE BALANCE and ACID-BASE BALANCE. Any problem that disrupts kidney function has the potential to impair general homeostasis and all aspects of urinary elimination (Fig. 67-1). Interaction with other organs and systems is necessary for the kidneys to function effectively. In addition,

when the kidneys are impaired, the buildup of toxic wastes affects all other body systems and can lead to life-threatening outcomes. This chapter describes a variety of infectious and noninfectious kidney disorders, kidney tumors, and kidney trauma. Acute kidney injury (AKI) and chronic kidney disease (CKD) are discussed in [Chapter 68](#).

**FIG. 67-1** Unbalanced body water, electrolytes, and waste products as a result of kidney problems that prevent adjustments in urinary elimination.

## Elimination Concept Exemplar Pyelonephritis

In the healthy adult, urine is normally sterile. Urinary tract infection (UTI) is an infection in any part of this normally sterile system. **Pyelonephritis** is a bacterial infection in the kidney and renal pelvis (McCance et al., 2014). It can be acute or chronic. Pyelonephritis interferes with urinary **ELIMINATION**, which is the excretion of waste from the body by the urinary system (as urine). Chapter 2 provides a summary of the concept of elimination in more detail.

### Pathophysiology

**Acute pyelonephritis** is an active bacterial infection, whereas **chronic pyelonephritis** results from repeated or continued upper urinary tract infections that occur almost exclusively in patients who have anatomic abnormalities of the urinary tract. Bacterial infection causes local (e.g., kidney) and systemic (e.g., fever, aches, and malaise) inflammatory symptoms.

In pyelonephritis, organisms usually move up from the urinary tract into the kidney tissue. This is more likely to occur when urine refluxes from the bladder into the ureters and then to the kidney. **Reflux** is the reverse or upward flow of urine toward the renal pelvis and kidney. Infection also can be transmitted by organisms in the blood, but this cause of pyelonephritis is rare unless the patient has impaired **IMMUNITY**.

Acute pyelonephritis involves **IMMUNITY** responses leading to acute tissue inflammation, local edema, tubular cell necrosis, and possible abscess formation. **Abscesses**, which are pockets of infection, can occur anywhere in the kidney. The infection is scattered within the kidney; healthy tissues can lie next to infected areas. Fibrosis and scar tissue develop from chronic inflammation in the kidney glomerular and tubular structures. As a result, filtration, reabsorption, and secretion are impaired; and kidney function is reduced (Fig. 67-2).

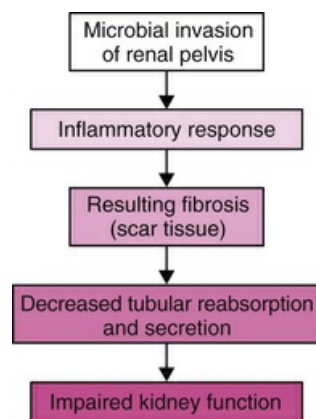

FIG. 67-2 Pathophysiology of pyelonephritis.

### Etiology and Genetic Risk

Single episodes of *acute pyelonephritis* result from bacterial infection, with or without obstruction or reflux. *Chronic pyelonephritis* usually occurs with structural deformities, urinary stasis, obstruction, or reflux. Conditions that lead to urinary stasis include prolonged bedrest and paralysis.

Obstruction can be caused by stones, kidney cancer, scarring from pelvic radiation or surgery, recurrent infection, or injury. Reflux may occur from scarring or result from anatomic anomalies. Reflux also results from bladder tumors, prostate enlargement, or urinary stones. Reduced bladder tone from diabetic neuropathy, spinal cord injury, and neurodegenerative diseases (e.g., spina bifida, multiple sclerosis) contributes to stasis and reflux.

Pyelonephritis from an ascending infection may follow manipulation of the urinary tract (e.g., placement of a urinary catheter), particularly in patients who have reduced **IMMUNITY** or diabetes. In patients with chronic kidney stone disease, stones may retain organisms, resulting in ongoing infection and kidney scarring. Drugs, such as high-dose or prolonged use of NSAIDs, can lead to

papillary necrosis and reflux.

The most common pyelonephritis-causing infecting organism among community-dwelling adults is *Escherichia coli*. *Enterococcus faecalis* is common in hospitalized patients. Both organisms are in the intestinal tract. Other organisms that cause pyelonephritis in hospitalized patients include *Proteus mirabilis*, *Klebsiella* species, and *Pseudomonas aeruginosa*. When the infection is bloodborne, common organisms include *Staphylococcus aureus* and the *Candida* and *Salmonella* species.

Other causes of kidney scarring contributing to increased risk for pyelonephritis are inflammatory responses resulting from IMMUNITY excesses with antibody reactions, cell-mediated immunity against the bacterial antigens, or autoimmune reactions.

### **Incidence and Prevalence**

Acute pyelonephritis is most common in women 20 to 30 years of age (Nicolle, 2016). Because chronic pyelonephritis is rarely characterized by infection alone, the incidence and prevalence is linked to the underlying condition or conditions that lead to relapsing inflammatory damage of the kidney. These conditions include congenital structural abnormality, neurogenic bladder dysfunction, or primary vesicoureteral reflux (Nicolle, 2016).

### **❖ Interprofessional Collaborative Care**

Depending on the severity of the disease, pyelonephritis may be managed in any care setting and in the community. About 20% of women with acute pyelonephritis are admitted to the hospital (Nicolle, 2016). The focus of care for patients with chronic pyelonephritis requires continuing attention to managing the structural or functional abnormality that contributes to recurrent infection and inflammatory fibrosis.

### **◆ Assessment: Noticing**

#### **History.**

Ask about recurrent urinary tract infections (UTIs), diabetes mellitus, stone disease, and known defects of the genitourinary tract. Ask about disease or treatment that results in reduced IMMUNITY, which also increases risk for pyelonephritis. Ask about kidney function; knowledgeable patients may be able to describe their stage of chronic kidney disease (CKD) if chronic pyelonephritis has led to permanent kidney damage. Ensure that a woman is not pregnant before radiographic imaging.

#### **Physical Assessment/Signs and Symptoms.**

Ask about specific symptoms of acute pyelonephritis (Chart 67-1). Chronic pyelonephritis has a less dramatic presentation but similar symptoms. Ask the patient to describe any urinary symptoms or abdominal discomfort. Inquire about any history of repeated low-grade fevers. Changes in urine color or odor may accompany bacteriuria. Chart 67-2 lists kidney-related effects of chronic pyelonephritis.

#### **▶ Chart 67-1**

### **Key Features**

#### **Acute Pyelonephritis**

- Fever
- Chills
- Tachycardia and tachypnea
- Flank, back, or loin pain
- Tenderness at the costovertebral angle (CVA)

- Abdominal, often colicky, discomfort
- Nausea and vomiting
- General malaise or fatigue
- Burning, urgency, or frequency of urination
- Nocturia
- Recent cystitis or treatment for urinary tract infection (UTI)

## Chart 67-2

### Key Features

#### Chronic Pyelonephritis

- Hypertension
- Inability to conserve sodium
- Decreased urine-concentrating ability, resulting in nocturia
- Tendency to develop hyperkalemia and acidosis

Inspect the flanks and gently palpate the costovertebral angle (CVA). Inspect both CVAs for enlargement, asymmetry, edema, or redness, all of which can indicate inflammation (Jarvis, 2016). If there is no tenderness to light palpation in either CVA, a primary health care provider firmly percusses each area. Tenderness or discomfort may indicate infection or inflammation.

#### Psychosocial Assessment.

Any infection in an older adult can lead to acute confusion. Assess the older adult who has new-onset confusion for signs and symptoms of urinary/renal infection.

The patient with any problem in the genitourinary area may have feelings of anxiety, embarrassment, or guilt. Listen for signs of anxiety or specific fears and prevent embarrassment during assessment. Feelings of guilt, often associated with sexual habits or practices, may be masked through delay in seeking treatment or through vague, nonspecific responses to specific or direct questions. Encourage patients to tell their own story in familiar, comfortable language.

#### Laboratory Assessment.

Urinalysis shows a positive leukocyte esterase and nitrite dipstick test and the presence of white blood cells (WBCs) and bacteria. Occasional red blood cells and protein may be present. The urine is cultured to determine the specific organisms causing the infection and the susceptibility or resistance of the specific organism to various antibiotics. The urine sample for culture and sensitivity testing is usually obtained by the clean-catch method. In patients with recurrent pyelonephritis, more specific testing of bacterial antigens and antibodies may help determine whether the same organism is responsible for the recurrent infections.

Blood cultures may be obtained to determine the source and spread of infectious organisms. Other blood tests include the WBC count and differential of the complete blood count, as well as C-reactive protein and erythrocyte sedimentation (ESR) rate to determine IMMUNITY responses and presence of inflammation. Serum tests of kidney function, such as blood urea nitrogen (BUN) and creatinine, are used as baseline and to trend recovery or deterioration. Estimate of glomerular filtration rate (GFR) also is used to trend kidney function.

#### Imaging Assessment.

An x-ray of the kidneys, ureters, and bladder (KUB) or CT is performed to visualize anatomy,

inflammation, fluid accumulation, abscess formation, and defects in kidneys and the urinary tract. These tests also identify stones, kidney tumors or cysts, or prostate enlargement. Urine reflux caused by incompetent bladder-ureter valve closure can be seen with a cystourethrogram. (See [Chapter 65](#) for more information on imaging assessment.)

### Other Diagnostic Assessment.

Other diagnostic tests include examining antibody-coated bacteria in urine, testing for certain enzymes (e.g., lactate dehydrogenase isoenzyme 5), and radionuclide renal scan. Examining urine for antibody-coated bacteria helps identify patients who may need long-term antibiotic therapy. High-molecular-weight enzymes in urine, such as lactate dehydrogenase isoenzyme 5, are present with any kidney tissue deterioration problem and give trend data. The renal scan can identify active pyelonephritis or abscesses in or around the kidney. A kidney biopsy may be performed to rule out less obvious causes of inflammation.

## NCLEX Examination Challenge 67-1

### Safe and Effective Care Environment

Which question does the nurse ask the client who has a urinary tract infection to assess the risk for possible pyelonephritis?

- A. What drugs do you take for asthma?
- B. How long have you had diabetes?
- C. How much fluid do you drink daily?
- D. Do you take your antihypertension drugs at night or in the morning?

### ◆Analysis: Interpreting

The priority collaborative problems for the patient with pyelonephritis are:

1. Pain (flank and abdominal) due to inflammation and infection
2. Potential for chronic kidney disease (CKD) disease due to kidney tissue destruction

### ◆Planning and Implementation: Responding

#### Managing Pain

##### Planning: Expected Outcomes.

With proper intervention, the patient with pyelonephritis is expected to achieve an acceptable state of comfort. Indicators include that he or she often or consistently demonstrates these behaviors:

- Uses pharmacologic relief measures
- Uses NSAIDs appropriately
- Uses best practices for catheter replacement when chronic catheter use is indicated
- Reports pain controlled

##### Interventions.

Interventions may be nonsurgical or surgical. Interventional radiologic techniques may be used to relieve obstruction or repair a stricture of the urinary tract.

##### Nonsurgical Management.

Interventions include the use of drug therapy, nutrition and fluid therapy, and teaching to ensure the patient's understanding of the treatment.

*Drug therapy* can reduce pain. Acetaminophen is preferred over NSAIDs because it does not

interfere with kidney autoregulation of blood flow. Reduction of fever will also reduce pain. Some patients may require the use of opioids in the short term for pain control.

Drug therapy with antibiotics is prescribed to treat the infection. At first the antibiotics are broad spectrum. After urine and blood culture and sensitivity results are known, more specific antibiotics may be prescribed. Antibiotics are given (usually IV in hospitalized patients; orally in community-dwelling patients) to achieve adequate blood levels or sterile blood culture results. A prophylactic antibiotic is not recommended for patients with impaired voiding or chronic catheter use because it does not limit recurrence or severity, of UTI (Nicolle, 2016).

*Catheter replacement* is supportive for a patient requiring a urinary catheter for 2 or more weeks (e.g., for neurogenic bladder or wound healing). This involves removal and replacement of the catheter and closed drainage system before starting antibiotic therapy. This intervention reduces bioburden by removing a device with a biofilm of concentrated organisms.

*Nutrition therapy* involves ensuring that the patient's nutrition intake has adequate calories from all food groups for healing to occur. A registered dietitian should be part of the interprofessional team. Fluid intake is recommended at 2 L/day, sufficient to result in dilute (pale yellow) urine, unless another health problem requires fluid restriction.

### **Surgical Management.**

Surgical interventions can correct structural problems causing urine reflux or obstruction of urine outflow or can remove the source of infection. Teach the patient the nature and purpose of the proposed surgery, the expected outcome, and how he or she can participate.

The surgical procedures may be one of these: **pyelolithotomy** (stone removal from the kidney), **nephrectomy** (removal of the kidney), ureteral diversion, or reimplantation of ureter(s) to restore proper bladder drainage.

A pyelolithotomy is needed for removal of a large stone in the kidney pelvis that blocks urine flow and causes infection. Nephrectomy is a last resort when all other measures to clear the infection have failed. For patients with poor ureter valve closure or dilated ureters, **ureteroplasty** (ureter repair or revision) or ureteral reimplantation (through another site in the bladder wall) preserves kidney function and eliminates infections.

### **Preventing Chronic Kidney Disease**

#### **Planning: Expected Outcomes.**

The patient is expected to conserve existing kidney function. Underlying genitourinary abnormalities must be identified, and appropriate interventions taken to manage a current infection and the risk for subsequent infections. The approach by the urologist or nephrologist depends on signs and symptoms as well as on patient history. Indicators include that he or she consistently demonstrates these behaviors:

- Describes the role of antibiotics and self-administration of drugs
- Explains and uses techniques to ensure adequate nutrition and hydration
- Describes the plan for post-treatment follow-up, including knowledge of recurrent symptoms
- Modifies prescribed regimen as directed by a health care professional

#### **Interventions.**

Specific antibiotics are prescribed to treat the infection. Stress the importance of completing the drug therapy as directed. Discuss with the patient and family the importance of regular follow-up examinations and completing the recommended diagnostic tests.

Blood pressure control slows the progression of kidney dysfunction. Ensure that the patient is able to detect adverse changes in blood pressure using community resources such as free blood pressure readings at community settings or retail pharmacies. When pyelonephritis causes or worsens CKD, ensure a referral to a nephrologist for additional assessment and management (see CKD in [Chapter 68](#)). Encourage the patient to drink sufficient fluid during waking hours to prevent dehydration because dehydration could further reduce kidney function. When dietary protein is restricted, a registered dietitian can help the family select appropriate food and proportions. Collaborate with the dietitian and reinforce the prescribed interventions.

### **Care Coordination and Transition Management**

Pyelonephritis may cause fear and anxiety in the patient and family. The severity of the acute process and its potential to develop into a chronic process are frightening. The patient and the family need reassurance that treatment and preventive measures can be successful.

### **Home Care Management.**

If no surgery is performed, the patient may need help with self-care, nutrition, and drug management at home. If surgery is performed, he or she may need help with incision care, self-care, and transportation for follow-up appointments.

### **Self-Management Education.**

After assessing the patient's and family's understanding of pyelonephritis and its therapy, explain:

- Drug regimen (purpose, timing, frequency, duration, and possible side effects)
- The role of nutrition and adequate fluid intake
- Best practices for chronic urinary catheter care, if needed
- The need for a balance between rest and activity, including any limitations after surgery
- The signs and symptoms of disease recurrence
- The use of previously successful coping mechanisms and community resources

Advise the patient to complete all prescribed antibiotic regimens and to report any side effects or unusual symptoms to the primary health care provider rather than stopping the drugs. Ensure that interprofessional care includes nutrition counseling, because many patients have special nutrition requirements, such as those for diabetes or pregnancy.

### **Health Care Resources.**

The patient may also briefly need a home health care nurse to help with drug or nutrition therapy at home. Housekeeping services may be helpful while he or she is regaining strength.

### **◆Evaluation: Reflecting**

Evaluate the care of the patient with pyelonephritis based on the identified priority patient problems. Expected outcomes may include that the patient will:

- Report that pain is controlled
- Be knowledgeable about the disease, its treatment, and interventions to prevent or reduce CKD progression

# Acute Glomerulonephritis

## ❖ Pathophysiology

Glomerulonephritis is categorized into conditions that primarily involve the kidney (primary glomerular nephritis) and those in which kidney involvement is only part of a systemic disorder (secondary glomerulonephritis). It is a group of diseases that injure and inflame the glomerulus, the part of the kidney that filters blood. Inflamed glomeruli allow passage of protein and blood in the urine. Glomerulonephritis is associated with high blood pressure, progressive kidney damage (leading to CKD), and edema. Anemia from reduced production of erythropoietin and high cholesterol often co-occur. Glomerulonephritis can cause altered urinary ELIMINATION.

**Acute glomerulonephritis** (GN) develops suddenly from an excess IMMUNITY response within the kidney tissues. Usually an infection is noticed before kidney symptoms of acute GN are present. The onset of symptoms is about 10 days from the time of infection. Usually patients recover quickly and completely from acute GN.

Many causes of primary GN are infectious (Table 67-1). Secondary glomerulonephritis can be caused by multi-system diseases (Table 67-2) and can manifest as acute or chronic disease. However, the division of primary and secondary glomerulonephritis is complex because diagnostic findings, histologic changes, and other changes are the same in both kidney and systemic disease, with both demonstrating altered IMMUNITY. Drugs and inherited disorders are also implicated in glomerulonephritis with an acute or chronic presentation.

**TABLE 67-1**

### Infectious Agents Associated With Glomerulonephritis

- Group A beta-hemolytic *Streptococcus*
- Staphylococcal or gram-negative bacteremia or sepsis
- Pneumococcal, *Mycoplasma*, or *Klebsiella pneumoniae*
- Syphilis
- Tuberculosis
- Hepatitis B and C
- Herpes
- Infectious mononucleosis
- Malaria
- Rocky Mountain spotted fever
- Cytomegalovirus infection
- Histoplasmosis
- Toxoplasmosis
- Varicella
- *Chlamydia psittaci* infection
- Coxsackievirus infection
- Any systemic bacterial, parasitic, fungal, or viral infection (potentially). Prompt antimicrobial and anti-inflammatory treatment reduces the risk for acute glomerulonephritis becoming a chronic condition.

**TABLE 67-2**

### Secondary Glomerular Diseases and Syndromes

- Systemic lupus erythematosus (SLE)
- Chronic pyelonephritis with vesicoureteral reflux
- Antiphospholipid antibody syndrome
- Small vessel vasculitis
- Allergic granulomatosis
- Henoch-Schönlein-Henoch purpura
- Goodpasture's syndrome and other basement membrane diseases
- Systemic necrotizing vasculitis
- Wegener's granulomatosis
- Periarthritis nodosa (also called *polyarteritis nodosa*)
- Fabry's disease
- Amyloidosis
- Diabetic glomerulopathy
- HIV-associated nephropathy
- Hereditary nephritis, including Alport's syndrome
- Multiple myeloma and other metastatic cancers
- Glomerular manifestations of sustained liver diseases (viral hepatitis B or C, autoimmune hepatitis, and cirrhosis)
- Sickle cell disease
- Hemolytic-uremic syndrome
- Thrombotic thrombocytopenia purpura

HIV, Human immune deficiency virus.

## ❖ Interprofessional Collaborative Care

### ◆ Assessment: Noticing

## History.

Ask about recent infections, particularly of the skin or upper respiratory tract, and about recent travel or other possible exposures to viruses, bacteria, fungi, or parasites. Recent illnesses, surgery, or other invasive procedures may suggest infection. Ask about any systemic diseases that alter IMMUNITY, such as systemic lupus erythematosus (SLE), which could cause acute GN.

## Physical Assessment/Signs and Symptoms.

Inspect the patient's skin for lesions or recent incisions, including body piercings, because these may be the source of organisms causing GN. Assess the face, eyelids, hands, and other areas for edema because edema is present in most patients with acute GN. Assess for fluid overload and pulmonary edema that may result from fluid and sodium retention occurring with acute GN. Ask about any difficulty breathing or shortness of breath. Assess for crackles in the lung fields, an S<sub>3</sub> heart sound (gallop rhythm), and neck vein distention.

Ask about changes in urine ELIMINATION patterns and any change in urine color, volume, clarity, or odor. The patient may describe blood in the urine as smoky, reddish brown, rusty, or cola colored. Ask about dysuria or oliguria. Weigh him or her to assess for fluid retention.

Take the patient's blood pressure and compare it with the baseline blood pressure. Mild-to-moderate hypertension occurs with acute GN as a result of impaired FLUID AND ELECTROLYTE BALANCE with fluid and sodium retention. The patient may have fatigue, a lack of energy, anorexia, nausea, and/or vomiting if uremia from severe kidney impairment is present.

## Considerations for Older Adults

### Patient-Centered Care QSEN

The less common symptoms of acute GN are more likely to occur in older adults. Circulatory congestion and pulmonary edema often are present, causing acute GN to be easily confused with new onset of acute exacerbation of heart failure (AEHF) (Touhy & Jett, 2016). Ask any older adult with symptoms of circulatory overload mimicking heart failure about urine ELIMINATION patterns to determine whether the problem may be related to acute GN.

## Laboratory Assessment.

Urinalysis shows red blood cells (*hematuria*) and protein (*proteinuria*). An early morning specimen of urine is preferred for urinalysis because the urine is concentrated, most acidic, and filled with more intact formed elements at that time. Microscopic examination often shows red blood cell casts, as well as casts from other substances.

A 24-hour urine collection for total protein assay is obtained. The protein excretion rate for patients with acute GN may be increased from 500 mg/24 hr to 3 g/24 hr. Serum albumin levels are decreased because this protein is lost in the urine and fluid retention causes dilution.

Serum creatinine and BUN provide information about kidney function and may be elevated, indicating impairment of ELIMINATION. The glomerular filtration rate (GFR), either estimated from a single serum and urine creatinine value or measured by the 24-hour urine test for creatinine clearance, may be decreased to 50 mL/min. Recall that the older adult has a decline in GFR, which may make GFR results challenging to interpret.

Other tests for indicators of IMMUNITY problems include antistreptolysin-O titers, C3 complement levels, cryoglobulins, antinuclear antibodies (ANAs), and circulating immune complexes. Testing for human immune deficiency virus (HIV) is recommended. Blood, skin, or throat cultures may be obtained.

Antistreptolysin-O titers are increased after group A beta-hemolytic *Streptococcus* infections. Complement levels are decreased when the complement system is activated. Type III cryoglobulins may be found during acute illness. ANAs suggest an IMMUNITY excess (autoimmune response), and systemic lupus erythematosus (SLE) is just one possibility. Serum immune complexes containing IgG and C3 are often detected.

## Other Diagnostic Assessment.

A kidney biopsy provides a precise diagnosis of the condition, assists in determining the prognosis,

and helps outline treatment (see [Chapter 65](#)). The specific tissue features are determined by light microscopy, immunofluorescent stains, and electron microscopy to identify cell type, the presence of immunoglobulins, or the type of tissue deposits.

### ◆ **Interventions: Responding**

Interventions focus on managing infection, preventing complications, and providing appropriate patient education.

*Managing infection* as a cause of acute GN begins with appropriate antibiotic therapy. Penicillin, erythromycin, or azithromycin is prescribed for GN caused by streptococcal infection. Check the patient's known allergies before giving any drug. Stress personal hygiene and basic infection control principles (e.g., handwashing) to prevent spread of the organism. Teach patients the importance of completing the entire course of the prescribed antibiotic.

*Modifying immunity* with drugs can also benefit patients with acute glomerulonephritis that is not due to acute infection but is related to excessive inflammation. Corticosteroids and cytotoxic drugs (e.g., cyclosporine, cyclophosphamide) to suppress IMMUNITY responses may be used. Patients receiving immunosuppressants need to take precautions to avoid exposure to new infections (see [Chapters 19](#) and [20](#) for more information).

*Preventing complications* is an important nursing intervention, especially when FLUID AND ELECTROLYTE BALANCE is disrupted. For patients with fluid overload, hypertension, and edema, diuretics and sodium and water restrictions are prescribed. The usual fluid allowance is equal to the 24-hour urine output plus 500 to 600 mL. Patients with oliguria usually have increased serum levels of potassium and blood urea nitrogen (BUN). Potassium and protein intake may be restricted to prevent hyperkalemia and uremia as a result of the elevated BUN. Antihypertensive drugs may be needed to control hypertension (see [Chapter 36](#)).

Nausea, vomiting, or anorexia indicates that uremia is present. Dialysis is necessary if uremic symptoms or fluid volume excess cannot be controlled with nutrition therapy and fluid management (see [Chapter 68](#)). *Plasmapheresis* (removal and filtering of the plasma to eliminate antibodies) also may be used (see [Chapter 40](#)).

Coordinate care to conserve patient energy and balance activity with rest to maintain function. Relaxation techniques and diversional activities can reduce emotional stress.

*Preparing for self-management* includes teaching the patient and family members about the purpose of prescribed drugs, the dosage and schedule, and potential adverse effects. Ensure that they understand diet and fluid restrictions. Advise the patient to measure weight and blood pressure daily at the same time each day. Instruct him or her to notify the primary health care provider of any sudden increase in weight or blood pressure.

If short-term dialysis is required to control FLUID AND ELECTROLYTE BALANCE or uremic symptoms, explain vascular access care and dialysis schedules and routines (see [Chapter 68](#)).

**Rapidly progressive glomerulonephritis (RPGN)** is a primary glomerulonephritis also called *crenscentic glomerulonephritis* because of the presence of crescent-shaped cells in the Bowman's capsule. RPGN develops acutely over several weeks or months. Patients become quite ill quickly and have symptoms of kidney impairment (fluid volume excess, hypertension, oliguria, electrolyte imbalances, and uremic symptoms). Regardless of treatment, RPGN often progresses to end-stage kidney disease (ESKD).

## ■ **NCLEX Examination Challenge 67-2**

### **Health Promotion and Maintenance**

When assessing a client with acute glomerulonephritis, which question about self-management will the nurse ask to determine whether the client is currently following best practices to slow progression of kidney damage?

- A. "Have you increased your protein intake to promote healing of the damaged nephrons?"
- B. "Do you avoid contact sports while you're taking cyclosporine?"
- C. "How are you evaluating the amount of daily fluid you drink?"

D. "Have you contacted anyone from our dialysis support services?"

# Chronic Glomerulonephritis

## ❖ Pathophysiology

Chronic glomerulonephritis, or *chronic nephritic syndrome*, develops over years to decades. Mild proteinuria and hematuria, hypertension, fatigue, and occasional edema are often the only symptoms.

Although the exact cause is not known, changes in kidney tissue result from infection, hypertension, inflammation from IMMUNITY excess, or poor kidney blood flow. Kidney tissue atrophies, and functional nephrons are greatly reduced. Biopsy in the late stages of atrophy may show glomerular changes, cell loss, protein and collagen deposits, and fibrosis of the kidney tissue. Microscopic examination shows deposits of immune complexes and inflammation.

The loss of nephrons reduces glomerular filtration. Hypertension and renal arteriole sclerosis are often present. The glomerular damage allows proteins to enter the urine. Chronic glomerulonephritis always leads to end-stage kidney disease (ESKD) (see [Chapter 68](#)).

## ❖ Interprofessional Collaborative Care

### ◆ Assessment: Noticing

#### History.

Ask about other health problems, including systemic diseases, kidney or urologic disorders, infectious diseases (i.e., streptococcal infections), and recent exposures to infections. Ask about overall health status and whether increasing fatigue and lethargy have occurred.

Identify the patient's urine ELIMINATION pattern. Ask whether the frequency of voiding has increased or the quantity of urine has decreased. Ask about changes in urine color, odor, or clarity and whether dysuria or incontinence has occurred. Nocturia is a common symptom.

Assess the patient's general comfort and ask whether new-onset dyspnea has occurred because fluid overload can occur with decreased urine output. Ask about and observe for changes in cognition (i.e., irritability, an inability to read, or incapacity during job-related functions) or disturbed concentration. Changes in memory and the ability to concentrate occur as waste products collect in the blood.

#### Physical Assessment/Signs and Symptoms.

Assess for systemic circulatory overload. Auscultate lung fields for crackles, observe the respiratory rate and depth, and measure blood pressure and weight. Assess the heart rate, rhythm, and presence of an S<sub>3</sub> heart sound. Inspect the neck veins for venous engorgement and check for edema of the feet and ankles, on the shins, and over the sacrum.

Assess for uremic symptoms, such as slurred speech, ataxia, tremors, or **asterixis** (flapping tremor of the fingers or the inability to maintain a fixed posture with the arms extended and wrists hyperextended). Inspect skin for a yellowish color, texture changes, bruises, rashes, or eruptions. Ask about itching and document areas of dryness or any excoriation from scratching.

#### Psychosocial Assessment.

A diagnosis of chronic glomerulonephritis is associated with psychosocial responses of uncertainty, loss, and fear of the need for lifestyle changes as the disease progresses. While obtaining the history, listen carefully for spoken and unspoken feelings of anger, resentment, futility, sadness, or anxiety, all of which may need further exploration.

#### Diagnostic Assessment.

Urine output decreases; and urinalysis shows protein, usually less than 2 g in a 24-hour collection. The specific gravity is fixed at a constant level of dilution (around 1.010) despite variable fluid intake. Red blood cells and casts may be in the urine.

The glomerular filtration rate (GFR) is low. The serum creatinine level is elevated, usually greater than 6 mg/dL (500 μmol/L) but may be as high as 30 mg/dL (2500 μmol/L) or more because of

poor waste ELIMINATION. The BUN is increased, often as high as 100 to 200 mg/dL (35 to 70 mmol/L).

Decreased kidney function disturbs FLUID AND ELECTROLYTE BALANCE. Sodium retention is common, but dilution of the plasma from excess fluid can result in a falsely normal serum sodium level (135 to 145 mEq/L [mmol/L]) or a low sodium level (less than 135 mEq/L [mmol/L]). When oliguria develops, potassium is not excreted, and hyperkalemia occurs when levels exceed 5.4 mEq/L (mmol/L).

Hyperphosphatemia develops with serum levels greater than 4.7 mg/dL (1.73 mmol/L). Serum calcium levels are usually low normal or are slightly below normal.

Disturbances of ACID-BASE BALANCE with acidosis develop from hydrogen ion retention and loss of bicarbonate. However, there may be a decrease in serum carbon dioxide (CO<sub>2</sub>) levels as patients breathe more rapidly to compensate for the acidosis. If respiratory compensation is present, the pH of arterial blood is between 7.35 and 7.45. A pH of less than 7.35 means that the patient's respiratory system is not completely compensating for the acidosis (see [Chapter 12](#)).

The kidneys are abnormally small on x-ray or CT in chronic glomerulonephritis.

### ◆ **Interventions: Responding**

Interventions focus on slowing the progression of the disease and preventing complications. Management is systemic and consists of diet changes, fluid intake sufficient to prevent reduced blood flow to the kidneys, and drug therapy to control the problems from uremia. Eventually ELIMINATION is so impaired that the patient requires dialysis or transplantation to prevent death. (Care for the patient requiring dialysis or transplantation is discussed in [Chapter 68](#).)

# Nephrotic Syndrome

## ❖ Pathophysiology

**Nephrotic syndrome (NS)** is an immunologic kidney disorder in which glomerular permeability increases so larger molecules pass through the membrane into the urine and are then excreted. This process causes massive loss of protein into the urine, edema formation, and decreased plasma albumin levels. Many agents and disorders are possible causes of NS. All glomerulonephritis diseases have features of nephrosis (Pendergraft et al., 2016)

The most common cause of glomerular membrane changes is altered IMMUNITY with inflammation. Defects in glomerular filtration can also occur as a result of genetic defects of the glomerular filtering system, such as Fabry disease. Altered liver function may occur with NS, resulting in increased lipid production and hyperlipidemia.

## ❖ Interprofessional Collaborative Care

The main feature of NS is increased protein ELIMINATION with severe proteinuria (with more than 3.5 g of protein in a 24-hour urine sample). Patients also have low serum albumin levels of less than 3 g/dL (30 g/L), high serum lipid levels, fats in the urine, edema, and hypertension (Chart 67-3). Renal vein thrombosis often occurs at the same time as NS, either as a cause of the problem or as an effect. NS may progress to end-stage kidney disease (ESKD), but treatment can prevent progression.

### ▶ Chart 67-3

## Key Features

### Nephrotic Syndrome

Sudden onset of these symptoms:

- Massive proteinuria
- Hypoalbuminemia
- Edema (especially facial and periorbital)
- Lipiduria
- Hyperlipidemia
- Delayed clotting or increased bleeding with higher-than-normal values for serum activated partial thromboplastin time (aPTT) coagulation or international normalized ratio for prothrombin (INR, PT)
- Reduced kidney function with elevated blood urea nitrogen (BUN) and serum creatinine and decreased glomerular filtration rate (GFR)

Management varies, depending on which process is causing the disorder (identified by kidney biopsy). Excess IMMUNITY may improve with suppressive therapy using steroids and cytotoxic or immunosuppressive agents. Angiotensin-converting enzyme inhibitors (ACEIs) can decrease protein loss in the urine, and cholesterol-lowering drugs can improve blood lipid levels. Heparin may reduce vascular defects and improve kidney function. Diet changes are often prescribed. If the glomerular filtration rate (GFR) is normal, dietary intake of proteins is needed. If the GFR is decreased, protein intake must be decreased. Mild diuretics and sodium restriction may be needed to control edema and hypertension. Assess the patient's hydration status because vascular dehydration is common. If plasma volume is depleted, kidney problems worsen. Acute kidney injury (AKI) may be avoided if adequate blood flow to the kidney is maintained.

# Nephrosclerosis

## ❖Pathophysiology

**Nephrosclerosis** is a degenerative disorder resulting from changes in kidney blood vessels. Nephron blood vessels thicken, resulting in narrowed lumens and decreased kidney blood flow. The tissue is chronically hypoxic, with ischemia and fibrosis developing over time.

Nephrosclerosis occurs with all types of hypertension, atherosclerosis, and diabetes mellitus. The more severe the hypertension, the greater the risk for severe kidney damage. Nephrosclerosis is rarely seen when blood pressure is consistently below 160/110 mm Hg. The changes caused by hypertension may be reversible or may progress to end-stage kidney disease (ESKD) within months or years.

Hypertension is the second leading cause of ESKD, with many patients requiring kidney replacement therapy (e.g., dialysis or transplantation).

## 🏠Cultural/Spiritual Considerations

### Patient-Centered Care QSEN

Hypertension is more common in African Americans and American Indians, and the risks for ESKD from hypertension are also greater for these ethnic groups (U.S. Renal Data Systems, 2015). Between 25 and 45 years of age, the ratio of African Americans to Caucasians at risk for ESKD from hypertension is nearly 20 : 1. At any health care encounter with an African-American or American Indian patient, blood pressure should always be assessed. If hypertension is present, treatment and patient education can help reduce the risk for development of ESKD.

## ❖Interprofessional Collaborative Care

Management focuses on controlling high blood pressure and reducing albuminuria to preserve kidney function. Although many antihypertensive drugs may lower blood pressure, the patient's response is important in ensuring long-term adherence to the prescribed therapy. Factors that promote adherence include once-a-day dosing, low cost, and minimal side effects.

Lack of knowledge or misinformation about hypertension poses many challenges to health care professionals working with patients who have hypertension. When kidney disease occurs, adherence to therapy is even more important for preserving health.

Many drugs can control high blood pressure (see [Chapter 36](#)), and more than one agent may be needed for best control. Angiotensin-converting enzyme inhibitors (ACEIs) are very useful in reducing hypertension and preserving kidney function. Diuretics can maintain FLUID AND ELECTROLYTE BALANCE in the presence of kidney function insufficiency. Hyperkalemia needs to be prevented when potassium-sparing diuretics, alone or in combination with other diuretics, are used to treat hypertensive patients with known kidney disease.

