Ask about age, gender, occupation, and where the patient lives. Thoroughly assess the current illness, including when it started, the severity of symptoms, associated problems, and any interventions to date. Ask the patient about when the HIV infection was diagnosed and which symptoms led to that diagnosis. Ask him or her to give a chronologic history of infections and problems since the diagnosis. Assess the patient's health history, including whether he or she received a blood transfusion between 1978 and 1985 in the United States or Canada (before routine blood testing for HIV contamination). Ask the immigrant patient about his or her history of transfusion therapy before coming to North America.

Ask the patient about sex practices, sexually transmitted infections (STIs), and major infectious diseases, including tuberculosis and hepatitis. If the patient has hemophilia, ask about treatment with clotting factors. Determine whether the patient has engaged in past or present injection drug usage. Assess the patient's cognitive function and knowledge level of the diagnosis, symptom management, diagnostic tests, treatments, community resources, and modes of HIV transmission. Also assess his or her understanding and use of safer sex practices and provide the appropriate patient teaching.

### Physical Assessment/Signs and Symptoms.

HIV disease and AIDS progress on a continuum. The patient with HIV disease may either have few symptoms and problems or may have problems that are acute rather than chronic. However, as the disease progresses, more severe health problems occur. Assess for clusters of symptoms that may indicate disease progression ([Chart 19-3](#)).

#### Chart 19-3

### Key Features

#### AIDS

##### Immunologic Signs and Symptoms

- Low white blood cell counts:
- CD4+/CD8+ ratio <2
- CD4+ count <200/mm<sup>3</sup> ( $0.2 \times 10^9/L$ )
- Hypergammaglobulinemia
- Opportunistic infections
- Lymphadenopathy
- Fatigue

##### Integumentary Signs and Symptoms

- Dry skin
- Poor wound healing
- Skin lesions

- Night sweats

### **Respiratory Signs and Symptoms**

- Cough
- Shortness of breath

### **GI Signs and Symptoms**

- Diarrhea
- Weight loss
- Nausea and vomiting

### **Central Nervous System Signs and Symptoms**

- Confusion
- Dementia
- Headache
- Fever
- Visual changes
- Memory loss
- Personality changes
- Pain
- Seizures

### **Opportunistic Infections**

- Protozoal infections:
  - Toxoplasmosis
  - Cryptosporidiosis
  - Isosporiasis
  - Microsporidiosis
  - Strongyloidiasis
  - Giardiasis
- Fungal infections:
  - Candidiasis

- *Pneumocystis jiroveci* pneumonia
- Cryptococcosis
- Histoplasmosis
- Coccidioidomycosis
- Bacterial infections:
  - *Mycobacterium avium* complex infection
  - Tuberculosis
  - Nocardiosis
- Viral infections:
  - Cytomegalovirus infection
  - Herpes simplex virus infection
  - Varicella-zoster virus infection

### Malignancies

- Kaposi's sarcoma
- Non-Hodgkin's lymphoma
- Hodgkin's lymphoma
- Invasive cervical carcinoma

### Opportunistic Infections.

The patient with HIV/AIDS often develops pathogenic infections and opportunistic infections. *Pathogenic infections* are caused by virulent organisms and occur even among adults with normal IMMUNITY. *Opportunistic infections* are those caused by overgrowth of the patient's microbiome (normal flora). Only when IMMUNITY is depressed are such organisms capable of causing infection.

Opportunistic infections occur because of the profound reduced IMMUNITY of the adult with HIV disease. They may result from primary infection or reactivation of a latent infection. Opportunistic infections account for many of the signs and symptoms observed in HIV/AIDS and can be protozoan, fungal, bacterial, or viral. More than one infection may be present at the same time. The presence of opportunistic infections may represent disease progression or a temporary further reduction of immunity. *These infections can result in death if appropriate treatment is not started quickly.* Priority nursing actions when caring for a patient who is HIV positive are continually assessing for and documenting the presence of an opportunistic infection and monitoring the patient's response to therapy. Report to the primary health care provider any signs and symptoms that may indicate an infection.

Opportunistic infections do not pose a threat to the immunocompetent health care worker caring for a patient with HIV disease or AIDS. However, when the patient with HIV disease or AIDS has a

pathogenic infection, health care personnel must use precautions appropriate to the specific disease to prevent disease spread. For example, when the adult with HIV/AIDS also has tuberculosis at a transmissible stage, Airborne Precautions are needed in addition to Standard Precautions. See [Chapter 23](#) for a more complete discussion on Transmission-Based Precautions for specific infectious diseases.

*Protozoal and fungal infections* are common among patients with AIDS. *Pneumocystis jirovecii* pneumonia (PCP) is a common opportunistic infection in adults infected with HIV. This organism is now considered a soil fungus. Assess for dyspnea on exertion, tachypnea, a persistent dry cough, and a persistent low-grade fever. The patient may report fatigue and weight loss. Auscultate breath sounds for crackles.

Toxoplasmosis encephalitis, caused by *Toxoplasma gondii*, is acquired through contact with contaminated cat feces or by ingesting infected undercooked meat. Assess the patient for subtle changes in mental status, neurologic deficits, headaches, and fever. Additional changes may include difficulties with speech, gait, and vision; seizures; lethargy; and confusion. Perform a comprehensive mental status examination and monitor the patient to detect subtle changes.

Cryptosporidiosis is an intestinal infection caused by *Cryptosporidium* organisms. In AIDS this illness ranges from a mild diarrhea to a severe wasting with electrolyte imbalance. Diarrhea may result in fluid loss of up to 15 to 20 L/day. Ask the patient about the presence of diarrhea and whether he or she has had an unplanned weight loss of 5 lb or more.

Fungal infection usually occurs by overgrowth of normal body flora. *Candida albicans* is part of the intestinal tract's natural flora. In the adult with AIDS, candidiasis (overgrowth of the *Candida* fungus) occurs because the reduced IMMUNITY can no longer control fungal growth. *Candida* stomatitis or esophagitis occurs often in AIDS. Patients may report food tasting "funny," mouth pain, difficulty in swallowing, and pain behind the sternum. On examination of the mouth and throat, you may see cottage cheese-like, yellowish white plaques and inflammation ([Fig. 19-5](#)). Esophagitis is diagnosed by endoscopic examination with biopsy and culture. Women with HIV disease or AIDS may have persistent vaginal candidiasis with severe pruritus (itching), perineal irritation, and a thick, white vaginal discharge.

**FIG. 19-5** Oral candidiasis (thrush). (From Marks, J., & Miller, J. [2006]. *Lookingbill & Marks' principles of dermatology* [4th ed.]. Philadelphia: Saunders.)

Cryptococcosis, caused by *Cryptococcus neoformans*, is a debilitating meningitis and can be a widely spread infection in AIDS. Ask about fever, headache, blurred vision, nausea and vomiting, neck stiffness, confusion, and other mental status changes. Patients may have seizures and other neurologic problems, or they may have mild malaise, fever, and headaches.

Histoplasmosis, caused by *Histoplasma capsulatum*, begins as a respiratory infection and progresses to widespread infection in the adult with AIDS. Assess for dyspnea, fever, cough, and weight loss. Check for enlargement of lymph nodes, the spleen, or the liver.

*Bacterial infections* are acquired from other people or sources and as overgrowth of skin flora.

*Mycobacterium avium* complex (MAC) is a common bacterial infection with AIDS and is caused by *M. intracellulare* or *M. avium*, which infects the respiratory or GI tract of patients with AIDS. MAC is a systemic infection. Assess for fever, debility, weight loss, malaise, and sometimes swollen lymph glands or organ disease.

Tuberculosis (TB), caused by *Mycobacterium tuberculosis*, occurs in 2% to 10% of adults with AIDS (CDC, 2009). More than 50% of all patients with AIDS and TB have extrapulmonary disease sites. Ask about cough, dyspnea, chest pain, fever, chills, night sweats, weight loss, and anorexia. Symptoms of extrapulmonary infection vary with the site. *The adult with TB and a CD4+ T-cell count below 200/mm<sup>3</sup> may not have a positive TB skin test (purified protein derivative [PPD]) because of an inability to mount an immune response to the antigen, a condition known as anergy.* Blood analysis by the fully automated nucleic acid amplification test (NAAT) for TB with results available in less than 2 hours is the most sensitive and rapid test for the presence of *M. tuberculosis*. It is very useful in the acute care setting to determine whether a symptomatic patient actually has TB. Other diagnostic tests include a chest x-ray, acid-fast sputum smear, and sputum culture.

## Nursing Safety Priority QSEN

### Action Alert

Maintain Airborne Precautions along with Standard Precautions for a patient with AIDS who also has TB symptoms until parameters other than a skin test come back negative for TB.

TB is spread by airborne routes. When particles from the patient's respiratory tract are aerosolized, anyone near him or her is at risk for inhaling the particles and the bacillus. Therefore the interprofessional team member who gives cough-inducing aerosol treatments such as pentamidine isethionate to patients with AIDS should be screened every 6 months to determine whether he or she has been infected with TB.

Pneumonia from bacterial infection recurs often among patients with AIDS, and two or more episodes of any type of bacterial pneumonia in a 12-month period are an AIDS case definition. Assess for chest pain, productive cough, fever, and dyspnea.

*Viral infection* from a virus other than HIV is common among adults with HIV disease that has progressed to AIDS. Cytomegalovirus (CMV) can infect many sites in adults with AIDS, including the eye (CMV retinitis), respiratory and GI tracts, and the central nervous system. CMV infection causes many nonspecific problems such as fever, malaise, weight loss, fatigue, and swollen lymph nodes. CMV retinitis impairs vision, ranging from slight impairment to total blindness. CMV can also cause diarrhea, abdominal bloating and discomfort, and weight loss. Ask the patient whether he or she has any of these symptoms. CMV can cause encephalitis, pneumonitis, adrenalitis, hepatitis, and disseminated infection.

Herpes simplex virus (HSV) infections in adults with HIV disease or AIDS occur in the perirectal, oral, and genital areas. The symptoms are more widespread and of longer duration than among adults who have full IMMUNITY. Numbness or tingling at the site of infection occurs up to 24 hours before blisters form. Lesions are painful, with chronic open areas after blisters rupture. Assess for fever, pain, bleeding, and enlarged lymph nodes in the affected area. Also assess for headache, myalgia, and malaise.

Varicella-zoster virus (VZV) infection (*shingles*) is not a new infection for adults with AIDS. This virus causes chickenpox and then remains present in the nerve ganglia. When adults who have had chickenpox previously have reduced IMMUNITY, VZV leaves the nerve ganglia and enters other tissue areas, causing shingles. Ask whether the patient has pain and burning along sensory nerve tracts (see [Chapter 41](#) for the dermatomes of sensory nerve locations), headache, and low-grade fever. Examine the skin for fluid-filled blisters with or without crusts.

### Malignancies.

Weakened IMMUNITY increases the risk for some cancers. These include Kaposi's sarcoma, lymphomas, invasive cervical cancer, lung cancer, GI cancer, and anal cancer.

*Kaposi's sarcoma (KS)* is the most common AIDS-related malignancy. The risk for KS is related to co-infection with human herpes virus-8.

KS develops as small, purplish brown, raised lesions on skin and mucous membranes that are

usually not painful or itchy (Fig. 19-6). In some patients lesions develop in the lymph nodes, mouth and throat, intestinal tract, or lungs. KS is diagnosed by biopsy examination of the lesion. Assess KS lesions for number, size, location, and whether they are intact and monitor their progression.

**FIG. 19-6** Kaposi's sarcoma lesions. (From Leonard, P. C. [2012]. *Building a medical vocabulary* [8th ed.]. St. Louis: Saunders.)

*Malignant lymphomas* occurring with AIDS are Hodgkin's lymphoma, non-Hodgkin's B-cell lymphomas such as Burkitt's lymphoma, immunoblastic lymphoma, and primary brain lymphoma. Symptoms include swollen lymph nodes, weight loss, fever, and night sweats.

*Human papilloma virus (HPV)* infection results in multiple types of malignancies and symptoms, but the most common in HIV infection are cervical and anal cancers. Cervical Papanicolaou (Pap) testing every 6 months is the standard of care for HIV-positive patients. In patients having anal intercourse, an anal Pap test, using the same medium as for a cervical Pap test, is used for the early detection and treatment of anal cancers.