# Polycystic Kidney Disease

## ❖ Pathophysiology

**Polycystic kidney disease (PKD)** is a genetic disorder in which fluid-filled cysts develop in the nephrons (Fig. 67-3). Relentless development and growth of cysts from loss of CELLULAR REGULATION and abnormal cell division result in progressive kidney enlargement. PKD is associated with hypertension, abdominal fullness and pain, episodes of cyst bleeding, hematuria, kidney stone formation, infections, and systemic disease (Chapman et al., 2015).

**FIG. 67-3** External surface (A) and internal surface (B) of a polycystic kidney. From Kumar, V., Abbas, A., Fausto, N., & Aster, J. (2010). *Robbins and Cotran pathologic basis of disease* (8th ed.). Philadelphia: Saunders.)

The cysts look like clusters of grapes (see Fig. 67-3). Over time, growing cysts damage the glomerular and tubular membranes. Each cystic kidney enlarges, becoming the size of a football, and may weigh 10 lb or more each. As cysts fill with fluid and become larger, kidney function becomes less effective, and urine formation and waste ELIMINATION are impaired.

Most patients with PKD have high blood pressure. The cause of hypertension is related to kidney ischemia from the enlarging cysts. As the vessels are compressed and blood flow to the kidneys decreases, the renin-angiotensin system is activated, raising blood pressure. Control of hypertension is a top priority because proper treatment can disrupt the process that leads to further kidney damage, as well as avoid complications such as stroke from hypertension.

Cysts may also occur in the liver and blood vessels. The incidence of cerebral *aneurysms* (outpouching and thinning of an artery wall) is higher in patients with PKD. Aneurysms may rupture, causing bleeding and sudden death. For unknown reasons, kidney stones occur in many patients with PKD. Heart valve problems (e.g., mitral valve prolapse), left ventricular hypertrophy, and colonic diverticula also are common in patients with PKD.

## Etiology and Genetic Risk

Kidney cysts are genetically and clinically related to many symptoms and problems. PKD can be inherited as either an autosomal-dominant trait or, less often, as an autosomal-recessive trait. Autosomal-dominant PKD is the most common inherited kidney disease. People who inherit the recessive form of PKD usually die in early childhood. The 5% to 10% incidence of PKD in patients with no family history occurs as a result of a new gene mutation. The number of genes that influence PKD is challenging and requires that geneticists and genetic counselors be a part of the

interprofessional team caring for patients with or at risk for the disease (Chapman et al., 2015). A clear genetic diagnosis can be made in about 90% of patients undergoing genetic testing when kidney cysts occur (Ong et al., 2015).

## Genetic/Genomic Considerations

### Patient-Centered Care QSEN

Autosomal-dominant PKD (ADPKD) is the most common form of the disease in adults, with a 50% risk of passing the mutated gene to their children. Fig. 67-4 shows a pedigree for a family with ADPKD. The onset, symptoms, and severity can vary; however, nearly 100% of people who inherit a PKD gene mutation will develop kidney cysts by age 30 (Online Mendelian Inheritance in Man [OMIM], 2016). ADPKD-1 is the most common and most severe form of the autosomal-dominant disease. ADPKD-2 has a slower rate of cyst formation, symptoms, and progression to end-stage kidney disease (ESKD) (OMIM, 2013).

**FIG. 67-4** Four-generation pedigree for autosomal-dominant polycystic kidney disease (ADPKD). Colored-in symbols indicate family members with ADPKD. Slashes indicate that the person has died.

There is no way to prevent PKD, although early detection and management of hypertension may slow the progression of kidney damage and impaired ELIMINATION. Genetic counseling may be useful for adults who have one parent with PKD. Family history analysis is used to help identify people at risk (see Fig. 67-4).

### Incidence and Prevalence

PKD affects about 600,000 people of all ethnic groups in the United States (National Kidney Foundation, 2016). Men and women have an equal chance of inheriting the disease because the gene responsible for PKD is on an autosome (see Chapter 5).

## Interprofessional Collaborative Care

### Assessment: Noticing

Because PDK is a chronic disease with periods of acute problems, most management occurs in the community rather than in an acute care hospital. With acute problems or when surgery is needed, initial care is in a hospital setting, and continuing care can occur in any setting.

### History.

Explore the family history of a patient with suspected or actual PKD and ask whether either parent was known to have PKD or whether there is any family history of kidney disease. Important information to obtain is the age at which the problem was diagnosed in the parent and any related complications. Ask about pain, abdominal discomfort, constipation, changes in urine color or frequency, hypertension, headaches, and a family history of stroke or sudden death.

### Physical Assessment/Signs and Symptoms.

Chart 67-4 lists key features of PKD. Pain is often the first symptom. Inspect the abdomen. A distended abdomen is common as the cystic kidneys swell and push the abdominal contents

forward. Polycystic kidneys are easily palpated because of their increased size. Use *gentle* abdominal palpation because the cystic kidneys and nearby tissues may be tender and palpation is uncomfortable. The patient also may have flank pain as a dull ache or as a sharp and intermittent discomfort. Dull, aching pain is caused by increased kidney size with distention, abnormal stimulation of sensory neurons in the kidney, or infection within the cyst. Sharp, intermittent pain occurs when a cyst ruptures or a stone is present. When a cyst ruptures, the patient may have bright red or cola-colored urine. Infection is suspected if the urine is cloudy or foul smelling or if there is **dysuria** (pain on urination).

#### Chart 67-4

### Key Features

#### Polycystic Kidney Disease

- Abdominal or flank pain
- Hypertension
- Nocturia
- Increased abdominal girth
- Constipation
- Bloody or cloudy urine
- Sodium wasting and inability to concentrate urine in early stage
- Progression to kidney failure with anuria

**Nocturia** (the need to urinate excessively at night) is an early symptom and occurs because of decreased urine concentrating ability. Patients with early PKD often have hyperfiltration leading to wasting of sodium and water, which disrupts FLUID AND ELECTROLYTE BALANCE. Later, as kidney function declines (i.e., reduced glomerular filtration rate [GFR]), the patient retains water and sodium, which causes hypertension, edema, and uremic symptoms such as anorexia, nausea, vomiting, pruritus, and fatigue (see [Chapter 68](#)). Because intracranial berry aneurysms often occur in patients with PKD, a severe headache with or without neurologic or vision changes requires attention.

#### Psychosocial Assessment.

A PKD diagnosis is associated with psychosocial responses of uncertainty, loss, and fear ([Tong et al., 2015](#)). The patient may have had a parent who died or relatives who required dialysis or transplantation. Listen for spoken and unspoken feelings of anger, resentment, futility, sadness, or anxiety. Such feelings may need further exploration. Feelings of guilt and concern for the patient's children may also complicate the issue.

#### Diagnostic Assessment.

Ultrasonography is used to provide initial screening for PKD. The definitive diagnostic test is an MRI. CT scan with angiography may be used to assess kidney perfusion. A finding of five or more kidney cysts on MRI is diagnostic of PKD ([Chapman et al., 2015](#)). Estimation of kidney size by MRI or CT helps determine total kidney volume and disease progression.

Urinalysis may show **proteinuria** (protein in the urine), which indicates a decline in kidney function and impaired ELIMINATION. Hematuria may be gross or microscopic. Bacteria in the urine indicate infection, usually in the cysts. Obtain a urine sample for culture and sensitivity testing when there is evidence of infection. As kidney function declines, serum creatinine and blood urea nitrogen (BUN) levels rise. With further decline, creatinine clearance decreases, and the GFR is low. Changes in kidney handling of sodium may cause either sodium losses or sodium retention.

Genetic testing is not routinely performed for diagnostic assessment of PKD. It may be considered for patients who have atypical imaging findings or for those with symptoms who have no family history of PKD.

### ◆ **Interventions: Responding**

Currently no treatments are effective in extending kidney function in PKD. Drug therapies to interrupt the pathways that promote malignant cyst formation such as molecular signaling for cell division or endothelial growth are being evaluated. Supportive interventions for PKD include management of hypertension and pain, reducing complications from infection and constipation, and slowing disease progression. Be attentive to the psychosocial issues of uncertainty and fear related to an inherited disorder, as well as reproductive issues. Genetic counseling is part of comprehensive care of the patient and family experiencing PKD.

When the disease progresses and the kidneys no longer function for waste ELIMINATION, care becomes similar to that needed for the patient with end-stage kidney disease (see [Chapter 68](#)).

### **Managing Blood Pressure.**

Blood pressure control is necessary to reduce cardiovascular complications and slow the progression of kidney dysfunction. Nursing interventions include education for self-management. Initially patients with PKD may have salt-wasting and should **NOT** follow a sodium-restricted diet. As the disease progresses and *sodium retention* occurs, restricting sodium may then help control blood pressure. See [Chapter 36](#) for hypertension management.

Drug therapy for blood pressure control is a mainstay of treatment when the disease progresses. Achieving a blood pressure goal of 120/80 slows kidney growth from cyst formation and sustains kidney function ([Chapman et al., 2015](#)). The most effective antihypertensive agents for PKD are angiotensin-converting enzyme inhibitors (ACEIs) ([Ong et al., 2015](#)). These drugs also help control the cell growth aspects of PKD and reduce microalbuminuria. ACEIs can cause birth defects and are contraindicated during pregnancy. Additional antihypertensive drugs, such as calcium channel blockers, beta blockers, and vasodilators, may be used (see [Chapter 36](#)).

Teach the patient and family how to measure and record blood pressure. Help the patient establish a schedule for self-administering drugs, monitoring daily weights, and keeping blood pressure records ([Chart 67-5](#)). Explain the potential side effects of the drugs. Make available written materials, such as drug teaching cards and booklets. Work with the patient and a dietitian to develop strategies to manage sodium and other dietary issues that contribute to hypertension.

#### **Chart 67-5**

### **Patient and Family Education: Preparing for Self-Management**

#### **Polycystic Kidney Disease**

- Measure and record your blood pressure daily and notify your primary health care provider for consistent changes in blood pressure.
- Take your temperature if you suspect you have a fever. If a fever is present, notify your physician or nurse.
- Weigh yourself every day at the same time of day and with the same amount of clothing; notify your primary health care provider or nurse if you have a sudden weight gain.
- Limit your intake of salt to help control your blood pressure once hyperfiltration is no longer a symptom of your disease (once chronic kidney disease [CKD] is present).
- Notify your primary health care provider or nurse if your urine smells foul or has a new occurrence of blood in it.
- Notify your primary health care provider or nurse if you have a headache that does not go away

or if you have visual disturbances because these are symptoms of a stroke or bleeding in the brain.

- Monitor bowel movements to prevent constipation.

### Managing Pain.

Because PKD-related pain is chronic, a multidisciplinary pain management approach is helpful. Drugs may include opioids along with acetaminophen. NSAIDs are used cautiously because they can reduce kidney blood flow. Aspirin-containing drugs are avoided to reduce bleeding risk.

Complementary therapy includes positioning and the application of dry heat to the abdomen or flank. Teach the patient methods of relaxation and comfort using deep breathing, guided imagery, or other strategies (see [Chapter 4](#) for pain management). When pain is severe, cysts can be reduced by needle aspiration and drainage; however, they usually refill. When the quality or severity of pain abruptly increases, assess for infection.

### Reducing Complications from Infection.

Fever, abdominal pain, and either leukocytosis or serum markers of inflammation (e.g., elevated erythrocyte sedimentation rate [ESR] or C-reactive protein [CRP]) may be associated with cystic or systemic infection. Blood and urine cultures may or may not be positive with cyst infection. Early infection management can prevent or reduce complications and acute kidney injury. Monitor serum creatinine levels because some antibiotics are nephrotoxic.

Percutaneous or surgical drainage of the cyst may be indicated. Prepare the patients similarly to a kidney biopsy described in [Chapter 65](#).

### Preventing Constipation.

Teach the patient who has adequate urine output to prevent constipation by maintaining adequate fluid intake (generally 2 to 3 L daily in food and beverages), maintaining dietary fiber intake, and exercising regularly. Explain that pressure on the large intestine may occur as the polycystic kidneys increase in size. These recommendations for bowel management might change, particularly when ESKD develops. Advise the patient about the use of stool softeners and bulk agents, including careful use of laxatives, to prevent chronic constipation.

### Slowing Progression of Chronic Kidney Disease.

Early in the disease when patients have hyperfiltration with decreased urine concentration, nocturia, and low specific gravity, urge them to drink at least 2 L of fluid daily to prevent dehydration, which can further reduce kidney function. Hyperfiltration may persist for several years. Maintaining adequate fluid intake can reduce the vasopressin release that reduces kidney blood flow.

As the disease progresses, protein intake may be limited to slow the development of ESKD. Help the patient and family understand the diet plan and why it was prescribed. Work closely with the dietitian to foster the patient's understanding.

Strategies for kidney protection include the use of a vasopressin-suppressing agent such as tolvaptan (Samsca, Jinarc) to improve blood flow, slow kidney volume growth, and sustain kidney function. The use of “statin” drugs to reduce the growth of kidneys has not yet been proven effective in adults with PKD ([Chapman et al., 2015](#)).

## Care Coordination and Transition Management

### Health Care Resources.

The Polycystic Kidney Research Foundation ([www.pkdcure.org](http://www.pkdcure.org)) and the National Kidney & Urologic Diseases Clearinghouse (NKUDIC) of the National Institute of Diabetes and Digestive and Kidney Diseases ([www.niddk.nih.gov](http://www.niddk.nih.gov)) conduct research and provide education about PKD. Many pamphlets are available; there is a fee for some materials. Chapters of the National Kidney Foundation (NKF) and the American Association of Kidney Patients (AAKP) also have resources for information and support.

## NCLEX Examination Challenge 67-3

### Health Promotion and Maintenance

Which statement made by a client newly diagnosed with polycystic kidney disease (PKD) in the hyperfiltration stage indicates to the nurse that additional teaching for self-management is needed?

- A. "I'll need to decrease my daily water intake."
- B. "I need to make certain my brothers and sisters know about this disease."
- C. "Probably the best time of day to take my lisinopril each day is with breakfast."
- D. "Regular low-impact exercise may help me feel better and help prevent constipation."

## Hydronephrosis and Hydroureter

### ❖ Pathophysiology

Hydronephrosis and hydroureter are problems of urinary ELIMINATION with outflow obstruction. Urethral strictures obstruct urine outflow and may contribute to bladder distention, hydroureter, and hydronephrosis. Prompt recognition and treatment are crucial to preventing permanent kidney damage.

In **hydronephrosis**, the kidney enlarges as urine collects in the renal pelvis and kidney tissue. Because the capacity of the renal pelvis is normally 5 to 8 mL, obstruction in the renal pelvis or at the point where the ureter joins the renal pelvis quickly distends the renal pelvis. Kidney pressure increases as the volume of urine increases. Over time, sometimes in only a matter of hours, the blood vessels and kidney tubules can be damaged extensively (Fig. 67-5).

**FIG. 67-5** Hydronephrosis is caused by obstruction in the upper part of the ureter. Hydroureter is caused by obstruction in the lower part of the ureter.

In patients with **hydroureter** (enlargement of the ureter), the effects are similar, but the obstruction is in the ureter rather than in the kidney. The ureter is most easily obstructed where the iliac vessels cross or where the ureters enter the bladder. Ureter dilation occurs above the obstruction and enlarges as urine collects (see Fig. 67-5).

Urinary obstruction causes damage when pressure builds up directly on kidney tissue. Tubular filtrate pressure also increases in the nephron as drainage through the collecting system is impaired and glomerular filtration decreases or ceases. Kidney necrosis can occur. Nitrogen waste products (urea, creatinine, and uric acid) and electrolytes (sodium, potassium, chloride, and phosphorus) are retained, and ACID-BASE BALANCE is impaired.

Causes of hydronephrosis or hydroureter include tumors, stones, trauma, structural defects, and fibrosis (McCance et al., 2014). With cancer, obstructed ureters may result from tumors pressing on the ureters, pelvic radiation, or surgical treatment. Early treatment of the causes can prevent ureteral problems and permanent kidney damage. The time needed to prevent permanent damage depends on the patient's kidney health. Permanent damage can occur in less than 48 hours in some patients and after several weeks in other patients.

## ❖ Interprofessional Collaborative Care

### ◆ Assessment: Noticing

Obtain a history from the patient, focusing on known kidney or urologic disorders. A history of childhood urinary tract problems may indicate previously undiagnosed structural defects. Ask about his or her usual pattern of urinary ELIMINATION, especially amount, frequency, color, clarity, and odor. Ask about recent flank or abdominal pain. Chills, fever, and malaise may be present with a urinary tract infection (UTI).

Inspect each flank to identify asymmetry, which may occur with a kidney mass, and *gently* palpate the abdomen to locate areas of tenderness. Palpate and percuss the bladder to detect distention, or use a bedside bladder scanner (see [Chapter 65](#)). Gentle pressure on the abdomen may cause urine leakage, which reflects a full bladder and possible obstruction.

Urinalysis may show bacteria or white blood cells if infection is present. When urinary tract obstruction is prolonged, microscopic examination may show tubular epithelial cells. Blood chemistries are normal unless glomerular filtration has decreased and waste ELIMINATION is impaired. Blood creatinine and BUN levels increase with a reduced GFR. Serum electrolyte levels may be altered with elevated blood levels of potassium, phosphorus, and calcium along with a metabolic acidosis (bicarbonate deficit). Urinary outflow obstruction can be seen with ultrasound (US) or CT.

### ◆ Interventions: Responding

Urinary retention and potential for infection are the primary problems. Failure to treat the cause of obstruction leads to infection and acute kidney injury (AKI).

#### Urologic Interventions.

If obstruction is caused by a kidney stone (calculus), it can be located and removed using cystoscopic or retrograde urogram procedures. See [Chapter 66](#) for more information about kidney stone management. After stone removal, a plastic stent is usually left in the ureter for a few weeks to improve urine flow in the area irritated by the stone. The stent is later removed by another cystoscopic procedure.

#### Radiologic Interventions.

When an abnormal narrowing of the urinary tract (**stricture**) causes hydronephrosis and cannot be corrected with urologic procedures, a **nephrostomy** is performed. Most nephrostomy drains provide only external drainage (diversion). Other styles of nephrostomy drains enter the kidney and extend to the bladder, draining urine out to a bag or past a ureteral obstruction and into the bladder. With these, there are both internal and external parts to the nephrostomy tubing. Externally, a fully external or an internal/external diversion drain appears the same. The urine output will fluctuate more if all urine goes to the bladder before external drainage.

#### Patient Preparation.

If possible, the patient is kept NPO for 4 to 6 hours before the procedure. Clotting studies (e.g., international normalized ratio [INR], prothrombin time [PT], and partial thromboplastin time [PTT]) should be normal or corrected. Drugs are used to reduce hypertension. The patient receives moderate sedation for the procedure.

#### Procedure.

The patient is placed in the prone position. The kidney is located under ultrasound or fluoroscopic guidance, and a local anesthetic is given. A needle is placed into the kidney, a soft-tipped guidewire is placed through the needle, and then a catheter is placed over the wire. The catheter tip remains in the renal pelvis, and the external end is connected to a drainage bag. The procedure immediately relieves the pressure and prevents further damage. The nephrostomy tube remains in place until the obstruction is resolved.

#### Follow-up Care.

Assess the amount of drainage in the collection bag. The amount of drainage depends on whether a ureteral catheter is also being used (with a separate drainage bag). Patients with ureteral tubes may

have all urine pass through to the bladder or may have it drain into the collection bags. The type of urine drainage system placed must be clearly communicated in the chart. If urine is expected to drain into the collection bag, assess the amount of drainage hourly for the first 24 hours. If the amount of drainage decreases and the patient has back pain, the tube may be clogged or dislodged.

Monitor the nephrostomy site for leaking urine or blood. Urine drainage may be bloody for the first 12 to 24 hours after the procedure and should gradually clear. If prescribed, the nephrostomy tube can be irrigated with 5 mL sterile saline to check patency and dislodge clots. It is common for diuresis to occur when a nephrostomy is placed for obstruction. Monitor intake and output hourly for the first several hours, and inform the surgeon if the patient begins to have symptoms of dehydration (i.e., hypotension, poor skin turgor, dry mucous membranes, increased thirst). Assess for indications of infection (i.e., fever, change in urine character).

## Nursing Safety Priority QSEN

### Critical Rescue

After nephrostomy, monitor the patient to recognize indications of complications (i.e., decreased or absent drainage, cloudy or foul-smelling drainage, leakage of blood or urine from the nephrostomy site, back pain). If any indications are present, respond by notifying the surgeon immediately.

## NCLEX Examination Challenge 67-4

### Physiological Integrity

When providing care to a client who has undergone a nephrotomy for hydronephrosis, which observation alerts the nurse to a possible complication? **Select all that apply.**

- A. Urine output of 15 mL for the first hour and then diminished
- B. Tenderness at the surgical site
- C. Pink-tinged urine draining from the nephrostomy
- D. A hematocrit value 3% lower than the preoperative value
- E. Sudden onset of abdominal pain that worsens after abdominal palpation
- F. Blood pressure of 180/90 that persists despite administration of pain medication
- G. The presence of a few small (less than 0.5 cm) clots with irrigation of the nephrostomy
- H. Bright red drainage through the nephrostomy tube 12 hours after the procedure

# Renovascular Disease

## ❖ Pathophysiology

Processes affecting the renal arteries may severely narrow the lumen and greatly reduce blood flow to the kidney tissues. Uncorrected renovascular disease, such as renal vein thrombosis or renal artery stenosis, atherosclerosis, or thrombosis, causes ischemia and atrophy of kidney tissue, leading to severe impairment of urinary ELIMINATION, FLUID AND ELECTROLYTE BALANCE, and ACID-BASE BALANCE.

Patients with renovascular disease, particularly those older than 50 years of age, often have a sudden onset of hypertension. Patients with high blood pressure but no family history of hypertension also may potentially have renal artery stenosis (RAS). RAS from atherosclerosis or blood vessel hyperplasia is the main cause of renovascular disease. Other causes include thrombosis and renal vessel aneurysms.

Atherosclerotic changes in the renal artery often occur along with sclerosis in the aorta and other major vessels. Renal artery changes are often located where the renal artery and aorta meet. Fibrotic changes of the blood vessel wall occur throughout the length of the renal artery.

## ❖ Interprofessional Collaborative Care

### ◆ Assessment: Noticing

Key features of renovascular disease are listed in [Chart 67-6](#). Hypertension usually first occurs after age 40 to 50, and often the patient does not have a family history of hypertension. Diagnosis is made by magnetic resonance angiography (MRA), renal ultrasound, radionuclide imaging, or renal arteriography. MRA provides an excellent image of the renal vasculature and kidney anatomy. Radionuclide imaging is a noninvasive way of evaluating kidney blood flow and excretory function. Combining radionuclide imaging with ingestion of an angiotensin-converting enzyme (ACE) inhibitor such as lisinopril (Prinivil, Zestril) improves the accuracy of the test. A renal arteriogram makes the features of the renal blood vessels visible.

### ▶ Chart 67-6

## Key Features

### Renovascular Disease

- Significant, difficult-to-control high blood pressure
- Poorly controlled diabetes or sustained hyperglycemia
- Elevated serum creatinine
- Decreased glomerular filtration rate (GFR)

### ◆ Interventions: Responding

Identifying the type of defect, extent of narrowing, and condition of the surrounding blood vessels is critical for treatment choice as is the patient's overall health. Many patients with renovascular disease also have cardiovascular disease, and both conditions require treatment.

RAS may be managed by drugs to control high blood pressure and by procedures to restore the blood supply to the kidney. Drugs may control high blood pressure but may not lead to long-term preservation of kidney function. In younger adults, a lifetime of treatment with many drugs for high blood pressure makes treatment difficult and outcomes uncertain.

Endovascular techniques are nonsurgical approaches to repair RAS. Stent placement with or without balloon angioplasty is an example of an endovascular intervention (see [Chapter 36](#)). These techniques are less risky and require less time for recovery than does renal artery bypass surgery. After the procedure, the patient usually remains under close observation for 24 hours to monitor for

sudden blood pressure fluctuations as the kidneys adjust to increased blood flow.

Renal artery bypass surgery is a major procedure and requires 2 or more months for recovery. A bypass may be performed for either one or both renal arteries. A synthetic blood vessel graft is inserted to redirect blood flow from the abdominal aorta into the renal artery, beyond the area of narrowing. A splenorenal bypass can also restore blood flow to the kidney. The process is similar to other arterial bypass procedures (see [Chapter 38](#)).

## Diabetic Nephropathy

**Diabetic nephropathy** is a vascular complication of diabetes mellitus (DM) and the leading cause of end-stage kidney disease (ESKD) in North America (U.S. Renal Data Systems, 2015). It occurs with either type 1 or type 2 DM. Severity of diabetic kidney disease is related to the degree of hyperglycemia the patient generally experiences. With poor control of hyperglycemia, the complicating problems of atherosclerosis, hypertension, and neuropathy (which promotes loss of bladder tone, urinary stasis, and urinary tract infection) are more severe and more likely to cause kidney damage. Chapter 64 discusses diabetic nephropathy. Management of diabetic nephropathy is the same as for chronic kidney disease (see Chapter 68).

### NCLEX Examination Challenge 67-5

#### Safe and Effective Care Environment

The charge nurse is preparing assignments on a busy medical unit. For this shift, there are two LPNs, two RNs, and one nursing assistant. Which client assignments are **most** appropriate? **Select all that apply.**

- A. An LPN is assigned to a client who is receiving the first dose of an oral immunomodulating agent to manage acute glomerulonephritis.
- B. An RN is assigned to the client who is receiving an IV corticosteroid twice daily to manage systemic lupus erythematosus that has resulted in chronic glomerulonephritis.
- C. An LPN is assigned to replace a urinary catheter (in place >2 weeks) in a client with a fever who requires a chronic urinary catheter to help healing from a genitourinary fistula.
- D. An RN is assigned to administer IV antibiotics to a client admitted with pyelonephritis.
- E. A nursing assistant is assigned to do all the morning baths.
- F. LPNs are assigned to clients who have oral drugs prescribed and will do the vital signs for those clients.
- G. An RN is assigned to the client who is being discharged with a new diagnosis of diabetic nephropathy that is serious (stage 3 CKD)

# Renal Cell Carcinoma

## ❖Pathophysiology

Renal cell carcinoma (RCC) or adenocarcinoma of the kidney is the most common type of kidney cancer and occurs as a result of impaired CELLULAR REGULATION. Healthy kidney tissue is damaged and replaced by cancer cells, which impairs urine ELIMINATION for that kidney.

Systemic effects occurring with this cancer type are called *paraneoplastic syndromes* and include anemia, erythrocytosis, hypercalcemia, liver dysfunction with elevated liver enzymes, hormonal effects, increased sedimentation rate, and hypertension.

Anemia and erythrocytosis may seem confusing; however, most patients with this cancer have *either* anemia or erythrocytosis, not both at the same time. There is some blood loss from hematuria, but the small amount lost does not cause anemia. The cause of the anemia and the erythrocytosis is related to kidney cell production of erythropoietin. At times, the tumor cells produce large amounts of erythropoietin, causing erythrocytosis. At other times, the tumor cells destroy the erythropoietin-producing kidney cells and anemia results.

Parathyroid hormone produced by tumor cells can cause hypercalcemia. Other hormone changes include increased renin levels (causing hypertension) and increased human chorionic gonadotropin (hCG) levels, which decrease libido and change secondary sex features.

RCC has five distinct carcinoma cell types: clear cell, papillary cell, chromophobe cell, collecting duct carcinoma, and unclassified type (McCance et al., 2014). A few RCCs are hereditary. The most well-known genetic syndrome that includes kidney cancer is von Hippel-Lindau syndrome. These cancers are highly vascular and may occur with cancers of the pancreas, central nervous system, and adrenal glands.

Kidney tumors are classified into four stages (Table 67-3). Complications include metastasis and urinary tract obstruction. The cancer usually spreads to the adrenal gland, liver, lungs, long bones, or the other kidney. When the cancer surrounds a ureter, hydroureter and obstruction may result.

<b>TABLE 67-3</b> <b>Staging Kidney Tumors</b>
<b>Stage I.</b> Tumors up to 2.5 cm are situated within the capsule of the kidney. The renal vein, perinephric fat, and adjacent lymph nodes have no tumor.
<b>Stage II.</b> Tumors are larger than 2.5 cm and extend beyond the capsule but are within Gerota's fascia. The renal vein and lymph nodes are not involved.
<b>Stage III.</b> Tumors extend into the renal vein, lymph nodes, or both.
<b>Stage IV.</b> Tumors include invasion of adjacent organs beyond Gerota's fascia or metastasize to distant tissues.
<small>Data from American Cancer Society. (2017). <i>Cancer facts and figures 2017</i>. Report No. 00-300M–No. 500817. Atlanta: Author.</small>

The causes of nonhereditary RCC are unknown, but the risk is slightly higher for adults who use tobacco or are exposed to cadmium and other heavy metals, asbestos, benzene, and trichloroethylene. Men are slightly more likely to acquire RCC, as are obese, African-American, or hypertensive individuals. Regardless of cause or predisposing factor, RCC forms when CELLULAR REGULATION is disrupted.

Kidney cancers account for about 70,390 new cases of cancer and 16,260 deaths annually in the United States and Canada (American Cancer Society [ACS], 2017; Canadian Cancer Society, 2016). The 5-year survival rate is 60% in the United States. RCC occurs most often in adults between 55 and 60 years of age.

## ❖ Interprofessional Collaborative Care

The most common treatment for RCC is a nephrectomy. When the cancer is local (i.e., only in the kidney), a nephrectomy can provide a cure. For patients with metastasis, nephrectomy is followed by targeted chemotherapy combined with cytokine treatment. Patients with RCC are at risk for CKD and cardiovascular complications. Patients need ongoing, interprofessional care with surveillance for best outcomes. Follow-up therapy is managed on an outpatient basis.

### ◆ Assessment: Noticing

#### History.

Ask the patient about his or her age, known risk factors (e.g., smoking or chemical exposures), weight loss, changes in urine color, abdominal or flank discomfort, and fever. Also ask whether any other family member has ever been diagnosed with cancer of the kidney, bladder, ureter, prostate gland, uterus, or ovary.

#### Physical Assessment/Signs and Symptoms.

Some patients with RCC have flank pain, obvious blood in the urine, and a kidney mass that can be palpated. Ask about the nature of the flank or abdominal discomfort. Patients often describe the pain as dull and aching. Pain may be more intense if bleeding into the tumor or kidney occurs. Inspect the flank area, checking for asymmetry or an obvious bulge. An abdominal mass may be felt with *gentle* palpation. A renal bruit may be heard on auscultation.

Bloody urine is a *late* common sign. Blood may be visible as bright red flecks or clots, or the urine may appear smoky or cola colored. Without gross hematuria, microscopic examination may or may not reveal red blood cells (RBCs).

Inspect the skin for pallor, darkening of the nipples, and, in men, breast enlargement (*gynecomastia*) caused by changing hormone levels. Other findings may include muscle wasting, weakness, and weight loss. All tend to occur late in the disease.

#### Diagnostic Assessment.

Urinalysis may show RBCs. Hematologic studies show decreased hemoglobin and hematocrit values, hypercalcemia, increased erythrocyte sedimentation rate, and increased levels of adrenocorticotropic hormone, human chorionic gonadotropin (hCG), cortisol, renin, and parathyroid hormone. Elevated serum creatinine and blood urea nitrogen (BUN) levels indicate impaired kidney function.

Kidney masses may be detected by CT scan or MRI. Ultrasound is also used to detect masses or for initial screening. Kidney biopsy may be considered to help target therapy.

### ◆ Interventions: Responding

Interventions focus on controlling the cancer and preventing metastasis (ACS, 2017).

#### Nonsurgical Management.

Microwave ablation (MWA) or cryoablation can slow tumor growth. It is a minimally invasive procedure carried out after MRI has precisely located the tumor. MWA is used most commonly for patients who have only one kidney or who are not surgical candidates.

Traditional chemotherapy has limited effectiveness against this cancer type. Use of biologic response modifiers (BRMs) such as interleukin-2 (IL-2), interferon (INF), and tumor necrosis factor (TNF) has increased survival time (see Chapters 17 and 22). Targeted therapy agents sorafenib (Nexavar), sunitinib (Sutent), and temsirolimus (Torisel) are approved as treatment for patients with advanced RCC. Sorafenib and sunitinib are oral drugs taken daily. They are multikinase inhibitors that slow cancer cell division and inhibit blood vessel growth in the tumor. Temsirolimus is a weekly IV infusion that blocks a protein that is needed for cell division, inhibiting cancer cell division. Other targeted drugs used to treat RCC are everolimus (Afinitor) and pazopanib (Votrient) (Burchum & Rosenthal, 2016).

#### Surgical Management.

Renal cell carcinoma is usually treated surgically by *nephrectomy* (kidney removal). Renal cell tumors are highly vascular, and blood loss during surgery is a major concern. Before surgery, the arteries supplying the kidney may be occluded (embolized) by the interventional radiologist to reduce bleeding during nephrectomy.

### Preoperative Care.

Instruct the patient about surgical routines (see [Chapters 14 to 16](#)). Explain the probable site of incision and the presence of dressings, drains, or other equipment after surgery. Reassure the patient about pain relief. Care before surgery may include giving blood and fluids IV to prevent shock.

### Operative Procedures.

The patient is placed on his or her side with the kidney to be removed uppermost. The trunk area is flexed to increase exposure of the kidney area. The eleventh or twelfth rib may need to be removed to provide better access to the kidney. The surgeon removes either part or all of the kidney and all visible tumor. The renal artery, renal vein, and fascia also may be removed. A drain may be placed in the wound before closure. The adrenal gland may be removed when the tumor is near this organ.

When a *radical* nephrectomy is performed, local and regional lymph nodes are also removed. The surgical approach may be transthoracic (as discussed in the previous paragraph), lumbar, or through the abdomen, depending on the size and location of the tumor. Radiation therapy may follow a radical nephrectomy.

### Postoperative Care.

Refer to [Chapter 16](#) for care of the patient after surgery. Nursing priorities are focused on assessing kidney function to determine effectiveness of the remaining kidney, pain management, and preventing complications.

*Monitoring* includes assessing for hemorrhage and adrenal insufficiency. Inspect the patient's abdomen for distention from bleeding. Check the bed linens under the patient because blood may pool there. Hemorrhage or adrenal insufficiency causes hypotension, decreased urine output, and an altered level of consciousness.

A decrease in blood pressure is an early sign of both hemorrhage and adrenal insufficiency. With hypotension, urine output also decreases immediately. Large water and sodium losses in the urine occur in patients with adrenal insufficiency, leading to impaired FLUID AND ELECTROLYTE BALANCE. As a result, a large urine output is followed by hypotension and oliguria (less than 400 mL/24 hr or less than 25 mL/hr). IV replacement of fluids and packed RBCs may be needed.

The second kidney is expected to provide adequate function, but this may take days or weeks. Assess urine output hourly for the first 24 hours after surgery (urine output of 0.5 mL/kg/hr or about 30 to 50 mL/hr is acceptable). A low urine output of less than 25 to 30 mL/hr suggests decreased blood flow to the remaining kidney and potential for acute kidney injury (AKI). The hemoglobin level, hematocrit values, and white blood cell count may be measured every 6 to 12 hours for the first day or two after surgery.

Monitor the patient's temperature, pulse rate, and respiratory rate at least every 4 hours. Accurately measure and record fluid intake and output. Weigh the patient daily.

The patient may be in a special care unit for 24 to 48 hours after surgery for monitoring of bleeding and adrenal insufficiency. A drain placed near the site of incision removes residual fluid. Because of the discomfort of deep breathing, the patient is at risk for atelectasis. Fever, chills, thick sputum, or decreased breath sounds suggest pneumonia.

*Managing pain* after surgery usually requires opioid analgesics (e.g., hydromorphone [Dilaudid] and morphine [Statex ) given IV. The incision was made through major muscle groups used with breathing and movement. Liberal use of analgesics is needed for 3 to 5 days after surgery to manage pain. Oral agents may be tried when the patient can eat and drink.

*Preventing complications* focuses on infection and management of adrenal insufficiency. Antibiotics may be prescribed during and after surgery to prevent infection. The need for additional antibiotics is based on evidence of infection. Assess the patient at least every 8 hours for indications of systemic infection or local wound infection.