### Endocrine Complications.

Patients with HIV disease may have disease-related and treatment-related endocrine problems such as gonadal dysfunction, body shape changes, adrenal insufficiency, diabetes mellitus, and elevated triglycerides and cholesterol (which increase the risk for cardiovascular problems).

Many HIV-positive men have low testosterone levels, and HIV-positive women often have irregular menstrual cycles. With this gonadal dysfunction comes a decrease in body muscle mass for both genders, with a decrease in weight and a change in libido, accompanied by a decrease in energy and an increase in fatigue.

Body shape changes from fat redistribution or fat deposition (known as lipodystrophy) are common in patients receiving antiretroviral therapies, especially protease inhibitors and nucleoside reverse transcriptase inhibitors. Symptoms include "buffalo humps" or cervical (neck) fat development and large abdominal fat accumulations. Other body areas such as the face, arms, and legs have a wasted appearance and show prominent vein patterns or sunken facial cheeks from loss of subcutaneous fat, known as *lipoatrophy*.

Adrenal dysfunction can result from the glands being infected by opportunistic infections, resulting in adrenal insufficiency. This problem causes fatigue, weight loss, nausea, vomiting, low blood pressure, and electrolyte disturbances and can be life threatening.

Patients taking protease inhibitors have a higher-than-expected incidence of type 2 diabetes mellitus and hyperlipidemia. These problems are seen even among patients who have no other risks for these health problems.

### Other Symptoms.

All body systems are affected in AIDS. HIV-associated neurocognitive disorder (HAND) and *AIDS dementia complex (ADC)* (also called *HIV-associated dementia complex*) refer to symptoms of central nervous system involvement. ADC occurs in many adults with AIDS and is a result of infection of cells within the central nervous system by HIV. HAND and ADC cause cognitive and motor impairments and behavioral changes. Symptoms range from barely noticeable to severe dementia.

(See [Chapter 42](#) for more discussion on dementia.)

Some neurologic problems may be a result of HIV infection or drug side effects, including peripheral neuropathies and myopathies. Assess for symptoms of peripheral neuropathy, which include paresthesias and burning sensations, reduced sensory perception, pain, and gait changes. Myopathies are accompanied by leg weakness, ataxia, and muscle pain.

*AIDS wasting syndrome* is not caused by any single factor. Diarrhea, malabsorption, anorexia, and oral and esophageal lesions can all contribute to persistent weight loss; and the patient may appear quite emaciated.

*Skin changes* include dry, itchy, irritated skin and many types of rashes. Folliculitis, eczema, or psoriasis may occur. Ask the patient about skin sensation changes and examine any rash or irritation. When the platelet count is low, petechiae or bleeding gums may be present.

*Kidney problems*, including HIV-associated nephropathy (HIVAN) are common. These problems range from discrete glomerular injury to acute and chronic kidney diseases. Compared with the general population, patients with HIV have a far higher risk for requiring a renal replacement intervention.

### Psychosocial Assessment.

Psychosocial data collection for a patient with AIDS is very important. Ask about the patient's social support system, including family, significant others, and friends. To protect confidentiality, learn who in this support system is aware of the diagnosis so it is not mentioned inadvertently. Health care professionals must respect the patient's choices as much as possible without compromising care. Offer resources to help with disclosure to sexual partners or significant others.

The patient may be closest to a lover or a friend who is not legally recognized as next of kin. Obtain the name and telephone number of that person and determine whether a health care proxy or durable power-of-attorney document has been signed.

Ask about the patient's ADLs and any changes that may have occurred since the diagnosis. Assess his or her employment status and occupation, immigration status, social activities and hobbies, living arrangements, and financial resources, including health insurance. Ask whether he or she uses drugs, including tobacco, alcohol, supplements, opioids, benzodiazepines, cocaine, crystal methamphetamine, or injection drugs.

To plan care and monitor changes, assess the patient's feelings, thoughts, and behaviors, which include such areas as anxiety level, mood, cognitive ability, energy, and activity level. Ask about any experiences with discrimination and how they were handled. After assessing the patient's level of self-concept, work with him or her to identify strengths and coping strategies. Ask about any feelings of depression; suicidal ideation, intent, or plan, as well as other psychosocial concerns. Also ask about the use of support groups or other community resources.

The patient with HIV disease has less energy as the disease progresses. Pace interviews, assessments, and interventions to match his or her energy level. When the patient is greatly fatigued, postpone or eliminate nonurgent tests or care activities. Document psychosocial assessment and the patient's use of interventions using his or her own words. Communicate this information to all members of the interprofessional team.

### Laboratory Assessment

#### Lymphocyte Counts.

Lymphocyte counts are performed as part of a complete blood count (CBC) with differential (see [Chapter 17](#)). The normal white blood cell (WBC) count is between 5000 and 10,000 cells/mm<sup>3</sup> (5 and 10 × 10<sup>9</sup>/L), with a differential of about 30% to 40% lymphocytes (an absolute number of 1500 to 4500 [1.5 to 4.5 × 10<sup>9</sup>/L]). Patients with AIDS are often leukopenic, with a WBC count of less than 3500 cells/mm<sup>3</sup>, and lymphopenic (<1500 lymphocytes/mm<sup>3</sup> [ $<1.5 \times 10^9/L$ ]).

*CD4+ T-cell and CD8+ T-cell* counts and percentages are part of an IMMUNITY profile. Adults with HIV disease and AIDS usually have a lower-than-normal number of CD4+ T-cells, whereas the number of CD8+ T-cells remains normal. The normal ratio of CD4+ to CD8+ T-cells is 2 : 1. In HIV disease and AIDS, because of the low number of CD4+ T-cells, this ratio is low. Low CD4+ T-cell counts and a low ratio are associated with more disease symptoms.

#### Antibody-Antigen Tests.

Antibody tests are used to measure the patient's response to the virus (the antigen) rather than parts of the virus. When the body is infected with HIV, it makes an antibody to the virus, usually within 3 weeks to 3 months after the infection first occurs. In some adults antibodies are not detectable until 36 months after initial infection. Measuring antibodies is an indirect test for HIV. *If an adult has a positive test result for HIV antibodies, it does not mean that he or she has HIV disease or AIDS—only that he or she has been infected with the virus.*

HIV antibodies can be measured by enzyme-linked immunosorbent assay (ELISA) and Western blot analysis, which is an older testing algorithm. This algorithm was the gold standard for many years and, while highly accurate, is more time consuming and expensive than fourth-generation testing. Using a third-generation test looks specifically for HIV IgG antibodies. When a positive test result is found, a confirmatory Western blot test is done, which is more sensitive and specific for HIV (co-infection with influenza A can cross-react with the third-generation test, leading to a false positive result). HIV antibodies are not detected for at least 21 days after exposure, and the confirmatory Western blot requires an additional 7 days before results can confirm infection. This time frame is known as the “window period” in which an adult is first infected with the virus and when viral replication is occurring but the immune system has not yet started making antibodies. Using this older algorithm, the period from the point of suspected infection to confirmation can take up to 28 days. *Therefore if the patient has unprotected sex with an HIV-positive adult one night and comes in for testing a week later, the ELISA will be negative, even though the patient may have active HIV. Thus testing during the window does not provide useful information* (Grimes et al., 2016; Taylor et al., 2015).

New technology allows for faster and more accurate initial diagnosis of HIV infection. The CDC now recommends the use of fourth-generation HIV assays that will detect HIV-IgM and IgG antibodies (positive in 21 days) and detect the presence of the p24 antigen (an HIV capsid protein) in serum (positive in 14 days). This type of testing reduces the window period in which false negatives are often reported. If the sample is negative, no further testing is required. If the sample is positive, step 2 in the new algorithm will be to differentiate between HIV-1 and HIV-2. If an indeterminate step 2 result is found, HIV-1 NAT (nucleic acid test) testing is done to detect HIV RNA, not only antibodies and antigens specific for HIV. If the sample is HIV-1 NAT+, it indicates acute HIV-1 infection. If HIV-1 NAT-, this sample is negative for HIV infection.

### **Viral Load Testing.**

*Viral load testing* directly measures the actual amount of HIV viral RNA particles present in 1 mL of blood. An uninfected adult has no viral load for HIV. A positive viral load test can measure as few as 40 particles/mL. High viral loads can be greater than 80,000 HIV particles/mL. The higher the viral load, the greater the risk for transmission. Current tests are not sensitive enough to measure viral loads less than 40/mL. An HIV-positive adult with an undetectable viral load can still transmit the virus, although this is less likely and transmission requires greater or multiple exposures. This test is the fastest way to determine HIV infectivity and therapy effectiveness.

In a newly infected adult a viral load is expressed about 10 days after infection (Taylor et al., 2015). HIV viral loads can be processed in as little as 24 hours. If positive, this is a clear diagnosis of HIV infection. One caution is that some immune systems can be strong enough to control the viral replication to report out an undetectable viral load. So in addition to running an HIV RNA, the fourth-generation testing should also be done, and the results reported out together. If the viral load is negative and the fourth-generation testing is negative, the specimen then is truly negative.

Some HIV testing uses techniques that are not blood based, and testing can be done anywhere, even at home. One test involves oral testing for HIV antibody. This test uses a device that is placed against the gum and cheek for 2 minutes. Fluid (called transmucosal exudate, not saliva) is drawn into an absorbable pad, which, in an HIV-positive adult, contains HIV-specific antibodies. The pad is placed in a solution; a positive result shows a change similar to a positive result in a urine pregnancy test. Total testing time is about 20 minutes. This test has the same accuracy as blood testing and can provide results quickly. If results are positive, a blood test is needed for confirmation.

Some home test kits require that a drop of blood be placed on a test card with a special code number. The card is mailed to a laboratory where the blood is tested for HIV antibodies. A special telephone number is called, and the code entered. Test results are then given. The OraQuick In-Home HIV Test uses oral transmucosal exudate, and results are ready at home in 20 to 40 minutes. The manufacturer recommends that the test be performed at least 3 months after a risk event has occurred. A positive result indicates the need for additional testing.

### Other Laboratory Assessment.

Other laboratory tests monitor the patient's overall health and detect or diagnose any infections or other problems related to HIV disease. These tests include blood chemistries; a CBC with differential and platelets; toxoplasmosis antibody titer; liver function tests; a serologic test for syphilis (STS); antigens and antibodies to hepatitis viruses A, B, and C; lipid profile; QuantiFERON TB testing or PPD; and cervical and anal Pap testing. Additional tests to evaluate the immune profile may include bone marrow aspiration with biopsy and cultures. Other tests may be performed to monitor toxicities from antiretroviral drugs.

## Genetic/Genomic Considerations

### Patient-Centered Care QSEN

The HIV genotype test is used before starting antiretroviral drugs to determine whether any mutations causing drug resistance exist in the strain of HIV that has infected the patient. This test helps the clinician choose which antiretroviral drugs are most likely to be effective against viral replication. It is also useful in patients who demonstrate initial success in antiretroviral therapy and then have rapid disease progression. Ensure that newly diagnosed patients also have a genotype test performed.

The human leukocyte antigen (HLA) B5701 allele test is a genetic test to determine how an adult will respond to a drug. Patients with a variant of this gene allele have a hypersensitivity reaction to abacavir (Ziagen) that ranges from mild fever, rash, nausea, and vomiting to fatal anaphylaxis. Abacavir should not be used without first testing for B5701; if positive, abacavir is never used either as a single drug or in combination drug preparations.

The Trofile Test is a blood test to determine the degree of expression of the CCR5 receptor on CD4+ cells. This test is needed before starting drug therapy with maraviroc, which is a CCR5 antagonist drug in the entry inhibitor class. If no CCR5 receptors are present, the drug is ineffective.

### Other Diagnostic Assessments.

Other diagnostic tests are performed on the basis of the patient's symptoms. These may include testing stool for ova and parasites; biopsies of the skin, lymph nodes, lungs, liver, GI tract, or brain; a chest x-ray; gallium scans; bronchoscopy, endoscopy, or colonoscopy; liver and spleen scans; CT scans; pulmonary function tests; and arterial blood gas (ABG) analysis.

## Clinical Judgment Challenge 19-1

### Patient-Centered Care, Evidence-Based Practice, Safety QSEN

A patient at an STI clinic is a worried-looking 28-year-old gay man who until a month ago was in a long-term mutually monogamous relationship. He became inebriated at a party last night and went home with a new acquaintance. Consensual unprotected sex occurred several times, and the patient was both a top and bottom partner. On awakening the partner was gone. This morning the patient is concerned about STI and HIV risks. His last HIV test, performed 2 weeks ago, was negative. He does not know how to contact the partner from last night, and he asks whether he should have another ELISA or that new "fast test" performed today.

1. Does the patient have cause for concern? Why or why not?
2. What will you tell him about testing today?
3. Is he a candidate for pre-exposure prophylaxis today? Why or why not?
4. Is he a candidate for postexposure prophylaxis today? Why or why not?
5. What other teaching or considerations are needed at this time?

### ◆Analysis: Interpreting

The priority collaborative problems for patients with AIDS are:

1. Potential for infection due to reduced IMMUNITY
2. Inadequate GAS EXCHANGE due to anemia, respiratory infection (*P. jiroveci* pneumonia [PCP], cytomegalovirus [CMV] pneumonitis), pulmonary Kaposi's sarcoma (KS), or anemia
3. Pain due to neuropathy, myelopathy, cancer, or infection
4. Inadequate NUTRITION due to increased metabolic need, nausea, vomiting, diarrhea, difficulty chewing or swallowing, or anorexia
5. Diarrhea due to infection, food intolerance, or drugs
6. Potential for reduced TISSUE INTEGRITY due to KS, infection, reduced NUTRITION, incontinence, immobility, hyperthermia, or cancer
7. Cognitive decline due to AIDS dementia complex (ADC), central nervous system infection, or cancer
8. Potential for psychosocial distress due to living with a life-threatening chronic disease that affects all aspects of life

### ◆Planning and Implementation: Responding

#### Preventing Infection.

The patient with AIDS is susceptible to opportunistic infections because of reduced IMMUNITY. Initial management focuses on supporting the patient's immunity by controlling the HIV infection with antiretroviral therapy. When the patient's immunity declines, management includes both prophylaxis and treatment of opportunistic infections.

#### Planning: Expected Outcomes.

The patient is expected to remain free of opportunistic *diseases* and other infection. Indicators include:

- Absence of chills, fever, or temperature instability
- Absence of purulent drainage or sputum
- Absence of diarrhea
- Absence of chest x-ray infiltration
- Maintenance of white blood cell (WBC) count within the patient's normal range

#### Interventions.

The adult who has HIV infection with reduced IMMUNITY is at greater risk for any type of infection. Teach him or her to avoid exposure to infection ([Chart 19-4](#)). [Chart 19-5](#) lists best practices for prevention of infection in a hospitalized patient with reduced immunity.

#### Chart 19-4

### Patient and Family Education Preparing for Self-Management

#### Prevention of Infection

During the times when your white blood cell counts are low:

- Avoid crowds and other large gatherings of people who might be ill.

- Do not share personal toilet articles such as toothbrushes, toothpaste, washcloths, or deodorant sticks with others.
- If possible, bathe daily, using an antimicrobial soap. If total bathing is not possible, wash the armpits, groin, genitals, and anal area twice a day with an antimicrobial soap.
- Clean your toothbrush at least weekly by either running it through the dishwasher or rinsing it in liquid laundry bleach (and then rinsing out the bleach with hot running water).
- Wash your hands thoroughly with an antimicrobial soap before you eat or drink, after touching a pet, after shaking hands with anyone, as soon as you come home from any outing, and after using the toilet.
- Avoid eating salads; raw fruits and vegetables; undercooked meat, fish, and eggs; and pepper and paprika.
- Wash dishes between use with hot, sudsy water or use a dishwasher.
- Do not drink water, milk, juice, or other cold liquids that have been standing for longer than an hour.
- Do not reuse cups and glasses without washing.
- Do not change pet litter boxes. If unavoidable, use gloves and wash hands immediately.
- Avoid turtles and reptiles as pets.
- Do not feed pets raw or undercooked meat.
- Take your temperature at least once a day and whenever you do not feel well.
- Report any of these indications of infection to your primary health care provider immediately:
  - Temperature greater than 100° F (37.8° C)
  - Persistent cough (with or without sputum)
  - Pus or foul-smelling drainage from any open skin area or normal body opening
  - Presence of a boil or abscess
  - Urine that is cloudy or foul smelling or that causes burning on urination
- Take all prescribed drugs.
- Do not dig in the garden or work with houseplants.
- Wear a condom (if you are a man) when having sex. If you are a woman having sex with a male partner, ensure that he wears a condom or use a female vaginal polyurethane condom.
- Avoid travel to areas of the world with poor sanitation or less-than-adequate health care facilities.

#### Chart 19-5

### Care of the Hospitalized Patient With Reduced Immunity

- Place the patient in a private room whenever possible.
- Use good handwashing technique or alcohol-based hand rubs before touching the patient or any of his or her belongings.
- Ensure that the patient's room and bathroom are cleaned at least once each day.
- Do not use supplies from common areas for neutropenic patients. For example, keep a dedicated box of disposable gloves in his or her room and do not share this box with any other patient. Provide single-use food products, individually wrapped gauze, and other individually wrapped items.
- Limit the number of personnel entering the patient's room.
- Monitor vital signs, including temperature, every 4 hours.
- Inspect the patient's mouth at least every 8 hours.
- Inspect the patient's skin and mucous membranes (especially the anal area) for the presence of fissures and abscesses at least every 8 hours.
- Inspect open areas such as IV sites every 4 hours for signs of infection.
- Change gauze-containing wound dressings daily.
- Obtain specimens of all suspicious areas for culture (as specified by the agency) and promptly notify the primary health care provider.
- Help the patient perform coughing and deep-breathing exercises.
- Encourage activity at a level appropriate for the patient's current health status.
- Keep frequently used equipment in the room for use with this patient only (e.g., blood pressure cuff, stethoscope, thermometer).
- Limit visitors to healthy adults.
- Use strict aseptic technique for all invasive procedures.
- Avoid the use of indwelling urinary catheters.
- Keep fresh flowers and potted plants out of the patient's room.
- Teach the patient to eat a low-bacteria diet (e.g., avoiding raw fruits and vegetables; undercooked meat, eggs, and fish; pepper and paprika as seasonings sprinkled on food right before eating).

#### Drug Therapy.

All currently licensed antiretroviral drugs have excellent activity against HIV; however, *it is important to remember that antiretroviral therapy only inhibits viral replication and does not kill the virus.* Treatment with only one antiretroviral agent (*monotherapy*) promotes drug resistance and does not improve life span. Instead multiple drugs from different classes are used in combinations. This approach, termed *combination antiretroviral therapy (cART)*, has reduced viral load, improved CD4+ T-cell counts, and slowed disease progression (Starr & Bradley-Springer, 2014). Tell patients that they must take the drugs correctly 90% of the time, making sure that, out of 10 doses, 9 are taken on time and correctly.

An important issue with cART is the development of drug-resistant mutations in the HIV

organism. When resistance develops, viral replication is no longer suppressed by the drugs. Testing is now possible to determine whether a strain of HIV has developed resistance to specific drugs (see the Genetic/Genomic Considerations box). Several factors contribute to the development of drug resistance to cART, with the most important being missed doses of drugs. When doses are missed, the blood drug concentrations become lower than those needed for inhibition of viral replication. The HIV then can replicate and produce new viral particles that are resistant to the drugs being used.

An important understanding about HIV resistance to one or more drugs is that, once a patient has HIV with resistant mutations, the resistant virus is stored in the body indefinitely, a process known as *archiving*. The drugs to which the virus is resistant are no longer used for that patient. Even years later, if the drug to which the HIV demonstrated resistance is tried again, the viruses with the resistant mutation come out of archival storage to defeat the drug.

## Nursing Safety Priority QSEN

### Drug Alert

Ensure that cART drugs are not missed, delayed, or administered in lower-than-prescribed doses in the inpatient setting. Teach patients the importance of taking the cART drugs exactly as prescribed to maintain their effectiveness. Even a few missed doses per month can promote drug resistance (remember the 90% rule).

The main actions of each drug category and representative drugs in each category are presented in [Chart 19-6](#). These categories are nucleoside reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), integrase inhibitors, fusion inhibitors, and entry inhibitors. Drawbacks to cART include the expense of the drugs, food and timing requirements, and the number of daily drugs. Newer combination drug formulations have reduced the number of tablets and capsules that need to be taken daily. However, the daily regimen continues to be lifelong and burdensome.

### Chart 19-6

## Common Examples of Drug Therapy

### HIV Infection

DRUG CATEGORY	NURSING IMPLICATIONS
<b>Nucleoside Reverse Transcriptase Inhibitors (NRTIs)</b> —These drugs have a structure similar to the four nucleoside bases of DNA, making them “counterfeit” bases. They fool the HIV enzyme <i>reverse transcriptase</i> into using these counterfeit bases so viral DNA synthesis and replication are suppressed.	
Abacavir (Ziagen) Didanosine (Videx EC) Emtricitabine (Emtriva) Lamivudine (EpiVir) Stavudine (Zerit) Tenofovir (Viread) Zidovudine (Retrovir)	Remind patients to avoid fatty and fried foods with these drugs <i>because they cause digestive upsets and may lead to pancreatitis when combined with NRTIs</i> . Teach patients to use precautions to prevent injury <i>because these drugs induce peripheral neuropathy</i> . Teach patients taking abacavir to report flu-like symptoms to the provider immediately <i>because these symptoms may indicate a hypersensitivity reaction that requires discontinuing the drug</i> . Instruct patients to avoid or severely limit alcoholic beverages <i>to reduce the risk for liver damage while on these drugs</i> . Do not give abacavir to a patient who tests positive for the HLA-B 5701 tissue type <i>because fatal allergic responses are likely</i> .
<b>Non-Nucleoside Reverse Transcriptase Inhibitors (NNRTIs)</b> —These drugs work by binding directly to the HIV-1 enzyme <i>reverse transcriptase</i> , preventing viral cell DNA replication, RNA replication, and protein synthesis. This action suppresses viral replication of the HIV-1 virus but does not affect HIV-2 viral replication.	
Delavirdine (Rescriptor) Efavirenz (Sustiva) Etravirine (Viramune) Rilpivirine (Edurant)	Check laboratory values for increases in liver enzymes and decreased red blood cells <i>because the most common side effects are anemia and liver toxicity</i> . Teach patients to take these drugs at least 1 hour before or 2 hours after taking an antacid <i>to avoid inhibiting GI absorption</i> . Instruct patients to notify the prescriber if a sore throat, fever, different types of rashes, blisters, or multiple bruises develop <i>because these are indications of a serious adverse drug effect</i> . Do not give delavirdine or efavirenz to pregnant women <i>because these two drugs have the potential to cause birth defects and developmental problems</i> .
<b>Protease Inhibitors (PIs)</b> —These drugs competitively block the HIV protease enzyme, preventing viral replication and release of viral particles. The HIV initially produces all of its proteins in one long strand, which must be broken down into separate smaller proteins by HIV protease to be active. Thus, when inhibited, viral proteins are not functional, and viral particles cannot leave the cell to infect other cells.	
Atazanavir (Reyataz) Darunavir (Prezista) Fosamprenavir (Lexiva) Indinavir (Crixivan) Lopinavir/ritonavir (Kaletra) Nelfinavir (Viracept) Saquinavir (Invirase) Tipranavir (Aptivus)	Instruct patients to not chew or crush these drugs <i>because this action may cause the drug to be absorbed too rapidly and increase the risk for side effects</i> . Teach patients to report jaundice, nausea and vomiting, or severe abdominal pain <i>because these drugs can induce liver toxicity</i> . Instruct patients to keep all appointments for laboratory work <i>because these drugs increase blood lipid levels and increase the risk for atherosclerosis and pancreatitis</i> . Remind patients to avoid St. John’s wort while taking these drugs <i>because the supplement reduces the effectiveness of all PIs</i> . Teach patients taking atazanavir and ritonavir to check their pulse daily and report low heart rate to the prescriber <i>because these two drugs can impair electrical conduction and lead to heart block</i> . Do not give darunavir or fosamprenavir to patients who have a known sulfa allergy <i>because these two drugs contain sulfa</i> .
<b>Integrase Inhibitors</b> —These drugs inhibit the HIV enzyme <i>integrase</i> , which the virus uses to insert the viral DNA into the host cell’s human DNA. Without this action viral proteins are not made, and viral replication is inhibited.	
Dolutegravir (TIVICAY) Elvitegravir (EVG) Raltegravir (Isentress)	Warn patients that diarrhea, nausea, rash, insomnia, and abdominal pain are common side effects of these drugs <i>because knowing the expected side effects decreases anxiety when they appear</i> . Suggest that patients take the drug with food <i>to reduce the GI side effects</i> . Instruct patients to not chew or crush these drugs <i>because this action may cause the drug to be absorbed too rapidly and increase the risk for side effects</i> . Instruct patients to report new-onset muscle pain or weakness <i>because these drugs can cause muscle breakdown (rhabdomyolysis), especially in adults taking a “statin” type of lipid-lowering drug</i> . Teach patients with diabetes to closely monitor blood glucose levels <i>because these drugs increase hyperglycemia</i> . Do not give raltegravir to pregnant women <i>because it is associated with an increased risk for birth defects</i> .
<b>Fusion Inhibitors</b> —These drugs block the fusion of HIV with a host cell by blocking the ability of gp41 to fuse with the host cell’s CD4 receptor. Without fusion, infection of new cells does not occur.	