Adrenal insufficiency is possible as a complication of kidney and adrenal gland removal. Although only one adrenal gland may be affected, the remaining gland may not be able to secrete

sufficient glucocorticoids immediately after surgery. Steroid replacements may be needed in some patients. [Chapter 62](#) discusses the signs and symptoms of acute adrenal insufficiency in detail along with specific nursing interventions.

## Clinical Judgment Challenge 67-1

### Patient-Centered Care; Teamwork and Collaboration; Evidence-Based Practice **QSEN**

You admit a 68-year-old woman who was diagnosed with renal cell carcinoma after experiencing a recurrent UTI with hematuria. When her UTI did not resolve with a second course of antibiotics, the cancer was discovered with a pelvic CT scan. She is on the surgical unit for exploratory surgery and possible nephrectomy. She asks, “Is it possible that the lump that was found on my CT is not cancer? Why not just do a biopsy? That is what happened when they found a lump in my breast, and it turned out not to be cancer. If it is cancer, could I walk out of here cured?”

1. What is the rationale for not using a biopsy to evaluate a kidney mass?
2. What are the characteristics of abnormal tissue that is cancer, distinctive from tissue that is not cancer? (You may need to refer to Chapter 21.)
3. Is nephrectomy a cure for renal cell cancer? Why or why not?
4. Following a nephrectomy, what are the concerns for this patient that require follow-up monitoring?

# Kidney Trauma

## ❖ Pathophysiology

Trauma to one or both kidneys may occur with penetrating wounds or blunt injuries to the back, flank, or abdomen. Another cause of kidney trauma is urologic procedures, such as extracorporeal shock wave lithotripsy, kidney biopsy, or percutaneous renal procedures. Blunt trauma accounts for most kidney injuries. Traumatic kidney injury is classified into five grades based on the severity of the injury. Grade one consists of low-grade injury in the form of kidney bruising, and grade five represents the most severe variety associated with shattering of the kidney and tearing of its blood supply. Adults of any age can suffer kidney trauma. Strategies to prevent trauma are reviewed in [Chart 67-7](#).

### Chart 67-7

## Patient and Family Education: Preparing for Self-Management

### Preventing Kidney and Genitourinary Trauma

- Wear a seat belt.
- Practice safe walking habits.
- Use caution when riding bicycles and motorcycles.
- Wear appropriate protective clothing when participating in contact sports.
- Avoid all contact sports and high-risk activities if you have only one kidney.

## ❖ Interprofessional Collaborative Care

### ◆ Assessment: Noticing

Obtain a history of the patient's usual health and the events involved in the trauma from the patient, a witness, or emergency personnel. Document the mechanism of injury to help determine the severity of the injury. For example, blunt trauma of the kidney from car crashes usually results in an injury of low severity. Critical information to acquire is a history of kidney or urologic disease, surgical intervention, or health problems such as diabetes or hypertension.

Ureteral or renal pelvic injury often causes diffuse abdominal pain. Urine outside of the urinary tract may be visible. Ask the patient about pain in the flank or abdomen. Is the pain dull? Sharp? Constant? Intermittent? Made worse by coughing?

Assess patients with kidney injuries carefully and thoroughly. Take the patient's blood pressure, apical and peripheral pulses, respiratory rate, and temperature. Inspect both flanks for bruising, asymmetry, or penetrating injuries. Also inspect the abdomen, chest, and lower back for bruising or wounds. Percuss the abdomen for distention. Inspect the urethra for blood.

Urinalysis shows hemoglobin or RBCs from tissue damage or kidney blood vessel rupture. Microscopic examination may also show red blood cell casts, which suggest tubular damage. Hemoglobin and hematocrit values decrease with blood loss (see [Chapter 37](#)).

Diagnostic procedures include ultrasound and CT. CT scan shows greater detail about blood vessel and tissue integrity. Hematomas within or through the kidney capsule can be seen, along with the integrity and patency of the urinary tract. If the patient is being taken to the operating room emergently, a high dose of ionic or nonionic IV contrast material can be given, followed by an abdominal x-ray (KUB) to visualize the traumatic injury and any organ damage.

### ◆ Interventions: Responding

## Nonsurgical Management.

*Drug therapy* is used for bleeding prevention or control. The need for clotting factors such as vitamin K and platelets is assessed, and they are given as needed.

*Fluid therapy* restores circulating blood volume and ensures adequate kidney blood flow. Crystalloid solutions replace water and some electrolytes and include 0.9% sodium chloride (normal saline solution [NSS]), 5% dextrose in 0.45% sodium chloride, and lactated Ringer's solution. When bleeding is extensive, packed RBC replacement restores hemoglobin and promotes oxygenation. Fresh frozen plasma or coagulation factors may help with uncontrolled bleeding. Plasma volume expanders, such as dextran or albumin, help restore plasma oncotic pressure and reduce the onset or severity of shock or fluid displacement to interstitial tissues.

During fluid restoration, give fluids at the prescribed rate and monitor the patient for signs of shock. Take vital signs as often as every 5 to 15 minutes. Measure and record urine output hourly. Output should be greater than 0.5 mL/kg/hr.

The interventional radiologist may use percutaneous or other instrumentation to drain collections of fluid or to embolize (clot) an artery or artery segment or place a stent to repair the urethra or ureters.

## Nursing Safety Priority QSEN

### Action Alert

If the urethral opening is bleeding, consult with the urologist or primary health care provider before attempting urinary catheterization to avoid making the injury worse.

## Surgical Management.

Most kidney injuries are managed without surgery. Many serious injuries can be treated with minimally invasive techniques such as angiographic embolization, which accesses the arteries of the kidneys through large blood vessels in the groin, similar to a cardiac catheterization. Surgery to explore the injured kidney occurs when the patient is in shock and may be losing a lot of blood from the kidney. Patients who have other significant abdominal injuries, such as injuries to the bowel, spleen, or liver, and require a laparotomy may also undergo inspection and repair of the injured kidney at the same time. The aim of surgical management is to repair the injured kidney and restore its ELIMINATION function. If the kidney is severely injured (Grade 5 injury), a nephrectomy is performed.

## Care Coordination and Transition Management

Teach the patient and family how to assess for infection and other complications following kidney trauma. The most common complications are urine leakage and delayed bleeding. Instruct the patient to check the pattern and frequency of urination and note whether the color, clarity, and amount appear normal. The development of an abscess surrounding the kidney also can occur. Instruct the patient to seek medical attention for worsening hematuria, any worrisome change, or pain with voiding. Chills, fever, lethargy, and cloudy, foul-smelling urine indicate a urinary tract infection or abscess formation. Traumatic kidney injury can also cause hypertension from changes in perfusion and activation of the renin-angiotensin-aldosterone system (see [Chapter 65](#) and [Fig. 65-5](#)). Advise the patient to seek medical care promptly for all new and concerning signs or symptoms.

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Report immediately any condition that obstructs urine flow. **QSEN: Safety**
- Check the blood pressure and urine output frequently in patients who have any type of kidney problem. **QSEN: Safety**
- Report immediately to the primary health care provider any sudden decrease of urine output in a patient with kidney disease or kidney trauma. In general, adult urine output expectations are 0.5-1 mL/kg/hr. **QSEN: Safety**
- Teach all patients with any kidney disorder strategies to prevent kidney damage from dehydration or trauma. **QSEN: Safety**
- Instruct patients with any type of kidney problem to weigh daily and to notify their primary health care provider if there is a sudden weight gain. **QSEN: Patient-Centered Care**

### Health Promotion and Maintenance

- Refer patients with polycystic kidney disease to a geneticist or a genetic counselor. **QSEN: Patient-Centered Care**
- Refer patients to community resources, support groups, and information organizations such as the National Kidney Foundation, the Polycystic Kidney Disease Foundation, and the American Association of Kidney Patients. **QSEN: Patient-Centered Care**
- Encourage patients with diabetes to achieve tight glycemic control. **QSEN: Patient-Centered Care**
- Encourage patients with hypertension to follow their treatment regimens to maintain blood pressure within the target range. **QSEN: Evidence-Based Practice**
- Teach patients to match daily urine output with fluid intake, usually at least 2 L for kidney health unless another health problem requires fluid restriction. **QSEN: Evidence-Based Practice**

### Psychosocial Integrity

- Allow the patient the opportunity to express fear or anxiety regarding the potential for chronic kidney disease and end-stage kidney disease. **QSEN: Patient-Centered Care**
- Assess the patient's level of comfort in discussing issues related to ELIMINATION and the genitourinary area. **QSEN: Patient-Centered Care**
- Use language with which the patient is comfortable during assessment of the kidney and urinary system. **QSEN: Patient-Centered Care**
- Explain treatment procedures to patients and families. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Teach patients the expected side effects and any adverse reactions to prescribed drugs, especially as they relate to kidney function. **QSEN: Patient-Centered Care**
- Teach patients the indications of disease recurrence and when to seek medical help. **QSEN: Patient-Centered Care**
- Teach patients on antibiotic therapy for a UTI (pyelonephritis) to complete the drug regimen. **QSEN: Evidence-Based Practice**
- Explain the genetics of autosomal-dominant polycystic kidney disease.
- Use laboratory data and signs and symptoms to determine the effectiveness of therapy for

pyelonephritis, polycystic kidney disease, glomerulonephritis, and renal cell carcinoma.

- Be aware of the signs and symptoms of hydronephrosis.
- Be aware of the relation between kidney disease and hypertension and the associated risk for cardiovascular events.

## CHAPTER 68

# Care of Patients With Acute Kidney Injury and Chronic Kidney Disease

Chris Winkelman

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is *ELIMINATION*.**

✚ The *ELIMINATION* concept exemplar for this chapter is Chronic Kidney Disease, p. 1398.

**The interrelated concepts for this chapter are:**

- ACID-BASE BALANCE
- FLUID AND ELECTROLYTE BALANCE
- IMMUNITY
- PERFUSION

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to coordinate high-quality care and promote urinary *ELIMINATION* in patients who have acute kidney injury or chronic kidney disease.
2. Teach the patient and caregiver(s) about home safety issues affected by impaired *ELIMINATION* and impairment of *FLUID AND ELECTROLYTE BALANCE* or *ACID-BASE BALANCE* resulting from acute kidney injury or chronic kidney disease.
3. Prioritize evidence-based care for patients with impaired urinary *ELIMINATION* from either acute kidney injury or chronic renal failure.

### Health Promotion and Maintenance

4. Identify community resources for patients requiring assistance with management of altered *ELIMINATION* as a result of acute kidney injury or chronic kidney disease.
5. Teach adults how to decrease the risk for acute kidney injury or chronic kidney disease resulting in impaired urinary *ELIMINATION*.

### Psychosocial Integrity

6. Implement nursing interventions to help patients and families cope with the psychosocial impact caused by acute kidney injury or chronic kidney disease.

### Physiological Integrity

7. Apply knowledge of anatomy, physiology, and pathophysiology to assess patients with impaired kidney function from acute kidney injury or chronic kidney disease affecting *ELIMINATION*, *FLUID AND ELECTROLYTE BALANCE*, or *ACID-BASE BALANCE*.
8. Teach the patient and caregiver(s) about common drugs and other strategies used for acute kidney injury and chronic kidney disease, including pain control and depression management.
9. Implement evidence-based nursing interventions to prevent complications in patients undergoing kidney replacement therapy when urinary *ELIMINATION* is not effective in clearing waste or toxins.

The kidney function of urinary ELIMINATION includes excretion of waste, FLUID AND ELECTROLYTE BALANCE, regulation of ACID-BASE BALANCE, and hormone secretion. These processes are greatly impaired with kidney function loss, and every organ system is affected. Acute kidney injury (AKI) is most common in the acute care setting, whereas chronic kidney disease (CKD) is more likely to be seen in community settings or as a coexisting condition in acute care settings. The features of AKI and CKD are described in Table 68-1.

**TABLE 68-1**  
**Features of Acute Kidney Injury and Chronic Kidney Disease**

CHARACTERISTIC	ACUTE KIDNEY INJURY	CHRONIC KIDNEY DISEASE
Onset	Sudden (hours to days)	Gradual (months to years)
% of nephron involvement	50%-95%	Varies by stage; generally symptomatic with 75% loss and dialysis with 90%-95% loss
Duration	May not progress; full recovery (return to baseline) possible ESKD occurs in 10%-20% with lifetime reliance on dialysis or kidney transplant	Progressive and permanent Treatment and lifestyle can slow progression and delay onset of ESKD
Prognosis	Good when kidney function is maintained or returns High mortality associated with renal replacement therapy requirements or prolonged illness	Progression of CKD depends on stage of GFR, stage of albuminuria, and specific conditions associated with the onset of the disorder ESKD fatal without a renal replacement therapy (dialysis or transplantation) Reduced life span and potential for complex medical regimen even with optimal treatment

CKD, Chronic kidney disease; ESKD, end-stage kidney disease; GFR, glomerular filtration rate.

Both types of kidney problems can require kidney replacement therapy (e.g., dialysis). When kidney function is permanently or persistently impaired, as with end-stage kidney disease (ESKD), dialysis or kidney transplant is a lifesaving approach for urinary ELIMINATION to maintain homeostasis, FLUID AND ELECTROLYTE BALANCE, and ACID-BASE BALANCE. ESKD reduces independence, shortens life, and decreases quality of life. Many diseases and conditions are associated with the onset and severity of kidney function loss.

When kidney function declines gradually, it is diagnosed as CKD, formerly termed *chronic renal failure (CRF)*. The patient may have many years of abnormal blood urea nitrogen and creatinine values, sometimes called *renal insufficiency*, before ESKD develops. When kidney function decline is sudden, acute kidney injury (AKI) is diagnosed. AKI can be a temporary condition that resolves, or it can progress to CKD. Even without progression to CKD, AKI is associated with high mortality in critically ill adults (Dirkes, 2015). AKI also can occur in a patient with established CKD. When these two conditions co-occur, the loss of kidney function and waste ELIMINATION is usually more severe and accelerated.

Acute kidney injury affects *many* body systems. Chronic kidney disease affects *every* body system. The problems that occur with kidney function loss are related to disturbances of FLUID AND ELECTROLYTE BALANCE, disturbances of ACID-BASE BALANCE, buildup of nitrogen-based wastes (uremia), and loss of kidney hormone function.

# Acute Kidney Injury

## ❖ Pathophysiology

**Acute kidney injury (AKI)** is a rapid reduction in kidney function resulting in a failure to maintain waste ELIMINATION, FLUID AND ELECTROLYTE BALANCE, and ACID-BASE BALANCE. AKI occurs over a few hours or days. The most current definition of AKI is an increase in serum creatinine by 0.3 mg/dL (26.2 μmol/L) or more within 48 hours; or an increase in serum creatinine to 1.5 times or more from baseline, which is known or presumed to have occurred in the previous 7 days; or a urine volume of less than 0.5 mL/kg/hr for 6 hours (Dirkes, 2016; KDIGO, 2013). Criteria for staging the severity of AKI are in Table 68-2. These criteria are not applied universally but do provide the best evidence to date for early identification of AKI (Hain & Paixao, 2015). New biomarkers of tubular injury have great promise for improving the diagnosis and management of AKI (Dirkes, 2015).

**TABLE 68-2**

**The KDIGO Classification System for Severity of Acute Kidney Injury**

STAGE	SERUM CREATININE	URINE OUTPUT
Stage 1	Increased × 1.5-1.9 baseline or by ≥ 0.3 mg/dL (≥ 26.2 μmol/L)	<0.5 mL/kg/hr for 6-12 hr
Stage 2	Increased × 2-2.9 baseline	<0.5 mL/kg/hr for ≥ 12 hr
Stage 3	Increased × 3 baseline or by >4 mg/dL (≥ 354 μmol/L) or initiation of renal replacement therapy	<0.3 mL/kg/hr for ≥ 24 hr or Anuria for ≥ 12 hr

KDIGO, [Kidney Disease: Improving Global Outcomes \(2013\)](#).

Although glomerular filtration rate (GFR) is accepted as the best overall indicator of kidney function, it is not accurate during acute and critical illness (Puzantian & Townsend, 2013). Estimations of GFR from serum creatinine are affected by metabolic problems and treatments during critical illnesses. Urine output is altered when diuretics or IV fluids are used. AKI also causes systemic effects and complications described in Table 68-3. These complications increase discomfort and risk for death. Duration of oliguria or anuria closely correlates with lack of recovery of kidney function; the longer the duration of oliguria or anuria, the less likely it is that the patient will return to full or baseline kidney function.

**TABLE 68-3**

---	--

## Etiology

The causes of AKI are reduced PERFUSION to the kidneys, damage to kidney tissue, and obstruction of urine outflow. Diseases and conditions associated with reduced kidney PERFUSION, kidney damage, and urinary obstruction are listed in Table 68-4. (The diseases in Table 68-3 are described elsewhere in this text.)

**TABLE 68-4**

**Diseases and Conditions That Contribute to Acute Kidney Injury**

<p><b>Perfusion Reduction (Prerenal Causes)</b></p> <ul style="list-style-type: none"> <li>• Blood or fluid loss (e.g., surgery or trauma; severe sepsis, septic shock, or hypovolemic shock)</li> <li>• Blood pressure drugs resulting in hypotension</li> <li>• Heart attack or heart failure resulting in low ejection fraction and low cardiac output</li> <li>• Infection (e.g., sepsis, septic shock)</li> <li>• Liver failure</li> <li>• Use of aspirin, ibuprofen (e.g., Advil, Motrin IB), naproxen (e.g., Aleve), or NSAIDs</li> <li>• Severe allergic reaction (anaphylaxis)</li> <li>• Severe burns</li> <li>• Severe dehydration</li> <li>• Renal artery stenosis</li> <li>• Bleeding or clotting in the kidney blood vessels (coagulopathy)</li> <li>• Atherosclerosis or cholesterol deposits that block blood flow in the kidneys</li> </ul>
<p><b>Kidney Damage (Intrinsic or Intrarenal Causes)</b></p> <ul style="list-style-type: none"> <li>• Glomerulonephritis or inflammation of the glomeruli</li> <li>• Bleeding in the kidney</li> <li>• Thrombi or emboli in the kidney blood vessels</li> <li>• Hemolytic uremic syndrome, a condition of premature destruction of red blood cells caused by infection</li> <li>• Systemic infection (sepsis)</li> <li>• Local infection (pyelonephritis)</li> <li>• Lupus, an immune system disorder causing glomerulonephritis</li> <li>• Drugs, such as certain chemotherapy agents, antibiotics, iodinated or hyperosmolar contrast media used during imaging tests (contrast-induced nephropathy), many antibiotics, and zoledronic acid (Reclast, Zometa), used to treat osteoporosis and high blood calcium levels (hypercalcemia)</li> <li>• Multiple myeloma, a cancer of the plasma cells</li> <li>• Scleroderma, a group of rare diseases affecting the skin and connective tissues</li> <li>• Thrombotic thrombocytopenic purpura (TTP), a rare platelet disorder that increases clotting</li> <li>• Ingested toxins, such as alcohol, heavy metals, and cocaine</li> <li>• Vasculitis, an inflammation of blood vessels</li> <li>• Ischemia in kidney tissue, including hypoxemia from respiratory and cardiac arrest</li> </ul>
<p><b>Urine Flow Obstruction (Postrenal Causes)</b></p> <ul style="list-style-type: none"> <li>• Bladder cancer</li> <li>• Cervical cancer</li> <li>• Colon cancer</li> <li>• Prostate cancer</li> <li>• Enlarged prostate (prostate hypertrophy)</li> <li>• Kidney stones (nephrolithiasis and ureterolithiasis)</li> <li>• Nerve damage involving the nerves that control the bladder (neurogenic bladder)</li> <li>• Blood clots in the urinary tract</li> </ul>

Notice that several conditions resulting in AKI are listed more than once in [Table 68-4](#). For example, coagulopathy (disorders of bleeding and clotting; see [Chapter 40](#)) reduces perfusion, causes inflammation and direct tissue damage, and creates obstruction of urinary flow.

Any patient with a pre-existing reduced GFR or elevated albumin-creatinine ratio is at increased risk for AKI during hospitalization ([Grams et al., 2015](#)). AKI is more likely to occur in hospitalized adults with advanced age or who have pre-existing conditions such as hypertension, diabetes, peripheral vascular disease, liver disease, or CKD ([Thornburg & Gray-Vickery, 2016](#)). Sepsis (see [Chapter 37](#)), cardiac surgery, hypotension, shock, or prolonged mechanical ventilation (see [Chapter 32](#)) also are independent risk factors for the development of AKI ([Vrtis, 2013](#)).

Traditionally, AKI caused by reduced PERFUSION with a sustained mean arterial pressure (MAP) of less than 65 mm Hg is classed as **prerenal failure**. It is the most common cause of AKI in acute care. Damage to kidney tissue is classed as **intrarenal** or **intrinsic renal failure** and reflects injury to the glomeruli, nephrons, or tubules. Obstruction of urine flow is also called **postrenal failure**. Although this classification system is controversial, it provides a framework to guide care for prevention and treatment of AKI ([Fournier, 2013](#)). Any of these conditions can occur together. Coagulopathies can cause prerenal, intrarenal, and postrenal AKI.

With prerenal or postrenal pathology, the kidney compensates by the three responses of constricting kidney blood vessels, activating the renin-angiotensin-aldosterone pathway, and releasing antidiuretic hormone (ADH). These responses increase blood volume and improve kidney PERFUSION. However, these same responses reduce urine ELIMINATION, resulting in **oliguria** (urine output less than 400 mL/day) and **azotemia** (the retention and buildup of nitrogenous wastes in the blood). Toxins can also cause blood vessel constriction in the kidney, leading to reduced kidney blood flow, oliguria, and azotemia.

Activated IMMUNITY and damage from kidney toxins (nephrotoxins) ([Table 68-5](#)) cause intracellular changes of the tubular system in kidney tissue. Inflammatory proteins and immune-mediated complexes can damage cells and tissues in the kidney. With extensive damage, tubular cells slough and nephrons lose the ability to repair themselves. The presence of tubular debris and sediment in urine from kidney tissue damage (intrarenal failure or *acute tubular necrosis*) is related to systemic ischemia, reduced kidney PERFUSION, or nephrotoxin exposure.

**TABLE 68-5**  
**Examples of Potentially Nephrotoxic Substances**

<p><b>Drugs</b></p> <p><i>Antibiotics/Antimicrobials</i></p> <ul style="list-style-type: none"> <li>• Amphotericin B</li> <li>• Colistimethate</li> <li>• Methicillin</li> <li>• Polymyxin B</li> <li>• Rifampin</li> </ul>	<p><i>Other Drugs</i></p> <ul style="list-style-type: none"> <li>• Acetaminophen</li> <li>• Captopril</li> <li>• Cyclosporine</li> <li>• Fluorinate anesthetics</li> <li>• Metformin</li> <li>• D-Penicillamine</li> </ul>
---	--

<ul style="list-style-type: none"> <li>• Sulfonamides</li> <li>• Tetracycline hydrochloride</li> <li>• Vancomycin</li> </ul>	<ul style="list-style-type: none"> <li>• Phenazopyridine hydrochloride</li> <li>• Quinine</li> </ul>
<b>Aminoglycoside Antibiotics</b> <ul style="list-style-type: none"> <li>• Gentamicin</li> <li>• Kanamycin</li> <li>• Neomycin</li> <li>• Netilmicin sulfate</li> <li>• Tobramycin</li> </ul>	<b>Other Substances</b> <ul style="list-style-type: none"> <li>• Carbon tetrachloride</li> <li>• Ethylene glycol</li> </ul>
<b>Chemotherapy Agents</b> <ul style="list-style-type: none"> <li>• Cisplatin</li> <li>• Cyclophosphamide</li> <li>• Methotrexate</li> </ul>	<b>Nondrug Chemical Agents</b> <ul style="list-style-type: none"> <li>• Radiographic contrast medium (e.g., iodinated media, hyperosmolar media, and gadolinium)</li> <li>• Pesticides</li> <li>• Fungicides</li> <li>• Myoglobin (from breakdown of skeletal muscle)</li> </ul>
<b>NSAIDs</b> <ul style="list-style-type: none"> <li>• Celecoxib</li> <li>• Flurbiprofen</li> <li>• Ibuprofen</li> <li>• Indomethacin</li> <li>• Ketorolac</li> <li>• Meclfenamate</li> <li>• Meloxicam</li> <li>• Nabumetone</li> <li>• Naproxen</li> <li>• Oxaprozin</li> <li>• Rofecoxib</li> <li>• Tolmetin</li> </ul>	<b>Heavy Metals and Ions</b> <ul style="list-style-type: none"> <li>• Arsenic</li> <li>• Bismuth</li> <li>• Copper sulfate</li> <li>• Gold salts</li> <li>• Lead</li> <li>• Mercuric chloride</li> </ul>

Even with severe AKI (i.e., stage 2 or 3 in [Table 68-2](#)), some adults return to baseline kidney function during recovery from illness. It is the responsibility of all health care professionals to be alert to the possibility of AKI and implement prevention strategies when risk factors are present. *Timely interventions to remove the cause of AKI may prevent progression to ESKD and the need for lifelong renal replacement therapy or a renal transplant.*

### Incidence and Prevalence

The reported prevalence of AKI from United States data ranges from 1% (community-acquired) up to 7.1% (hospital-acquired) among adults admitted to a hospital. As many as 30% of patients admitted to an ICU experience an episode of AKI ([Fournier, 2013](#)). Transient azotemia and oliguria are common among all inpatients. AKI is associated with an in-hospital and 1-year mortality rate of up to 60% ([Ralib et al., 2013](#)).

### Health Promotion and Maintenance

*Keep in mind that dehydration (severe blood volume depletion) reduces PERFUSION and can lead to AKI even in adults who have no known kidney problems.* Urge all healthy adults to avoid dehydration by drinking 2 to 3 L of water daily. This is especially important for athletes or anyone who performs strenuous exercise or work and sweats heavily.

Nurses have an essential role in the prevention of AKI in hospitalized patients. Always be on the lookout for signs of impending kidney dysfunction through assessment and close monitoring of laboratory values. Early recognition and correction of problems causing reduced urinary ELIMINATION may avoid kidney tissue damage. Evaluate the patient's fluid status. Accurately measure intake and output and check body weight to identify changes in fluid balance. Note the characteristics of the urine and report new sediment, hematuria (smoky or red color), foul odor, or other worrisome changes. Immediately report a urine output of less than 0.5 mL/kg/hr that persists for more than 2 hours to the primary health care provider ([Ralib et al., 2013](#)). Waiting for 6 hours of oliguria to meet AKI criteria may allow progression of kidney damage—act early!

## Nursing Safety Priority QSEN

### Critical Rescue

In any acute care setting, preventing volume depletion and providing intervention early when volume depletion occurs are nursing priorities. Reduced PERFUSION from volume depletion is a common cause of AKI. Assess continually to recognize the signs and symptoms of volume depletion (low urine output, decreased systolic blood pressure, decreased pulse pressure, orthostatic hypotension, thirst, rising blood osmolarity). Respond by intervening early with oral fluids or, in the patient who is unable to take or tolerate oral fluid, requesting an increase in IV fluid rate from the primary health care provider to prevent permanent kidney damage.

Monitor laboratory values for any changes that reflect poor kidney function. A significant increase in creatinine, especially when the increase occurs over hours or a few days, is a concern

and must be reported urgently to the primary health care provider. Other laboratory values that help monitor kidney function include serum blood urea nitrogen (BUN); serum potassium, sodium, and osmolarity; and urine specific gravity, albumin-creatinine ratio, and electrolytes. Know the baseline (steady-state) GFR because a reduced GFR makes the patient more vulnerable to AKI.

Be aware of nephrotoxic substances that the patient may ingest or be exposed to (see [Table 68-5](#)). Question any prescription for potentially nephrotoxic drugs, and validate the dose before the patient receives the drug. Many antibiotics have nephrotoxic effects. NSAIDs can cause or increase the risk for AKI. Combining two or more nephrotoxic drugs dramatically increases the risk for AKI. If a patient must receive a known nephrotoxic drug, closely monitor laboratory values, including BUN, creatinine, and drug peak and trough levels, for indications of reduced kidney function. When nephrotoxic agents are used, including contrast medium, nephrons may be protected by administering a pretreatment oral or IV bolus of fluid volume ([Lambert et al., 2017](#)).

## ❖ Interprofessional Collaborative Care

AKI is managed initially in the hospital setting, most commonly in an ICU. During the acute phase of the problem, members of the interprofessional team include the nephrologist, nephrology nurse, registered dietitian, pharmacist, and dialysis technician. The responsibilities of each of these professionals are described within the interventions sections of this chapter. When the patient is discharged before urinary ELIMINATION returns to normal, continuing management is needed as part of the transition to community care.

### ◆ Assessment: Noticing

#### History.

The accurate diagnosis of AKI, including its cause, depends on a detailed history. Know the risk factors for and criteria of AKI and chronic kidney disease (CKD). Ask about any change in urine appearance, frequency, or volume.

Ask about recent surgery or trauma, transfusions, allergic (hypersensitivity) reactions, or other factors that might lead to reduced kidney PERFUSION. Obtain a drug history, especially use of antibiotics and NSAIDs. Ask about recent imaging procedures requiring injection of a contrast medium. Coexisting conditions of advanced age, diabetes, long-term hypertension, major or systemic infection (sepsis), systemic inflammation, low cholesterol levels, and coagulopathy or treatment for bleeding or clotting disorders increase the risk for AKI ([Dirkes, 2016](#)).

To identify IMMUNITY-mediated AKI (i.e., acute glomerulonephritis), ask about acute illnesses such as influenza, colds, gastroenteritis, and sore throats. Allergic reactions from a drug or food allergy may result in AKI as late as 10 days after exposure. Ask about rashes, hives, or fever and evaluate the white blood cell differential for an increased eosinophil count.

Anticipate AKI following any episode of hypotension or shock. Any problem in which the blood volume is depleted can contribute to AKI by reducing PERFUSION. Such problems include cardiac bypass surgery, extensive bowel preparations, being NPO before surgery, or dehydration from exercise. Recent use of IV vasopressors (e.g., epinephrine or norepinephrine) may contribute to AKI when blood volume is reduced (hypovolemia).

Consider whether there is a history of urinary obstructive problems. Ask the patient about any difficulty in starting the urine stream, changes in the amount or appearance of the urine, narrowing of the urine stream, nocturia, urgency, or symptoms of kidney stones. Also ask about any cancer history that may cause urinary obstruction.

## 🏠 Considerations for Older Adults

### Patient-Centered Care QSEN

Prevention of AKI in older adults first involves recognition of their increased vulnerability to kidney injury. There is a 20% greater rate of AKI among older adults in an ICU compared to younger adults ([Hain & Paixao, 2015](#)). Structural and functional changes in the aging kidney contribute to the risk for AKI. As kidneys age, there are fewer nephrons, more sclerotic glomeruli, and renal artery arteriosclerosis leading to reduced kidney PERFUSION and a decline in GFR. Age-

related changes in tubular function decrease the ability to regulate sodium and potassium balance and to concentrate urine, increasing the risk for blood volume depletion (Touhy & Jett, 2016).

The use of multiple drugs is associated with drug-induced AKI, particularly in acute and critical care settings. Assess risk and take actions to reduce exposure to nephrotoxic agents, avoid hypotension and hypovolemia, evaluate drug-drug interactions for potential adverse kidney effects, and stop unnecessary drugs to maintain kidney function in older adults.

### Physical Assessment/Signs and Symptoms.

If a patient has a urinary catheter, assess urine output every hour after surgery until stable, during fluid resuscitation for shock or hypotension, and when the patient has a high risk for AKI following hospital admission. Even a brief period of oliguria, defined as less than 0.5 mL/kg/hour of urine output for 2 or more hours, can signal AKI.

Other symptoms of AKI are related to the buildup of nitrogenous wastes (azotemia) and decreased urine output (oliguria). As AKI progresses in severity, the patient may have symptoms of fluid overload because fluid is not eliminated. Indications of fluid overload include pulmonary crackles, dependent and generalized edema (*anasarca*), decreased oxygenation (low peripheral oxygenation or SpO<sub>2</sub>), confusion, increased respiratory rate, and dyspnea. See [Chapter 11](#) for assessment of fluid overload.

Evaluate vital signs to recognize early hypoperfusion and hypoxemia. Symptoms of reduced blood volume such as mean arterial pressure (MAP) <65 mm Hg, tachycardia, thready peripheral pulses, or decreasing cognition may indicate risk for AKI from poor PERFUSION; whereas an SpO<sub>2</sub> <88% may indicate potential hypoxic or ischemic damage to kidney tissue.

### Laboratory Assessment.

The many changes in laboratory values in the patient with AKI are similar to those occurring in chronic kidney disease (CKD) ([Chart 68-1](#)). Expect to see rising creatinine and BUN levels and abnormal blood electrolytes values. However, patients with AKI usually do *not* have the anemia associated with CKD unless there is blood loss from another condition (e.g., surgery, trauma) or when BUN levels are high enough to break (lyse) red blood cells.

#### Chart 68-1

### Laboratory Profile

#### Kidney Disease

TEST	NORMAL RANGE FOR ADULTS	VALUES IN KIDNEY DISEASE
Serum creatinine	Male: 0.6-1.2 mg/dL (53-106 μmol/L) Female: 0.5-1.1 mg/dL (44-97 μmol/L) Older adults: Decreased Older adults: May be slightly increased	<b>In Chronic Kidney Disease</b> May increase by 0.5-1.0 mg/dL (50-100 μmol/L) every 1-2 years May be as high as 15-30 mg/dL (500-1000 μmol/L) before symptoms of severe CKD are present <b>In Acute Kidney Injury</b> Increase of 1-2 mg/dL (100-200 μmol/L) every 24-48 hr May increase 1-6 mg/dL (100-600 μmol/L) in 1 week or less
Serum sodium	136-145 mEq/L (136-145 mmol/L)	Normal, increased, or decreased
Serum potassium	3.5-5.0 mEq/L (3.5-5.0 mmol/L)	Increased
Serum phosphorus (phosphate)	3.0-4.5 mg/dL (0.97-1.45 mmol/L) Older adults: May be slightly decreased	Increased
Serum calcium	Total calcium: 9.0-10.5 mg/dL (2.25-2.75 mmol/L) Ionized calcium: 4.5-5.6 mg/dL (1.05-1.3 mmol/L) Older adults: Slightly decreased	Decreased
Serum magnesium	1.3-2.1 mEq/L (0.74-1.07 mmol/L)	Increased
Serum carbon dioxide combining power (bicarbonate) (venous)	23-30 mEq/L (23-30 mmol/L)	Decreased
Arterial blood pH	7.35-7.45	Decreased (in metabolic acidosis) or normal
Arterial blood bicarbonate ( )	21-28 mEq/L (21-28 mmol/L)	Decreased
Arterial blood PaCO <sub>2</sub>	35-45 mm Hg	Decreased
Hemoglobin	Female: 12-16 g/dL (120-160 g/L) Male: 14-18 g/dL (140-180 g/L) Older adults: Slightly decreased	Decreased
Hematocrit	Female: 37%-47% (0.37-0.47 volume fraction) Male: 42%-52% (0.42-0.52 volume fraction) Older adults: May be slightly decreased	Decreased to 20%
Blood osmolality	280-300 mOsm/L (mmol/L)	Elevated in volume-depleted states, increasing the risk for acute kidney injury
Blood osmolality	280-300 mOsm/kg (mmol/kg)	Elevated in volume-depleted states, increasing the risk for acute kidney injury

CKD, Chronic kidney disease; SI, International System of Units.

Data from Pagana, K., Pagana, T., & Pike-McDonald, S. (2013). *Mosby's Canadian manual of diagnostic and laboratory tests*. St.

In early AKI, urine tests provide important information. Urine sodium levels may reflect an inability to concentrate urine. Urine may be dilute with a specific gravity near 1.000 or concentrated with a specific gravity greater than 1.030. The presence of urine sediment (e.g., red blood cells, casts, and tubular cells), myoglobin, or hemoglobin may lead to nephron damage.

### Imaging Assessment.

Ultrasonography is useful in the diagnosis of kidney and urinary tract obstruction. Dilation of the renal calyces and collecting ducts, as well as stones, can be detected. Ultrasonography can show kidney size and patency of the ureters. Small kidney size may indicate an underlying CKD with loss of kidney tissue.