Enfuvirtide (Fuzeon)	Teach patients how to prepare and inject the drug subcutaneously to ensure correct dosage and effectiveness. Assess injection sites for warmth, swelling, redness, skin hardening, or bump formation because these are indications of injection site reactions. Instruct patients to report pain or numbness in the hands or feet because this drug can induce peripheral neuropathy. Teach patients to report jaundice, nausea and vomiting, or severe abdominal pain because this drug can induce liver toxicity. Teach patients to observe for and report cough, shortness of breath, fever, and purulent mucus because this drug increases the risk for severe respiratory infections, including pneumonia.
<b>Entry Inhibitors/CCR5 Antagonists</b> —These drugs prevent cellular infection with HIV by blocking the CCR5 receptor on CD4+ T-cells. (The virus's gp120 must bind to the CD4 receptor, and its gp41 must bind to the CCR5 receptor or to the CXCR4 receptor for entry into host cells.)	
Maraviroc (Selzentry)	Instruct patients to not chew or crush this drug because this action may cause the drug to be absorbed too rapidly and increase the risk for side effects. Teach patients to change positions slowly because hypotension is a common side effect, especially orthostatic hypotension. Teach patients to report jaundice, nausea and vomiting, or severe abdominal pain because these drugs can induce liver toxicity. Instruct patients to report pain or numbness in the hands or feet because this drug can induce peripheral neuropathy.
<b>Combination Products</b> —Each ingredient has the same mechanism of action and nursing implications as the parent drug class.	
Atripla (emtricitabine, tenofovir, & efavirenz) Combivir (lamivudine & zidovudine) Complera (emtricitabine, rilpivirine, & tenofovir) Epzicom (lamivudine & abacavir) Genvoya (elvitegravir, cobicistat*, emtricitabine, & tenofovir) Stribild (elvitegravir, cobicistat*, emtricitabine, & tenofovir) Truvada (emtricitabine & tenofovir) Triumeq (dolutegravir, abacavir, & lamivudine)	

\*Cobicistat is a metabolizing enzyme inhibitor that allows other drugs in the combination to remain active longer, boosting their pharmacologic action. It is not a specific antiretroviral agent.

Most antiretroviral drugs have significant side effects and many drug interactions. Be sure to consult a drug reference book for usual dosages, side effects, and nursing interventions.

An interesting complication of effective cART in some patients whose CD4+ T-cell counts rise and IMMUNITY returns to normal is the development of immune reconstitution inflammatory syndrome (IRIS). As the drugs begin to suppress HIV replication and the T4-cells slowly begin to rebound, the T4-cells “recognize” several opportunistic infections (e.g., tuberculosis, cryptococcosis, *Mycobacterium avium* complex, pneumocystis pneumonia, cytomegalovirus, hepatitis) that were present before but not recognized because of severe immunosuppression. With the T4-cells now in sufficient numbers and active, they begin to sound the alarm about the presence of these opportunistic infections. The T4-cells generate an inflammatory reaction with high fever, chills, and, depending on which infection the immune system is reacting against, worsening disease. For example, IRIS is common with those co-infected with HIV and TB. TB symptoms initially become much worse after starting cART. Because some symptoms are similar to those of drug therapy side effects and other problems, IRIS may go undiagnosed and untreated, increasing the risk for death. When IRIS is recognized, short-term therapy with corticosteroids can reduce the inflammatory responses.

### Complementary and Integrative Health.

Complementary therapies are often used by adults with HIV/AIDS, although the effectiveness of these therapies has not been established. Some products alter the effects of prescription drugs. Ask the patient which botanical or homeopathic agents he or she is using and check with the pharmacist to determine known drug interactions with cART therapy.

## NCLEX Examination Challenge 19-3

### Safe and Effective Care Environment

A client diagnosed with AIDS who is receiving combination antiretroviral therapy (cART) now has a CD4+ T-cell count of 525 cells/mm<sup>3</sup>. How will the nurse interpret this result?

- A. The client can reduce the dosages of the prescribed drugs.
- B. The virus is resistant to the current combination of drugs.
- C. The client no longer has AIDS.
- D. The drug therapy is effective.

### Enhancing Gas Exchange

#### Planning: Expected Outcomes.

The patient is expected to maintain adequate GAS EXCHANGE with oxygenation and perfusion and to have minimal dyspnea. Indicators include:

- Rate and depth of respiration within the normal range
- Pulse oximetry within the normal range
- Absence of cyanosis or pallor and abnormal breath sounds

### Interventions.

The nurse or respiratory therapist uses drug therapy, respiratory support and maintenance, comfort, and rest to enhance GAS EXCHANGE.

*Drug therapy* is a mainstay for GAS EXCHANGE problems resulting from infection. Drug therapy is started after an infectious cause for respiratory difficulty is identified. A common respiratory infection in adults with HIV disease is *P. jiroveci* pneumonia (PCP). The treatment of choice for PCP is trimethoprim with sulfamethoxazole (Apo-Sulfatrim ♣, Bactrim, Cotrim, Septra). Many patients have adverse reactions to this drug, including nausea, vomiting, hyponatremia, rashes, fever, leukopenia, thrombocytopenia, and hepatitis.

Pentamidine isethionate (Pentacarinat ♣, Pentam), usually given IV or IM, is also used to treat PCP. Aerosolized pentamidine isethionate is used as prophylaxis for patients with CD4+ T-cell counts below 200 ( $0.2 \times 10^9/L$ ) or 14% and for those who have already had PCP.

Other drug therapies include bronchodilators to improve airflow, as well as dapsone (Avlosulfon) and atovaquone (Mepron), which can be used as alternative therapies to trimethoprim-sulfamethoxazole for existing PCP or as prophylaxis. For moderate-to-severe PCP, steroids may be used to reduce the inflammation.

*Respiratory support and maintenance* help maintain GAS EXCHANGE and avoid complications. Assess the respiratory rate, rhythm, and depth, breath sounds, and vital signs and monitor for cyanosis at least every 8 hours. Apply oxygen and humidify the room as prescribed. Also monitor mechanical ventilation, perform suctioning and chest physical therapy as needed, and evaluate blood gas results.

*Comfort* can help improve GAS EXCHANGE. Assess the patient's comfort. The patient with difficulty breathing is often more comfortable with the head of the bed elevated. Pace activities to reduce shortness of breath and fatigue.

*Rest and activity changes* are needed when GAS EXCHANGE is impaired. Most patients with HIV/AIDS have fatigue, especially when respiratory problems also are present. Consult with the patient to pace activities to conserve energy. Schedule non-time-critical activities such as bathing so he or she is not fatigued at mealtime.

### Managing Pain.

The patient with severe HIV disease or AIDS often has pain from many causes. Pain can result from enlarged organs stretching the viscera or compressing nerves. Tumor invasion of bone and other tissues can cause pain, as can compression of nerves from swollen lymph nodes. Many patients with AIDS have peripheral neuropathy-induced pain from the disease or drug therapies (Anastasi et al., 2013). Many have generalized joint and muscle pain.

### Planning: Expected Outcomes.

The patient is expected to achieve an acceptable level of comfort and pain reduction. Indicators include:

- Reporting that pain is controlled to a level that is acceptable to him or her
- Absence of indicators of acute pain (increased heart rate and blood pressure)
- Absence of facial grimacing, teeth clenching
- Willingness to move and participate in self-care

### Interventions.

Drug therapy and other approaches are used together to manage pain in the patient with HIV/AIDS, depending on the cause of the pain.

*Comfort measures* include the use of pressure-relieving mattress pads, warm baths or other forms of hydrotherapy, massage, and applying heat or cold to painful areas to reduce pain levels, with or without drug therapy. Take care when moving or assisting the patient. Use lift sheets to avoid pulling or grasping the patient with joint pain. The patient may be thin and have poor circulation, contributing to pain and discomfort. Help him or her change positions often.

*Drug therapy* with different drug classes is used to manage different types of pain. For arthralgia and myalgia, NSAIDs may reduce inflammation and increase comfort. Pregabalin (Lyrica) may provide some relief from muscle and joint pain. Neuropathic pain may respond to tricyclic antidepressants such as amitriptyline (Elavil) or to anticonvulsant drugs such as gabapentin (Neurontin), phenytoin (Dilantin), or carbamazepine (Tegretol), although these drugs often interact with antiretroviral drugs. These drugs may take days to weeks before a full effect is seen. During this time opioids may be needed to control pain.

When opioids are used, assess the patient for pain intensity and quality. Mild-to-moderate pain is treated with weaker opioids such as hydrocodone or codeine. More intense pain is treated with stronger opioids such as oxycodone, morphine, hydromorphone (Dilaudid), or fentanyl transdermal (Duragesic). Combinations of weak and strong opioids along with nonopioid drugs may be used to provide the best sustained pain relief and allow the patient to participate in activities to the extent that he or she wishes.

*Complementary and integrative therapies* are used by many patients with pain from HIV/AIDS. These include acupuncture, massage, guided imagery, distraction, progressive relaxation, body-talk, and biofeedback. Integrative therapies can be used with traditional and pharmacologic measures to improve comfort.

### **Enhancing Nutrition.**

Many patients with AIDS have difficulty maintaining their weight and NUTRITION status, and a registered dietitian is part of the interprofessional health care team. This problem may be caused by fatigue, anorexia, nausea and vomiting, difficult or painful swallowing, diarrhea, intestinal malabsorption, or wasting syndrome.

#### **Planning: Expected Outcomes.**

The patient is expected to maintain optimal weight through adequate NUTRITION and hydration. Indicators include:

- Selecting foods high in calories and protein
- Maintaining current weight or gaining weight
- Drinking at least 2 to 3 L of fluids per day
- Maintaining normal blood levels of ferritin, albumin, prealbumin, and hemoglobin

#### **Interventions.**

Because there are many factors for poor NUTRITION in AIDS, diagnostic procedures are needed to determine the cause. Once the cause is determined, appropriate therapy is initiated. For example, in candidal esophagitis, nutrition is affected by swallowing difficulties.

*Drug therapy* can include ketoconazole (Nizoral) or fluconazole (Diflucan) orally, or IV amphotericin B (Fungizone). Administer the drug as prescribed and monitor for side effects such as nausea and vomiting, which also affect NUTRITION. Provide mouth care and ice chips and keep unpleasant odors out of the patient's environment. Antiemetics are used as needed.

*Nutrition therapy* includes monitoring weight, intake and output, and calorie count. Assess food preferences and dietary cultural or religious practices. Collaborate with the dietitian to teach the patient about the need for a high-calorie and high-protein diet. Encourage him or her to avoid dietary fat, because fat intolerance often occurs as a result of the disease and as a side effect of some antiretroviral drugs. Other strategies include providing small, frequent meals that are often better tolerated than large meals. Supplemental vitamins and fluids are indicated in some cases. For the patient who cannot achieve adequate NUTRITION through food, tube feedings or total parenteral nutrition may be needed.

*Mouth care* can improve appetite. When this nursing action is delegated to unlicensed assistive personnel (UAP), instruct them to offer the patient rinses of sodium bicarbonate with sterile water or normal saline several times a day. Explain to UAP the reason the patient needs to use a soft toothbrush and the need to drink plenty of fluids. For oral pain general analgesics or oral anesthetic gels and solutions may be needed. Avoid the use of alcohol-based mouthwashes.

### **Minimizing Diarrhea.**

Patients with AIDS often suffer from diarrhea. Sometimes an infectious cause (e.g., *Giardia*,

*Cryptosporidium*, or amoeba) can be determined and treated; or the cause is determined, but no effective therapy is available. Many patients are lactose intolerant, and HIV disease worsens the condition. Diarrhea may occur as a side effect of drug therapy. In some cases no cause can be identified.

#### **Planning: Expected Outcomes.**

The patient is expected to have decreased diarrhea; to maintain fluid, electrolyte, and NUTRITION status; and to reduce incontinence. Indicators include:

- Has a stool amount and character that are appropriate for the diet
- Recognizes urge to defecate
- Maintains control of stool passage

#### **Interventions.**

For most patients with AIDS and diarrhea, symptom management is all that is available. Antidiarrheals such as diphenoxylate hydrochloride (Diarsed 🍀, Lomotil) or loperamide (Imodium), given on a regular schedule, provide some relief. Consult with the dietitian and teach about appropriate foods. Recommended dietary changes include less roughage; less fatty, spicy, and sweet food; and no alcohol or caffeine. Some patients obtain relief when they eliminate dairy products or eat smaller amounts of food more often and drink plenty of fluids, especially between meals. If dehydration accompanies diarrhea, IV fluid infusions may be needed.

Assess the perineal skin every 8 to 12 hours for a change in skin TISSUE INTEGRITY. Provide a bedside commode or a bedpan if the patient cannot reach the bathroom in time. Teach UAP performing this care to provide the patient with privacy, support, and understanding. Explain the need to keep the patient's perineal area clean and dry and to wear gloves during this care. Instruct UAP to report any skin changes in the perineal area, including persistent redness, rashes, blisters, or open areas. Collaborate with a wound care specialist for more interventions to manage anal excoriation and discomfort.

#### **Restoring Skin Integrity.**

Impaired TISSUE INTEGRITY in AIDS may be related to Kaposi's sarcoma (KS) of the skin, mucous membranes, and internal organs. Lesions may be localized or widespread. Large lesions can cause pain, restrict movement, and impede circulation, causing open, weeping, painful lesions. Another cause of impaired tissue integrity may be skin infection with herpes simplex virus (HSV) or varicella zoster virus (VZV) (shingles).

#### **Planning: Expected Outcomes.**

The patient is expected to have healing of any existing lesions and avoid increased skin breakdown or secondary infection. Indicators include:

- Absence of new lesions or open skin areas
- Existing lesions become smaller in diameter
- Absence of pus, induration, or redness in, from, or around skin lesions

#### **Interventions.**

Often KS responds well to effective antiretroviral drug therapy. With time and cART, many lesions disappear. For lesions that do not respond to cART, KS can be treated with local radiation, intralesional or systemic chemotherapy, systemic interferon, cryotherapy, or topical retinoids.

Treatment of painful KS lesions includes analgesics and comfort measures. Keep open, weeping KS lesions clean and dressed to prevent infection. Many patients with KS are concerned about their appearance and the risk for being identified as HIV positive. Makeup (if lesions are closed), long-sleeved shirts, and hats may help maintain a normal appearance.

For the patient with a herpes simplex virus (HSV) outbreak, provide good skin care directly or delegate this care to UAP. Stress the importance of keeping the area clean and dry. Teach UAP to clean abscesses at least once per shift with normal saline and allow them to air-dry. This infection is painful and requires analgesics, assistance with position, and other comfort measures. Modified Burow's solution (Domeboro) soaks promote healing for some patients. HSV infection is treated with acyclovir (Zovirax) or valacyclovir (Valtrex).

## Enhancing Cognition.

Neurologic changes and confusion are major areas of concern for patients with HIV disease or AIDS. These changes may be due to psychological stressors accompanying the disease or organic disorders caused by opportunistic infections, cancer, or HIV encephalitis.

### Planning: Expected Outcomes.

The patient is expected to show improved mental status. Indicators include that the patient demonstrates these behaviors:

- Identifies self and significant others
- Identifies correct month and year
- Recalls immediate, recent, and remote information accurately

### Interventions.

Patients with AIDS suffer from enormous loss and psychological stress, which complicates the assessment of changes in behavior or affect. Assess baseline neurologic and mental status by using neurologic assessment tools (see [Chapter 41](#)) to compare any changes. Evaluate the patient for subtle changes in memory, ability to concentrate, affect, and behavior. It is important to determine whether the cause of the neurologic changes is treatable.

*Reorient* the confused patient to person, time, and place as needed. Coordinate with all members of the interprofessional team to ensure that reorientation methods are performed by everyone who interacts with the patient. Remind the patient of your identity and explain what is to be done at any given time. Give simple directions; use short, uncomplicated sentences; explain activities in simple language; and involve him or her in daily planning. Ask significant others to bring in familiar items from home. When possible, arrange all items in the patient's environment in the same location as at home. Calendars, clocks, radios, and putting the bed close to a window may help keep the patient oriented.

*Drug therapy* is used for different conditions that can cause confusion in the adult with AIDS. Psychotropic drugs are used to manage ongoing behavioral problems or emotional disorders. Antidepressants and anxiolytics may be prescribed.

*Safety measures* are crucial to the well-being of the confused patient. He or she may not be aware of activities or surroundings and may need help with bathing, dressing, eating, ambulating, and other ADLs. Make the environment, whether a hospital room or long-term care facility, safe and comfortable.

Some patients with AIDS have seizures. Institute seizure precautions, including keeping side rails in the up position and having oxygen and suctioning equipment available. Anticonvulsants may be added to the drug therapy.

Assess the patient with neurologic symptoms for increased intracranial pressure (ICP). If not recognized and managed early, ICP can lead to permanent brain damage and death. Increased ICP in patients with HIV disease is most commonly managed with corticosteroids.

## Nursing Safety Priority QSEN

### Critical Rescue

Assess the patient frequently to recognize any changes in level of consciousness (one of the earliest signs of increased ICP), vital signs, pupil size or reactivity, or limb strength. If any of these are present, respond by reporting them immediately to the primary health care provider for appropriate intervention.

*Support* the family and friends of the patient who has neurologic impairment. There is great trauma in seeing a loved one unable to care for himself or herself or showing childlike behavior. Teach UAP, the family, and significant others how to reorient the patient. Encourage them to continue to provide the patient with news of family happenings or current events. Coordinate with the social worker to identify community resources for the patient and family.

## Addressing Psychosocial Distress.

As discussed earlier, patients diagnosed with HIV disease have many issues that can lead to psychosocial distress in the forms of depression, anxiety, fear, isolation, and loss. The disease is chronic, debilitating, and fatal. Treatments are expensive, and both the disease and the associated drug therapy induce changes in function and appearance. The disease carries social stigma, regardless of how it was acquired.

The psychosocial issues of a patient with HIV/AIDS are usually ongoing and require many coping adaptations. The role of the medical-surgical nurse in addressing these issues is a more basic continuation of comprehensive therapy. Having a mental health professional as part of the interprofessional care team is essential. The role of this person is extensive and beyond the scope of this chapter.

### **Planning: Expected Outcomes.**

The patient is expected to express his or her personal strengths and self-worth.

### **Interventions.**

Being supportive, honest, caring, and open to the patient's thoughts and feelings form the basis of addressing psychosocial issues. Acceptance of the patient is key to respectful communication. Listen to what he or she has to say about his or her perspectives on the disease and on the reason for this hospitalization.

Be attuned to indications of depression and follow up by asking whether the patient is considering hurting himself or herself. If you believe the patient does have suicidal ideation, communicate this to the interprofessional team immediately. Ask whether he or she would like you to contact his or her usual mental health professional or any other person who usually provides emotional support.

Approach all interactions with the patient in a caring and professional manner. Whenever possible, without violating Standard Precautions, use bare-handed touch while providing care or any other interaction. Using touch during back rubs, hair care, administering medications, or even just shaking hands communicates acceptance. Ensure that unlicensed assistive personnel (UAP) are approaching the patient with the same attitude they approach all other patients. Reiterate with UAP which specific actions do not require wearing gloves.

Spending time with the patient also communicates acceptance. Even just a few minutes beyond what is needed to administer medications or perform an assessment demonstrates caring rather than fear. Allow for privacy, but do not isolate the patient. Encourage self-care, independence, control, and decision-making by helping him or her to set short-term, attainable goals and offering praise when goals are achieved.

At times drug therapy with antidepressants or anxiolytics may be needed long term or for situational issues. If the patient uses such drug therapies on a regular basis, be certain that they are prescribed during the hospitalization. If a new drug is started, record the patient's responses to the therapy.

## **Care Coordination and Transition Management**

The management of HIV/AIDS as a chronic disease occurs in many settings, most often at home. Hospitalizations occur during periods of severe infection or other acute exacerbations of symptoms. As the illness becomes more severe, the patient may need referral to a long-term care facility, home care agency, or hospice. In collaboration with the social worker, dietitian, and others, work with patients to plan what will be needed and how they will manage at home with self-care and ADLs.

### **Home Care Management.**

Before the patient is discharged to home, assess his or her status, ability to perform self-care activities, and plans to maintain communication with primary health care providers. Home care can range from help with ADLs for those with weakness, debility, or limited function to around-the-clock nursing care, drugs, and NUTRITION support for severely ill patients. Assess available resources, including family members and significant others willing and able to be caregivers. Help the family make arrangements for outside caregivers or respite care, if needed. Patients may need referrals or help in planning housing, finances, insurance, legal services, and spiritual counseling. Coordinate with the case manager to ensure that these issues are addressed.

Usually a home care nurse makes an initial visit to the patient with AIDS for assessment

purposes, and care is followed up by home care aides. Reassessment is needed if the patient becomes more debilitated. [Chart 19-7](#) lists assessment areas for the patient with AIDS at home.

### **Chart 19-7**

## **Focused Assessment**

### **The Person With AIDS**

Assess cardiovascular and respiratory status:

- Vital signs
- Presence of acute chest pain or dyspnea
- Presence of cough
- Presence of fever
- Activity tolerance

Assess nutrition status:

- Food intake
- Weight loss or gain
- General condition of skin
- Financial resources

Assess neurologic status:

- Cognitive changes
- Motor changes
- Sensory disturbances

Assess GI status:

- Mouth and oropharynx
- Presence of dysphagia
- Presence of abdominal pain

- Presence of nausea, vomiting, diarrhea, constipation

Assess psychological status:

- Feelings, thoughts, and behaviors
- Presence of anxiety, fear, or depression
- Suicide ideation, intent, or plan
- Support systems within the family and community

Assess activity and rest:

- ADLs
- Mobility and ambulation
- Fatigue
- Sleep pattern
- Presence of pain

Assess home environment:

- Safety hazards
- Structural barriers affecting functional ability

Assess patient's and caregiver's adherence and understanding of illness and treatment, including:

- Symptoms to report to nurse
- Medication schedule and side or toxic effects

Assess patient's and caregiver's coping skills.

### **Self-Management Education.**

*Teaching the patient, family, and friends is a high priority when preparing for discharge.* Instruct about modes of transmission and preventive behaviors (e.g., guidelines for safer sex; not sharing toothbrushes, razors, and other potentially blood-contaminated articles). Caregivers also need instruction about best practices for Infection Control Precautions to prevent transmission while caring for the patient in the home ([Chart 19-8](#)), nursing techniques to use in the home, and coping or support strategies.

#### **Chart 19-8**

### Infection Control for Home Care of the Person With AIDS

#### Direct Care

- Follow Standard Precautions and good handwashing techniques.
- Do not share razors or toothbrushes.

#### Housekeeping

- Wipe up feces, vomit, sputum, urine, or blood or other body fluids and the area with soap and water. Dispose of solid wastes and solutions used for cleaning by flushing them down the toilet. Disinfect the area by wiping with a 1 : 10 solution of household bleach (1 part bleach to 10 parts water). Wear gloves during cleaning.
- Soak rags, mops, and sponges used for cleaning in a 1 : 10 bleach solution for 5 minutes to disinfect them.
- Wash dishes and eating utensils in hot water and dishwashing soap or detergent.
- Clean bathroom surfaces with regular household cleaners and then disinfect them with a 1 : 10 solution of household bleach.