CT scans without contrast medium can determine adequacy of kidney PERFUSION and identify obstruction or tumors. Contrast medium is usually avoided to prevent further kidney damage (Lambert et al., 2017). An MRI may be used in place of CT scan.

X-rays of the pelvis or kidneys, ureters, and bladder (KUB) may provide an initial view of kidneys and the urinary tract to determine the cause of AKI. Enlarged kidneys with obstruction may show hydronephrosis. X-rays can show stones obstructing the renal pelvis, ureters, or bladder. More commonly, ultrasound is used to screen for hydronephrosis.

A nuclear medicine study called MAG3 may be used to determine the nature of the kidney failure and measure GFR. A renal scan can determine whether PERFUSION of the kidneys is sufficient. Cystoscopy or retrograde pyelography may be needed to identify obstructions of the lower urinary tract (see Chapter 65).

### Other Diagnostic Assessments.

Kidney biopsy is performed if the cause of AKI is uncertain and symptoms persist or an immunologic disease is suspected. Prepare the patient before the test, particularly managing both hypotension and hypertension. Hypertension increases the risk for intrarenal hemorrhage following needle biopsy. Provide follow-up care. Be aware of all test results and understand how they might affect the treatment regimen. (See Chapter 65 for a detailed discussion of diagnostic tests related to the kidney.)

## NCLEX Examination Challenge 68-1

### Safe and Effective Care Environment

The client is a 62-year-old admitted 2 days ago with traumatic injuries and hypovolemic shock from a car crash. The nurse reviewing the client's daily laboratory test results notices the following values. Which result is **most important** to report to the primary health care provider immediately?

- A. Serum sodium 132 mEq/L (mmol/L)
- B. Serum potassium 6.9 mEq/L (mmol/L)
- C. Blood urea nitrogen 24 mg/dL (mmol/L)
- D. Hematocrit 32% (0.32 volume fraction); hemoglobin 9.2 g/dL (92 g/L)

### ◆Interventions: Responding

Avoid hypotension and maintain normal fluid balance (*euvolemia*) to prevent and manage AKI. A reduction in kidney PERFUSION may initially not be recognized when there is no associated drop in systemic blood pressure. Autoregulation and the renin-angiotensin-aldosterone system (RAAS) effectively maintain normal kidney perfusion and glomerular filtration rate. However, these mechanisms may not be adequate in the critically ill patient, and some experts suggest maintaining a mean arterial pressure (MAP) of 80 mm Hg in high-risk or critically ill adults (Hain & Paixao,

2015). Ensure that the patient's MAP goal is shared with all interprofessional health team members.

Reduce exposure to nephrotoxic agents and drugs that alter kidney perfusion. When such substances cannot be avoided, monitor drug levels and communicate with the pharmacist to adjust doses to minimize harm. Contrast media can have serious toxic effects on tubular cells (Lambert et al., 2017). Ensure that kidney function is assessed before an imaging test that includes contrast media. A large volume of contrast, agents with high osmolarity (>2000 mOsm/L [mmol/L]), and frequent administration (given twice in 3 months or more often) of agents are more likely to cause contrast-induced nephropathy. Ensure that kidney function is assessed before an imaging test and that both the radiologist and the requesting primary health care provider are aware of reduced kidney function before contrast medium is given.

Communicate with the radiologist so the lowest dose of the contrast agent is used in high-risk adults. Adequate hydration is essential to prevent contrast-induced nephropathy (Honicker & Holt, 2016; Lambert et al., 2017). The patient may receive IV fluids at a rate of 1 mL/kg/hr for 12 hours before the imaging test or at 3 mL/kg/hour for 1 hour just before the procedure to ensure hydration and dilution of the contrast medium and to speed urinary ELIMINATION of the agent. A common desired outcome for patients undergoing a procedure with contrast medium is a urine output of 150 mL/hr for the first 6 hours after administration of the contrast agent.

Observations about new-onset or increased peripheral edema, increased daily weight, and reduced urine output can identify patients with a positive fluid balance from AKI who may require treatment with fluid restriction or diuretic therapy. Impairment of ACID-BASE BALANCE and electrolyte imbalance can occur and may require treatment, especially in older adults.

Blood sampling of patients at risk for AKI allows early recognition of elevated serum creatinine levels and trend data. Communicate observations about worsening kidney function early and often to the primary health care provider so interventions can promote kidney health and interrupt the progression of AKI when it occurs.

Not all patients with AKI experience oliguria. IMMUNITY and inflammatory causes of AKI may allow proteins to enter the glomerulus, and these proteins can hold fluid in the filtrate, causing a *polyuria* (excess urine output) that disrupts FLUID AND ELECTROLYTE BALANCE. During AKI with high-volume urine output, hypovolemia and electrolyte *loss* are the main problems. The patient in the diuretic phase of AKI needs a plan of care that focuses on fluid and electrolyte *replacement* and monitoring. Onset of polyuria can signal the start of recovery from AKI.

Surviving kidney tubule cells possess a remarkable ability to regenerate and proliferate, and early identification can stop progression of AKI, as well as aid in recovery of kidney function. Base the desired outcomes of care on collaboration and communication with interprofessional team members. Update the plan of care for either restriction (when fluid overload from new AKI is present) or liberal administration of fluid (to prevent AKI or promote elimination of contrast medium) based on timely and accurate team communication.

Frequent laboratory value monitoring, close surveillance of intake and output, drug therapy, nutrition, careful administration of fluids and minerals, and renal replacement therapy are commonly used to manage AKI.

## NCLEX Examination Challenge 68-2

### Safe and Effective Care Environment

Which actions/interventions are **most important** for the nurse to perform when caring for a 70-year-old client who is scheduled for a contrast-medium enhanced CT scan? **Select all that apply.**

- A. Assess for coexisting conditions of pre-existing diabetes, heart failure, and established CKD.
- B. Assess the hourly urine output for at least 6 hours before the procedure.
- C. Assess creatinine clearance using a 24-hour urine collection test.
- D. Alert the primary health care provider to a serum creatinine that has increased from 0.2 to 0.4 mg/dL (20-40 μmol/L) in the previous 24 hours.
- E. Alert the primary health care provider to a glomerular filtration rate (GFR) <60 mL/min/1.73 m<sup>2</sup>.

- F. Assess for hypovolemia, including evaluation of the mean arterial pressure (MAP).
- G. Collaborate with the primary health care provider to determine whether isotonic IV fluids should be infused before the test.
- H. Discuss with the primary health care provider about whether the client's prescribed diuretic should be held immediately before the test.

### Drug Therapy.

The interprofessional team consults the inpatient pharmacist for drug adjustment based on kidney function. As kidney function changes, drug dosages are changed. It is important to be knowledgeable about the site of drug metabolism and especially careful when giving drugs. Continuously monitor the patient with AKI for adverse drug events and interactions of the drugs that he or she is receiving. Diuretics may be used to increase urine output in AKI. Diuretic-induced urine output does not preserve kidney function or stop AKI, but diuretics do rid the body of retained fluid and electrolytes in the patient with AKI that has not progressed to end-stage kidney disease (ESKD).

Fluid challenges are often used to promote kidney PERFUSION. In patients without fluid overload, 500 to 1000 mL of normal saline may be infused over 1 hour. Patients with AKI often require central venous pressure (CVP) monitoring during a fluid challenge. When cardiac disease is also present and worsening, measurement of pulmonary arterial pressure by means of a pulmonary artery catheter for accurate evaluation of hemodynamic status may be needed. During fluid challenges, closely assess the response to fluid and slow the infusion if indications of fluid overload, particularly respiratory distress, occur.

Investigation is ongoing to identify biomarkers that can indicate kidney injury early. Neutrophil gelatinase-associated lipocalin (NGAL) and cystatin C appear to signal adverse changes in the kidney and may be useful to guide treatment ([Dirkes, 2015](#)).

### Nutrition Therapy.

Patients who have AKI often have a high rate of *catabolism* (protein breakdown). Increases in metabolism and protein breakdown may be related to the stress of illness and the increase in blood levels of catecholamines, cortisol, and glucagon. The rate of protein breakdown correlates with the severity of uremia and azotemia. Catabolism causes the breakdown of muscle protein and increases azotemia.

The interprofessional team's registered dietitian in the ICU setting calculates the patient's protein and caloric needs. A consultation may need to be requested for inpatients outside of the ICU or for those in the community settings. Work with the dietitian to establish a diet with specified amounts of protein, sodium, and fluids. For the patient who does not require dialysis, 0.6 g/kg of body weight or 40 g/day of protein is usually prescribed. For patients who require dialysis, the protein level needed ranges from 1 to 1.5 g/kg. The dietary sodium ranges from 60 to 90 mEq/kg (mmol/kg). If high blood potassium levels are present, dietary potassium is restricted to 60 to 70 mEq/kg (mmol/kg). The daily amount of fluid permitted is calculated to be equal to the urine volume plus 500 mL. Assess food intake every shift to ensure that caloric intake is adequate.

Many patients with AKI are too ill, or their appetite is too poor to meet caloric goals. For these patients, nutrition support with oral supplements, enteral nutrition, or parenteral nutrition (PN or hyperalimentation) is needed. Nutrition support in AKI aims to provide sufficient nutrients to maintain or improve nutrition status, preserve lean body mass, restore or maintain fluid balance, and preserve kidney function.

There are several kidney-specific formulations of oral supplements and enteral solutions (e.g., Nepro, Suplena Renalcal, and NovaSource Renal). Most specialty formulas for patients with kidney problems are lower in sodium, potassium, and phosphorus and higher in calories than are standard feedings. Enteral nutrition, delivered with a nasogastric or nasojejunal tube (these tubes can also be placed orally), can be used for nutrition support. If PN is used, the IV solutions are mixed to meet the patient's specific needs. Because kidney function is unstable in AKI, continuously monitor intake and output and serum electrolyte levels to determine how the supplementation affects FLUID AND ELECTROLYTE BALANCE. IV fat emulsion (Intralipid) infusions can provide a nonprotein source of calories. In uremic patients, fat emulsions are used in place of glucose to avoid the problems of

excessive sugars.

### Kidney Replacement Therapy.

Kidney replacement therapy (KRT), also called renal replacement therapy (RRT), is used for patients with loss of kidney function and inadequate waste ELIMINATION. Indications for KRT include symptomatic uremia (e.g., pericarditis, neuropathy, decline in cognition), persistent or rapidly rising high potassium levels (i.e., greater than 6.5 mEq/L [mmol/L]), severe metabolic acidosis (pH less than 7.1), or fluid overload that inhibits tissue PERFUSION. When AKI occurs with drug or alcohol intoxication, KRT also can remove toxins.

Immediate vascular access for KRT in patients with AKI is made by placement of a catheter specific for dialysis (Fig. 68-1). The temporary catheter is placed in a central vein, most often the internal jugular (Schell-Chaple, 2017), using best practices to avoid catheter-associated bloodstream infections (see Chapter 13). Placement of the catheter requires informed consent and a “time-out” similar to other surgical procedures (see Chapter 14, Care of Preoperative Patients). This catheter is not used to acquire blood samples, give drugs or fluid, or monitor central venous pressure. Provide site care in accordance with agency policy and best practices to avoid catheter-related bloodstream infection (CRBSI).

**FIG. 68-1** Subclavian dialysis catheters. These catheters are radiopaque tubes that can be used for hemodialysis access. The Y-shaped tubing allows arterial outflow and venous return through a single catheter. **A**, Mahurkar catheters, made of polyurethane and used for short-term access. **B**, PermCath catheter, made of silicone and used for long-term access. (Courtesy Kendall Company, Bothell, WA.)

A long-term dialysis catheter may be placed in the radiology department using a tunneling technique under moderate sedation. Under ultrasound or fluoroscopic guidance, the physician makes a small incision where the internal jugular vein passes behind the clavicle. A 6- to 8-cm tunnel is created away from the site of the incision. A long-term hemodialysis catheter is inserted through the tunnel and into the jugular vein. Keeping a segment of the catheter within the subcutaneous tissues before entering the jugular vein reduces the risk for infection. This central catheter is used only for dialysis and requires aseptic dressing changes.

Dialysis catheters have two lumens, one for outflow and one for inflow. This allows the patient's blood to flow out and, once dialyzed, to be returned through the inflow lumen. Some catheters have a third lumen to sample venous blood or give drugs and fluid during dialysis.

## Intermittent Versus Continuous Kidney Replacement Therapy.

Kidney replacement therapy (KRT) is a supportive strategy to purify blood, substituting for the normal function of the kidney. Particles are separated from blood based on the different ability of particles to pass through (diffuse) a membrane or across the peritoneal lining. KRT can be delivered intermittently, continuously, or as a hybrid of these approaches. Mortality is significant, regardless of modality, among patients who require KRT.

Intermittent KRT, sometimes called *hemodialysis*, is delivered over 3 to 6 hours. Generally a technician or dialysis nurse brings the dialysis machine to the bedside of a critically ill patient. Patients who do not need intensive care may be transported to an inpatient dialysis unit for the duration of the KRT treatment.

Intermittent KRT uses a dialysis machine to mix and monitor the *dialysate* (the fluid that helps remove the unwanted particles and waste products from blood). Dialysate is prescribed by the nephrology health care provider as an admixture to restore electrolytes and minerals to normal levels in the blood. The machine also monitors the flow of blood while it is outside of the body. Alarms are set and monitored by the dialysis technician or nurse to ensure safe and effective flow. This type of KRT is delivered three or four times weekly and requires anticoagulation in the dialysis circuit. However, dialysis creates shifts of fluid and electrolytes that may not be tolerated in critically ill patients. Another form of intermittent KRT is peritoneal dialysis, which is more commonly used for end-stage kidney disease. This therapy is discussed in detail in the Peritoneal Dialysis section of this chapter.

Continuous kidney replacement therapies (CKRTs), also known as *hemofiltration*, are alternative methods for removing wastes and restoring both ACID-BASE BALANCE and FLUID AND ELECTROLYTE BALANCE. They are used in hospitalized adults who are too unstable to tolerate the changes in blood pressure that occur with intermittent conventional hemodialysis. As with hemodialysis, blood is passed through a filter to remove waste and undesired particles. Unlike intermittent hemodialysis, CKRT removes and returns blood over 12 to 24 hours each day (Schell-Chaple, 2017). Another difference between CKRT and intermittent hemodialysis is the approach used to remove particles from blood. Hemofiltration uses ultrafiltration, whereas diffusion is used in intermittent dialysis to remove toxins and other particles. *Ultrafiltration* is the separation of particles from a suspension by passage through a filter with very fine pores. In ultrafiltration, the separation is performed by convective transport. During intermittent hemodialysis, separation depends on differential diffusion. Some approaches to CKRT combine ultrafiltration with diffusion (combined hemofiltration and hemodialysis).

CKRT occurs only in the ICU because of (1) the need for frequent monitoring and specialized skill set of the nurse to maintain safety during *extracorporeal circulation* (blood flow outside the body), and (2) the need for ongoing monitoring and replacement of fluid and electrolytes (Schell-Chaple, 2017). The American Nephrology Nurses Association provides resources for intermittent and continuous KRT policies and procedures.

Several strategies can be used to provide hemofiltration to critically ill patients. Continuous venovenous hemofiltration (CVVH) is more commonly used. CVVH is powered by a pump that drives blood from the patient catheter into the dialyzer (filter). The ultrafiltrate fluid is then collected into a bag for disposal. There may be a second pump that acts on the ultrafiltrate tubing to create negative pressure and increase fluid removal. Replacement fluid is infused via the inflow circuit in some systems. The pump increases the risk for an air embolus, and KRT systems have alarms that detect air. These systems also use anticoagulants but at lower doses than needed for systems using arterial access. CVVH can also be combined with dialysis (continuous venovenous hemofiltration and dialysis [CVVHD]). CVVHD is similar to intermittent KRT except that the rates of blood circulation and waste ELIMINATION are much slower with CVVHD, thus the need for continuous therapy (Dirkes, 2015).

Another modality for KRT is a hybrid of continuous and intermittent approaches. Slow continuous ultrafiltration (SCUF) provides slow removal of fluid over 12 to 24 hours and may be useful when azotemia or uremia is not a concern. Sustained low-efficiency dialysis (SLED) uses the dialysis machine to deliver prolonged dialysis for 12 to 24 hours. Lower blood flow and dialysate flow rates remove both particles and water and may be better tolerated by the unstable or critically ill patient, with fewer episodes of hypotension.

Continuous KRT is expensive and resource intensive. It requires consultation and collaboration with the nephrologist and close collaboration with a dialysis nurse. Conservative management of

FLUID AND ELECTROLYTE BALANCE, ACID-BASE BALANCE, and drug therapy is an acceptable and reasonable approach to manage AKI.

### Posthospital Care.

Patients with AKI may have many outcomes. Some patients recover and return to baseline kidney function and general health. Others have partial recovery with mild or moderate chronic kidney disease (CKD). Still others may require permanent KRT. Some die from the acute illness.

The care for a patient with AKI after discharge from the hospital varies, depending on the status of the kidney function when the patient is discharged. Resolution of kidney injury may occur over several months, and follow-up care may be provided by a nephrologist or by the primary health care provider in consultation with the nephrologist. Frequent medical visits are necessary, as are scheduled laboratory blood and urine tests to monitor kidney function. A dietitian can plan modifications to the patient's diet according to the degree of kidney function and ongoing nutrition needs. Fluid restrictions and daily weights may be advised to avoid fluid overload while kidneys are recovering.

About 10% of patients who receive KRT for AKI in the hospital develop end-stage kidney disease (ESKD) and require intermittent dialysis or kidney transplantation (Dirkes, 2015). For patients who require dialysis at discharge following AKI, follow-up care is similar to that needed for patients with ESKD from CKD (see [Care Coordination and Transition Management](#) in the CKD section). Depending on their level of independence and family support, patients may need home care nursing or social work assistance.

## NCLEX Examination Challenge 68-3

### Health Promotion and Maintenance

The nurse is preparing a client for discharge who developed an acute kidney injury during coronary artery bypass graft surgery. The nurse notices that the client has a serum creatinine of 1.2 mg/dL (106 μmol/L) and a glomerular filtration rate (GFR) of 75 mL/kg/1.73 m<sup>2</sup>. Which is the **priority** nursing action?

- A. Reminding the client to remain hydrated by drinking 500 mL of an electrolyte-based solution daily
- B. Encouraging the client to reduce protein intake to reduce creatinine production until the follow-up visit with the nephrologist occurs
- C. Checking the remaining values on the metabolic panel and informing the primary care provider of all results before the client is discharged
- D. Educating the client about the need for follow-up, including re-evaluation of serum creatinine with the primary care provider or nephrologist in 8-12 weeks

## Elimination Concept Exemplar Chronic Kidney Disease

### Pathophysiology

Unlike acute kidney injury (AKI), **chronic kidney disease (CKD)** is a progressive, irreversible disorder, and kidney function does *not* recover (Taal, 2016). It is defined as abnormalities in kidney structure or function that alter health and are present for longer than 3 months (KDIGO, 2013).

When kidney function and waste ELIMINATION are too poor to sustain life, CKD becomes **end-stage kidney disease (ESKD)**. Terms used with CKD include **azotemia** (buildup of nitrogen-based wastes in the blood), **uremia** (azotemia with symptoms [Chart 68-2]), and **uremic syndrome**. See Table 68-1 for a comparison of AKI and CKD.

#### Chart 68-2

### Key Features

#### Uremia

- Metallic taste in the mouth
- Anorexia
- Nausea
- Vomiting
- Muscle cramps
- Uremic “frost” on skin
- Itching
- Fatigue and lethargy
- Hiccups
- Edema
- Dyspnea
- Paresthesias

### Stages of Chronic Kidney Disease

CKD is classified into five stages based on glomerular filtration rate (GFR) category. Direct measurement of urine creatinine (described in Chapter 65, using a 3-hour or 24-hour urine collection) is needed for most accurate GFR estimation. The five stages of CKD are described in Table 68-6. CKD starts with a normal GFR but increased risk for kidney damage. In the first stage, the patient may have a normal GFR (greater than 90 mL/min) but have abnormal urine findings, structural abnormalities, or genetic traits that point to kidney disease. The patient is at increased risk for kidney damage from infection, IMMUNITY responses with inflammation, pregnancy, dehydration, and hypotension. Careful management of conditions such as diabetes, hypertension, and heart failure can slow the onset and progression of CKD.

**TABLE 68-6**

**Stages of Chronic Kidney Disease**

STAGE	ESTIMATED GLOMERULAR FILTRATION RATE	INTERVENTION
Stage 1		

<b>Stage 1</b> At risk; normal kidney function but urine findings, structural abnormalities, or genetic trait points to kidney disease	>90 mL/min	Screen for risk factors and manage care to reduce risk: <ul style="list-style-type: none"> <li>• Uncontrolled hypertension</li> <li>• Diabetes with poor glycemic control</li> <li>• Congenital or acquired anatomic or urinary tract abnormalities</li> <li>• Family history of genetic kidney diseases</li> <li>• Exposure to nephrotoxic substances</li> </ul>
<b>Stage 2</b> Mild chronic kidney disease (CKD); reduced kidney function; laboratory values and other findings (e.g., structural changes) point to kidney disease	60-89 mL/min	Focus on reduction of risk factors.
<b>Stage 3</b> Moderate CKD	30-59 mL/min	Implement strategies to slow disease progression.
<b>Stage 4</b> Severe CKD	15-29 mL/min	Manage complications. Discuss patient preferences and values. Educate about options and prepare for renal replacement therapy.
<b>Stage 5</b> End-stage kidney disease (ESKD)	<15 mL/min	Implement renal replacement therapy or kidney transplantation.

In Stage 2 CKD, GFR is reduced, ranging between 60 and 89 mL/min, and albuminuria may be present. Kidney nephron damage has occurred, and there may be slight elevations of metabolic wastes in the blood because of nephron loss. Levels of blood urea nitrogen (BUN), serum creatinine, uric acid, and phosphorus are not sensitive enough to define this stage. Increased output of dilute urine may occur at this stage of CKD and lead to severe dehydration.

## Nursing Safety Priority QSEN

### Action Alert

Teach patients with mild chronic kidney disease (CKD) that carefully managing fluid volume, blood pressure, electrolytes, and other kidney-damaging diseases by following prescribed drug and nutrition therapies can slow progression to end-stage kidney disease (ESKD).

In Stage 3 CKD, GRF reduction continues and ranges between 30 and 59 mL/min, and albuminuria is usually present. Nephron damage is greater, and azotemia reflecting poor waste ELIMINATION is present. Ongoing management of the underlying conditions that cause nephron damage is essential, especially diabetes mellitus and blood pressure control. Restriction of fluids, proteins, and electrolytes is needed. Stage 3 is further divided into 3a and 3b to more accurately assess the risk for complications from CKD as GFR decreases below 45 mL/min/1.73 m<sup>2</sup>.

Over time, patients progress to Stage 4 CKD and *end-stage kidney disease* (ESKD) (Stage 5). Waste ELIMINATION is poor with excessive amounts of urea and creatinine building up in the blood, and the kidneys cannot maintain homeostasis. Severe impairments of FLUID AND ELECTROLYTE BALANCE and ACID-BASE BALANCE occur. Without kidney replacement therapy, death results from ESKD.

Three albuminuria stages also are considered in evaluating CKD. These stages are defined by the albumin-to-creatinine ratio in urine. The first stage (A1) is none to mildly increased albumin, up to 29 mg/g creatinine (<3 mg/mmol) and is sometimes called *microalbuminuria*. The second (A2) stage has values of 30 to 300 mg/g creatinine (3 to 30 mg/mmol). The stage of greatest kidney damage (A3) has values >300 mg/g creatinine (>30 mg/mmol). The risk for progression of CKD, ESKD, and mortality is increased when urine albumin increases. Albumin in the urine is a marker of kidney damage, whereas GFR reflects kidney function. The combined values help identify adults at risk for progression of CKD and complications and guide interventions.

## Kidney Changes

CKD with greatly reduced GFR causes many problems, including abnormal urine production, severe disruption of FLUID AND ELECTROLYTE BALANCE, and metabolic abnormalities. Because healthy nephrons become larger and work harder, urine production and water ELIMINATION are sufficient to maintain essential homeostasis until about three fourths of kidney function is lost. As the disease progresses, the ability to produce diluted urine is reduced, resulting in urine with a fixed osmolarity (*isosthenuria*). As kidney function continues to decline, the BUN increases, and urine output decreases. Patients with CKD can have a 10% to 20% increase in extracellular fluid volume, including blood volume (Scher et al., 2015). At this point, the patient is at risk for fluid overload with edema, pulmonary crackles, shortness of breath, and pleural or pericardial effusion (with symptoms of a friction rub on auscultation and/or decreased breath sounds or heart sounds).

## Metabolic Changes

*Urea and creatinine* excretion are disrupted by CKD. Creatinine comes from proteins in skeletal muscle. The rate of creatinine excretion depends on muscle mass, physical activity, and diet. Without major changes in diet or physical activity, the serum creatinine level is constant. Creatinine is partially excreted by the kidney tubules, and a decrease in kidney function leads to a buildup of serum creatinine. Urea is made from protein metabolism and is excreted by the kidneys. The BUN level normally varies directly with protein intake.

*Sodium* excretion changes are common. Early in CKD, the patient is at risk for *hyponatremia* (sodium depletion) because there are fewer healthy nephrons to reabsorb sodium. Thus sodium is lost in the urine. Polyuria of mild-to-moderate CKD also causes sodium loss.

In the later stages of CKD, kidney excretion of sodium is reduced as urine production decreases. Then sodium retention and high serum sodium levels (*hypernatremia*) occur with only modest increases in dietary sodium intake. This problem leads to severe disruption of FLUID AND ELECTROLYTE BALANCE (see [Chapter 11](#)). Sodium retention causes hypertension and edema.

Even with sodium retention, the serum sodium level may appear normal because plasma water is retained at the same time. If fluid retention occurs at a greater rate than sodium retention, the serum sodium level is falsely low because of dilution (see [Chart 68-1](#)).

*Potassium* excretion occurs mainly through the kidney. Any increase in potassium load during the later stages of CKD can lead to **hyperkalemia** (high serum potassium levels). Normal serum potassium levels of 3.5 to 5 mEq/L (mmol/L) are maintained until the 24-hour urine output falls below 500 mL. High potassium levels then develop quickly, reaching 7 to 8 mEq/L (mmol/L) or greater. Life-threatening changes in cardiac rate and rhythm result from this elevation because of abnormal depolarization and repolarization. Other factors contribute to high potassium levels in CKD, including the ingestion of potassium in drugs, failure to restrict dietary potassium, tissue breakdown, blood transfusions, and bleeding or hemorrhage. (See [Chapter 11](#) for discussion of potassium problems.)

ACID-BASE BALANCE is affected by CKD. In the early stages, blood pH changes little because the remaining healthy nephrons increase their rate of acid excretion. As more nephrons are lost, acid excretion is reduced and metabolic acidosis results (see [Chapter 12](#)).

Many factors lead to acidosis in CKD. First, the kidneys cannot excrete excessive hydrogen ions (acids). Normally, tubular cells move hydrogen ions into the urine for excretion, but ammonium and bicarbonate are needed for this movement to occur ([Norton et al., 2017b](#)). In patients with CKD, ammonium production is decreased and reabsorption of bicarbonate does not occur. This process leads to a buildup of hydrogen ions and reduced levels of bicarbonate (*base deficit*). High potassium levels further reduce kidney ammonium production and excretion.

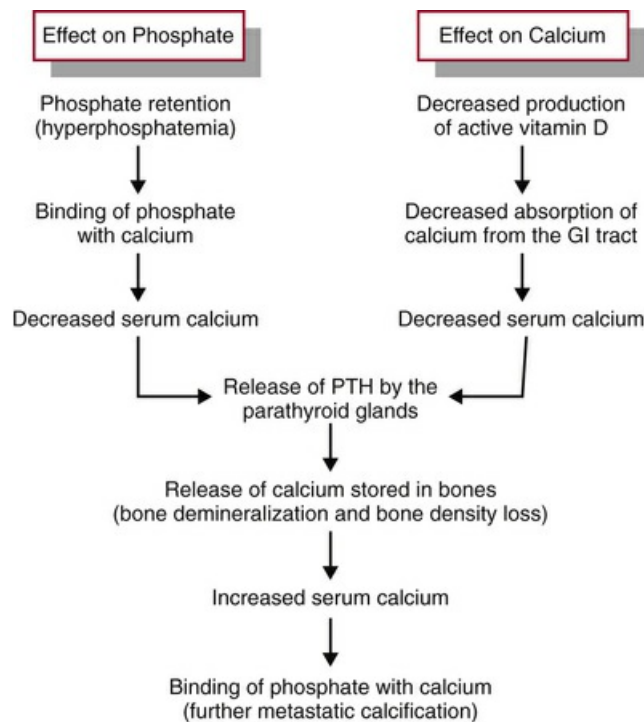

As CKD worsens and acid retention increases, increased respiratory action is needed to keep blood pH normal. The respiratory system adjusts or compensates for the increased blood hydrogen ion levels (acidosis or decreased pH) by increasing the rate and depth of breathing to excrete carbon dioxide through the lungs. This breathing pattern, called **Kussmaul respiration**, increases with worsening kidney disease. Serum bicarbonate measures the extent of metabolic acidosis (bicarbonate deficit). Patients usually need alkali replacement to counteract acidosis.

*Calcium and phosphorus* balance is disrupted by CKD. A complex, balanced normal reciprocal relationship exists between calcium and phosphorus (used interchangeably with phosphate) and is influenced by vitamin D (see [Chapter 11](#)). The kidney produces a hormone needed to activate vitamin D, which then enhances intestinal absorption of calcium.

Normally, excess dietary phosphorus is excreted by the kidneys in the urine. In CKD, phosphorus overload leads to secretion of a phosphaturic hormone from bone ([Fukagawa et al., 2013](#)). This hormone, fibroblast growth factor 3 (FGFR3), contributes to mineral imbalance.

Parathyroid hormone (PTH) controls the amount of phosphorus in the blood by causing tubular excretion of phosphorus when there is an excess. An early effect of CKD is reduced phosphorus excretion ([Fig. 68-2](#)). As plasma phosphorus levels increase (*hyperphosphatemia*), calcium levels decrease (*hypocalcemia*). Chronic low blood calcium levels stimulate the parathyroid glands to release more PTH. With additional PTH, calcium is released from storage areas in bones (*bone resorption*), which results in bone density loss. The extra calcium from the bone is needed to balance the excess plasma phosphorus level. The problem of low blood calcium levels is made worse with severe CKD because kidney cell damage also reduces production of active vitamin D. Thus less calcium is absorbed through the intestinal tract in the absence of sufficient vitamin D ([Norton et al.,](#)

2017b).

**FIG. 68-2** Effects of kidney dysfunction on phosphorus and calcium balance. *PTH*, Parathyroid hormone.

The problems in bone metabolism and structure caused by CKD-induced low calcium levels and high phosphorus levels are called **renal osteodystrophy**. Bone mineral loss causes bone pain, spinal sclerosis, fractures, bone density loss, osteomalacia, and tooth calcium loss.

Crystals formed from excessive calcium or phosphorus are called *metastatic calcifications* and may precipitate in many body areas. When the plasma level of the calcium-phosphorus product (serum calcium level multiplied by the serum phosphorus level) exceeds 70 mg/dL (6 mmol/L), the crystals may lodge in the kidneys, heart, lungs, blood vessels, joints, eyes (causing conjunctivitis), and brain. Itching increases with calcium-phosphorus imbalances.

Calcium is also deposited in atherosclerotic plaques in the lining of blood vessels. Vascular calcium deposits are a marker of significant risk for cardiovascular disease.

## Cardiac Changes

*Hypertension* is common in most patients with CKD. It may be either the cause or the result of CKD. In patients who have other causes of hypertension such as atherosclerosis, the increased blood pressure damages the glomerular capillaries, and eventually ESKD results.

CKD itself elevates blood pressure by causing fluid and sodium overload and dysfunction of the renin-angiotensin-aldosterone system (RAAS). Hypertension alone can damage kidney arterioles, reducing *PERFUSION*. A decrease in kidney blood flow results in the production and release of a number of signaling chemicals, including renin, to improve blood flow to the kidney. The release of renin triggers the production of angiotensin and aldosterone. Angiotensin causes blood vessel constriction and increases blood pressure. Aldosterone stimulates kidney tubules to reabsorb sodium and water. These actions increase plasma volume and raise blood pressure. However, in the presence of CKD, an increase in blood pressure may not result in increased blood flow, and the production of renin continues, which creates a cycle of vasoconstriction in kidney arterioles and peripheral arterioles. The result is severe hypertension that is difficult to manage and worsens kidney function. Many patients with CKD have heart damage and enlargement from the long-term hypertension that results in coronary artery damage and poor coronary artery perfusion.

*Hyperlipidemia* occurs in CKD from changes in fat metabolism that increase triglyceride, total cholesterol, and low-density lipoprotein (LDL) levels. These changes increase the patient's risk for coronary artery disease and acute cardiac events. Problems with lipids and atherosclerosis are

greatly increased for the patient with both CKD and diabetes mellitus.

*Heart failure* may occur in CKD because the workload on the heart is increased as a result of anemia, hypertension, and fluid overload. Left ventricular enlargement and heart failure are common in ESKD. Uremia may cause *uremic cardiomyopathy*, the uremic toxin effect on the myocardium. Heart failure also may occur in these patients because of hypertension and coronary artery disease. Cardiac disease is a leading cause of death in patients with ESKD.

*Pericarditis* also occurs in patients with CKD. The pericardial sac becomes inflamed by uremic toxins or infection. If it is not treated, this problem leads to pericardial effusion, cardiac tamponade, and death. Symptoms include shortness of breath from low cardiac output, severe chest pain, tachycardia, narrow *pulse pressure* (close values for systolic and diastolic blood pressure), low-grade fever, and a pericardial friction rub that can be heard with a stethoscope placed over the left sternal border. Dysrhythmias may occur with uremia and uremic pericarditis. Treatment of tamponade, which is a medical emergency, requires immediate removal of pericardial fluid by placement of a needle, catheter, or drainage tube into the pericardium.

### Hematologic and Immunity Changes

Anemia is common in patients in the later stages of CKD and worsens CKD symptoms. The causes of anemia include a decreased erythropoietin level with reduced red blood cell (RBC) production, decreased RBC survival time from uremia, and iron and folic acid deficiencies (Norton et al., 2017b). The patient may have increased bleeding or bruising as a result of impaired platelet function.

CKD causes reduced IMMUNITY, which increases the risk for infection. Uremia disrupts white blood cell (WBC) production and function, decreasing host defenses. Protein, fluid, and electrolyte abnormalities contribute to inflammation and further immunity impairment.

### Gastrointestinal Changes

Uremia affects the entire GI system. The flora of the mouth change with uremia. The mouth contains the enzyme *urease*, which breaks down urea into ammonia. The ammonia generated remains and then causes halitosis (uremic fetor) and *stomatitis* (mouth inflammation). Anorexia, nausea, vomiting, and hiccups are common in patients with uremia. The specific cause of these problems is unknown but may be related to high BUN and creatinine levels and acidosis.

Peptic ulcer disease is common in patients with uremia, but the exact cause is unclear. Uremic colitis with watery diarrhea or constipation may also be present with uremia. Ulcers may occur in the stomach or intestine, causing erosion of blood vessels. The blood loss caused by these erosions may lead to hemorrhagic shock from severe GI bleeding.

### Cognitive and Functional Changes

Although CKD may be asymptomatic in the early stages, as it progresses complications include cognitive and physical impairment. There is also increased risk for systemic drug toxicity and adverse effects from interventions used to prevent or treat CKD.

### Etiology and Genetic Risk

The causes of CKD are complex (Table 68-7). More than 100 different disease processes can result in progressive loss of kidney function (see also Chapter 67). Two main causes of CKD leading to dialysis or kidney transplantation are hypertension and diabetes mellitus. African-American patients are much more likely to develop ESKD and have hypertensive ESKD.