#### Laundry

- Rinse clothes, towels, and bedclothes if they become soiled with feces, vomitus, sputum, urine, or blood. Dispose of the soiled water by flushing it down the toilet. Launder these clothes with hot water and detergent with 1 cup of bleach added per load of laundry.
- Keep soiled clothes in a plastic bag.

#### Waste Disposal

- Dispose of needles and other “sharps” in a labeled puncture-proof container such as a coffee can with a lid or empty liquid bleach bottle, using Standard Precautions, to avoid needlestick injuries. Decontaminate full containers by adding a 1 : 10 bleach solution. Then seal the container with tape and place it in a paper bag. Dispose of the container in the regular trash.
- Remove solid waste from contaminated trash (e.g., paper towels or tissues, dressings, disposable incontinence pads, disposable gloves); then flush the solid waste down the toilet. Place the contaminated trash items in tied plastic bags and dispose of them in the regular trash.

Teach the patient, family, and friends how to protect the patient from infection, how to identify the presence of infections, and what to do if these appear. Teach about the use of self-care strategies such as good hygiene, balanced rest and exercise, skin care, mouth care, and safe administration and potential side effects of all prescribed drugs. During diet teaching stress good NUTRITION; the need to avoid raw or rare fish, fowl, or meat; thorough washing of fruits and vegetables; and proper food refrigeration.

Teach the patient to avoid large crowds, especially in enclosed areas; not to travel to countries with poor sanitation; and to avoid cleaning pet litter boxes. [Chart 19-4](#) lists more strategies to teach the patient and family how to avoid infection.

#### Psychosocial Preparation.

Patients with AIDS often fear social stigma and rejection. Help patients identify strengths and coping strategies for difficult situations. Support family members and friends in efforts to help the patient and provide protection from discrimination.

Encourage patients to continue as many usual activities as possible. Except when too ill or too

weak, they can continue to work and participate in most social activities. Support them in their selection of friends and relatives with whom to discuss the diagnosis. Stress that sexual partners and care providers should be informed; beyond that, it is up to the patient. Some patients have depression or anxiety about the future. Almost all feel the burden of having a fatal disease widely considered unacceptable and feel compelled to maintain some secrecy about the illness. Referrals to community resources, mental health professionals, and support groups can help the patient verbalize fears and frustrations and cope with the illness.

### Health Care Resources.

In many cities community groups and volunteers assist adults with AIDS. The types and number of services vary by agency and city, but many include HIV testing and counseling, clinic services, buddy systems, support groups, respite care, education and outreach, referral services, and housing. Patients may need referrals to other local resources such as home care agencies, companies that provide home IV therapy, community mental health/behavioral health agencies, Meals on Wheels, transportation services, and others. In addition, educational materials and support groups are available through Internet access.

### ◆Evaluation: Reflecting

The overall outcomes for care of patients with AIDS are to maintain the highest possible level of function for as long as possible, reduce infections, and maintain quality of life and dignity during the course of progressive illness. Evaluate the care of the patient with AIDS on the basis of the identified priority problems. Expected outcomes include that he or she will:

- Adhere to the prescribed drug therapy regimen at least 90% of the time
- Practice safer sex techniques all of the time
- Remain free from opportunistic infections
- Have adequate GAS EXCHANGE
- Achieve an acceptable level of physical comfort
- Attain adequate weight and NUTRITION and fluid status
- Maintain TISSUE INTEGRITY
- Remain oriented
- Identify personal strengths
- Use effective coping strategies
- Maintain a support system and involvement with others

## Clinical Judgment Challenge 19-2

### Ethics; Patient-Centered Care; Teamwork and Collaboration **OSEN**

During morning rounds, one of the unlicensed assistive personnel (UAP) makes a comment to another UAP that she is glad not to be assigned to that “nasty” patient with AIDS today. The patient has also requested not to be assigned to this UAP because she wears gloves for all actions and tries to provide care without touching him.

1. How will you address this issue with the UAP?
2. Should you force this UAP to provide care to this patient? Why or why not?
3. What should you say to the patient?
4. Which, if any, ethical issues are in play here? (You may need to review the principles of ethics in Chapter 1).

# Get Ready for the NCLEX® Examination!

## Key Points

Review these key points for each NCLEX Client Needs Category.

### Safe and Effective Care Environment

- Use Standard Precautions for all patients, regardless of age, gender, race or ethnicity, sexual orientation, education level, and profession. **QSEN: Safety**
- Follow the best practices outlined in [Chart 19-5](#) to protect the hospitalized immunosuppressed patient from infection. **QSEN: Safety**
- Use correct handwashing techniques before providing any care to a patient who has reduced IMMUNITY. **QSEN: Safety**
- Teach unlicensed assistive personnel (UAP) to use Standard Precautions. **QSEN: Teamwork and Collaboration**
- Collaborate with the primary health care provider, registered dietitian, respiratory therapist, pharmacist, social worker, and case manager to individualize patient care for the adult with HIV disease and AIDS in any care setting. **QSEN: Teamwork and Collaboration**
- Teach the patient and family to protect against infection transmission by following the recommendations in [Chart 19-4](#). **QSEN: Safety**
- Teach the patient and family about the signs of infection and when to seek medical advice. **QSEN: Safety**

### Health Promotion and Maintenance

- Urge all patients who are HIV positive to use condoms and other precautions during sexual intimacy even if the partner is also HIV positive. **QSEN: Evidence-Based Practice**
- Teach patients with protein-calorie malnutrition which foods to include in the diet to promote better NUTRITION. **QSEN: Patient-Centered Care**
- Urge patients to adhere to their antiviral drug regimen. **QSEN: Evidence-Based Practice**
- Refer patients newly diagnosed with HIV infection to local resources and support groups. **QSEN: Patient-Centered Care**

### Psychosocial Integrity

- Urge all patients who are HIV positive to inform their sexual partners of their HIV status. **QSEN: Patient-Centered Care**
- Respect the patient's right to inform or not to inform family members about his or her HIV status. **Ethics**
- Ensure the confidentiality of the patient's HIV status. **Ethics**
- Use a nonjudgmental approach when discussing sexual practices, sexual behaviors, and recreational drug use. **QSEN: Patient-Centered Care**
- Encourage the patient to express his or her feelings about a change in health status or the diagnosis of an “incurable” disease. **QSEN: Patient-Centered Care**
- Allow patients who have a change in physical appearance to express feelings of loss and mourn this change. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Use prescribed oxygen therapy, drug therapy, and respiratory support to improve GAS EXCHANGE for the patient with respiratory problems related to reduced IMMUNITY. **QSEN: Evidence-Based Practice**

- Use pharmacologic and nonpharmacologic therapies to reduce pain for the patient with HIV disease and AIDS. **QSEN: Patient-Centered Care**
- Teach the patient and caregivers the schedule, side effects, and possible drug interactions of combination antiretroviral therapy (cART). **QSEN: Patient-Centered Care**
- Pace nonurgent health care activities to reduce the risk for fatigue for patients with AIDS. **QSEN: Patient-Centered Care**
- Assess the patient with impaired IMMUNITY every shift for signs of infection. Document the assessment findings and report any indication of infection immediately to the primary health care provider. **QSEN: Safety**
- Assess the TISSUE INTEGRITY of the perianal region of a patient with AIDS-related diarrhea after every bowel movement. **QSEN: Evidence-Based Practice**

## CHAPTER 20

# Care of Patients With Hypersensitivity (Allergy) and Autoimmunity

M. Linda Workman

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is IMMUNITY.**

✚ The IMMUNITY concept exemplar for this chapter is Angioedema, p. 361.

**The interrelated concept for this chapter is GAS EXCHANGE.**

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to coordinate high-quality care and protect the patient experiencing problems of overactive IMMUNITY, including allergic reactions and autoimmunity.
2. Teach the patient and caregiver(s) how overactive IMMUNITY affects home safety.

### Health Promotion and Maintenance

3. Teach patients with allergies how to protect themselves against harm from a hypersensitivity reaction and from therapies used to treat overactive IMMUNITY.

### Psychosocial Integrity

4. Implement nursing interventions to help the patient and family cope with the psychosocial impact caused by hypersensitivity or autoimmunity.

### Physiological Integrity

5. Apply knowledge of anatomy and physiology to assess patients who have health problems related to overactive IMMUNITY.
6. Teach the patient and caregiver(s) about common drugs used for control of autoimmunity and other forms of overactive IMMUNITY.

Usually IMMUNITY with inflammation is a protective and helpful response. However, when the response is overactive (excessive) or when it is directed against normal body tissues, damage can result ([Abbas et al., 2015](#); [McCance et al., 2014](#)).

## Hypersensitivities/Allergies

**Hypersensitivity** or **allergy** is overactive IMMUNITY with inflammation occurring in response to the presence of an **antigen** (foreign protein or allergen) to which the patient usually has been previously exposed. It can cause problems that range from being uncomfortable (e.g., itchy, watery eyes, or sneezing) to life threatening (e.g., allergic asthma, angioedema, anaphylaxis, bronchoconstriction, or circulatory collapse). The terms *hypersensitivity* and *allergy* are used interchangeably. Hypersensitivity reactions are classified into four basic types, determined by differences in timing, pathophysiology, and symptoms (Table 20-1). Each type may occur alone or along with one or more of the other types (McCance et al., 2014).

**TABLE 20-1**  
**Mechanisms and Examples of Types of Hypersensitivities**

MECHANISM	CLINICAL EXAMPLES
<b>Type I: Rapid or Immediate</b> Reaction of IgE antibody on mast cells with antigen, which results in release of mediators, especially histamine	Hay fever (rhinosinusitis) Allergic asthma Anaphylaxis Angioedema
<b>Type II: Cytotoxic</b> Reaction of IgG with host cell membrane or antigen adsorbed by host cell membrane	Autoimmune hemolytic anemia Goodpasture's syndrome Myasthenia gravis
<b>Type III: Immune Complex-Mediated</b> Formation of immune complex of antigen and antibody, which deposits in walls of blood vessels and results in complement release and inflammation	Serum sickness Vasculitis Systemic lupus erythematosus Rheumatoid arthritis
<b>Type IV: Delayed</b> Reaction of sensitized T-cells with antigen and release of lymphokines, which activates macrophages and induces inflammation	Poison ivy Graft rejection Positive TB skin tests Sarcoidosis

IgE, Immunoglobulin E; IgG, immunoglobulin G; TB, tuberculosis.

### Type I: Rapid Hypersensitivity Reactions

Type I, or rapid hypersensitivity, also called *atopic allergy*, is the most common type of hypersensitivity from overactive IMMUNITY. It results from the increased production of the immunoglobulin E (IgE) antibody class. Acute inflammation occurs when IgE responds to an antigen such as pollen and causes the release of histamine and other vasoactive amines from basophils, eosinophils, and mast cells. Examples of type I reactions include angioedema, anaphylaxis, and allergic asthma (discussed in Chapter 30); atopic allergies such as hay fever and allergic rhinosinusitis; and allergies to substances such as latex, bee venom, peanuts, iodine, shellfish, drugs, and many other allergens. Allergens can be contacted in these ways:

- Inhaled (plant pollens, fungal spores, animal dander, house dust, grass, ragweed)
- Ingested (foods, food additives, drugs)
- Injected (bee venom, drugs, biologic substances such as contrast dyes)
- Skin or mucous membrane contacted (latex, pollens, foods, environmental proteins)

Some reactions occur just in the areas exposed to the antigen such as the mucous membranes of the nose and eyes, causing symptoms of rhinorrhea, sneezing, and itchy, red, watery eyes. Other reactions may involve all blood vessels and bronchiolar smooth muscle, causing widespread blood vessel dilation, decreased cardiac output, and bronchoconstriction. This condition is known as **anaphylaxis**, which is a medical emergency and must be treated immediately (see the **Anaphylaxis** section).

The mechanism for type I reactions is the same, regardless of whether they are widespread and severe, or localized and annoying. On first exposure to an allergen, the patient initially responds by making antigen-specific IgE. This IgE binds to the surface of basophils and mast cells (Fig. 20-1). These cells have many granules containing vasoactive amines (including histamine) that are released when stimulated. Once the antigen-specific IgE is formed, the patient is sensitized to that allergen.

**FIG. 20-1** Degranulation and histamine release. **A**, Mast cell with IgE. **B**, Mast cell degranulation and histamine release when allergen binds to IgE.

When the sensitized patient is re-exposed to the allergen, the resulting response has a primary phase and a secondary phase. In the primary phase, the allergen binds to two adjacent IgE molecules on the surface of a basophil or mast cell, which alters the cell membrane. The membrane opens and releases the vasoactive amines into tissue fluids (see Fig. 20-1).

The most common vasoactive amine is *histamine*, a short-acting biochemical. Histamine causes capillary leak, nasal and conjunctival mucus secretion, and pruritus (itching), often occurring with erythema (redness). These symptoms of inflammation last for about 10 minutes after histamine is first released. When the allergen is continuously present, mast cells continuously release histamine and other inflammatory proteins, prolonging the response.

The secondary phase results from the release of other cellular proteins. These other proteins draw more white blood cells to the area and stimulate a more general inflammatory reaction through actions of leukotriene and prostaglandins (other mediators of inflammation; see Chapter 17). This reaction occurs in addition to the allergic reaction stimulated in the primary phase. The resulting inflammation increases the symptoms and continues the response.

The production of high IgE levels in response to antigen exposure is genetically based on the inheritance of many genes. Although allergic tendencies are inherited, specific allergies are *not* inherited. For example, a woman who has an allergy to penicillin but not to peanuts may have a child with an allergy to peanuts but not to penicillin.

## Immunity Concept Exemplar Angioedema

### Pathophysiology

Angioedema is a severe type I hypersensitivity reaction that involves the blood vessels and all layers of the skin, mucous membranes, and subcutaneous tissues in the affected area (Abbas et al., 2015). Unlike the superficial responses of allergic rhinosinusitis, the angioedema response is a deep-tissue problem of IgE-mediated release of inflammatory proteins.

Although angioedema can occur in any part of the body, it is most often seen in the lips, face, tongue, larynx, and neck (Fig. 20-2). Intestinal angioedema can also occur, with problems of severe abdominal pain, cramping, nausea, and vomiting. It can be difficult to differentiate this problem from any other acute abdominal problem.

**FIG. 20-2** Angioedema of the face, lips, and mouth. (From Auerbach, P. (2008). *Wilderness medicine* (5th ed.). Philadelphia: Mosby; courtesy Sheryl Olson.)

Exposure to any ingested drug or chemical can cause the problem. The most common drugs associated with angioedema are angiotensin-converting enzyme inhibitors (ACEIs) used for hypertension ([United States Food and Drug Administration \[FDA\], 2014](#)) and NSAIDs. Although only about 1 in 1000 adults taking these drugs develops angioedema, they are commonly prescribed, which accounts for the high incidence of the response among users of ACEIs and NSAIDs.

Although the greatest risk for angioedema from ACEIs is within the first 24 hours after taking the first dose, the reaction can occur after days, months, and even years of therapy ([Chan & Soliman, 2015](#)). This delay in onset of symptoms is confusing to patients who may not understand the association of the angioedema with the drug or drugs they have been taking.

## Cultural/Spiritual Considerations

### Patient-Centered Care QSEN

Black adults, especially African Americans, have a higher incidence of angioedema and laryngeal edema from ACEIs (FDA, 2014). In a large study of ACEI-induced angioedema, 55% of fatalities occurred among blacks (Kim et al., 2014). Any ACEI should be used cautiously in black patients. Be sure to observe the patient carefully for any signs and symptoms of angioedema and laryngeal edema after the first dose. Teach black patients taking a drug from this category about the signs and symptoms of angioedema and the importance of going to an emergency department or calling 911 immediately if symptoms appear.

### Interprofessional Collaborative Care

Angioedema from a drug exposure can occur anywhere but is more likely to happen in the home or community. Management requires at least a brief hospitalization.

### Assessment: Noticing

#### History.

An accurate and detailed history helps identify the possible cause of angioedema. Ask the patient to list all drugs taken on a regular basis, especially drugs for blood pressure control. Although more information can be helpful, intervention is critically important because laryngeal edema can cause the patient to lose his or her airway. Defer further history until interventions have been implemented.

Often a patient may have only lip swelling or a slight itching in the back of the throat from time to time before a fully developed case of angioedema occurs. Ask the patient specifically about whether he or she has had such a problem, when it occurred, how long it lasted, and whether any drugs were taken to reduce the symptoms. Also ask about any other allergies the patient may have. Not all patients with angioedema have a history of other allergic reactions. Because a tendency toward type I allergic responses can be inherited, ask about the presence of allergies among parents and siblings.

### Physical Assessment/Signs and Symptoms.

The patient with angioedema (with or without laryngeal edema) has deep, firm swelling of the face, lips, tongue, and neck. He or she may have difficulty speaking or drinking because the lips are so stiff from swelling. The face can be so distorted that friends and relatives may not recognize the patient. Often nasal swelling interferes with breathing through the nose. When swelling occurs around the eyes and eyelids, the patient may not be able to see. Some patients may have urticaria (hives), but many do not. Problems that indicate a need for immediate intervention are the inability to swallow, the feeling of a lump in the throat, or stridor.

### Psychosocial Assessment.

The patient with angioedema is often anxious and frightened. These feelings worsen if breathing is impaired. The rapid change in appearance is also disturbing to patients and families.

### Diagnostic Assessment.

Usually the patient is diagnosed based on the signs and symptoms. No specific test can diagnose angioedema, and valuable time should not be wasted in laboratory testing during an acute episode. For patients who have recurring angioedema not associated with a particular drug exposure, a blood test for C1-INH may be performed to determine whether a genetic deficiency of this substance may be the cause. This problem is known as *hereditary angioedema* and is rare. C1-INH is an enzyme that controls the C1 type of complement (see [Chapter 17](#)). When too little of this enzyme is present, complement proteins are easily activated and can cause inappropriate inflammatory reactions.

## NCLEX Examination Challenge 20-1

### Safe and Effective Care Environment

Which questions are **most important** for the nurse to first ask a client who comes to the emergency department with signs of severe angioedema? **Select all that apply.**

- A. "Are you able to swallow?"
- B. "When did you last eat or drink?"
- C. "Do you have an allergy to cortisone?"
- D. "What drugs do you take on a daily basis?"
- E. "Is there any possibility that you may be pregnant?"
- F. "Do any members of your family also have allergies?"

#### ◆Analysis: Interpreting

The priority collaborative problems for patients with angioedema are:

1. Potential for airway obstruction due to mucosal swelling
2. Anxiety due to cerebral hypoxia and threat of death

#### ◆Planning and Implementation: Responding

### Maintaining a Patent Airway.

Interventions focus on stopping the reaction and ensuring an adequate airway.

#### Planning: Expected Outcomes.

The patient with angioedema is expected to maintain a patent airway and adequate GAS EXCHANGE. Indicators include:

- End tidal carbon dioxide level within the normal range
- Rate and depth of respiration within the normal range
- Pulse oximetry within the normal range

#### Interventions.

Prompt intervention can reverse angioedema before laryngeal edema forms and intubation is needed. Oxygen by nasal cannula is applied to help maintain GAS EXCHANGE. Because the reaction is mediated through antibodies and release of vasoactive amines (especially bradykinin), useful drugs include corticosteroids, diphenhydramine, and epinephrine. Indications for intubation are the presence of stridor and the inability of the patient to swallow.

Drug therapy may need to continue for several hours after angioedema has initially resolved. Usually the agent that caused the angioedema has a longer half-life than the drugs used to treat it. This means that initial drug therapy can successfully shrink the facial, oral, and airway edema to the extent that symptoms are no longer felt or observed. However, if drug therapy is completely stopped at this point, the agent still circulating can cause angioedema to redevelop. Once drug therapy has stopped, the IV access remains, and the patient is closely monitored for 2 to 6 hours. If the angioedema does not recur, the patient is usually discharged to home.

If laryngeal edema forms and intubation is not possible, an emergency tracheostomy is needed. Location of the tracheotomy (incision into the trachea) must be below the level of the edema to ensure adequate airflow to the site of GAS EXCHANGE. Mechanical ventilation is usually not needed. The tracheostomy tube is discontinued when the patient can easily breathe around the tube. (See [Chapter 28](#) for detailed information about tracheostomy.)

### Minimizing Anxiety

#### Planning: Expected Outcomes.

The patient with angioedema is expected to have decreased anxiety as the angioedema resolves. Indicators include that the patient:

- Verbalizes reduced anxiety
- Displays no distress or facial tension

#### Interventions.

Anxiety is made worse by any breathing difficulty. Stay with the patient and assure him or her that proper treatment is occurring. Apply oxygen and monitor patient responses to drug and oxygen therapy. Continually assess pulse oximetry, respiratory status, and the patient's ability to swallow. Reassure the patient that, with drug therapy, the swelling will resolve and his or her appearance will return to normal within 6 to 12 hours.

### Care Coordination and Transition Management

Severe angioedema is an acute emergency. With successful management the patient is discharged to resume his or her usual activities. The most important aspects of care coordination are to determine the cause of the angioedema, teach the patient to avoid the offending agent, and ensure that he or she knows to seek emergency care as soon as any signs or symptoms of the problem occur.

#### ◆Evaluation: Reflecting

Evaluate the care of the patient with angioedema based on the identified priority patient problems. The expected outcomes are that the patient:

- Maintains a patent airway
- Has anxiety reduced
- Knows what to do should angioedema recur

## Anaphylaxis

### ❖ Pathophysiology

Anaphylaxis, the most life-threatening example of a type I hypersensitivity reaction, occurs rapidly and systemically. It affects many organs within seconds to minutes after allergen exposure. Anaphylaxis episodes can vary in severity and can be fatal. *The major factor in fatal outcomes for anaphylaxis is a delay in the administration of epinephrine* (Crawford & Harris, 2015a). Almost any substance can trigger anaphylaxis in a susceptible adult. Drugs and dyes are often causes of anaphylaxis in acute care settings; food and insect stings or bites are common causes in community settings.

### Health Promotion and Maintenance

Anaphylaxis has a rapid onset and a potentially fatal outcome (even with appropriate intervention); thus prevention and early intervention are critical. *Teach the patient with a history of allergic reactions to avoid known allergens whenever possible, to wear a medical alert bracelet, and to alert health care personnel about specific allergies.* Some patients must carry an emergency anaphylaxis kit (e.g., a kit with injectable epinephrine, sometimes called a *bee sting kit*) or an epinephrine injector such as the AnaPen ❖, EpiPen, or Twinject automatic injector. The EpiPen is a spring-loaded injector that delivers 0.3 mg of epinephrine per 2-mL dose directly into the subcutaneous tissue (Fig. 20-3). Teach patients how to care for and use the device (Chart 20-1).

FIG. 20-3 EpiPen and EpiPen Jr. self-injectors for epinephrine. (Courtesy Dey, Napa, CA)

### Chart 20-1

## Patient and Family Education: Preparing for Self-Management

### Care and Use of Automatic Epinephrine Injectors

- Practice assembly of injection device with a non-drug-containing training device provided through the injection device manufacturer.
- Keep the device with you at all times.
- When needed, inject the drug into the top of your thigh, slightly to the outside, holding the device so the needle enters straight down.
- You can inject the drug right through your pants; just avoid seams and pockets where the fabric is thicker.
- Use the device when *any* symptom of anaphylaxis is present and call 911. It is better to use the drug when it is not needed than to not use it when it is needed!!!
- Whenever you need to use the device, get to the nearest hospital for monitoring for at least the next 4 to 6 hours.

- Have at least two drug-filled devices on hand in case more than one dose is needed.
- Protect the device from light and avoid temperature extremes.
- Carry the device in the case provided by the manufacturer.
- Keep safety cap in place until you are ready to use the device.
- Check the device for:
  - Expiration date—If the date is close to expiring or has expired, obtain a replacement device.\*
  - Drug clarity—If the drug is discolored, obtain a replacement device.
  - Security of cap—If the cap is loose or comes off accidentally, obtain a replacement device.

\*Some manufacturers have an automatic notification service to let you know your device is about to expire.