**NOTE:** List is not all-inclusive.

## Incidence and Prevalence

The number of patients being treated for CKD is increasing, particularly among older adults. About 11% of adults in the United States have CKD, with more than half at stages 3 or 4 ([Centers for Disease Control and Prevention \[CDC\], 2016](#)). Over 800,000 people in the United States are being treated for ESKD ([U.S. Renal Data Systems \[USRDS\], 2015](#)). In Canada, more than 6000 adults have ESKD ([Kidney Foundation of Canada, 2015](#)). About 25% of patients receiving treatment for ESKD die in the first year of dialysis. [Chart 68-3](#) addresses the prevention of kidney and urinary problems.

### Chart 68-3

## Patient and Family Education: Preparing for Self-Management

### Prevention of Kidney and Urinary Problems

- Be alert to the general appearance of your urine. Note any changes in its color, clarity, or odor.
- Changes in the frequency or volume of urine passage occur with changes in fluid intake. More frequent or infrequent voiding not associated with changes in fluid intake may signal health problems.
- Any discomfort or distress with the passage of urine is not normal. Pain, burning, urgency, aching, or difficulty with initiating urine flow or complete bladder emptying is of some concern. Report such symptoms to your primary health care provider.
- The kidneys need 1 to 2 liters of fluid a day to flush out your body wastes. Water is the ideal flushing agent.
- Avoid sugary, high-calorie drinks; they provide low-quality calories that contribute to weight gain and sugar-induced urination.
- Changes in kidney function are often silent for many years. Periodically ask your primary health care provider to measure your kidney function with a blood test (serum creatinine) and a urinalysis.
- If you have a history of kidney disease, diabetes mellitus, hypertension (high blood pressure), or a family history of kidney disease, you should know your serum creatinine level and your glomerular filtration rate (either estimated from serum creatinine or measured with a 24-hour creatinine urine collection). At least one checkup per year that includes laboratory blood and urine testing of kidney function is recommended.
- If you are identified as having decreased kidney function, ask about whether any prescribed drug, diagnostic test, or therapeutic procedure will present a risk to your current kidney function. Evaluate the contribution of diet to risk for kidney disease with your primary health care provider or a dietitian. Check out all nonprescription drugs with your primary health care provider or pharmacist before using them.

### Health Promotion and Maintenance

Health promotion activities to prevent or delay the onset of CKD focus on controlling the diseases that lead to its development, such as diabetes and hypertension. Educating and encouraging the patient to accept lifestyle modifications and how to implement them are incorporated into the ongoing plan of care. Diet adjustments (e.g., sodium, protein, and cholesterol restriction), weight

maintenance (i.e., achieve body mass index of 22 to 25 kg/m<sup>2</sup>), smoking cessation, participation in 30 to 60 minutes of moderate-intensity exercise daily, and limitation of alcohol to 1 or 2 drinks daily are examples of lifestyle recommendations for the patient with CKD. Identifying patients who have diabetes or hypertension at an early stage is critical to CKD prevention (Norton et al., 2017a). Teach patients to adhere to drug and diet regimens and to engage in regular physical activity to prevent the blood vessel changes and kidney cell damage that lead to CKD. Instruct patients with diabetes to keep their blood glucose levels within the prescribed range. Teach patients with hypertension that drug therapy reduces vessel damage. Urge patients with diabetes or hypertension to have yearly testing for urine albumin-to-creatinine ratio (UACR) along with serum creatinine and BUN.

Teach adults treated for an infection anywhere in the kidney/urinary system to take all antibiotics as prescribed. Urge adults to drink at least 2 L of water daily unless a health problem requires fluid restriction. Caution adults who use NSAIDs to use the lowest dose for the briefest time period because these drugs interfere with blood flow to the kidney. High-dose and long-term NSAID use reduces kidney function.

## NCLEX Examination Challenge 68-4

### Health Promotion and Maintenance

A 48-year-old African-American man is newly diagnosed with hypertension and Stage 1 chronic kidney disease (CKD). His primary health care provider has prescribed a thiazide diuretic. The client reports that he has increased his activity and changed his diet, which resulted in a 10-lb (4.5-kg) weight loss in the past 2 months. The client says he feels well and does not want to take any drugs. What is the nurse's **best** response?

- A. "Reducing your blood pressure may slow or prevent progression of your chronic kidney disease."
- B. "Your primary health care provider prescribed the diuretic because it will reverse the damage caused by kidney disease."
- C. "Taking medications is a personal decision, and you have the right to decline this prescription."
- D. "Because your lifestyle changes have resulted in weight loss, this intervention is all that is needed to reduce your risk for progression of kidney disease."

### Interprofessional Collaborative Care

Although the patient with CKD may require hospitalization during exacerbation of imbalances or when other health problems require it, the vast majority of care occurs in the community. For best outcomes, the patient with CKD must be engaged in self-management. Because patients with CKD are at risk for so many adverse outcomes (not just ESKD), the interprofessional care team includes many specialists and health care professionals (e.g., nephrologists, nephrology nurses, pharmacists, registered dietitians, mental health therapists, physical therapists, case managers, social workers, clergy or pastoral care workers). The responsibilities of these interprofessional team members are described within the interventions sections for CKD. With so many professionals involved, care coordination is essential to positive outcomes in this population (Hain, 2015). The nurse coordinates the interprofessional team to support and counsel the patient and family, often over many years of treatment. The nurse has the most contact with the patient when he or she is hospitalized or undergoing in-center dialysis treatments.

#### Assessment: Noticing

##### History.

When taking a history from a patient with risk for or actual CKD, document the patient's age and gender. Accurately measure weight and height and ask about usual weight and recent weight gain or loss. Weight gain may indicate fluid retention from poor kidney function with disrupted FLUID

AND ELECTROLYTE BALANCE. Weight loss may be the result of anorexia from uremia.

Ask about a history of kidney and urologic disorders, chronic health problems, and drug use. Chronic hypertension, diabetes, inflammatory diseases of systemic lupus erythematosus or arthritis, cancer, and tuberculosis can cause decreased kidney function. Ask the patient about family members' kidney disease that might indicate a genetic problem.

Document the use of current and past prescribed and over-the-counter drugs because many drugs are nephrotoxic and drug interactions can cause kidney damage (see [Table 68-5](#)) (Burchum & Rosenthal, 2016). Ask whether the patient has had x-rays or CT scan with contrast medium.

Examine the patient's dietary habits and discuss any GI problems. A change in the taste of foods often occurs with CKD. Patients may report that sweet foods are not as appealing or that meats have a metallic taste. Ask about the presence of nausea, vomiting, anorexia, hiccups, diarrhea, or constipation. These symptoms may be the result of excess wastes that the body cannot eliminate because of kidney disease.

Ask about the patient's energy level and any recent injuries or bleeding. Explore changes in his or her daily routine as a possible *result* of fatigue. Fatigue is a common and often profound problem among patients with CKD, particularly among patients receiving dialysis. Weakness, drowsiness, and shortness of breath suggest impending pulmonary edema or neurologic degeneration. Ask about bruising or bleeding caused by hematologic changes from uremia.

Discuss urine ELIMINATION in detail, including frequency of urination, appearance of the urine, and any difficulty starting or controlling urination. These data can help identify urologic problems that may influence kidney function.

### Physical Assessment/Signs and Symptoms.

CKD causes changes in all body systems ([Chart 68-4](#)). Most symptoms are related to changes in FLUID AND ELECTROLYTE BALANCE, ACID-BASE BALANCE, and buildup of nitrogenous wastes.

#### Chart 68-4

### Key Features

#### Severe Chronic and End-Stage Kidney Disease

##### Neurologic Symptoms

- Lethargy and daytime drowsiness
- Inability to concentrate or decreased attention span
- Seizures
- Coma
- Slurred speech
- Asterixis (jerky movements or “flapping” of the hands)
- Tremors, twitching, or jerky movements
- Myoclonus
- Ataxia (alteration in gait)
- Paresthesias from peripheral neuropathy

##### Cardiovascular Symptoms

- Cardiomyopathy
- Hypertension

- Peripheral edema
- Heart failure
- Uremic pericarditis
- Pericardial effusion
- Pericardial friction rub
- Cardiac tamponade
- Cardiorenal syndrome

### **Respiratory Symptoms**

- Uremic halitosis
- Tachypnea
- Deep sighing, yawning
- Kussmaul respirations
- Uremic pneumonitis
- Shortness of breath
- Pulmonary edema
- Pleural effusion
- Depressed cough reflex
- Crackles

### **Hematologic Symptoms**

- Anemia
- Abnormal bleeding and bruising
- Reduced white blood cell count
- Increased risk for infection

### **Gastrointestinal Symptoms**

- Anorexia
- Nausea
- Vomiting
- Metallic taste in the mouth
- Changes in taste acuity and sensation
- Uremic colitis (diarrhea)
- Constipation

- Uremic gastritis (possible GI bleeding)
- Uremic fetor (breath odor)
- Stomatitis

### Urinary Symptoms

- Polyuria, nocturia (early)
- Oliguria, anuria (later)
- Proteinuria
- Hematuria
- Diluted, straw-colored urine appearance (early)
- Concentrated and cloudy urine appearance (later)

### Integumentary Symptoms

- Decreased skin turgor
- Yellow-gray pallor
- Dry skin
- Pruritus
- Ecchymosis
- Purpura
- Soft-tissue calcifications
- Uremic frost (late, premonitory)

### Musculoskeletal Symptoms

- Muscle weakness and cramping
- Bone pain
- Fractures
- Renal osteodystrophy

### Reproductive Symptoms

- Decreased fertility
- Infrequent or absent menses
- Decreased libido
- Impotence
- Sexual dysfunction

### Metabolic Symptoms

- Hyperparathyroidism
- Hyperlipidemia
- Alterations in vitamin D, calcium, and phosphorus adsorption and metabolism
- Metabolic acidosis
- Hyperkalemia

### Psychosocial Symptoms

- Depression
- Fatigue
- Sleep disturbances
- Sexual dysfunction
- Cognitive impairment
- Unemployment

*Neurologic symptoms* of CKD and uremic syndrome vary (see [Chart 68-4](#)). Observe for problems ranging from lethargy to seizures or coma, which may indicate uremic encephalopathy. Fluid overload can cause changes in cognition. Assess for sensory changes that appear in a glove-and-stocking pattern over the hands and feet (*peripheral neuropathy*). Check for weakness in upper and lower extremities (*uremic neuropathy*). Fatigue can result in decreased activity.

If untreated, encephalopathy can lead to seizures and coma. Dialysis is used emergently when neurologic problems result from CKD. The symptoms of encephalopathy may resolve with dialysis. However, improvement in neuropathy can be limited by severe or recurrent episodes of brain dysfunction. Depression may compound cognitive and neurologic problems.

*Cardiovascular symptoms* of CKD result from fluid overload, hypertension, heart failure (HF), pericarditis, potassium-induced dysrhythmias, and cholesterol/calcium (plaque, atherosclerosis) deposits in blood vessels. Assess for indications of reduced sodium and water excretion. Blood volume overload, if untreated, leads to hypertension, pulmonary edema, peripheral edema, and HF.

Assess heart rate and rhythm, listening for extra sounds (particularly an  $S_3$ ), irregular patterns, or a pericardial friction rub. Unless a dialysis vascular access has been created, measure blood pressure in each arm. Assess the jugular veins for distention, and assess for edema of the feet, shins, and sacrum and around the eyes. Crackles during lung auscultation and shortness of breath with exertion and at night suggest fluid overload.

*Respiratory symptoms* of CKD also vary (e.g., breath that smells like urine [*uremic fetor* or uremic halitosis], deep sighing, yawning, shortness of breath). Observe the rhythm, rate, and depth of breathing. Tachypnea and **hyperpnea** (increased depth of breathing) occur with metabolic acidosis.

With severe metabolic acidosis, extreme increases in rate and depth of ventilation (Kussmaul respirations) occur. A few patients have pneumonitis, or *uremic lung*. In these patients, assess for thick sputum, reduced coughing, tachypnea, and fever. A pleural friction rub may be heard with a stethoscope. Patients often have pleuritic pain with breathing. Auscultate the lungs for crackles, which indicate fluid overload.

*Hematologic symptoms* of CKD include anemia and abnormal bleeding. Check for indicators of anemia (e.g., fatigue, pallor, lethargy, weakness, shortness of breath, dizziness). Check for abnormal bleeding by observing for bruising, petechiae, purpura, mucous membrane bleeding in the nose or gums, or intestinal bleeding (black, tarry stools [**melena**]).

*GI symptoms* of CKD include foul breath (halitosis) and mouth inflammation or ulceration. Document any abdominal pain, cramping, or vomiting. Test all stools for occult blood.

*Skeletal symptoms* of CKD are related to osteodystrophy from poor absorption of calcium and continuous bone calcium loss. Adults with osteodystrophy have thin, fragile bones that are at risk

for fractures with even slight trauma. Vertebrae become more compact and may bend forward, leading to an overall loss of height. Ask about changes in height and bone pain. Observe for spinal curvatures and any unusual bumps or protrusions in bone areas that may indicate fractures. Handle the patient carefully during examination and care.

*Urine symptoms* in CKD reflect the kidneys' decreasing function. Urine amount, frequency, and appearance change. Protein, sediment, or blood may be in the urine.

The amount and composition of the urine change as kidney function decreases and waste ELIMINATION is disrupted. With the onset of mild-to-moderate CKD, the urine may be more dilute and clearer because tubular reabsorption of water is reduced. The actual urine output in a patient with CKD varies with the amount of remaining kidney function. The patient with severe CKD or ESKD usually has oliguria, but some patients continue to produce 1 L or more daily. Daily urine volume usually changes again after dialysis is started. A long duration of oliguria is an indication that recovery of kidney function is not to be expected.

*Skin symptoms* of CKD occur as a result of uremia. Pigment is deposited in the skin, causing a yellowish coloration, or darkening when skin is brown or bronze. The anemia of CKD causes sallowness, appearing as a faded suntan on lighter-skinned patients.

Skin oils and turgor are decreased in patients with uremia. A distressing problem of uremia is severe *pruritus* (itching). **Uremic frost**, a layer of urea crystals from evaporated sweat, may appear on the face, eyebrows, axillae, and groin in patients with advanced uremic syndrome. Assess for bruises (*ecchymosis*), purple patches (*purpura*), and rashes.

### Psychosocial Assessment.

CKD and its treatment disrupt many aspects of a patient's life. Psychosocial assessment and support are part of the nurse's role from the time that CKD is first diagnosed. With ongoing issues, a mental health professional is an important member of the care team. Ask about the patient's understanding of the diagnosis and what the treatment regimen means to him or her (e.g., diet, drugs, dialysis). Assess for anxiety and fear and for coping styles used by the patient and family. CKD affects family relations, social activity, work patterns, body image, and sexual activity. The chronic nature of severe CKD and ESKD, the many treatment options, and the uncertainties about the disease and its treatment require ongoing psychosocial assessment, psychosocial interventions, and ongoing support. Support the recommendations of the mental health professional.

### Laboratory Assessment.

CKD causes extreme changes in many laboratory values (see [Chart 68-1](#)). Monitor these blood values: creatinine, blood urea nitrogen (BUN), sodium, potassium, calcium, phosphorus, bicarbonate, hemoglobin, and hematocrit. Also monitor GFR for trends.

A urinalysis is performed. In the early stages of CKD, urinalysis may show protein, glucose, red blood cells (RBCs) and white blood cells (WBCs), and decreased or fixed specific gravity. Urine osmolality is usually decreased. As CKD progresses, urine output decreases dramatically, and osmolality increases. A urine albumin-to-creatinine ratio (UACR) provides important information about kidney function and damage.

Glomerular filtration rate (GFR) can be estimated from serum creatinine levels, age, gender, race, and body size. But this type of estimation is generally used for screening rather than for staging of CKD. Estimation of GFR based on a formula that includes serum creatinine is also useful to calculate drug dose or drug frequency when reduced kidney function is a concern. However, to determine stage of CKD, a urine collection of 3 hours to 24 hours is usually done to assess creatinine clearance. A spot urine albumin-to-creatinine ratio also is completed.

In severe CKD, serum creatinine and BUN levels may be used to determine the presence and degree of uremia. Serum creatinine levels may increase gradually over a period of years, reaching levels of 15 to 30 mg/dL (500 to 1000 mcmol/L) or more, depending on the patient's muscle mass. BUN levels are directly related to dietary protein intake. Without protein restriction, BUN levels may rise to 10 to 20 times the value of the serum creatinine level. With dietary protein restriction, BUN levels are elevated but less than those of non-protein-restricted patients. Fluid balance also affects BUN.

### Imaging Assessment.

Few x-ray findings are abnormal with CKD. Bone x-rays of the hand can show renal

osteodystrophy. With long-term ESKD, the kidneys shrink (except for ESKD caused by polycystic kidney disease) and may be 8 to 9 cm or smaller. This small size results from atrophy and fibrosis. If CKD progresses suddenly, a kidney ultrasound or CT scan without contrast medium may be used to rule out an obstruction. (See [Chapter 65](#) for a complete description of diagnostic tests for kidney function.)

### ◆**Analysis: Interpreting**

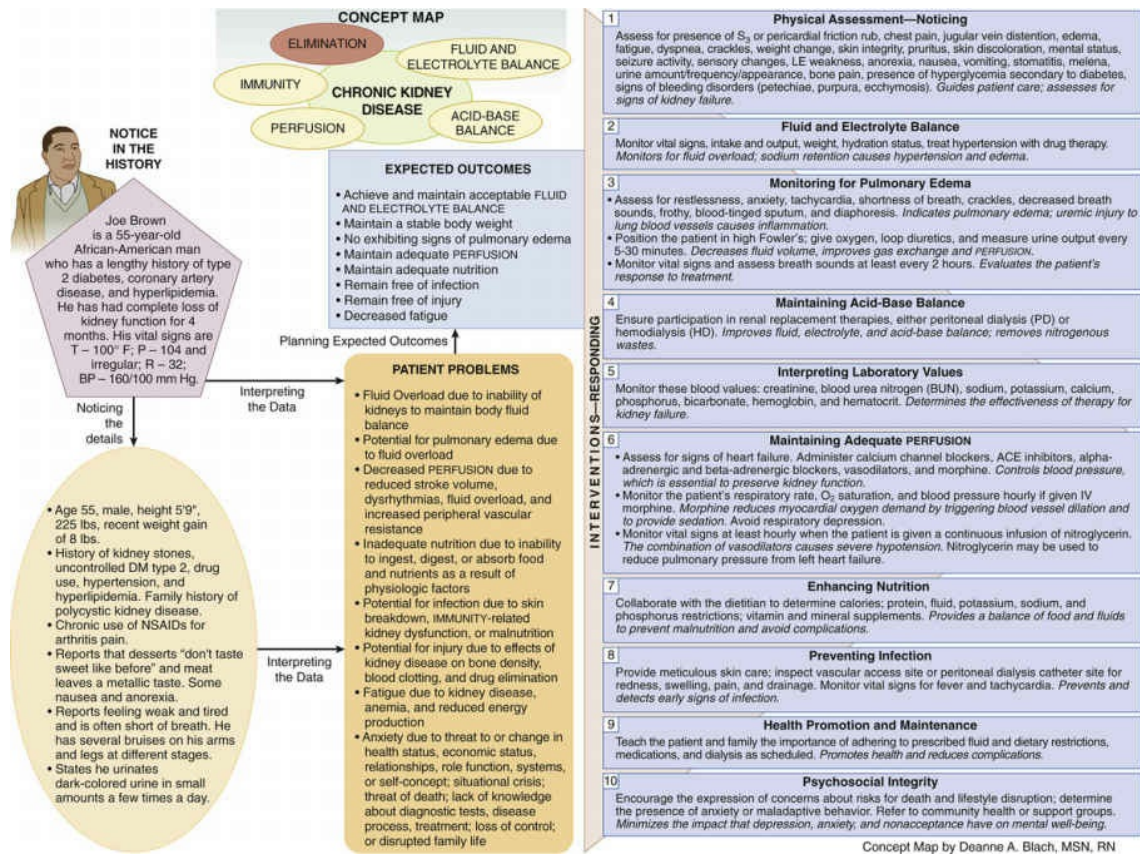

The patient with CKD usually has progressive reduction of kidney function. Management generally occurs in the community setting. In the acute or long-term care setting, the focus of care is to manage problems and prevent complications of CKD. The priority collaborative problems for patients with CKD include:

1. Fluid overload due to the inability of diseased kidneys to maintain body fluid balance
2. Potential for pulmonary edema due to fluid overload
3. Decreased cardiac function due to reduced stroke volume, dysrhythmias, fluid overload, and increased peripheral vascular resistance
4. Weight loss due to inability to ingest, digest, or absorb food and nutrients as a result of physiologic factors
5. Potential for infection due to skin breakdown, IMMUNITY-related kidney dysfunction, or malnutrition
6. Potential for injury due to effects of kidney disease on bone density, blood clotting, and drug elimination
7. Fatigue due to kidney disease, anemia, and reduced energy production
8. Anxiety due to change in health status, economic status, relationships, role function; threat of death; lack of knowledge about diagnostic tests, disease process, treatment; loss of control; or disrupted family life
9. Potential for depression due to chronic debilitating illness

### ◆**Planning and Implementation: Responding**

The Concept Map discusses nursing care issues related to patients who have end-stage kidney disease (ESKD).

## Managing Fluid Volume

### Planning: Expected Outcomes.

The patient with CKD is expected to achieve and maintain an acceptable FLUID AND ELECTROLYTE BALANCE. Indicators include that blood pressure, central venous pressure, and electrolytes are normal or nearly normal. Body weight is stable ( $\pm 2$  lb overnight and 5 lb weekly) and does not increase more than 3 lb between dialysis sessions.

### Interventions.

Management of the patient with CKD includes drug therapy, nutrition therapy, fluid restriction, and dialysis (when the patient reaches Stage 5). Hemodialysis is performed intermittently for 3 to 4 hours, typically 3 days per week. Alternatively, some patients with ESKD receive peritoneal dialysis. Peritoneal dialysis (PD) uses the peritoneum as the dialyzing membrane. The dialysate is infused through a catheter tunneled into the peritoneum. Dialysis for ESKD is described later in this chapter.

The purpose of fluid management is to attain fluid balance and prevent complications of fluid overload (Chart 68-5). Monitor the patient's intake and output and hydration status. Assess for indications of fluid overload (e.g., lung crackles, edema, distended neck veins).

### Chart 68-5

## Best Practice for Patient Safety & Quality Care QSEN

### Managing Fluid Volume

- Weigh the patient daily at the same time each day, using the same scale, with the patient wearing the same amount and type of clothing, and graph the results.
- Observe the weight graph for trends (1 L of water weighs 1 kg).

- Accurately measure all fluid intake and output.
- Teach the patient and family about the need to keep fluid intake within prescribed restricted amounts and to ensure that the prescribed daily amount is evenly distributed throughout the 24 hours.
- Monitor for these symptoms of fluid overload at least every 4 hours during critical illness:
- Decreased urine output
- Rapid, bounding pulse
- Rapid, shallow respirations
- Presence of dependent edema
- Auscultation of crackles or wheezes
- Presence of distended neck veins in a sitting position
- Decreased oxygen saturation
- Elevated blood pressure
- Narrowed pulse pressure
- Assess level of consciousness and degree of cognition.
- Ask about the presence of headache or blurred vision.

*Drug therapy* with diuretics is prescribed for patients with mild-to-severe CKD to increase urinary ELIMINATION of fluid. The increased urine output with this therapy helps reduce fluid overload and hypertension in patients who still have some urine output. Diuretics are seldom used in ESKD after dialysis is started because, as kidney function is reduced, these drugs can accumulate and harm the remaining kidney cells and the patient's hearing.

Assess fluid status by obtaining daily weights and reviewing intake and output. Daily weight gain in these patients indicates fluid retention rather than true body weight gain. Estimate the amount of fluid retained: 1 kg of weight equals about 1 L of fluid retained. Weigh the patient daily at the same time each day, on the same scale, wearing the same amount of clothing, and after voiding (if the patient is not anuric). Monitor weight for changes before and after dialysis.

*Fluid restriction* is often needed. Consider all forms of fluid intake, including oral, IV, and enteral sources, when calculating fluid intake. Help the patient spread oral fluid intake over a 24-hour period. Monitor his or her response to fluid restriction, and notify the primary health care provider if symptoms of fluid overload persist or worsen.

## Preventing Pulmonary Edema

### Planning: Expected Outcomes.

The patient with CKD is expected to remain free of pulmonary edema by maintaining optimal fluid balance. Indicators include that the patient has no breathing difficulty and no adventitious lung sounds (e.g., crackles, wheezes) with auscultation and that oxygen saturation remains greater than 92%.

## Interventions.

Pulmonary edema can result from left-sided heart failure related to fluid overload or from blood vessel injury. In left-sided heart failure, the heart is unable to eject blood adequately from the left ventricle, leading to an increased pressure in the left atrium and in the pulmonary blood vessels. The increased pressure causes fluid to cross the capillaries into the pulmonary tissue, forming edema (McCance et al., 2014). Pulmonary edema can also occur from injury to the lung blood vessels as a result of uremia. This condition causes inflammation and capillary leak. Fluid then leaks from pulmonary circulation into the lung tissue and alveoli. It may also leak into the pleural space, causing a *pleural effusion*.

Assess the patient for early indicators of pulmonary edema, such as restlessness, anxiety, rapid heart rate, shortness of breath, and crackles that begin at the base of the lungs. As pulmonary edema worsens, the level of fluid in the lungs rises. Auscultation reveals increased crackles and decreased breath sounds. The patient may have frothy, blood-tinged sputum. As cardiac and pulmonary function decrease further, the patient becomes diaphoretic and cyanotic.

The patient with pulmonary edema usually is admitted to the hospital for aggressive treatment and continuous cardiac monitoring. Place the patient in a high-Fowler's position and give oxygen to improve gas exchange. Drug therapy with kidney failure and pulmonary edema is difficult because of potential adverse drug effects on the kidneys (Burchum & Rosenthal, 2016). Loop diuretics such as IV furosemide (Lasix) are used to manage pulmonary edema. Kidney impairment increases the risk for *ototoxicity* (ear damage with hearing loss) with furosemide; thus IV doses are given cautiously. Diuresis usually begins within 5 minutes of giving IV furosemide. Measure urine output hourly until the patient is stabilized. Monitor vital signs and assess breath sounds at least every 2 hours to evaluate the patient's response to this treatment.

IV morphine (1 to 2 mg) can be prescribed to reduce myocardial oxygen demand by triggering blood vessel dilation and to provide sedation. Dosage adjustments are needed to achieve the desired response and avoid respiratory depression. Monitor the patient's respiratory rate, oxygen saturation, and blood pressure hourly during this therapy. Other drugs that dilate blood vessels, such as nitroglycerin, may be given as a continuous infusion to reduce pulmonary pressure from left heart failure. Monitor vital signs at least hourly because this drug combination may cause severe hypotension.

Monitor serum electrolyte levels daily and report abnormalities to the primary health care provider so imbalances can be corrected quickly. If using ECG monitoring, identify dysrhythmias as they occur and report changes in rhythm that affect consciousness or blood pressure immediately to the provider. Monitor oxygen saturation levels by pulse oximetry and consult with the respiratory therapist for the optimal method to deliver oxygen (e.g., facemask, nasal cannula, or noninvasive mechanical support [see Chapter 28]). Monitor the patient for worsening of the condition with indications of increasing hypoxemia (decreasing SpO<sub>2</sub> values, restlessness, decreased cognition, or new-onset confusion). Temporary intubation and mechanical ventilation may be needed if respiratory failure occurs.

Patients with CKD who have existing cardiac problems, high blood pressure, or chronic fluid retention are at increased risk for developing pulmonary edema. They are less likely to respond quickly to treatment and are more likely to develop problems related to drug therapy. Kidney replacement therapy with ultrafiltration or dialysis may be used to reduce fluid volume.

## Increasing Cardiac Function

### Planning: Expected Outcomes.

The patient with CKD is expected to attain and maintain adequate cardiac function. Indicators include that systolic and diastolic blood pressures, ejection fraction, peripheral pulses, and cognitive status are either normal or nearly normal.

### Interventions.

Many patients with long-standing hypertension are at risk for CKD and accelerated progression of kidney failure once CKD occurs. *Therefore blood pressure control is essential in preserving kidney function* (Norton et al., 2017a). To control blood pressure, diuretics (especially thiazides), calcium channel blockers, angiotensin-converting enzyme inhibitors (ACEIs), alpha-adrenergic and beta-adrenergic blockers, and vasodilators may be prescribed. ACEIs are the most effective drugs to

decrease cardiovascular events when patients have CKD and hypertension. Calcium channel blockers can improve the GFR and blood flow within the kidney.

More information on the specific drugs for blood pressure control can be found in [Chapter 36](#). Indications vary, depending on the patient, and these drugs are used carefully to avoid complications. Different dosages and combinations may be tried until blood pressure control is adequate and side effects are minimized. A common desired outcome of therapy for patients with CKD is to keep blood pressure below 135/85 ([Scher et al., 2015](#)).

Teach the patient and family to measure blood pressure daily. Evaluate their ability to measure and record blood pressure accurately using their own equipment. Recheck measurement accuracy on a regular basis. Teach the patient and family about the relationship of blood pressure control to diet and drug therapy. Instruct the patient to weigh daily and to bring records of blood pressure measurements and drug administration times and weights for discussion with the physician, nurse, or registered dietitian.

Assess the patient on an ongoing basis for signs and symptoms of reduced cardiac output, heart failure, and dysrhythmias. These topics are discussed in [Chapters 34, 35, and 38](#).

## Enhancing Nutrition

### Planning: Expected Outcomes.

The patient with CKD is expected to maintain adequate nutrition. He or she should have a protein-caloric intake appropriate for his or her weight-to-height ratio, muscle tone, and laboratory values (serum albumin, hematocrit, hemoglobin).

### Interventions.

The nutrition needs and diet restrictions for the patient with CKD vary according to the degree of kidney function and the type of kidney replacement therapy used ([Table 68-8](#)). The purpose of nutrition therapy is to provide the food and fluids needed to prevent malnutrition and avoid complications from CKD ([Norton et al., 2017a](#)).

**TABLE 68-8**

**Dietary Restrictions Needed for Severe Kidney Disease**

DIETARY COMPONENT	WITH CHRONIC UREMIA	WITH HEMODIALYSIS	WITH PERITONEAL DIALYSIS
Protein	0.55-0.60 g/kg/day	1.0-1.5 g/kg/day	1.2-1.5 g/kg/day
Fluid	Depends on urine output but may be as high as 1500-3000 mL/day	500-700 mL/day plus amount of urine output	Restriction based on fluid weight gain and blood pressure
Potassium	60-70 mEq or mmol daily	70 mEq or mmol daily	Usually no restriction
Sodium	1-3 g/day	2-4 g/day	Restriction based on fluid weight gain and blood pressure
Phosphorus	700 mg/day	700 mg/day	800 mg/day

The patient is referred to a dietitian for dietary teaching and planning. Work with the dietitian to teach the patient about diet changes that are needed as a result of CKD. Common changes include control of protein intake; fluid intake limitation; restriction of potassium, sodium, and phosphorus intake; taking vitamin and mineral supplements; and eating enough calories to meet metabolic need.

*Protein restriction* early in the course of the disease prevents some of the problems of CKD and may preserve kidney function ([Norton et al., 2017b](#)). Protein is restricted on the basis of the degree of kidney and waste ELIMINATION impairment (reduced glomerular filtration rate [GFR]) and the severity of the symptoms. Buildup of waste products from protein breakdown is the main cause of uremia.

The GFR and treatment of CKD are used to guide safe levels of protein intake. A patient with a severely reduced GFR who is *not* undergoing dialysis is usually permitted 0.55 to 0.60 g of protein per kilogram of body weight (e.g., 40 g of protein daily for a 150-lb [70-kg] adult). If protein is lost in the urine, it is added to the diet in amounts equal to that lost. Protein requirements are calculated by the registered dietitian based on actual body weight (corrected for edema), not ideal body weight.

The patient with ESKD receiving dialysis needs *more* protein because some protein is lost through dialysis. Protein requirements are tailored according to the patient's post-dialysis, or "dry," weight. Generally patients receiving hemodialysis are allowed about 1 to 1.5 g of protein/kg/day. Suggested

protein-containing foods are meat and eggs. If protein intake is not adequate, muscle wasting can occur. BUN and serum prealbumin levels are used to monitor the adequacy of protein intake. Decreased serum prealbumin levels indicate poor protein intake.

*Sodium restriction* is needed in patients with little or no urine output to maintain FLUID AND ELECTROLYTE BALANCE. Both fluid and sodium retention cause edema, hypertension, and heart failure (HF). Most patients with CKD retain sodium; a few cannot conserve sodium.

Estimate fluid and sodium retention status by monitoring the patient's body weight and blood pressure. In uremic patients not receiving dialysis, sodium is limited to 1 to 3 g daily, and fluid intake depends on urine output. In patients receiving dialysis, the sodium restriction is 2 to 4 g daily, and fluid intake is limited to 500 to 700 mL plus the amount of any urine output. Instruct the patient not to add salt at the table or during cooking. Many foods are significant sources of sodium (e.g., processed food, fast food, potato chips, pretzels, pickles, ham, bacon, sausage) and difficult to moderate or remove from one's diet. Inattention to sodium intake can increase the duration or number of dialysis treatments and contribute to *disequilibrium syndrome* (feeling "zonked") following dialysis.

*Potassium restriction* may be needed because high blood potassium levels can cause dangerous cardiac dysrhythmias. Monitor the ECG for tall, peaked T waves caused by hyperkalemia. Document serum potassium levels. Instruct the patient with ESKD to limit potassium intake to 60 to 70 mEq (mmol) daily. Teach him or her to read labels of seasoning agents carefully for sodium and potassium content. [Chart 11-6](#) lists common foods that are low in potassium and are permitted, along with foods that are high in potassium and should be avoided. Instruct patients to avoid salt substitutes composed of potassium chloride. Those receiving peritoneal dialysis or who are producing urine may not need potassium restriction.

*Phosphorus restriction* for control of phosphorus levels is started early in CKD to avoid renal osteodystrophy. Monitor serum phosphorus levels. Dietary phosphorus restrictions and drugs to assist with phosphorus control may be prescribed. Phosphate binders must be taken at mealtime. Most patients with CKD already restrict their protein intake; and, because high-protein foods are also high in phosphorus, this reduces phosphorus intake. [Chapter 11](#) lists foods high in potassium, sodium, and phosphorus. Cinacalcet (Sensipar), a drug to control parathyroid hormone excess, is also used to manage hyperphosphatemia and hypocalcemia.

*Vitamin and mineral supplementation* is needed daily for most patients with CKD. Low-protein diets are also low in vitamins, and water-soluble vitamins are removed from the blood during dialysis. Anemia also is a problem in patients with CKD because of the limited iron content of low-protein diets and decreased kidney production of erythropoietin. Thus supplemental iron is needed. Calcium and vitamin D supplements may be needed, depending on the patient's serum calcium levels and bone status.

*Nutrition needs* for patients undergoing peritoneal dialysis (PD) are slightly different from those for patients undergoing dialysis. Because protein is lost with the dialysate in PD, protein replacement is needed. Often 1.2 to 1.5 g of protein per kilogram of body weight per day is recommended. Patients may have anorexia and have difficulty eating enough protein. High-calorie oral supplements may also be needed (e.g., Magnacal Renal, Ensure Plus). Sodium restriction varies with fluid weight gain and blood pressure. Usually dietary potassium does not need to be restricted because the dialysate is potassium free, causing excess potassium to be removed from the blood. Any potassium restriction is determined by serum potassium levels.

Collaborate with the dietitian to assess each patient's nutrition needs. Teach the patient the dietary regimen and evaluate his or her understanding of and adherence to it. Give the patient and family written examples of the diet to promote adherence. Help patients adapt diet restrictions to their budget, ethnic background, and food preferences.

## **NCLEX Examination Challenge 68-5**

### **Health Promotion and Maintenance**

When the nurse caring for a client with severe chronic kidney disease asks what dietary modifications he has made for the disease, he reports the following actions. Which action indicates to the nurse that additional client education is needed?

- A. Using a scale to measure protein weight
- B. Taking calcium and vitamin D supplements daily
- C. Eliminating bananas, citrus fruits, and avocados
- D. Using a salt-substitute instead of ordinary table salt

## Preventing Infection

### Planning: Expected Outcomes.

The patient with CKD is expected to remain free of infection. Indicators include that the patient will have mild or no fever, no lymph node enlargement, negative urine culture, negative dialysis access site culture, and white blood cell count either within the normal range or only slightly elevated.

### Interventions.

Provide meticulous care to nonintact skin areas (e.g., incisions, drain sites, puncture sites, cracked or excoriated skin, pressure injuries) and preventive skin care to intact areas. For patients undergoing dialysis, inspect the vascular access site or peritoneal dialysis catheter insertion site every shift for redness, swelling, pain, and drainage. Monitor vital signs for signs and symptoms of infection (e.g., fever, tachycardia).

## Preventing Injury

### Planning: Expected Outcomes.

The patient with CKD is expected to remain free of injury. Indicators include that the patient is free of these problems:

- Pathologic fractures
- Toxic side effects from drug therapy
- Bleeding

### Interventions.

*Injury prevention strategies* are needed because the patient with long-standing CKD may have brittle, fragile bones that fracture easily and cause little pain. When lifting or moving a patient with fragile bones, use a lift sheet rather than pulling the patient. Teach unlicensed assistive personnel (UAP) the correct use of lift sheets. Observe for normal range of joint motion and for any unusual surface bumps or depressions over bony areas.

Managing drug therapy in patients with CKD is a complex clinical problem. Many over-the-counter drugs contain agents that alter kidney function. Therefore it is important to obtain a detailed drug history. Know the use of each drug, its side effects, and its site of metabolism.

Certain drugs must be avoided, and the dosages of others must be adjusted according to the degree of remaining kidney function (Gloe et al., 2016). As the patient's kidney function decreases, consult with the nephrologist and pharmacist to determine if further dosage adjustments are necessary. Assess for side effects and indications of drug toxicity and notify the prescriber as appropriate.

## Nursing Safety Priority QSEN

### Drug Alert

Monitor the patient with severe CKD or ESKD closely for drug-related complications and ensure that dosages are adjusted as needed (Gloe et al., 2016). Consult with the pharmacist to determine safe effective doses.

Many drugs are routinely given to patients with CKD (Chart 68-6). Know the rationale for these drugs and the nursing interventions. Many patients also have cardiac disease and may require

cardiac drugs such as digoxin. Patients with severe CKD and ESKD are particularly at risk for digoxin toxicity because the drug is excreted by the kidneys. When caring for patients with CKD who are receiving digoxin, monitor for indications of toxicity, such as nausea, vomiting, visual changes, restlessness, headache, confusion, bradycardia, and tachycardia. Monitor the serum drug levels to be certain they are in the therapeutic range (0.8 to 2 ng/mL). Closely monitor serum potassium levels of patients receiving digoxin because low potassium levels increase the risk for dysrhythmias and digoxin toxicity (Burchum & Rosenthal, 2016).

### Chart 68-6

## Common Examples of Drug Therapy

### Chronic Kidney Disease

DRUG	NURSING IMPLICATIONS
<b>Loop Diuretics</b> —Increase urine output to manage volume overload when urinary elimination is still present <ul style="list-style-type: none"> <li>Furosemide (Lasix)</li> <li>Bumetanide (Bumex, Burinex)</li> <li>Dose varies with severity of kidney damage; not effective in ESKD</li> </ul>	Monitor intake and output to assess therapy effectiveness. Generally the expected outcome is for output to be greater than intake by 500-1000/mL/24 hr. Monitor electrolytes because these drugs result in loss of potassium; this can be a desired effect in patients with hyperkalemia.
<b>Vitamins and Minerals</b> —Used to replace those lost through dialysis or poorly absorbed as a result of dietary restrictions and to lower vitamin or mineral excesses that could lead to more problems	
<b>Phosphate binders</b> form an insoluble calcium-phosphate complex to inhibit GI absorption to prevent hyperphosphatemia and renal osteodystrophy from hypocalcemia: <ul style="list-style-type: none"> <li>Calcium acetate (PhosLo)</li> <li>Calcium carbonate (Caltrate, Oysterical, others)</li> </ul> Noncalcium phosphate binders reduce blood phosphate levels without disturbing calcium levels: <ul style="list-style-type: none"> <li>Lanthanum carbonate</li> <li>Sevelamer (Renagel, Renvela)</li> </ul>	Teach patients to take drugs with meals to increase the effectiveness in slowing or preventing the absorption of dietary phosphorus. Teach patients not to take these drugs within 2 hours of other scheduled drugs to prevent the inhibited absorption of other drugs, especially cardiac drugs and antibiotics. Monitor both serum phosphorus and calcium levels because these drugs lower phosphorus and can cause hypercalcemia. Monitor for constipation because these can cause significant constipation, leading to fecal impaction or ileus. Teach patients to report muscle weakness, slow or irregular pulse, or confusion to the prescriber because these are symptoms of hypophosphatemia, which require dosage adjustment.
<b>Multivitamins and vitamin B supplements:</b> <ul style="list-style-type: none"> <li>Folic acid/folate (vitamin B<sub>9</sub>, Folvite, Novo-Folacid, cyanocobalamin (B<sub>12</sub>))</li> </ul>	Teach patients to take the drugs after dialysis to prevent the supplement from being removed from the blood during dialysis. Teach patients to take iron supplements (ferrous sulfate) with meals to reduce nausea and abdominal discomfort.
<b>Oral iron salts:</b> <ul style="list-style-type: none"> <li>Ferrous sulfate (Feosol, others)</li> <li>Ferrous fumarate (Slow Fe, others)</li> <li>Ferrous gluconate (Fergon, others)</li> </ul>	Teach patients to take stool softeners daily while taking iron supplements, which can cause constipation. Remind patients that iron supplements change the color of the stool because knowing the expected side effects decreases anxiety when they appear.
<b>Parenteral iron salts:</b> <ul style="list-style-type: none"> <li>Iron dextran (IV) (INFeD)</li> <li>Iron sucrose (IV) (Venofer)</li> </ul>	A test dose of iron dextran is recommended before IV administration because the incidence of allergic reactions is high. Do not mix with drug with other parenteral drugs because there are many incompatibilities.
<b>Vitamin D:</b> <ul style="list-style-type: none"> <li>Calcitriol (Rocaltrol, Calcijex, Vectical)</li> <li>Paricalcitol (Zemlar)</li> <li>Doxercalciferol (Hectorol)</li> </ul>	Monitor serum levels of calcium because this active form of vitamin D suppresses parathyroid production and can lead to hypocalcemia. Monitor serum levels of vitamin D because this is a lipid-soluble vitamin that can be overingested and lead to toxicity.
<b>Erythropoietin-Stimulating Agents (ESAs)</b> —Prevent or correct anemia caused by kidney disease through the stimulation of the bone marrow to increase red blood cell production and maturation <ul style="list-style-type: none"> <li>Epoetin alfa (Epogen, Procrit, generic)</li> <li>Darbepoetin alfa (Aranesp)</li> </ul>	Monitor hemoglobin values because these drugs can overproduce blood cells, which increases blood viscosity and causes hypertension. This problem increases the risk for a myocardial infarction. The drug should not be given when hemoglobin levels are greater than 13 g/dL (130 g/L). Teach patients to report any of these side effects to the prescriber as soon as possible: chest pain, difficulty breathing, high blood pressure, rapid weight gain, seizures, skin rash or hives, or swelling of feet or ankles because these symptoms indicate possible serious cardiac complications.
<b>Parathyroid Hormone Modulator</b> —Reduces parathyroid gland production of parathyroid hormone by decreasing the gland's sensitivity to calcium. This action helps maintain blood calcium and phosphorus levels closer to normal and can reduce renal osteodystrophy in patients with chronic kidney disease. <ul style="list-style-type: none"> <li>Cinacalcet (Sensipar)</li> </ul>	Monitor blood levels of calcium and phosphorus to assess drug therapy effectiveness and recognize imbalances of these important electrolytes. Teach the patient to monitor for and report diarrhea and muscle pain (myalgia), which are indications of calcium and/or phosphorus imbalance.

ESKD, End-stage kidney disease.

## Nursing Safety Priority QSEN

### Drug Alert

Doses of digoxin are much lower than for most drugs. When digoxin is administered to older adults with kidney disease, the prescribed daily dose may be even lower (0.0625 mg). Check and recheck the dosage before administering digoxin to a patient with kidney disease.

Drugs to control an excessively high phosphorus level include phosphate-binding agents. These drugs help prevent renal osteodystrophy and related injuries. Stress the importance of taking these agents and all prescribed drugs.

*Hypophosphatemia* (low serum phosphorus levels) is a complication of phosphate binding, especially in patients who do not eat adequately but continue to take phosphate-binding drugs. *Hypercalcemia* (high serum calcium levels) can occur in patients taking calcium-containing compounds to control phosphorus excess. In patients taking aluminum-based phosphate binders for prolonged periods, aluminum deposits may cause bone disease or neurologic problems.

Monitor the patient for muscle weakness, anorexia, malaise, tremors, and bone pain.

Teach patients with kidney disease to avoid antacids containing magnesium. These patients cannot excrete magnesium and thus should avoid additional intake.

Some drugs, in addition to those used to treat kidney failure, require special attention because they either are normally excreted by the kidney or can further damage the kidney. These drugs include antibiotics, opioids, antihypertensives, diuretics, insulin, and heparin.

Many antibiotics are safe for patients with CKD, but those excreted by the kidney and those that are nephrotoxic require dose adjustment (Gloe et al., 2016). To prevent complications of bloodstream infection from mouth bacteria, prophylactic antibiotics are given to patients with CKD before dental procedures.

Give opioid analgesics cautiously in patients with Stage 3 or 4 CKD or ESKD because the effects often last longer. Patients with uremia are sensitive to the respiratory depressant effects of these drugs. Because opioids are broken down by the liver and not the kidneys, the dosages are often the same, regardless of the level of kidney function. Monitor the patient's reactions closely after opioids are given to determine whether adjustments are needed.

As CKD progresses, the patient with diabetes often requires reduced doses of insulin or antidiabetic drugs because the failing kidneys do not excrete or metabolize these drugs well. Thus the drugs are effective longer, increasing the risk for hypoglycemia (Gloe et al., 2016). Monitor blood glucose levels at least four times daily to assess whether a dosage change is needed.

Poor platelet function and capillary fragility in CKD make anticoagulant therapy risky. Monitor patients receiving heparin, warfarin, or any anticoagulant every shift for bleeding. See [Chapter 40](#) for more information on caring for patients at increased risk for bleeding.

## Minimizing Fatigue

### Planning: Expected Outcomes.

The patient with CKD is expected to conserve energy by balancing activity and rest. Indicators include that the patient participates in self-care activities, has interest in surroundings, and demonstrates mental concentration.

### Interventions.

Some causes of fatigue in the patient with CKD include vitamin deficiency, anemia, and buildup of urea. All patients are given vitamin and mineral supplements because of diet restrictions and vitamin losses from dialysis. Avoid giving these supplements right before hemodialysis (HD) treatment because they will be dialyzed out of the body and the patient will receive no benefit.

The anemic patient with CKD is treated with agents to stimulate red blood cell production. The desired outcome of this therapy is to maintain a hemoglobin level around 10 g/dL (100 g/L). This therapy triggers bone marrow production of red blood cells if the patient has adequate iron stores. Iron supplements may be needed in patients who are iron deficient. Many who receive these drugs report improved appetite and sexual function along with decreased fatigue. The increased production of all blood cells from this therapy may increase blood pressure. The improved appetite challenges patients in their attempts to maintain protein, potassium, and fluid restrictions and requires additional education.

## Reducing Anxiety

### Planning: Expected Outcomes.

The patient with CKD is expected to have reduced tension and apprehension. Indicators include that the patient consistently demonstrates these behaviors:

- Uses effective coping strategies
- Reports an absence of anxiety

### Interventions.

Perform an ongoing assessment of the patient's anxiety level. Observe behavior for cues indicating increasing anxiety (e.g., anxious facial expressions, clenching of hands, tapping of feet, withdrawn posture, absence of eye contact) and provide interventions to decrease the anxiety level. Evaluate the support systems and the involvement of family and friends with the patient's care. Provide

ongoing supportive interventions throughout therapy.

Unfamiliar settings and lack of knowledge about treatments and tests can increase the patient's anxiety level. Explain all procedures, tests, and treatments. Identify the patient's knowledge needs about kidney disease. Provide instruction at a level that he or she can understand using a variety of written and visual materials.

Provide continuity of care, whenever possible, by using a consistent and trusting nurse-patient relationship to decrease anxiety and encourage the patient to discuss his or her thoughts and feelings about any current problems or concerns.

Encourage the patient to ask questions and discuss fears about the diagnosis, treatment strategies, common outcomes. An open atmosphere that allows for discussion can decrease anxiety. Facilitate discussions with family members about the prognosis and the impact on lifestyle.

### **Recognizing and Managing Depression.**

In people with CKD the number and severity of symptoms and the presence of comorbidities may lead to depression (Tsai et al., 2015). Loss, such as loss of work or family roles may contribute to depression. Depressive symptoms have been associated with nonadherence to CKD treatments. Sleep disturbances, also interrelated with depression, are common among adults receiving dialysis for ESKD.

#### **Planning: Expected Outcomes.**

The patient with CKD is expected to participate in self-care, have minimal social isolation, demonstrate effective coping, and have minimal spiritual distress related to CKD and its treatments. Indicators include that the patient consistently demonstrates these behaviors:

- Expresses feelings about performing self-care activities
- Initiates and assists with ADLs
- Sleeps and reports feeling refreshed from sleeping
- Discusses concerns about work and leisure involvement
- Maintains contact with family and friends
- Identifies resources such as self-help groups and religious communities for support

#### **Interventions.**

Assess for indicators of despair and loneliness. Encourage involvement in decisions and community support groups. Identify community resources to maintain independence, including delivered meals, transportation, and financial or health care options. Ask about sleep patterns and quality. Assess the coping mechanisms and successful methods of dealing with problems.

In the general population, drugs are commonly used to manage depression. However, pharmacologic effects of drugs in adults with CKD or those receiving dialysis are altered and may need additional monitoring with alternative approaches for effective care. Care coordination for patients with CKD is essential because multiple health care professions may be involved in delivering care. Care coordination helps to avoid adverse drug effects (and drug-drug interactions), avoid hospitalizations, and decrease problems related to depression.

### **Kidney Replacement Therapies**

Kidney replacement therapy (KRT) is needed when the pathologic changes of stage 4 and stage 5 CKD are life threatening or pose continuing discomfort. When the patient can no longer be managed with conservative therapies, such as diet, drugs, and fluid restriction, dialysis is indicated. Transplantation may be discussed at any time.

#### **Hemodialysis.**

Intermittent hemodialysis (HD) is the most common KRT used with ESKD (Table 68-9). Dialysis removes excess fluids and waste products and restores FLUID AND ELECTROLYTE BALANCE and ACID-BASE BALANCE. HD involves passing the patient's blood through an artificial semipermeable membrane to perform the kidney's filtering and excretion functions. Safe HD therapy requires technicians to provide meticulous care to the machines delivering HD and nurses to implement and supervise direct care. Technical or human error can lead to avoidable complications (e.g.,

hemolysis, air embolism, dialysate error, contamination, exsanguination).

**TABLE 68-9**  
**Comparison of Hemodialysis and Peritoneal Dialysis**

HEMODIALYSIS	PERITONEAL DIALYSIS
<b>Advantages</b>	
More efficient clearance of wastes Short time needed for treatment	Flexible schedule for exchanges Few hemodynamic changes during and following exchanges Fewer dietary and fluid restrictions
<b>Complications</b>	
Disequilibrium syndrome Muscle cramps and back pain Headache Itching Hemodynamic and cardiac adverse events (hypotension, cell lysis contributing to anemia, cardiac dysrhythmias) Infection Increased risk for subdural and intracranial hemorrhage from anticoagulation and changes in blood pressure during dialysis	Protein loss Peritonitis Hyperglycemia from dialysate Respiratory distress Bowel perforation Infection Weight gain; discomfort from "carrying" 1-2 L in abdomen during dwell time; potential for back pain or development of hernia
<b>Contraindications</b>	
Hemodynamic instability or severe cardiac disease Severe vascular disease that prevents vascular access Serious bleeding disorders Uncontrolled diabetes	Extensive peritoneal adhesions, fibrosis, or active inflammatory GI disease (e.g., diverticulitis, inflammatory bowel conditions) Ascites or massive central obesity Recent abdominal surgery
<b>Access</b>	
Vascular fistula, shunt, or catheter	Intra-abdominal catheter
<b>Procedure</b>	
Complex; requires a second person trained in the technique whether completed at home or at a dialysis unit/center Special training for center personnel and in-home use	Simple, easier to complete at home compared with at-home hemodialysis Less complex training; typically managed by patient; can be managed by one person

### Patient Selection.

Any patient may be considered for intermittent HD therapy. Starting HD depends on symptoms from disruptions of FLUID AND ELECTROLYTE BALANCE and waste and toxin accumulation, not the GFR alone. Dialysis is started immediately for patients who have:

- Acidosis that is severe (pH <7.2) or does not respond to therapy
- Fluid overload that does not respond to diuretics (including fluid overload with pulmonary edema or pericarditis)
- Symptomatic hyperkalemia with ECG changes
- **Calciphylaxis** (thrombosis and skin necrosis that can occur in stage 5 CKD)
- Toxin ingestion such as dialyzable drug overdose or poisoning (see [Table 68-13](#))

Most commonly, hemodialysis for CKD is started when uremic symptoms (e.g., intractable nausea and vomiting, confusion, seizures, or severe bleed from platelet dysfunction) occur.

Many patients survive for years with HD therapy, and others may live only a few months. Length of survival with HD therapy depends on patient age, the cause of CKD, and the presence of other diseases, such as cardiovascular conditions or diabetes. Selection criteria include:

- Irreversible kidney failure when other therapies are unacceptable or ineffective
- No disorders that would seriously complicate HD
- Patient values and preferences
- Expected ability to continue or resume roles at home, work, or school

### Dialysis Settings.

Patients with CKD may receive HD treatments in many settings, depending on specific needs. Regardless of the setting for therapy, they need ongoing nursing support to maintain this complex and lifesaving treatment.

Patients may be dialyzed in a hospital-based center if they have recently started treatment or have complicated conditions that require close supervision. Stable patients not requiring intense supervision may be dialyzed in a community or freestanding dialysis center. Selected patients may participate in self-care in an ambulatory care center or with in-home HD.

In-home HD is the least disruptive treatment and allows the patient to adapt the regimen to his or her lifestyle. Newer technologies and HD equipment are making home dialysis an easier process to learn. It is growing in popularity and use. A water treatment system must be installed in the home to provide a safe, clean water supply for the dialysis process.

### Procedure.

Dialysis works using the passive transfer of toxins by diffusion. **Diffusion** is the movement of

molecules from an area of higher concentration to an area of lower concentration. The rate of diffusion during dialysis is most dependent on the difference in the solute concentrations between the patient's blood and the dialysate. Large molecules, such as RBCs and most plasma proteins, cannot pass through the membrane.

When HD is started, blood and **dialysate** (dialyzing solution) flow in opposite directions across an enclosed semipermeable membrane. The dialysate contains a balanced mix of electrolytes and water that closely resembles human plasma. On the other side of the membrane is the patient's blood, which contains nitrogen waste products, excess water, and excess electrolytes. During HD, the waste products move from the blood into the dialysate because of the difference in their concentrations (diffusion). Some water is also removed from the blood into the dialysate by *osmosis*. Electrolytes can move in either direction, as needed, and take some fluid with them. Potassium and sodium typically move out of the plasma into the dialysate. Bicarbonate and calcium generally move from the dialysate into the plasma. This circulating process continues for a preset length of time, removing nitrogenous wastes, reestablishing FLUID AND ELECTROLYTE BALANCE, and restoring ACID-BASE BALANCE. Water volume may be removed from the plasma by applying positive or negative pressure to the system.

The HD system includes a dialyzer, dialysate, vascular access routes, and an HD machine. The artificial kidney, or **dialyzer** (Fig. 68-3), has four parts: a blood compartment, a dialysate compartment, a semipermeable membrane, and an enclosed support structure.

**FIG. 68-3** Hollow fiber dialyzer (artificial kidney) used in hemodialysis. (From Feehally, J., Floege, J., & Johnson, R. [2007]. *Comprehensive clinical nephrology* [3rd ed.]. Philadelphia: Mosby.)

Dialysate is made from water and chemicals and is free of any waste products or drugs. It is usually dispensed from the pharmacy in an acute care setting. The solution may be mixed in large or small batches by technicians in dialysis centers. Because bacteria and other organisms are too large to pass through the membrane, dialysate is not sterile. Water used in dialysate must meet specific standards and requires special treatment before mixing the dialysate. Dialysate composition may be altered for the patient's needs for management of electrolyte imbalances. During HD, the dialysate is warmed to 100° F (37.8° C) to increase the diffusion rate and prevent hypothermia.

The HD machine has built-in safety features such as the ability to record patient vital signs, blood

and dialysate flows, arterial and venous pressures, delivered dialysis dose, plasma volume changes, and temperature changes. If any of these problems are detected, an alarm sounds to protect the patient from life-threatening complications.

All dialyzers function in a similar manner. Fig. 68-4 shows a comparison of fluid and particle movement across the dialyzer membranes, comparing intermittent HD with continuous kidney replacement circuits. For intermittent HD, the number and length of treatments depend on the amount of wastes and fluid to be removed, the clearance capacity of the dialyzer, and the blood flow rate to and from the machine. Fig. 68-5 shows a typical intermittent dialysis machine. Most patients receive three 4-hour treatments over the course of a week. For those with some ongoing urine production, two 5- to 6-hour treatments a week may be adequate. If the patient gains large amounts of fluid, a longer HD treatment time may be needed to remove the fluid without hypotension or other severe side effects.

**FIG. 68-4** Comparison of hemodialysis and hemofiltration fluid and solute movements across the membrane. Demonstrates this movement in hemodialysis (A) and hemofiltration (B). The arrows that cross the membrane indicate the predominant direction of movement of each solute through the membrane; the relative size of the arrows indicates the net amounts of the solute transferred. Other arrows indicate the direction of flow. (From Feehally, J., Floege, J., & Johnson, R. [2007]. *Comprehensive clinical nephrology* [3rd ed.]. Philadelphia: Mosby.)

**FIG. 68-5** Renal replacement therapy with an intermittent hemodialysis machine. (Courtesy Gambro Lundia AB, Lund, Sweden.)

### Anticoagulation.

Blood clotting can occur during dialysis. Anticoagulation, usually with heparin, is delivered into the blood circuit via a pump. In patients with high risk for bleeding, a reduced dose, regional

anticoagulation (using citrate rather than heparin for anticoagulation or reversing heparin actions by administering protamine before returning blood to the patient), or no anticoagulation may be used. Patient response to heparin varies, and the dose is adjusted on the basis of each patient's need.

Heparin remains active in the body for 4 to 6 hours after dialysis, increasing the patient's risk for hemorrhage during and immediately after HD treatments. Invasive procedures must be avoided during that time. Monitor him or her closely for any signs of bleeding or hemorrhage. Protamine sulfate is an antidote to heparin and always should be available in the dialysis setting.

### Vascular Access.

Vascular access is required for hemodialysis (Table 68-10 and Fig. 68-6). The procedure requires the availability of a high blood flow: at least 250 to 300 mL/min, usually for a period of 3 to 4 hours (Norton et al., 2017b). Normal venous cannulation does not provide this high rate of blood flow.

**TABLE 68-10**  
**Types of Vascular Access for Hemodialysis**

ACCESS TYPE	DESCRIPTION	LOCATION	TIME TO INITIAL USE
<b>Permanent</b>			
AV fistula	An internal anastomosis of an artery to a vein	Forearm Upper arm	2-4 mo or longer
AV graft	Synthetic vessel tubing tunneled beneath the skin, connecting an artery and a vein	Forearm Upper arm Inner thigh	1-2 wk
<b>Temporary</b>			
Dialysis catheter	A specially designed catheter with separate lumens for blood outflow and inflow	Subclavian vein, internal jugular, or femoral vein	Immediately after insertion and x-ray confirmation of placement
Subcutaneous catheter	An internal device with two access ports and a cuff or dual-lumen catheter inserted into a large central vein	Subclavian vein, internal jugular, or femoral vein	Dedicated use; do not access for blood sampling or drug administration

AV, Arteriovenous.

**FIG. 68-6** Frequently used means for gaining vascular access for hemodialysis include arteriovenous fistula (**A**), arteriovenous graft (**B**), external arteriovenous shunt (**C**), femoral vein catheterization (**D**), and subclavian vein catheterization (**E**). **A** and **B** are options for long-term vascular access for hemodialysis. **C**, **D**, and **E** are used for short-term access for intermittent hemodialysis or for continuous renal replacement therapy in acute care.

*Long-term vascular access* is internal for most patients having long-term HD (see [Table 68-10](#)). The two common choices are an internal arteriovenous (AV) fistula or an AV graft (see [Fig. 68-6A-C](#)). *AV fistulas* are formed by surgically connecting an artery to a vein. The vessels used most often are the radial or brachial artery and the cephalic vein of the nondominant arm. Fistulas increase venous blood flow to the 250 to 400 mL/min needed for effective dialysis.

Time is needed after the surgeon creates the AV fistula for it to develop into a usable access site for HD. As the AV fistula “matures,” the increased pressure of the arterial blood flow into the vein causes the vessel walls to thicken. This thickening increases their strength and durability for repeated cannulation. The amount of time needed for the fistula to mature varies. Some fistulas may not be ready for use for as long as 4 months after the surgery, and a temporary vascular access (AV shunt or HD catheter) is used during this time. [Fig. 68-7](#) shows a mature fistula.

**FIG. 68-7** A mature fistula for hemodialysis access. The increased pressure from the anastomosed artery forced blood into the vein. This process caused the vein to dilate enough for fistula needles to be placed for hemodialysis. When the vein is sufficiently dilated, a process that takes 8 to 12 weeks, the fistula is said to be *developed* or *mature*.

To access a fistula, cannulate it by inserting two needles: one toward the venous blood flow and one toward the arterial blood flow. This procedure allows the HD machine to draw the blood out through the arterial needle and return it through the venous needle.

*Arteriovenous grafts* are used when the AV fistula does not develop or when complications limit its use. The polytetrafluoroethylene (PTFE) graft is a synthetic material (GORE-TEX). This type of graft is commonly used for older patients using HD. [Figs. 68-6A](#) and [68-7](#) show a patient's fistula.

### Precautions.

Precautions are needed to ensure the functioning of an internal AV fistula or AV graft. First assess for adequate circulation in the fistula or graft and in the lower portion of the arm. Check distal pulses and capillary refill in the arm with the fistula or graft. Then check for a bruit or a thrill by auscultation or palpation over the access site. [Chart 68-7](#) lists best practices for care of the patient with an HD access.

### Chart 68-7

## Best Practice for Patient Safety & Quality Care QSEN

### Caring for the Patient With an Arteriovenous Fistula or Arteriovenous Graft

- Do not take blood pressure readings using the extremity in which the vascular access is placed.
- Do not perform venipunctures or start an IV line in the extremity in which the vascular access is placed.
- Palpate for thrills and auscultate for bruits over the vascular access site every 4 hours while the patient is awake.
- Assess the patient's distal pulses and circulation in the arm with the access.
- Elevate the affected extremity after surgery.
- Encourage routine range-of-motion exercises.
- Check for bleeding at needle insertion sites.

- Assess for indications of infection at needle sites.
- Instruct the patient not to carry heavy objects or anything that compresses the extremity in which the vascular access is placed.
- Instruct the patient not to sleep with his or her body weight on top of the extremity in which the vascular access is placed.

## Nursing Safety Priority QSEN

### Action Alert

Because repeated compression can result in the loss of the vascular access, avoid taking the blood pressure or performing venipunctures in the arm with the vascular access. Do not use an AV fistula or graft for general delivery of IV fluids or drugs.

### Complications.

Complications can occur with any type of access. Common problems include thrombosis or stenosis, infection, aneurysm formation, ischemia, and heart failure (Norton et al., 2017b). Table 68-11 lists strategies to prevent access complications.

**TABLE 68-11**

### Interventions for Preventing Complications in Hemodialysis Vascular Access

ACCESS TYPE	BLEEDING	INFECTION	CLOTTING
AV fistula or AV graft	Apply pressure to the needle puncture sites.	Prepare skin using best practices before cannulation. Typically 2% chlorhexidine is used, similar to central line skin preparation. Between hemodialysis sessions, the patient should wash the area with antibacterial soap and rinse with water.	Avoid constrictive devices such as blood pressure cuffs and tourniquets. Rotate needle insertion sites with each hemodialysis treatment. Assess for thrill and bruit.
Hemodialysis catheters (temporary and permanent)	Assess the access site every time you monitor vital signs.	Use aseptic technique to dress site and access catheter. Do not use catheters for blood sampling, IV fluids, or drug administration.	Place a heparin or heparin/saline dwell solution after hemodialysis treatment.

AV, Arteriovenous.

Thrombosis, or clotting of the AV access, is the most frequent complication. Most grafts fail because of high-pressure arterial flow entering the venous system. The muscle layers of the veins react to this increased pressure by thickening. The venous thickening reduces or occludes blood flow. An interventional radiologist can re-open failing grafts with the injection of a thrombolytic drug (e.g., tPA) to dissolve the clot. The clot usually dissolves within minutes, and often a stricture is revealed at the point where the graft and the vein connect. The stricture can be corrected by balloon angioplasty.

Most infections of the vascular access are caused by *Staphylococcus aureus* introduced during cannulation. Prepare the skin with an antibacterial agent according to agency policy before cannulation to prevent infection. When using dialysis catheters, be sure to use only the cleansing agent recommended by the catheter manufacturer. Some disinfectants can damage the catheter (Stupak et al., 2016).

Aneurysms can form in the fistula and are caused by repeated needle punctures at the same site. Large aneurysms may cause loss of the fistula's function and require surgical repair.

Ischemia occurs in a few patients with vascular access when the fistula decreases arterial blood flow to areas below the fistula (*steal syndrome*). Symptoms vary from cold or numb fingers to gangrene. If the collateral circulation is poor, the fistula may need to be surgically tied off, and a new one created in another area to preserve extremity circulation.

Shunting of blood directly from the arterial system to the venous system through the fistula can cause heart failure in patients with limited cardiac function. This complication is rare; but, if it does occur, the fistula may need to be revised to reduce arterial blood flow.

### Temporary Vascular Access.

Temporary access with special catheters can be used for patients requiring immediate HD. A catheter designed for HD may be inserted into the subclavian, internal jugular, or femoral vein. The lumens of these devices are much smaller than the permanent accesses, and more time (4 to 8 hours) is required to complete a dialysis session.

Subcutaneous devices may also be surgically inserted to provide temporary access for HD. Implanted beneath the skin, these devices are composed of two small metallic ports with attached catheters that are inserted into large central veins. The ports of subcutaneous devices have internal mechanisms that open when needles are inserted and close when needles are removed. Blood from one port flows from the body to the HD machine and returns to the body via the other port.

### Hemodialysis Nursing Care.

Many drugs are dialyzable (i.e., can be partially or completely removed from the blood during dialysis). Coordinate with the nephrology health care provider to assess the patient's drug regimen and determine which drugs should be held until after HD treatment. [Table 68-12](#) lists common dialyzable drugs that should be given *after* rather than before HD. Consult the dialysis nurse or nephrologist to determine if antihypertensive drugs should be given before a scheduled dialysis treatment; some short-acting antihypertensives can contribute to hypotension during dialysis.

**TABLE 68-12**  
**Examples of Dialyzable Drugs**

Consult the pharmacist, nephrologist, or dialysis nurse to plan the best time to administer a drug based on the dialysis schedule.	
<b>Aminoglycosides</b> <ul style="list-style-type: none"> <li>• Amikacin</li> <li>• Gentamicin</li> <li>• Tobramycin</li> </ul> <b>Antituberculosis Agents</b> <ul style="list-style-type: none"> <li>• Ethambutol</li> <li>• Isoniazid</li> </ul> <b>Antiviral and Antifungal Agents</b> <ul style="list-style-type: none"> <li>• Acyclovir</li> <li>• Ganciclovir</li> <li>• Fluconazole</li> </ul> <b>Cephalosporins</b> <ul style="list-style-type: none"> <li>• Cefactor</li> <li>• Cefazolin</li> <li>• Cefoxitin</li> <li>• Cefprozime</li> <li>• Ceftriaxone</li> <li>• Cefuroxime</li> <li>• Cefepime</li> </ul>	<b>Anticonvulsants</b> <ul style="list-style-type: none"> <li>• Ethosuximide</li> <li>• Gabapentin</li> <li>• Phenobarbital</li> </ul> <b>Penicillins</b> <ul style="list-style-type: none"> <li>• Amoxicillin</li> <li>• Ampicillin</li> <li>• Cloxacillin</li> <li>• Dicloxacillin</li> <li>• Mezlocillin</li> <li>• Penicillin G</li> <li>• Ticarcillin</li> </ul> <b>Miscellaneous</b> <ul style="list-style-type: none"> <li>• Aztreonam</li> <li>• Cimetidine</li> <li>• Vitamins</li> <li>• Clavulanic acid</li> <li>• Allopurinol</li> <li>• Enalapril</li> <li>• Aspirin</li> </ul>

The time required to complete an HD treatment usually is at least 4 hours. During this time patients may use various distraction techniques to prevent boredom, such as reading, watching television or videos, visiting with friends or relatives, playing video games, or working puzzles. This time can be used also for brief health teaching opportunities.

### Post-Dialysis Care.

Closely monitor the patient immediately and for several hours after dialysis for any side effects from the treatment. Common problems include hypotension, headache, nausea, vomiting, dizziness, and muscle cramps.

Obtain vital signs and weight for comparison with pre-dialysis measurements. Blood pressure and weight are expected to be reduced as a result of fluid removal. Hypotension may require rehydration with IV fluids, such as normal saline. The patient's temperature may also be elevated because the dialysis machine warms the blood slightly. If he or she has a fever, sepsis may be present, and a blood sample is needed for culture and sensitivity.

The heparin or citrate required during HD increases the risk for excessive bleeding. All invasive procedures must be avoided for 4 to 6 hours after dialysis. Continually monitor the patient for hemorrhage during and for at least 1 hour after dialysis ([Chart 68-8](#)).

### Chart 68-8

## Best Practice for Patient Safety & Quality Care QSEN

### Caring for the Patient Undergoing Hemodialysis

- Weigh the patient before and after dialysis.
- Know the patient's dry weight.
- Discuss with the nephrology health care provider or pharmacist whether any of the patient's

drugs should be withheld until after dialysis.

- Be aware of events that occurred during previous dialysis treatments.
- Measure blood pressure, pulse, respirations, and temperature.
- Assess for indications of orthostatic hypotension.
- Assess the vascular access site when taking vital signs and follow agency policy for central line care and dressing changes.
- Observe for bleeding at the vascular access site and other sites where skin integrity is disrupted because anticoagulants given during dialysis and the presence of uremia increase bleeding risk.
- Assess the patient's level of consciousness.
- Assess for headache, nausea, and vomiting.
- Assess serum laboratory tests to evaluate effectiveness of treatment in removing wastes and achieving desired outcomes (e.g., FLUID AND ELECTROLYTE BALANCE, reduction of uremia).

### Complications of Hemodialysis.

Few adverse events occur during a 3- to 4-hour HD treatment under current practice protocols. Improved water treatment, more physiologic solutions, and improvements in HD equipment and procedures have significantly improved safe care for patients receiving this treatment. Complications during HD include hypotension, dialysis disequilibrium syndrome, cardiac events, and reactions to dialyzers (Norton et al., 2017b).

## Nursing Safety Priority QSEN

### Critical Rescue

Monitor the patient closely during dialysis to recognize hypotension, which is common. Heat transfer from warm solutions can result in vasodilation and a drop in blood pressure. When this occurs, reduce the temperature of the dialysate to 35° C (95° F). Fluid shifts from the plasma volume related to differences in electrolyte concentrations between HD solutions and blood also reduce blood pressure. Respond to modest declines in blood pressure by adjusting the rate of dialyzer blood flow and placing the patient in a legs-up (Trendelenburg) position. Respond to sustained or symptomatic hypotension by giving a fluid bolus of 100 to 250 mL of normal saline, albumin, or mannitol (if prescribed). A second bolus may be needed. If hypotension persists, new-onset myocardial injury or pericardial disease may be a contributing factor; respond by applying oxygen, reducing the blood flow, and notifying the primary health care provider urgently. Discontinue HD when hypotension continues despite two bolus infusions.

*Dialysis disequilibrium syndrome* may develop during HD or after HD has been completed. It is characterized by mental status changes and can include seizures or coma, although this severity of disequilibrium syndrome is rare with today's HD practice. A mild form of disequilibrium syndrome includes symptoms of nausea, vomiting, headaches, fatigue, and restlessness. It is thought to be the result of a rapid reduction in electrolytes and other particles. Reducing blood flow at the onset of symptoms can prevent this syndrome.

Cardiac events during HD are associated with underlying cardiovascular disease, especially left ventricular hypertrophy, coronary vascular disease, and a history of cardiac dysrhythmias. These conditions are described in [Chapters 34, 35, and 38](#). Although cardiac arrest is a rare event, the setting should be equipped with an automatic defibrillator and staff or family trained in cardiopulmonary resuscitation. Often cardiac arrest is related to new-onset cardiac ischemia. This problem is managed in an acute care setting in which the presence of myocardial disease can be evaluated and cardiac treatment optimized.

Pericardial disease is a complication of patients with ESKD. Assess the patient's heart sounds for

the presence of a pericardial rub before starting dialysis. Intensification of dialysis may be used to treat this complication. Other treatment might include NSAID use or surgery.

Reactions to dialyzers still occur, although more biocompatible membranes and careful attention to rinsing the dialyzer before use (to eliminate sterilizing agents) have reduced this adverse event during HD. Reactions occur during a “first-time” use of the filter and resemble an anaphylactic episode early during HD, with profound hypotension. (Chapter 20 describes anaphylactic reactions.) With suspected dialyzer reactions, do not return the blood to the patient and discontinue HD. Corticosteroids may be used to treat the IMMUNITY reaction.

Other potential complications of HD require the nurse to monitor the level of consciousness and vital signs frequently during treatment and to slow or stop HD when symptoms occur. Hypoglycemia is a rare adverse HD event and more likely to occur when the patient has diabetes. It is managed by providing glucose and increasing dialysis glucose concentration in subsequent treatments. Hemorrhage can occur when needle dislodgment or circuit connections become loose and is amplified by anticoagulation used to maintain circuit patency. Some hemolysis occurs because of mechanical trauma to red blood cells, contributing to anemia in the patient with CKD and, perhaps, to sensations of dyspnea or chest tightness.

*Infectious diseases* transmitted by blood transfusion are a serious complication of long-term HD. Two of the most serious blood-transmitted infections are hepatitis and HIV infection. *Hepatitis B infection* and *hepatitis C infection* in patients with CKD have decreased because the use of erythropoietin-stimulating agents (ESAs) has reduced the need for blood transfusions to maintain red blood cell counts. Hepatitis is a problem because of the blood access and the risk for contamination during HD. The viruses can be transmitted through the use of contaminated needles or instruments, by entry of contaminated blood through open wounds in the skin or mucous membranes, or through transfusions with contaminated blood. Monitor all patients receiving HD for indications of hepatitis (see Chapter 58).

The risk for HIV transmission is reduced by the consistent practice of Standard Precautions, routine screening of donated blood for HIV, and decreased need for blood transfusions with CKD and ESKD. Patients who have been undergoing HD or who received frequent transfusions during the early to middle 1980s may have been infected at that time and are at risk for acquired immune deficiency syndrome (AIDS) (see Chapter 19).

## Considerations for Older Adults

### Patient-Centered Care QSEN

Between the years 2000 and 2010, a threefold increase in the number of older adults diagnosed with CKD occurred. In 2010, the number of patients ages 60 years and older increased to more than 25% of patients beginning ESKD therapy (USRDS, 2015). The overall mean age for new patients requiring dialysis is 64.6. Patients older than 65 years who are receiving HD are at greater risk for dialysis-induced hypotension. Older adults require more frequent monitoring during and after dialysis

### Peritoneal Dialysis.

Peritoneal dialysis (PD) allows exchanges of wastes, fluid, and electrolytes to occur in the peritoneal cavity. However, PD is slower than hemodialysis (HD), and more time is needed to achieve the same effect. Other disadvantages of PD are the protein loss in outflow fluid, risk for peritoneal injury, and potential discomfort from indwelling fluid. Advantages and complications are listed in Table 68-9. The use of PD has decreased and currently accounts for less than 10% of dialysis (USRDS, 2015).

### Patient Selection.

Most patients with CKD can select either HD or PD. For those who are unstable and those who cannot tolerate anticoagulation, PD is less hazardous than HD. For some patients, vascular access problems may eliminate HD as an option. At times a patient may use PD until a new arteriovenous (AV) fistula matures. PD is often the treatment of choice for older adults because it offers more flexibility if his or her status changes frequently.

Peritoneal dialysis *cannot* be performed if peritoneal adhesions are present or if extensive intra-abdominal surgery has been performed (Norton et al., 2017b). In these cases, the surface area of the peritoneal membrane is not sufficient for adequate dialysis exchange. Peritoneal membrane fibrosis may occur after repeated infection, which decreases membrane permeability.

### Procedure.

A siliconized rubber (Silastic) catheter is surgically placed into the abdominal cavity for infusion of dialysate (Fig. 68-8A-B). Usually 1 to 2 L of dialysate is infused by gravity (*fill*) into the peritoneal space over a 10- to 20-minute period, according to the patient's tolerance. The fluid stays (*dwells*) in the cavity for a specified time prescribed for each patient individually by the nephrologist. It then flows out of the body (*drains*) by gravity into a drainage bag. The peritoneal outflow contains the dialysate and the excess water, electrolytes, and nitrogen-based waste products. The dialyzing fluid is called peritoneal *effluent* on outflow. The three phases of the process (infusion, or “fill”; dwell; and outflow, or drain) make up one PD exchange. The number and frequency of PD exchanges are prescribed by the physician, depending on symptoms and laboratory data.

**FIG. 68-8** Peritoneal dialysis catheter. **A**, The actual Silastic peritoneal dialysis catheter. **B**, Positioning of the Silastic catheter within the abdominal cavity. (A from Geary, D.F., & Schaefer, F. [2008]. *Comprehensive pediatric nephrology*. Philadelphia: Mosby.)

### Process.

Peritoneal dialysis occurs through diffusion and osmosis across the semipermeable peritoneal membrane and capillaries. The peritoneal membrane is large and porous. It allows particles and water to move from an area of higher concentration in the blood to an area of lower concentration in the dialyzing fluid (diffusion).

The peritoneal cavity is rich in capillaries and is a ready access to the blood supply. The fluid and waste products dialyzed from the patient move through the blood vessel walls, the interstitial tissues, and the peritoneal membrane and are removed when the dialyzing fluid is drained from the body.

PD efficiency is affected by many factors. Infection can cause scarring and reduce capillary blood flow. Vascular disease and decreased PERFUSION of the peritoneum reduce PD diffusion. For PD, water removal depends on the concentration of the dialysate. PD efficiency can be altered by the *tonicity* (i.e., number of particles per liter of fluid) of the dialysate. Increasing the dialysate glucose concentration makes the solution more hypertonic (Schreiber, 2016). The more hypertonic the solution, the greater the osmotic pressure for water filtration and fluid removal from the patient

during an exchange. The dialysate concentration is prescribed on the basis of the patient's fluid status.

### Dialysate Additives.

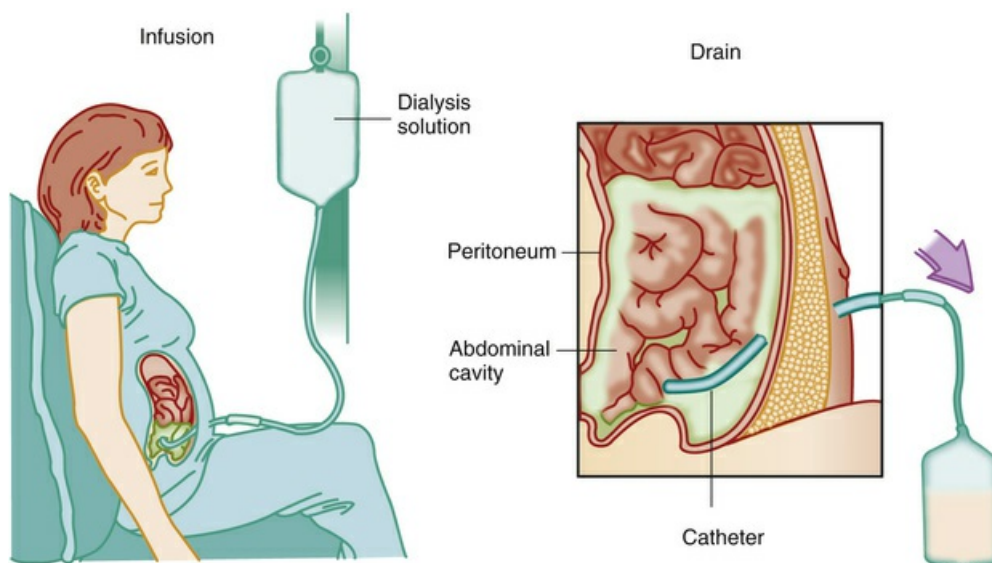

Heparin may be added to the dialysate to prevent clotting of the catheter or tubing. Usually intraperitoneal (IP) heparin is needed only after new catheter placement or if peritonitis occurs. IP heparin is not absorbed systemically and does not affect blood clotting.

Other agents that may be given in the dialysate include potassium and antibiotics. Commercially prepared dialysate does not contain potassium. Some patients need potassium added to the dialysate to prevent hypokalemia. Antibiotics may be given by the IP route when peritonitis is present or suspected. Potassium and antibiotics are not mixed in the same dialysate bag because interactions may reduce the antibiotic effect.

### Types of Peritoneal Dialysis.

Many types of PD are available, including continuous ambulatory PD, multiple-bag continuous ambulatory PD, automated PD, intermittent PD, and continuous-cycle PD. The type selected depends on the patient's ability and lifestyle. The two most commonly used types of PD are continuous ambulatory peritoneal dialysis and continuous cycling peritoneal dialysis.

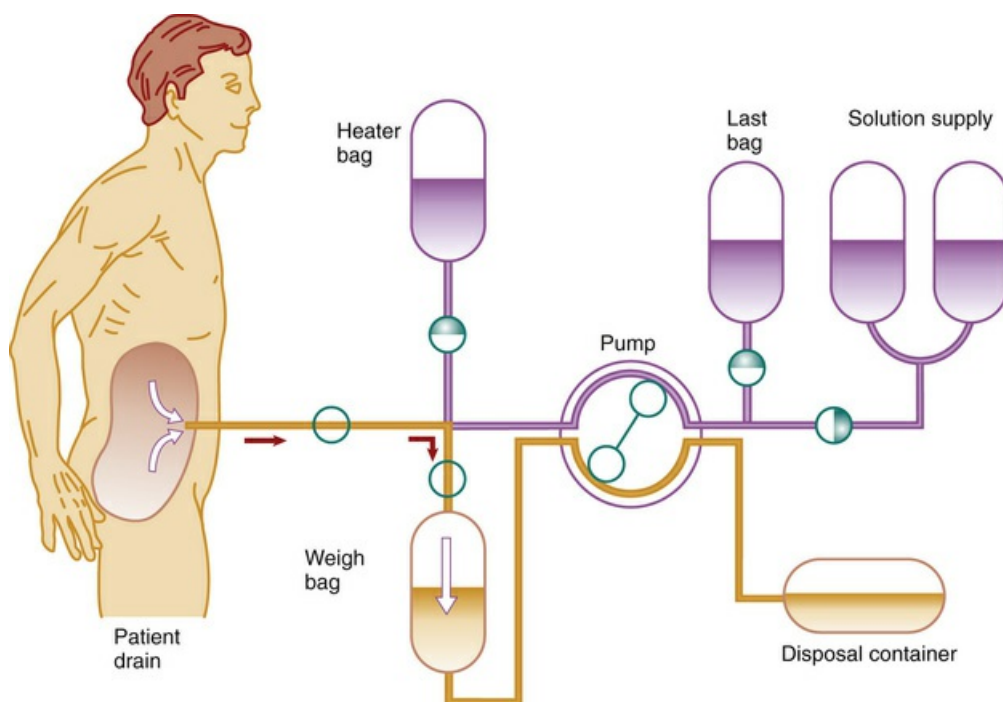

*Continuous ambulatory peritoneal dialysis (CAPD)* is performed by the patient with the infusion of four 2-L exchanges of dialysate into the peritoneal cavity. Each time, the dialysate remains for 4 to 8 hours, and these exchanges occur 7 days a week (Figs. 68-9 to 68-11). During the dwell period, the patient can use a continuous connect system or disconnect and then reconnect at a later time. Most patients using PD long term prefer to complete exchanges overnight with an automatedycler (automatic peritoneal dialysis [APD], described in the following paragraphs).

**FIG. 68-9** Peritoneal dialysis exchange for control of fluids, electrolytes, nitrogenous wastes, blood pressure, and acid-base balance. The peritoneal membrane acts as the dialyzing membrane.

**FIG. 68-10** Patient performing continuous ambulatory peritoneal dialysis (CAPD). Note that the patient can walk with this setup.

**FIG. 68-11** Peritoneal dialysis machine circuit in automated peritoneal dialysis (APD).

With the continuous *connect* system (straight transfer set), the dialysate bag is attached to the catheter by 48-inch tubing. The empty bag and tubing are folded and worn beneath the clothing until they are used for outflow. After draining, the patient removes the bag and connects a new bag to repeat the process.

With the *disconnect* system (Y-transfer set), the patient removes the connecting tubing and empties the dialysate bag after inflow and attaches a cap to the PD catheter. The disconnect system

eliminates the need to wear the tubing and bag but requires opening the system two extra times with each exchange. The extra opening of the system increases the risk for infection.

With CAPD, no machine is necessary, and no partner is required. However, it is best for a partner also trained in CAPD to be available as a support for the patient if illness occurs. Devices to assist in the safe, sterile connection of the tubing spike into the dialysate bag are available. These are useful for patients with poor vision, limited manual dexterity, or reduced hand and arm strength. CAPD allows constant removal of fluid and wastes and more closely resembles kidney action than HD. Some patients even perform their own exchanges while hospitalized.

*Continuous-cycle peritoneal dialysis (CCPD)* is a form of automated dialysis that uses an automated cycling machine. Exchanges occur at night while the patient sleeps. The final exchange of the night is left to dwell through the day and is drained the next evening as the process is repeated. CCPD offers the advantage of 24-hour dialysis, as in CAPD, but the sterile catheter system is opened less often.

*Automated peritoneal dialysis (APD)* may be used in the acute care setting, the ambulatory care dialysis center, or the patient's home. APD uses a cycling machine for dialysate inflow, dwell, and outflow according to preset times and volumes. A warming chamber for dialysate is part of the machine (Fig. 68-12). The functions are programmed for the patient's specific needs. A typical prescription calls for 30-minute exchanges (10/10/10 for inflow, dwell, and outflow) for a period of 8 to 10 hours. The machines have many safety monitors and alarms and are relatively simple to learn to use.

**FIG. 68-12** Cycler machine for automated peritoneal dialysis at home. (Courtesy Baxter International, Inc., Deerfield, IL.)

Automated peritoneal dialysis has advantages. It permits in-home dialysis during sleep, allowing the patient to be dialysis free during waking hours. The incidence of peritonitis is reduced with APD because fewer connections and disconnections are needed. Also, APD can be used to deliver larger volumes of dialysis solution for patients who need higher clearances.

*Intermittent peritoneal dialysis (IPD)* combines osmotic pressure gradients with true dialysis. The patient usually requires exchanges of 2 L of dialysate at 30- to 60-minute intervals, allowing 15 to 20 minutes of drain time. For most patients, 30 to 40 exchanges of 2 L three times weekly are needed. IPD treatments can be automated or manual.

### Complications.

Complications are possible with PD, but many can be prevented with meticulous care and appropriate patient education for self-management. Problems and complications are more common when evidence-based guidelines for catheter care are not followed.

*Peritonitis* is the major complication of PD, most commonly caused by connection site contamination. To prevent peritonitis, use meticulous sterile technique when caring for the PD catheter and when connecting and disconnecting dialysate bags (Chart 68-9).

### © Chart 68-9

## Best Practice for Patient Safety & Quality Care QSEN

### Caring for the Patient With a Peritoneal Dialysis Catheter

- Mask yourself and your patient. Wash your hands.
- Put on sterile gloves. Remove the old dressing. Remove the contaminated gloves.
- Assess the area for signs of infection, such as swelling, redness, or discharge around the catheter site.
- Use aseptic technique:
- Open the sterile field on a flat surface and place two precut 4 × 4-inch gauze pads on the field.
- Place three cotton swabs soaked in povidone-iodine or other solution prescribed by the nephrology health care provider on the field. Put on sterile gloves.
- Use cotton swabs to clean around the catheter site. Use a circular motion starting from the insertion site and moving away toward the abdomen. Repeat with all three swabs.
- As an alternative (if recommended by the nephrology health care provider or clinic), cleanse the area with sterile gauze pads using soap and water. Use a circular motion starting from the insertion site and moving away toward the abdomen. Rinse thoroughly.
- Apply precut gauze pads over the catheter site. Tape only the edges of the gauze pads.

## Nursing Safety Priority QSEN

### Action Alert

Monitor the patient to recognize indications of peritonitis (e.g., cloudy dialysate outflow (effluent), fever, abdominal tenderness, abdominal pain, general malaise, nausea, and vomiting). *Cloudy or opaque effluent is the earliest indication of peritonitis.* Examine all effluent for color and clarity to detect peritonitis early. When peritonitis is suspected, respond by sending a specimen of the dialysate outflow for culture and sensitivity study, Gram stain, and cell count to identify the infecting organism.

*Pain* during the inflow of dialysate is common when patients are first started on PD therapy. Usually this pain no longer occurs after a week or two of PD. Cold dialysate increases discomfort. Warm the dialysate bags before instillation by using a heating pad to wrap the bag or by using the warming chamber of the automated cycling machine. *Microwave ovens are not recommended for warming dialysate.*

Exit site and tunnel infections are serious complications. The exit site from a PD catheter should be clean, dry, and without pain or inflammation. Exit-site infections (ESIs) can occur with any type of PD catheter. These infections are difficult to treat and can become chronic, leading to peritonitis, catheter failure, and hospitalization. Dialysate leakage and pulling or twisting of the catheter increase the risk for ESIs. A Gram stain and culture should be performed when exit sites have purulent drainage.

Tunnel infections occur in the path of the catheter from the skin to the cuff. Symptoms include redness, tenderness, and pain. ESIs are treated with antimicrobials. Deep cuff infections may require catheter removal.

Poor dialysate flow is often related to constipation. To prevent constipation, a bowel preparation

is prescribed before placement of the PD. If prescribed, giving an enema before starting PD may also prevent flow problems. Teach patients to eat a high-fiber diet and to use stool softeners to prevent constipation. Other causes of flow difficulty include kinked or clamped connection tubing, the patient's position, fibrin clot formation, and catheter displacement.

Ensure that the drainage bag is lower than the patient's abdomen to enhance gravity drainage. Inspect the connection tubing and PD system for kinking or twisting. Ensure that clamps are open. If inflow or outflow drainage is still inadequate, reposition the patient to stimulate inflow or outflow. Turning the patient to the other side or ensuring that he or she is in good body alignment may help. Having the patient in a supine low-Fowler's position reduces abdominal pressure. Increased abdominal pressure from sitting or standing or from coughing contributes to leakage at the PD catheter site.

Fibrin clot formation may occur after PD catheter placement or with peritonitis. Milking the tubing may dislodge the fibrin clot and improve flow. An x-ray is needed to identify PD catheter placement. If displacement has occurred, the nephrology health care provider repositions the PD catheter.

*Dialysate leakage* is seen as clear fluid coming from the catheter exit site. When dialysis is first started, small volumes of dialysate are used. It may take patients 1 to 2 weeks to tolerate a full 2-L exchange without leakage around the catheter site. Leakage occurs more often in obese patients, those with diabetes, older adults, and those on long-term steroid therapy. During periods of catheter leak, patients may require hemodialysis (HD) support.

*Other complications* of PD include bleeding, which is expected when the catheter is first placed, and bowel perforation, which is serious. When PD is first started, the outflow may be bloody or blood tinged. This condition normally clears within a week or two. After PD is well established, the effluent should be clear and light yellow. Observe for and document any change in the color of the outflow. Brown-colored effluent occurs with a bowel perforation. If the outflow is the same color as urine and has the same glucose level, a bladder perforation is probable. Cloudy or opaque effluent indicates infection.

### Nursing Care During In-Hospital Peritoneal Dialysis.

In the hospital setting, PD is routinely started and monitored by the nurse. Before the treatment, assess baseline vital signs, including blood pressure, apical and radial pulse rates, temperature, quality of respirations, and breath sounds. Weigh the patient, always on the same scale, before the procedure and at least every 24 hours while receiving treatment. Weight should be checked after a drain and before the next fill to monitor the patient's "dry weight." Baseline laboratory tests, such as electrolyte and glucose levels, are obtained before starting PD and repeated at least daily during the PD treatment.

In the hospital setting, especially with a new access, continually monitor the patient receiving PD fluid exchanges. Take and record vital signs every 15 to 30 minutes. Assess for respiratory distress, pain, or discomfort. Check the dressing around the catheter exit site every 30 minutes for wetness during the procedure. Monitor the prescribed dwell time and initiate outflow. Assess blood glucose levels in patients who absorb glucose.

Observe the outflow pattern (outflow should be a continuous stream after the clamp is completely open). Measure and record the total amount of outflow after each exchange. Maintain accurate inflow and outflow records when hourly PD exchanges are performed. When outflow is less than inflow, the difference is retained by the patient during dialysis and is counted as fluid intake. Weigh the patient daily to monitor fluid status.

## NCLEX Examination Challenge 68-6

### Physiological Integrity

A client who performs home continuous ambulatory peritoneal dialysis reports that the drainage (effluent) has become cloudy in the past 24 hours. What is the nurse's **best first** action?

- A. Remove the peritoneal catheter.
- B. Notify the nephrology health care provider immediately.

C. Obtain a sample of effluent for culture and sensitivity.

D. Explain to the client the need to keep the dialysate in the refrigerator to prevent bacterial overgrowth.

### **Kidney Transplantation.**

Dialysis and kidney transplant are life-sustaining *treatments* for end-stage kidney disease (ESKD). Kidney transplant is not considered a “cure.” Each patient, in consultation with a nephrologist, determines which type of therapy is best suited to his or her physical condition and lifestyle. About 17,000 to 18,000 kidney transplants are performed yearly in the United States, and about 1200 to 1400 are performed yearly in Canada ([Kidney Foundation of Canada, 2015](#); [Tran & Miniard, 2017](#)). Currently about 165,000 people are awaiting kidney transplant in North America. The median time on the waiting list is 678 days ([USRDS, 2015](#)).

#### **Candidate Selection Criteria.**

Candidates for transplantation must be free of medical problems that might increase the risks from the procedure. The usual age-range for kidney transplant is 2 to 70 years. Patients older than 70 years are considered for transplant on an individual basis.

The patient is thoroughly assessed before he or she is considered for a kidney transplant. Patients who have advanced, uncorrectable cardiac disease are excluded from the procedure because these problems are made worse by transplantation. Other conditions that preclude kidney transplant include metastatic cancer, chronic infection, and severe psychosocial problems such as alcoholism or chemical dependency. Long-standing pulmonary disease increases the risk for complications and death from respiratory infection. Patients with diseases of the GI system, such as peptic ulcers and diverticulosis, require treatment before transplantation because some diseases are made worse by the large doses of steroids used after surgery.

The urinary system is completely evaluated to ensure normal urine flow. Many patients with ESKD have not used their lower urinary tract for years, and ureteral or bladder problems may require surgical correction before a kidney is transplanted.

Patients with a recent history of cancer are treated with dialysis because of the shortage of donor organs and the uncertain life expectancy of these patients. In addition, the drugs used after the procedure increase the risk for cancer recurrence. If more than 2 to 5 years have passed since cancer eradication, the patient can be considered for a transplant.

Diabetes and other endocrine problems cause great risks. Patients with these problems can have a kidney transplant but require intense observation and management to limit complications. Other pre-existing conditions are considered on an individual basis, depending on the patient's health status. Kidney transplantation is considered for most patients with ESKD and is the optimal therapy for many adults.

#### **Donors.**

Kidney donors may be living donors (related or unrelated to the patient), non-heart-beating donors (NHBDs), and cadaveric donors. The available kidneys are matched on the basis of tissue type similarity between the donor and the recipient. NHBDs are patients declared dead by cardiopulmonary criteria. Kidneys from NHBDs are removed (harvested) immediately after death in cases in which patients have previously given consent for organ donation. If immediate removal must be delayed, the organ is preserved by infusing a cool preservation solution into the abdominal aorta after death is declared and until surgery can be performed. Cadaveric donors are usually people who suffered irreversible brain injury, most often as a result of trauma. These donors are maintained with mechanical ventilation and must have sufficient PERFUSION for the kidneys to remain viable.

Organs from living *related* donors (LRDs) have the highest rates of kidney graft survival (90%). A living donor is one who is medically compatible with the recipient ([Ficorelli et al., 2013](#)). LRDs are usually at least 18 years old and are seldom older than 65 years, although there are donors over 70 years of age with good outcomes for both the donor and recipient ([Medina-Polo et al., 2014](#)). Physical criteria for donors include:

- Absence of systemic disease and infection
- No current active cancer

- No hypertension or kidney disease
- Adequate kidney function as determined by diagnostic studies

LRDs must express a clear understanding of the surgery and a willingness to give up a kidney. Some transplant centers require a psychiatric evaluation to assess the donor's motivation.

A paired or chain exchange donation can be done when two kidney donor/recipient pairs have blood types that are not compatible (Vazquez, 2015). The recipients trade donors so each recipient can receive a kidney with a compatible blood type and tissue type (Fig. 68-13). Once the evaluations of all donors and recipients are completed, the series of kidney transplant operations are scheduled to occur consecutively ([www.paireddonation.org](http://www.paireddonation.org)).

**FIG. 68-13** Example of a paired exchange kidney donation. *Donor 1* is related to or acquainted with *recipient 1* and has agreed to donate a kidney but is not a blood type or tissue type match with *recipient 1*. *Donor 1* is compatible with *recipient 2* and agrees to donate a kidney to *recipient 2* if *donor 2* agrees to donate a kidney to *recipient 1* with confirmed compatibility to *recipient 1*.

Because of advances in immunosuppressant therapy and medical management, the U.S. Department of Health and Human Services (USDHHS) and the Kidney Foundation of Canada report a 1-year kidney transplant graft survival to be almost 95% for all centers in the North America (Kidney Foundation of Canada, 2015; USDHHS, 2015).

### Preoperative Care.

Many issues related to patient health and the actual transplant procedure must be addressed before surgery. The *Clinical Pathway* on the *Evolve* website highlights care needs for the patient undergoing kidney transplantation.

*Immunologic studies* are needed because the major barrier to transplant success after a suitable donor kidney is available is the body's ability to reject "foreign" tissue. This immunologic process can attack the transplanted kidney and destroy it. For normal protective IMMUNITY to be overcome, tissue typing with human leukocyte antigen (HLA) studies and blood typing are performed on all candidates. A donated kidney *must* come from a donor who is the same blood type as the recipient. The HLAs are the main immunologic feature used to match transplant recipients with compatible donors. The more similar the antigens of the donor are to those of the recipient, the more likely the transplant will be successful, and rejection will be avoided (see Chapter 17).

Nursing actions before surgery include teaching about the procedure and care after surgery, in-depth patient assessment, coordination of diagnostic tests, and development of treatment plans. See Chapter 14 for more discussion of standard preoperative nursing care.

The patient usually requires dialysis within 24 hours of the surgery and often receives a blood transfusion before surgery. Usually blood from the kidney donor is transfused into the recipient. This procedure increases graft survival of organs from living related donors (LRDs).

## Operative Procedures.

The donor nephrectomy procedure varies depending on whether the donor is a non-heart-beating donor (NHBD), cadaveric donor, or living donor. The NHBD or cadaveric donor nephrectomy is a sterile autopsy procedure performed in the operating room. All arterial and venous vessels and a long piece of ureter are preserved. After removal, the kidneys are preserved until time for implantation into the recipient. The technique for kidney removal from living donors is a laparoscopic procedure. Donors need postoperative nursing care and support for the psychological adjustment to loss of a body part.

Transplantation surgery usually takes several hours. The new kidney is placed in the right or left anterior iliac fossa (Fig. 68-14) instead of the usual kidney position. This placement allows easier connection of the ureter and the renal artery and vein. It also allows for easier kidney palpation. The recipient's own failed kidneys are not removed unless chronic kidney infection is present or, as in the case of polycystic kidney disease, the nonfunctioning, enlarged kidneys cause pain. After surgery, the patient is taken to the postanesthesia care unit and then, when stable, to a designated unit in the transplant center or to a critical care unit.

**FIG. 68-14** Placement of a transplanted kidney in the right iliac fossa.

## Postoperative Care.

Care of the recipient after surgery requires nurses to be knowledgeable about the expected responses and potential complications. Nursing care includes ongoing physical assessment, especially evaluation of kidney function. The most common complications occurring in patients after kidney transplant are rejection and infection (Tran & Miniard, 2017). Drug therapy used to prevent tissue rejection reduces IMMUNITY, impairs healing, and increases the risk for infection.

Urologic management is essential to graft success. A urinary catheter is placed for accurate measurements of urine output and decompression of the bladder. Decompression prevents stretch on sutures and ureter attachment sites on the bladder.

Assess urine output at least hourly during the first 48 hours. An abrupt decrease in urine output (see Table 68-2) may indicate complications such as rejection, acute kidney injury (AKI), thrombosis, or obstruction. Examine the urine color. The urine is pink and bloody right after surgery and gradually returns to normal over several days to several weeks, depending on kidney function. Obtain daily urine specimens for urinalysis, glucose measurement, the presence of acetone, specific gravity measurement, and culture (if needed).

Occasionally, continuous bladder irrigation is prescribed to decrease blood clot formation, which could increase pressure in the bladder and endanger the graft. Perform routine catheter care, according to agency policy, to reduce catheter-associated urinary tract infection (CAUTI). The catheter is removed as soon as possible to avoid infection, usually 3 to 5 days after surgery. After surgery, the function of the transplanted kidney (graft) can result in either oliguria or diuresis.

Oliguria may occur as a result of ischemia and acute kidney injury (AKI), rejection, or other complications. To increase urine output, the nephrology health care provider may prescribe diuretics and osmotic agents. Closely monitor the patient's fluid status because fluid overload can cause hypertension, heart failure, and pulmonary edema. Evaluate his or her fluid status by weighing daily, measuring blood pressure every 2 to 4 hours, and measuring intake and output.

Instead of oliguria, the patient may have diuresis, especially with a kidney from a living related donor (LRD). Monitor intake and output and observe for disruptions of FLUID AND ELECTROLYTE BALANCE, such as low potassium and sodium levels. Excessive diuresis may cause hypotension.

## Nursing Safety Priority QSEN

### Critical Rescue

Monitor the patient to recognize hypotension. If hypotension or excessive diuresis (e.g., unanticipated urine output 500 to 1000 mL greater than intake over 12 to 24 hours or other goal for intake and output) is present, respond by notifying the nephrology health care provider because hypotension reduces PERFUSION and oxygen to the new kidney, threatening graft survival.

### Complications.

Many complications are possible after kidney transplantation. Early detection and intervention improve the chances for graft survival.

*Rejection* is the most serious complication of transplantation and is the leading cause of graft loss. A reaction occurs between the tissues of the transplanted kidney and the antibodies and cytotoxic T-cells in the recipient's blood. These substances treat the new kidney as a foreign invader and cause tissue destruction, thrombosis, and eventual kidney necrosis.

The three types of rejection are hyperacute, acute, and chronic. Acute rejection is the most common type with kidney transplants. It is treated with increased immunosuppressive therapy and often can be reversed. Rejection is diagnosed by symptoms, a CT or renal scan, and kidney biopsy. [Table 68-13](#) lists the features of the three types of rejection. [Chapter 17](#) discusses their causes and treatment.

**TABLE 68-13**  
**Comparison of Hyperacute, Acute, and Chronic Post-Transplant Rejection**

HYPERACUTE REJECTION	ACUTE REJECTION	CHRONIC REJECTION
<b>Onset</b>		
Within 48 hours after surgery	1 week to any time after surgery; occurs over days to weeks	Occurs gradually during a period of months to years
<b>Signs and Symptoms</b>		
Increased temperature	Oliguria or anuria	Gradual increase in BUN and serum creatinine levels
Increased blood pressure	Temperature over 100° F (37.8° C)	
Pain at transplant site	Increased blood pressure Enlarged, tender kidney Lethargy Elevated serum creatinine, BUN, potassium levels Fluid retention	Fluid retention Changes in serum electrolyte levels Fatigue
<b>Treatment</b>		
Immediate removal of the transplanted kidney	Increased doses of immunosuppressive drugs	Conservative management until dialysis required

*BUN*, Blood urea nitrogen.

Ischemia from delayed transplantation following harvesting can contribute to acute kidney injury (AKI). Newly transplanted patients with AKI may need dialysis until adequate urine output returns and the blood urea nitrogen (BUN) and creatinine levels normalize. Biopsy can be used to determine if oliguria is the result of AKI or rejection.

*Thrombosis* of the major renal blood vessels may occur during the first 2 to 3 days after the transplant. A sudden decrease in urine output may signal impaired PERFUSION resulting from thrombosis. Ultrasound of the kidney may show decreased or absent blood supply. Emergency surgery is required to prevent ischemic damage or graft loss.

*Renal artery stenosis* may result in hypertension. Other signs include a bruit over the artery anastomosis site and decreased kidney function. A CT or renal scan can quantify the PERFUSION to the kidney. The involved artery may be repaired surgically or by balloon angioplasty in the radiology department. The decision to perform a balloon repair is determined by the amount of healing time after the surgery.

Other vascular problems include vascular leakage or thrombosis, both of which require an emergency transplant nephrectomy.

*Other complications* may involve the surgical wound or urinary tract. Wound problems, such as hematomas, abscesses, and lymphoceles (cysts containing lymph fluid), increase the risk for infection and exert pressure on the new kidney. Infection from reduced IMMUNITY is a major cause of death in the transplant recipient (Tran & Miniard, 2017). Prevention of infection is essential. Strict aseptic technique and handwashing must be rigorously enforced. Transplant recipients may not have the usual symptoms of infection because of the immunosuppressive therapy. Low-grade fevers, mental status changes, and vague reports of discomfort may be the only symptoms before sepsis. Always consider the possibility of infection with any patient after a kidney transplant. Urinary tract complications include ureteral leakage, fistula, or obstruction; stone formation; bladder neck contracture; and graft rupture. Surgical intervention may be required.

### Immunosuppressive Drug Therapy.

The success of kidney transplantation depends on changing the patient's IMMUNITY response so the new kidney is not rejected as a foreign organ. Immunosuppressive drugs protect the transplanted organ. These drugs include corticosteroids, inhibitors of T-cell proliferation and activity (azathioprine, mycophenolic acid, cyclosporine, and tacrolimus), mTOR inhibitors (to disrupt stimulatory T-cell signals), and monoclonal antibodies. Chapter 17 discusses the mechanisms of action for these agents and the associated patient responses. Patients taking these drugs are at an increased risk for death from infection. Usually, the patient receives a period of high-dose (induction) therapy followed by lower-dose maintenance immunosuppressive therapy.

Some patients do not follow the maintenance regimen correctly and are at high risk for losing the transplanted kidney. Work with the patient to ensure adherence to the drug regimen.

Despite the complexity of drug regimens following kidney transplantation, 85.5% of patients are living 5 years after transplantation compared with 35.8% of patients who receive dialysis for 5 years. The costs of hemodialysis (HD) are three times the cost of kidney transplantation over the same 5 years (Kidney Foundation of Canada, 2015; USRDS, 2015).

Although rejection is uncommon with immunosuppressive therapy, kidney transplant recipients are at risk for cardiovascular disease (the most common cause of death among kidney transplant recipients), diabetes, cancer, and infections. Prevention and management of these complications are important to maintaining the health of the transplanted kidney and prolonging patient survival. Be aware that some patient groups, including African Americans, Hispanic Americans, and Native Americans have a greater incidence of graft failure and systemic complications (especially cardiovascular disease) after transplantation.

## Nursing Safety Priority QSEN

### Action Alert

Teach patients and families about the importance of adhering to the antirejection drug regimen to prevent transplant rejection.

## Care Coordination and Transition Management

### Home Care Management.

Because of the complex nature of CKD, its progressive course, and many treatment options, a case manager is helpful in planning, coordinating, and evaluating care. As kidney disease progresses, the patient is seen by a nephrologist or nephrology nurse practitioner regularly. Together with the dietitian and social worker, evaluate the home environment and determine equipment needs before discharge. Once the patient is discharged, nephrology home care nurses direct care and monitor progress.

Provide health teaching about the diet in kidney disease and the progression of disease. As CKD approaches end-stage kidney disease (ESKD), treatment with hemodialysis (HD), peritoneal dialysis (PD), or transplantation is selected. For each form of treatment, the patient and partner must learn about the procedures and consider his or her personal lifestyle, support systems, and

methods of coping. Decision making about treatment type or even whether to pursue treatment is difficult for patients and families. Provide information and emotional support to help patients with these decisions.

Teach patients who select hemodialysis (HD) about the machine and vascular access care. If in-home HD is selected, preparations are needed for the appropriate equipment, including a water-treatment system. A nephrology nurse is essential for a successful transition to at-home HD to teach the patient and monitor treatment and care. This nurse performs a home care visit before discharge to coordinate equipment setup. Family members must be available to respond to alarms during treatment. Nocturnal HD is a growing modality, and additional safety considerations must be addressed, including a plan for treatment discontinuation or generator backup during power outages. Regardless of whether the treatment occurs at home or in a center, promote independence through teaching and best practices in self-management.

The patient receiving PD needs extensive training in the procedure and help in obtaining equipment and the many supplies needed. A nephrology nurse assesses patients, monitors vital signs, assesses adherence with drug and diet regimens, and monitors for indications of peritonitis.

The nurse plays a vital role in the long-term care of the patient with a kidney transplant by facilitating acceptance and understanding of the antirejection drug regimen as a part of daily life. Carefully monitor patients for indications of graft rejection and for complications, such as infection. [Chart 68-10](#) shows the focused assessment for the patient following kidney transplant.

### **Chart 68-10**

## **Focused Assessment**

### **The Patient Following Kidney Transplant**

Assess cardiovascular and respiratory status, including:

- Vital signs, with special attention to blood pressure
- Presence of S<sub>3</sub> or pericardial friction rub
- Presence of chest pain
- Presence of edema (periorbital, pretibial, sacral)
- Jugular vein distention
- Presence of dyspnea
- Presence of crackles, beginning at the lung bases and extending upward

Assess nutritional status, including:

- Weight gain or loss
- Presence of anorexia, nausea, or vomiting

Assess kidney status, including:

- Amount, frequency, and appearance of urine (in nonanuric patients)
- Presence of bone pain
- Presence of hyperglycemia secondary to diabetes

Assess hematologic status, including:

- Presence of petechiae, purpura, ecchymosis
- Presence of fatigue or shortness of breath

Assess GI status, including:

- Presence of stomatitis
- Presence of melena

Assess integumentary status, including:

- Skin integrity
- Presence of pruritus
- Presence of skin discoloration

Assess neurologic status, including:

- Changes in mental status
- Presence of seizure activity
- Presence of sensory changes
- Presence of lower-extremity weakness

Assess laboratory data, including:

- BUN
- Serum creatinine
- Creatinine clearance
- CBC

- **Electrolytes**

Assess psychosocial status, including:

- **Presence of anxiety**
- **Presence of maladaptive behavior**

*BUN*, Blood urea nitrogen; *CBC*, complete blood count.

### **Self-Management Education.**

Instruct patients and family members in all aspects of nutrition therapy, drug therapy, and complications. Teach them to report complications, such as fluid overload and infection. When a patient has a specific form of therapy, such as dialysis or transplantation, focus teaching on the chosen type of intervention. Assess the need for immunizations and request a prescription to administer needed ones before transplantation (Tran & Miniard, 2017).

Hemodialysis (HD) is the most complex form of therapy for the patient and family to understand. Even if patients receive HD in a dialysis center instead of at home, they are expected to have some knowledge of the process. Teach the patient or a family member to care for the vascular access and to report signs of infection and clotting. Teaching also includes instructing the patient to assess daily for a bruit and thrill in the vascular access. Those who plan to have in-home HD will need a partner. Both the patient and the partner must be taught the entire process of HD and must be able to perform it independently before the patient is discharged.

Peritoneal dialysis (PD) involves extensive health teaching for the patient and family. Emphasize sterile technique because peritonitis is the most common complication of PD. Instruct patients to report any symptoms of peritonitis, especially cloudy effluent and abdominal pain. If peritonitis develops, teach patients how to give themselves antibiotics by the intraperitoneal (IP) route. Stress the importance of completing the antibiotic regimen. Remind patients that repeated episodes of peritonitis can reduce the effectiveness of PD, which may require the transfer to HD.

The patient receiving a kidney transplant also needs extensive health teaching. Provide instruction about drug regimens, home monitoring, immunosuppression, symptoms of rejection, infection, and prescribed changes in the diet and activity level.

### **Psychosocial Preparation.**

In collaboration with the patient's mental health professional or counselor, provide psychosocial support for the patient and family. Help the patient adjust to the diagnosis of kidney failure and eventually accept the treatment regimens.

Many patients view dialysis as a cure instead of lifelong management. For many patients, reduction of uremic symptoms and improved ELIMINATION in the first weeks after starting dialysis treatment create a sense of well-being (the "honeymoon" period). They feel better physically, and their mood may be happy and hopeful. At this time they tend to overlook the discomfort and inconvenience of dialysis. Use this time to begin health teaching. Stress that, although symptoms are reduced, not to expect a complete return to the previous state of well-being before ESKD.

Many patients become discouraged during the first year of treatment. This mood state may last a few months to a year or longer. The difficulties of incorporating dialysis into daily life are staggering, and patients may become depressed as problems occur. They may struggle with the idea of having to be permanently dependent on a disruptive therapy. Patients may feel helpless and dependent. Some patients may deny the need for dialysis or may not adhere to drug therapy and diet restrictions. Monitor any behaviors that may contribute to nonadherence and suggest psychiatric referrals. Help the patient and family focus on the positive aspects of the treatments. Continue health education with patients as active participants and decision makers.

Most patients with CKD eventually enter a phase of acceptance or resignation. Each patient reacts differently. To make this long-term adaptation, he or she must adjust to continuous change. Concerns depend on the patient's health and specific treatment method.

After patients have accepted or become resigned to the chronic aspect of their disease, they

usually attempt to return to their previous activities. However, resuming the previous level of activity may not be possible. Help patients develop realistic expectations that allow them to lead active, productive lives.

### Health Care Resources.

Professionals from many disciplines are resources for the patient with ESKD. Home care nurses monitor the patient's status and evaluate maintenance of the prescribed treatment regimen (HD or PD). Social services are often involved because of the complex process of applying for financial aid to pay for the required medical care. A physical therapist may be beneficial in helping to improve the patient's functional health. A dietitian can help the patient and family members understand special dietary needs. A psychiatric evaluation may be needed if depressive symptoms are present. Pharmacists provide invaluable insight and teaching about drug therapy and adjustments to meet outcomes. Clergy and pastoral care specialists offer spiritual support.

Patients with CKD are routinely followed by a nephrologist. Organizations such as the National Kidney Foundation (NKF), the American Kidney Fund, and the National Association of Patients on Hemodialysis and Transplantation (NAPHT) may be helpful to patients and families.

### ◆Evaluation: Reflecting

Evaluate the care of the patient with CKD based on the identified priority problems. The expected outcomes are that, with appropriate management, the patient should:

- Achieve and maintain appropriate FLUID AND ELECTROLYTE BALANCE
- Maintain an adequate nutrition status
- Avoid infection at the vascular access site
- Use effective coping strategies
- Prevent or slow systemic complications of CKD, including osteodystrophy
- Report an absence of physical signs of anxiety or depression

## 👤Clinical Judgment Challenge 68-1

### Patient-Centered Care OSEN

Jamie is a 48-year-old woman who received a living related donor (LRD) kidney transplant 6 months ago. Today she learns that her blood sugar, which has been elevated since starting immunosuppressant therapy, is 180 mg/dL and her A1C is 8. You find her crying after her visit to the transplant surgeon, who advises that she start on an antidiabetic drug. The surgeon has left to consult with the nephrologist and primary health care provider to determine the best drug or drugs for glycemic control. Jamie states, "I can't take another med; I already take 10 tablets each day! Why is this happening to me?"

1. How will you respond to her feelings of anxiety or concern related to the number of tablets taken daily and feelings of "why me/why now"?
2. Which additional information would you gather to better understand the patient's emotional reaction to the new treatment plan?
3. Should you ask about who donated the kidney? Why or why not?
4. What possibility exists that some of Jamie's current emotional state is influenced by her antirejection drug therapy regimen? If a possibility does exist, which category of drugs is most likely to have a negative influence and why?
5. What are the next steps in communicating the patient concerns and emotional state to the interprofessional team members who are involved in Jamie's care?

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Use sterile technique when initiating and providing kidney replacement therapy. **QSEN: Safety**
- Implement fall precautions and consider physical therapy referral for patients with CKD osteodystrophy to prevent fractures. **QSEN: Safety**
- Use skin protective measures to reduce injury and pressure injury in patients with CKD. **QSEN: Safety**
- Alert health care providers to patient assessments that indicate hypotension, dehydration, or hypovolemia to avoid inadequate kidney PERFUSION. **QSEN: Teamwork and Collaboration**
- Avoid taking blood pressure measurements or drawing blood from an arm with a vascular access (AV fistula or graft). **QSEN: Safety**
- Do not use a kidney replacement vascular access device (the AV fistula or graft site) to give IV fluids. **QSEN: Safety**

### Health Promotion and Maintenance

- Encourage patients with AKI, CKD, or end-stage kidney disease (ESKD) to follow fluid and dietary restrictions regarding sodium, potassium, and protein. **QSEN: Evidence-Based Practice**
- Teach patients the expected side effects, any adverse reactions to prescribed drugs, and when to contact the prescriber. **QSEN: Safety**
- Teach patients using peritoneal dialysis the early signs and symptoms of peritonitis. **QSEN: Patient-Centered Care**
- Teach patients receiving immunosuppressive therapy for kidney transplantation to assess themselves daily for fever, general malaise, and nausea or vomiting, as well as changes in urine output and weight gain that indicate new fluid retention. **QSEN: Patient-Centered Care**

### Psychosocial Integrity

- Allow patients the opportunity to express concerns about the disruption of lifestyle and considerations for end-of-life care as a result of kidney failure. **QSEN: Patient-Centered Care**
- Use language and terminology that are comfortable and understandable for the patient. **QSEN: Patient-Centered Care**
- Assess the patient for anxiety, depression, and nonacceptance of the diagnosis or treatment plan. **QSEN: Patient-Centered Care**
- Refer patients to community resources and support groups. **QSEN: Informatics**

### Physiological Integrity

- Report immediately any condition that obstructs urine flow. **QSEN: Safety**
- Collaborate with the dietitian to teach patients about needed fluid, sodium, potassium, or dietary protein restriction to maintain FLUID AND ELECTROLYTE BALANCE. **QSEN: Teamwork and Collaboration**
- Inform the primary health care provider urgently or immediately about hemodynamic instability, change in cognition, signs of infection, newly abnormal serum electrolytes, and urine output less than 0.5 mL/kg/hr for more than 2 to 4 hours (unless the patient is oliguric or anuric from ESKD). **QSEN: Teamwork and Collaboration**
- Teach patients in the early stages of CKD the symptoms of dehydration. **QSEN: Patient-Centered**

### Care

- Evaluate the patient's laboratory values, especially the metabolic panel, trends in serum creatinine, GFR, and albumin-to-creatinine ratio to assess the status of kidney problems and communicate concerning changes to the interprofessional team. **QSEN: Teamwork and Collaboration**
- Teach patients in the later stages of CKD the indications of fluid overload and hyperkalemia. **QSEN: Patient-Centered Care**
- Avoid all invasive procedures in the 4 to 6 hours following hemodialysis. **QSEN: Evidence-Based Practice**

## Selected Bibliography

## UNIT XVI

# Interprofessional Collaboration for Patients With Problems of the Reproductive System

### OUTLINE

---

Chapter 69 Assessment of the Reproductive System

Chapter 70 Care of Patients With Breast Disorders

Chapter 71 Care of Patients With Gynecologic Problems

Chapter 72 Care of Patients With Male Reproductive Problems

Chapter 73 Care of Transgender Patients

Chapter 74 Care of Patients With Sexually Transmitted Infections

## CHAPTER 69

# Assessment of the Reproductive System

---

Donna D. Ignatavicius

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is SEXUALITY.**

**The interrelated concept for this chapter is COMFORT.**

## LEARNING OUTCOMES

### Health Promotion and Maintenance

1. Teach patients about evidence-based guidelines for selected reproductive screening tests.

### Psychosocial Integrity

2. Identify general psychological responses to reproductive health problems that affect SEXUALITY.

### Physiological Integrity

3. Briefly review the anatomy and physiology of the male and female reproductive systems.
4. Identify reproductive changes associated with aging and their implications for nursing care.
5. Perform a focused physical assessment of the patient with male or female reproductive system problems.
6. Explain the use of laboratory testing for patients with suspected or actual reproductive health problems.
7. Describe the postprocedure care and health teaching for a client undergoing a biopsy to determine the presence of cancer, including interventions for increasing COMFORT.
8. Develop an evidence-based teaching plan for a patient undergoing endoscopic studies for reproductive health problems.

The first health care professional to assess the patient with a reproductive system health problem or hear a patient's concern about a reproductive problem is often the nurse. These problems typically affect SEXUALITY, both its physical and psychosocial aspects, and are difficult for many people to discuss. Assessment of the male and the female reproductive systems should be part of every complete physical assessment. *Be aware of and sensitive to gender identity and differences in sexual orientation and practices.* A more detailed discussion of human SEXUALITY is found in [Chapter 2](#).

# Anatomy and Physiology Review

## Structure and Function of the Female Reproductive System

The female reproductive system is located both outside (external) and inside (internal) the body.

### External Genitalia

The external female genitalia, or **vulva**, extend from the mons pubis to the anal opening. The mons pubis is a fat pad that covers the symphysis pubis and protects it during coitus (sexual intercourse).

The labia majora are two vertical folds of adipose tissue that extend posteriorly from the mons pubis to the perineum. The size of the labia majora varies, depending on the amount of fatty tissue present. The skin over the labia majora is usually darker than the surrounding skin and is highly vascular. It protects inner vulval structures and enhances sexual arousal.

The labia majora surround two thinner, vertical folds of reddish epithelium called the *labia minora*. The labia minora are highly vascular and have a rich nerve supply. Emotional or physical stimulation produces marked swelling and sensitivity. Numerous sebaceous glands in the labia minora lubricate the entrance to the vagina. The clitoris is a small, cylindrical organ that is composed of erectile tissue with a high concentration of sensory nerve endings. During sexual arousal, the clitoris becomes larger and increases sexual sensation.

The vestibule is a longitudinal area between the labia minora, the clitoris, and the vagina that contains Bartholin glands and the openings of the urethra, Skene's glands (paraurethral glands), and vagina. The two Bartholin glands, located deeply toward the back on both sides of the vaginal opening, secrete lubrication fluid during sexual excitement. Their ductal openings are usually not visible.

The area between the vaginal opening and the anus is the perineum. The skin of the perineum covers the muscles, fascia, and ligaments that support the pelvic structures.

### Internal Genitalia

The internal female genitalia are shown in Fig. 69-1. The vagina is a hollow tube that extends from the vestibule to the uterus. Ovarian hormones (primarily *estrogen*) influence the amounts of glycogen and lubricating fluid secreted by the vaginal cells. The normal vaginal bacteria (flora) interact with the secretions to produce lactic acid and maintain an acidic pH (3.5 to 5.0) in the vagina. This acidity helps prevent infection in the vagina.

FIG. 69-1 Internal female genitalia.

At the upper end of the vagina, the uterine cervix projects into a cup-shaped vault of thin vaginal tissue. The recessed pockets around the cervix permit palpation of the internal pelvic organs. The posterior area provides access into the peritoneal cavity for diagnostic or surgical purposes.

The uterus (or “womb”) is a thick-walled, muscular organ attached to the upper end of the vagina. This inverted pear-shaped organ is located within the true pelvis, between the bladder and the rectum. The uterus is made up of the body and the cervix.

The cervix is a short (1 inch [2.5 cm]), narrowed portion of the uterus and extends into the vagina. The surfaces of the cervix and the canal are the sites for Papanicolaou (Pap) testing. (See discussion later in this chapter.)

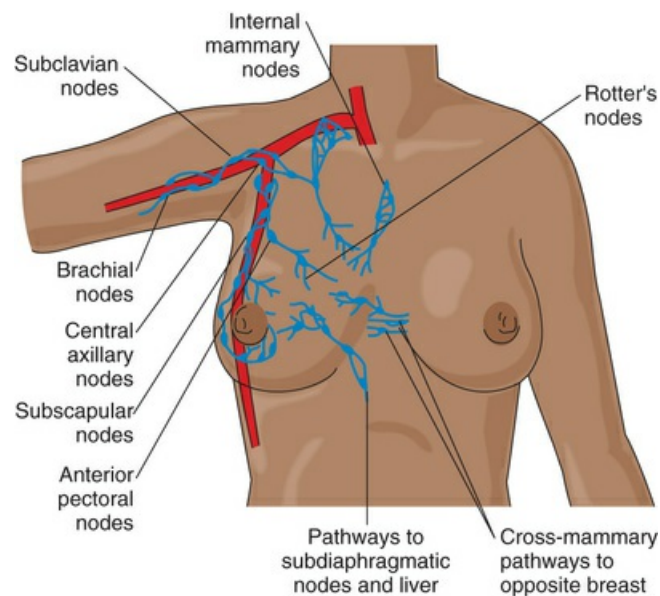

The fallopian tubes (uterine tubes) insert into the fundus of the uterus and extend laterally close to the ovaries. They provide a duct between the ovaries and the uterus for the passage of ova and sperm. In most cases, the ovum is fertilized in these tubes.

The ovaries are a pair of almond-shaped organs located near the lateral walls of the upper pelvic cavity. After menopause, they become smaller. These small organs develop and release ova and produce the sex steroid hormones (estrogen, progesterone, androgen, and relaxin). Adequate amounts of these hormones are needed for normal female growth and development and to maintain a pregnancy.

## Breasts

The female breasts are a pair of mammary glands that develop in response to secretions from the hypothalamus, pituitary gland, and ovaries. The breasts are an accessory of the reproductive system that nourish the infant after birth.

Breast tissue is composed of a network of glandular and ductal tissue, fibrous tissue, and fat. The proportion of each component of breast tissue depends on genetic factors, nutrition, age, and obstetric history. The breasts are supported by ligaments that are attached to underlying muscles. They have abundant blood supply and lymph flow that drain from an extensive network toward the axillae (Fig. 69-2).

**FIG. 69-2** Lymphatic drainage of the female breast.

## Structure and Function of the Male Reproductive System

The male reproductive system also consists of external and internal genitalia. The primary male hormone for sexual development and function is *testosterone*. Testosterone production is fairly constant in the adult male. Only a slight and gradual reduction of testosterone production occurs in the older adult male until he is in his 80s. Low testosterone levels decrease muscle mass, reduce

skin elasticity, and lead to changes in sexual performance.

The penis is an organ for urination and intercourse consisting of the body or shaft and the glans penis (the distal end of the penis). The glans is the smooth end of the penis and contains the opening of the urethral meatus. The urethra is the pathway for the exit of both urine and semen. A continuation of skin covers the glans and folds to form the prepuce (foreskin). Surgical removal of the foreskin (**circumcision**) for religious or cultural reasons is a common procedure in the United States and other Western countries.

The scrotum is a thin-walled, fibromuscular pouch that is behind the penis and suspended below the pubic bone. This pouch protects the testes, epididymis, and vas deferens in a space that is slightly cooler than inside the abdominal cavity. The scrotal skin is darkly pigmented and contains sweat glands, sebaceous glands, and few hair follicles. It contracts with cold, exercise, tactile stimulation, and sexual excitement.

The internal male genitalia are shown in Fig. 69-3. The major organs are the testes and prostate gland. The testes are a pair of oval organs in the scrotum that produce sperm and testosterone. Each testis is suspended in the scrotum by the spermatic cord, which provides blood, lymphatic, and nerve supply to the testis. Sympathetic nerve fibers are located on the arteries in the cord, and sympathetic and parasympathetic fibers are on the vas deferens. When the testes are damaged, these autonomic nerve fibers transmit excruciating pain and a sensation of nausea.

**FIG. 69-3** Internal male genitalia.

The epididymis is the first portion of a ductal system that transports sperm from the testes to the urethra and is a site of sperm maturation. The vas deferens, or ductus deferens, is a firm, muscular tube that continues from the tail of each epididymis. The end of each vas deferens is a reservoir for sperm and tubular fluids. They merge with ducts from the seminal vesicle to form the ejaculatory ducts at the base of the prostate gland. Sperm from the vas deferens and secretions from the seminal vesicles move through the ejaculatory duct to mix with prostatic fluids in the prostatic urethra.

The prostate gland is a large accessory gland of the male reproductive system that can be palpated via the rectum. The gland secretes a milky alkaline fluid that adds bulk to the semen, enhances sperm movement, and neutralizes acidic vaginal secretions. Men older than 50 years commonly have an enlarged prostate (benign prostatic hyperplasia [BPH]), which can cause problems such as overflow incontinence and nocturia (nighttime urination). Prostate function depends on adequate levels of testosterone.

## Reproductive Changes Associated With Aging

Age affects the function of both the male and the female reproductive systems. Many changes in the reproductive system occur as people age (Chart 69-1).

### Chart 69-1

## Nursing Focus on the Older Adult

### Changes in the Reproductive System Related to Aging

PHYSIOLOGIC CHANGE	NURSING INTERVENTIONS	RATIONALES
<b>Women</b>		
Graying and thinning of the pubic hair	Discuss changes with the patient (applies to all structures for both women and men).	Education helps prevent problems with body image (applies to all structures for both women and men).
Decreased size of the labia majora and clitoris		
Drying, smoothing, and thinning of the vaginal walls	Provide information about vaginal estrogen therapy and water-soluble lubricants.	Education enables the patient to make informed decisions about the treatment of vaginal dryness, which can cause painful intercourse.
Decreased size of the uterus Atrophy of the endometrium Decreased size and marked convolution of the ovaries Loss of tone and elasticity of the pelvic ligaments and connective tissue	Provide information about Kegel exercises to strengthen pelvic muscles. Urinary incontinence can be a major problem.	Strengthening exercises may prevent or reduce pelvic relaxation and urinary incontinence.
Increased flabbiness and fibrosis of the breasts, which hang lower on the chest wall; decreased erection of the nipples	Teach or reinforce the importance of breast self-awareness, clinical breast examinations, and mammography.	These methods can detect masses or other changes that may indicate the presence of cancer.
<b>Men</b>		
Graying and thinning of the pubic hair	Teach or reinforce the importance of testicular self-examination (TSE).	TSE may detect changes that may indicate cancer.
Increased drooping of the scrotum and loss of rugae	Teach the patient the signs of urethral obstruction and the importance of prostate cancer screening.	Education helps the patient detect enlargement or obstruction, which may indicate the presence of cancer.
Prostate enlargement, with an increased likelihood of urethral obstruction		

## Health Promotion and Maintenance

Many health problems of the reproductive system can be prevented through health promotion strategies and avoidance of risky lifestyle behaviors. For example, following recommended best practices for routine preventive screenings, such as mammography and Pap tests, can detect cancer early so it can be treated for a cure. Sexually transmitted infections (STIs) and other reproductive infections can be avoided using safe sex practices such as condoms or abstinence. Teach patients about these health promotion strategies and the rationale for practicing them. Additional health promotion interventions are described under specific reproductive health problems within this unit.

## Assessment: Noticing and Interpreting

### Patient History

Establish a trusting relationship with the patient. Many patients are hesitant to share their reproductive history or concerns about **SEXUALITY**. Respect their choice to refuse to answer questions about their reproductive problems or sexual practices. Assess the patient's health habits, such as diet, sleep, and exercise patterns. Low levels of body fat may be related to ovarian dysfunction. Assess for alcohol, tobacco, and drug use (prescribed, over-the-counter [OTC], and illicit drugs), because **libido** (sex drive), sperm production, and the ability to have or sustain an erection can be affected by these substances.

Ask female patients about the date and result of their most recent Pap test, breast self-examination, and vulvar self-examination. Determine when male patients older than 50 years had their last prostate examination and prostate-specific antigen test.

Ask about childhood illnesses that could have an effect on the reproductive system. For example, mumps in men may cause **orchitis** (painful inflammation and swelling of the testes) and can lead to testicular atrophy and sterility. Also ask whether the patient has had any infections. Pelvic inflammatory disease or a ruptured appendix followed by peritonitis can cause pelvic scarring and strictures or adhesions in the fallopian tubes. **Salpingitis** (uterine tube infection) is often caused by chlamydia, a sexually transmitted infection (STI), and can result in female infertility. A history of infections or prolonged fever in males may have damaged sperm production or caused obstruction of the seminal tract, which can cause infertility.

Assess for chronic illnesses or surgeries that could affect reproductive function. Disorders that affect a woman's metabolism or nutrition can depress ovarian function and cause **amenorrhea** (absence of menses). Patients with diabetes mellitus may experience physiologic changes such as vaginal dryness or impotence. Chronic disorders of the nervous system, respiratory system, or cardiovascular system can alter the sexual response.

Ask whether the patient has been treated with radiation therapy. Inquire about the prolonged use of corticosteroids, internal or external estrogen, testosterone, or chemotherapy drugs, which can lead to reproductive system dysfunction.

## Gender Health Considerations

### Patient-Centered Care QSEN

Data about sexual activity are vital parts of the patient's history. Sexual orientation and gender identity should not be assumed. Patients who are lesbian, gay, bisexual, transgender, and queer/questioning (LGBTQ) are often not fully assessed by health care professionals. These patients usually feel more comfortable sharing information about their reproductive health and sexual activity when approached in a caring, nonjudgmental way. Chapter 1 describes sensitive interviewing techniques that are appropriate for LGBTQ patients. Chapter 73 in this unit discusses assessment and care of transgender patients in detail.

## Cultural/Spiritual Considerations

### Patient-Centered Care QSEN

Other cultural beliefs and practices influence lifestyle and **SEXUALITY**. A person's religious beliefs often influence specific sexual practices, the acceptable number of sexual partners, and contraceptive use. Be sensitive to these differences by being nonjudgmental and showing acceptance.

## Nutrition History

A nutrition history is important when assessing the reproductive system. Fatigue and low libido may occur as a result of poor diet and anemia. The World Cancer Research Fund estimates that

about one quarter to one third of the new *preventable* cancer cases in the United States in 2017 are related to overweight or obesity, physical inactivity, and poor nutrition ([American Cancer Society \[ACS\], 2017a](#)). Ask the patient to recall his or her dietary intake for a recent 24-hour period to assess nutritional quality.

Assess the patient's height, weight, and body mass index. The patient may be hesitant to discuss practices such as bingeing, purging, anorexic behaviors, or excessive exercise. A certain level of body fat and weight is necessary for the onset of menses and the maintenance of regular menstrual cycles. Decreased body fat results in insufficient estrogen levels.

## Gender Health Considerations

### Patient-Centered Care QSEN

Women have special nutrition needs. Heavy menstrual bleeding, particularly in women who have intrauterine devices, may require iron supplements. Teach all women about their body's need for calcium. Although adequate calcium intake throughout life is needed, it is especially important during and after menopause to help prevent osteoporosis caused by decreased estrogen production (see Chapter 50).

### Family History and Genetic Risk

The family history helps determine the patient's risk for conditions that affect reproductive functioning. A delayed or early development of secondary sex characteristics may be a familial pattern.

The current age and health status of family members are important. Evidence of medical diseases or reproductive problems in family members (e.g., diabetes, endometriosis, reproductive cancer) provides a fuller understanding of the patient's current symptoms. For example, daughters of women who were given diethylstilbestrol (DES) to control bleeding during pregnancy are at increased risk for infertility and reproductive tract cancer.

Specific *BRCA1* and *BRCA2* gene mutations increase the overall risk for breast or ovarian cancer ([ACS, 2017c](#)). Men with first-degree relatives (e.g., father, brother) with prostate cancer are at greater risk for the disease than are men in the general population.

### Current Health Problems

Patients often seek medical attention as a result of impaired COMFORT, bleeding, discharge, and masses ([Chart 69-2](#)). Pain related to reproductive system disorders may be confused with symptoms usually associated with GI or urinary health problems (e.g., urinary frequency). Ask the patient to describe the nature of the pain, including its type, intensity, timing and location, duration, and relationship to menstrual, sexual, urinary, or GI function. Assess the factors that exacerbate (worsen) or relieve the pain. Ask about sleeping patterns and if pain or other symptoms affect the ability to get adequate rest.

## Chart 69-2

### Best Practice for Patient Safety & Quality Care QSEN

#### Assessing the Patient With Reproductive Health Problems

PATIENT CONCERN	NURSING ASSESSMENT
Pain	Type and intensity of pain Location and duration of pain Factors that relieve or worsen pain Relationship to menstrual, sexual, urinary, or GI function Medications
Bleeding	Presence or absence of bleeding Character and amount of bleeding Relationship of bleeding to events or other factors (e.g., menstrual cycle) Onset and duration of bleeding Presence of associated symptoms, such as pain
Discharge	Amount and character of discharge Presence of genital lesions, bleeding, itching, or pain Presence of symptoms or discharge in sexual partner
Masses	Location and characteristics of mass Presence of associated symptoms, such as pain Relationship to menstrual cycle

Heavy *bleeding* or a lack of bleeding may concern the patient. The possibility of pregnancy in any sexually active woman with amenorrhea must be considered. Postmenopausal bleeding needs to be evaluated. Ask the patient to describe the amount and characteristics of abnormal vaginal bleeding. Assess whether the bleeding occurs in relation to the menstrual cycle or menopause, intercourse, trauma, or strenuous exercise. For male patients, ask about the presence of penile bleeding. Ask any patient who has abnormal bleeding about associated symptoms, such as pain, cramping or abdominal fullness, a change in bowel habits, urinary difficulties, and weight changes.

*Discharge* from the male or female reproductive tract can cause irritation of the surrounding tissues, itching, altered COMFORT, embarrassment, and anxiety. Ask about the amount, color, consistency, odor, and chronicity of discharge that may be present from orifices used during sexual activity. Drugs (e.g., antibiotics) and clothing (e.g., tight jeans, synthetic underwear fabric) may cause or worsen genital discharge. Many types of discharge are caused by STIs or other infection (see [Chapter 74](#)).

*Masses* in the breasts, testes, or inguinal area are evaluated. Patients can sometimes relate changes in character or size of masses to menstrual cycles, heavy lifting, straining, or trauma. Ask about associated symptoms such as tenderness, heaviness, pain, dimpling, and tender lymph nodes.

## Physical Assessment

### Assessment of the Female Reproductive System

The clinical nurse generalist does not perform a comprehensive female or male reproductive examination. However, you should perform a focused assessment related to specific concerns of the patient. The primary health care provider conducts a more detailed gynecologic assessment as described in the following paragraphs; the clinical nurse often assists with the examination.

Immediately before the pelvic and breast examinations, ask the patient to empty her bladder and undress completely. Drape the patient adequately to provide modesty throughout the examination. Remove drapes only over the region being examined and replace them after that area has been assessed. Mirrors can be used to facilitate teaching if the patient so desires. The examination should be performed in a room that has adequate lighting for body inspection, has comfortable temperature, and ensures privacy.

The physical examination of the female reproductive system includes the breasts (see [Chapter 70](#)), abdomen, and pelvic examination. The patient's arms should be at her sides or over her chest to allow better relaxation of the abdominal muscles. During the gynecologic examination, the primary health care provider palpates for symptomatic and asymptomatic abdominopelvic masses, which can be of reproductive, intestinal, or urinary tract origin. Gynecologic masses, such as ovarian masses, may be further differentiated from lesions on the body of the uterus during the bimanual portion of the pelvic examination.

Inspection of the female genitalia and the pelvic examination are usually performed at the end of a head-to-toe physical assessment. The patient is often more apprehensive about these portions of the examination than about any other part. Impaired COMFORT or lack of privacy during previous pelvic or breast examinations may prevent the patient from relaxing.

Other than determining pregnancy or infertility, a pelvic examination is indicated to assess for:

- Menstrual irregularities
- Unexplained abdominal or vaginal pain
- Vaginal discharge, itching, sores, or infection
- Rape trauma or other pelvic injury
- Physical changes in the vagina, cervix, and uterus

### Assessment of the Male Reproductive System

Unless a male patient seeks health care for a specific problem, the primary health care provider may not perform a reproductive assessment, depending on the setting and the age of the patient. Men are often embarrassed and anxious when the reproductive system is assessed. The patient may be concerned about impaired COMFORT, the developmental stage of his genitalia, or the possibility of an erection during the examination. If he does have an erection, the examiner should assure him that this is a normal response to a tactile stimulus (touch) and should continue the examination.

Explain each step of the assessment procedure before it is performed. The patient needs to be

reassured that the health care provider will stop and change the assessment plan or technique if the patient experiences pain during the examination. Teach relaxation techniques and provide nonjudgmental support during the examination to increase COMFORT, especially during the rectal examination to palpate the prostate gland.

## Psychosocial Assessment

The psychosocial assessment may provide information about factors that affect the patient's health status. During the social history, ask about sources of support, strengths, and coping reactions to illness or dysfunction.

## Cultural/Spiritual Considerations

### Patient-Centered Care **QSEN**

A patient's personal experiences, culture, and/or spiritual beliefs may influence his or her SEXUALITY and ability to enjoy a satisfactory sex life. These factors may include:

- Sexual trauma or abuse inflicted during childhood or adulthood
- Punishment for masturbation
- Psychological trauma
- Cultural influences, such as the idea of female passivity during intercourse
- Concerns about sexual partners or sexual lifestyle
- Use of alcohol or street drugs

Fears may affect the patient's satisfaction with SEXUALITY or body image. He or she may also be concerned about the potential or actual reaction of family members to reproductive health problems (see [Chart 69-2](#)). Use nonjudgmental listening to continue development of trust between yourself and the patient, allowing the patient to openly express feelings or concerns.

## Diagnostic Assessment

### Laboratory Assessment

[Chart 69-3](#) summarizes important laboratory tests associated with reproductive function. The **Papanicolaou test (Pap test)**, or **Pap smear**, is a cytologic study that is effective in detecting precancerous and cancerous cells within the female patient's cervix. It is done immediately before the pelvic examination. A speculum is inserted into the vagina, and several samples of cells from the cervix are obtained with a small brush or spatula. The specimens are placed on a glass slide and sent to the laboratory for examination.

### **Chart 69-3**

## Laboratory Profile

### Reproductive Assessment