## Nursing Safety Priority QSEN

### Action Alert

The medical records (paper or electronic) of patients with a history of anaphylaxis should prominently display the list of specific allergens. Ask the patient about drug allergies before giving any drug or agent. If he or she has a known allergy, be sure to document the allergen and the typical response produced and communicate the allergy and its response to other members of the interprofessional care team. Be aware of common cross-reacting agents. For example, a patient who is allergic to penicillin is also likely to react to cephalosporins because both have a similar chemical structure.

Take precautionary measures if a drug or agent must be used despite a history of allergic reactions. Start an IV and place intubation equipment and a tracheostomy set at the bedside. The patient is often premedicated with diphenhydramine (Benadryl, Allerdryl ) or a corticosteroid.

### Interprofessional Collaborative Care

#### Assessment: Noticing

A major problem with anaphylaxis management is that initial symptoms may be subtle, such as sudden severe abdominal cramping and diarrhea. A set of three criteria, listed in [Chart 20-2](#), is used for diagnosis of anaphylaxis. A patient is considered to have anaphylaxis whenever any *one* of these three criteria is met, and interventions are started immediately.

## Chart 20-2

### Key Features

#### Anaphylaxis

##### Clinical Criteria 1

Onset within minutes to hours of skin or mucous membrane problems involving swollen lips, tongue, soft palate, uvula; widespread hives; pruritus; or flushing along with any *one* of these new-

onset symptoms:

- Respiratory distress or ineffectiveness:
- Dyspnea
- Bronchospasms
- Wheezes
- Stridor
- Hypoxia
- Cyanosis
- Peak expiratory rate flow lower than the patient's usual rate
- Hypotension or any indication of reduced perfusion resulting in organ dysfunction:
- Loss of consciousness
- Incontinence
- Hypotonia
- Absent deep tendon reflexes

### Clinical Criteria 2

Onset within minutes to hours of *two* or more of these symptoms after a patient has been exposed to a potential allergen:

- Skin or mucous membrane problems involving swollen lips, tongue, soft palate, uvula; widespread hives; pruritus; or flushing
- Respiratory distress or ineffectiveness as evidenced by any dyspnea, bronchospasms, wheezes, stridor, hypoxia, cyanosis, or peak expiratory rate flow lower than the patient's usual
- Hypotension or any indication of reduced perfusion resulting in organ dysfunction such as loss of consciousness, incontinence, hypotonia, or absent deep tendon reflexes
- Persistent GI problems such as nausea or vomiting, cramping, abdominal pain

### Clinical Criteria 3

Onset within minutes to hours of hypotension with systolic blood pressure lower than 90 mm Hg or 30% lower than the patient's baseline systolic pressure.

Adapted from Simons, E., Ardusso, L., Bilo, M. B., El-Gamal, Y., Ledford, D., Ring, J., et al. (2011). World Allergy Organization guidelines for the assessment and management of anaphylaxis. *WAO Journal*, 4(2), 13-37.

Patients often have feelings of apprehension, weakness, and impending doom early in the

reaction and are anxious and frightened. These feelings are followed quickly by generalized itching and urticaria (hives). Erythema and angioedema of the eyes, lips, or tongue may occur next. Intensely itchy hives may appear and may merge to form large, red blotches.

Histamine and other mediators cause inflammation, bronchoconstriction, mucosal edema, and excess mucus production. Respiratory symptoms include congestion, rhinorrhea, dyspnea, and increasing respiratory distress with audible wheezing with reduced GAS EXCHANGE.

On auscultation, crackles, wheezing, and reduced breath sounds are heard. Patients may have laryngeal edema as a “lump in the throat,” hoarseness, and stridor (a crowing sound). Distress increases as the tongue and larynx swell and more mucus is produced. Stridor increases as the airway begins to close. Increasing bronchoconstriction can lead to reduced chest movement and impaired airflow. Respiratory failure may follow from laryngeal edema, suffocation, or lower airway constriction causing hypoxemia (poor blood oxygenation).

The patient is hypotensive and has a rapid, weak, irregular pulse from extensive capillary leak and vasodilation. He or she is faint and diaphoretic with increasing anxiety and confusion.

## Nursing Safety Priority QSEN

### Critical Rescue

Closely monitor any patient receiving a drug that is associated with anaphylaxis to recognize symptoms early. If you suspect anaphylaxis, respond by immediately notifying the Rapid Response Team because most anaphylaxis deaths occur from dysrhythmias, shock, and cardiopulmonary arrest that are related to treatment delay.

#### ◆Interventions: Responding

Assess GAS EXCHANGE first. Emergency respiratory management is critical during an anaphylactic reaction because the severity of the reaction increases with time. The upper and lower airways become bronchoconstricted, which quickly impairs airflow and leads to arrest. Establish or stabilize the airway. If an IV drug is suspected to be causing the anaphylaxis, stop the drug immediately but do not remove the venous access because restarting an IV is difficult when the patient is severely hypotensive. Change the IV tubing and hang normal saline. Additional emergency interventions for patients with anaphylaxis are listed in [Chart 20-3](#).

### Chart 20-3

## Best Practice for Patient Safety & Quality Care QSEN

### Emergency Care of the Patient With Anaphylaxis

- Immediately assess the respiratory status, airway, and oxygen saturation of patients who show any symptom of an allergic reaction.
- Call the Rapid Response Team.
- Ensure that intubation and tracheotomy equipment is ready.
- Apply oxygen using a high-flow, nonrebreather mask at 90% to 100%.
- Immediately discontinue the IV drug or infusing solution of a patient having an anaphylactic reaction to that drug or solution. **Do not** discontinue the IV, but change the IV tubing and hang normal saline.
- If the patient does not have an IV, start one immediately and run normal saline.
- Be prepared to administer epinephrine IV (preferred) or IM.
- Epinephrine 1 : 1000 concentration, 0.3 to 0.5 mL IV push or IM

- Repeat drug administration as needed every 5 to 15 minutes until the patient responds.
- Keep the head of the bed elevated about 10 degrees if hypotension is present; if blood pressure is normal, elevate the head of the bed to 45 degrees or higher to improve ventilation.
- Raise the feet and legs.
- Stay with the patient.
- Reassure the patient that the appropriate interventions are being instituted.

The patient with anaphylaxis is usually anxious or frightened and often expresses a sense of impending doom. Stay with the patient and reassure him or her that the appropriate interventions are being instituted.

*Epinephrine (1 : 1000) 0.3 to 0.5 mL is the first-line drug for anaphylaxis.* It is given IM or IV when symptoms appear (see [Chart 20-3](#)). This drug constricts blood vessels, improves cardiac contraction, and dilates the bronchioles. The same dose may be repeated every 5 to 15 minutes if needed ([Vacca & McMahon-Bowen, 2013](#)).

## Nursing Safety Priority QSEN

### Critical Rescue

Monitor susceptible patients for signs and symptoms of anaphylaxis. When you recognize anaphylaxis, respond by administering epinephrine as quickly as possible. Most deaths from anaphylaxis are related to delay in epinephrine administration.

Antihistamines such as diphenhydramine (Benadryl, Allerdryl ) 25 to 100 mg are second-line drugs and are given IV or IM for angioedema and urticaria. Other drugs used to support cardiovascular function during anaphylaxis are the same as those used in hypovolemic shock (see [Chapter 37](#)). If needed, an endotracheal tube may be inserted, or an emergency tracheostomy may be performed.

If the patient can breathe independently, give oxygen to reduce hypoxemia and promote GAS EXCHANGE. Start oxygen therapy via a high-flow nonrebreather facemask at 90% to 100% *before* arterial blood gas results are obtained. Monitor pulse oximetry to determine gas exchange adequacy. Arterial blood gases may be drawn to determine therapy effectiveness. Use suction to remove excess mucus and other secretions, if indicated. Continually assess the respiratory rate and depth, and assess breath sounds continually for bronchospasm, wheezing, crackles, and stridor. Elevate the bed to 45 degrees unless severe hypotension is present.

For bronchospasms the patient may be given an inhaled beta-adrenergic agonist such as metaproterenol (Alupent) or albuterol (Proventil) via high-flow nebulizer every 2 to 4 hours. Corticosteroids are added to emergency interventions, but they are not effective immediately. Oral steroids are continued (at lower doses) after the anaphylaxis is under control to prevent the late recurrence of symptoms.

Continually assess for changes in any system or for effects of drug therapy. For severe anaphylaxis the patient is admitted to an ICU for cardiac, pulmonary arterial, and capillary wedge pressure monitoring. Observe for fluid overload from the rapid drug and IV fluid infusions and report changes to the primary health care provider immediately. The patient is discharged from the hospital when respiratory and cardiovascular functions have returned to normal.

## Allergic Rhinosinusitis

### Pathophysiology

Allergic rhinosinusitis, or *hay fever*, is triggered by IMMUNITY and inflammatory reactions to airborne allergens, especially plant pollens, molds, dust, animal dander, wool, food, and air pollutants. Some

acute episodes are “seasonal,” recurring at the same time each year and lasting only a few weeks. It can also occur continuously when an adult is exposed to certain allergens. Unlike angioedema, this form of type I reaction usually involves only superficial layers of the skin and mucous membranes and their associated blood vessels.

Symptoms of allergic rhinosinusitis are the same as those for rhinosinusitis caused by infection (see [Chapter 31](#)). These include pain over the cheek radiating to the teeth, tenderness to percussion over the sinuses, referred pain to the temple or back of the head, and general facial pain that is worse when bending forward.

### ❖ **Interprofessional Collaborative Care**

Management first focuses on symptom relief and patient education. Teach the patient about correct use of the drug therapy prescribed. When the specific allergen is identified, such as animal dander, teach him or her to avoid coming into contact with the allergen. If symptoms do not respond to typical drug therapy or if they are severe and chronic, the patient may need immunotherapy for greater relief.

*Drug therapy* for symptom relief can be effective in reducing the allergic response and making the patient more comfortable. Drugs commonly include decongestants and intranasal steroid spray. *Antihistamines*, *leukotriene inhibitors*, and *mast cell stabilizers* block or reduce the amount of chemical mediators in nasal and sinus tissues and prevent local edema and itching. *Decongestants* constrict blood vessels and decrease edema. Analgesics may be given for pain.

*Immunotherapy*, also known as *desensitization therapy* or *allergy shots*, involves subcutaneous injections of very dilute solutions of the identified allergens. Thus allergy testing by skin testing or intradermal testing must be performed first to correctly identify the allergens. A 0.05-mL dose of this solution is injected subcutaneously. Usually an increasing dose is given weekly until the patient is receiving a 0.5-mL dose. The patient is then started on the lowest dose of the next higher concentration of allergen solution. The process is repeated with increasing concentrations of allergen solutions until the patient is receiving the maximum dose of the greatest concentration (usually 1 : 100), depending on his or her response. The recommended full course of treatment is about 5 years.

Immunotherapy appears to reduce allergic responses by competition. In theory, the very small amounts of allergen first injected are too low to bind to the IgE already present but are enough to induce immunoglobulin G (IgG) production against that allergen. IgG is not attached to either mast cells or basal cells, and allergens that bind to IgG do not trigger allergic responses. IgG then clears the allergen from the body. By gradually increasing the allergen injection, large amounts of IgG are produced against the allergen. When the patient is then exposed to the allergen in the environment, the IgG binds to it and clears it from the body before IgE can bind to it and trigger an allergic reaction. Because so much more IgG can be produced compared with IgE, IgG is successful in the competition to bind the allergen ([Abbas et al., 2015](#)).

## **Clinical Judgment Challenge 20-1**

### **Safety; Patient-Centered Care** QSEN

Your 52-year-old next-door neighbor comes to your house and tells you that he woke up an hour ago with swollen lips and swelling of his lower face. He tells you that in the past hour his tongue also has become swollen, making it difficult for him to speak clearly. He is supposed to leave in 2 hours for the airport for a week-long business trip. When you ask him whether this has ever happened to him before, he says “No,” and wonders if he is “coming down with something.” When you ask him which medications he has taken today, he tells you that he took his usual 81 mg of aspirin and his usual lisinopril 10 mg on arising this morning. He asks whether he should just take diphenhydramine (Benadryl) and head for the airport.

1. What should your first assessment be? Provide a rationale for your answer.
2. Do you think he has angioedema or anaphylaxis? Explain your choice.
3. Are either of his usual medications associated with this type of response?

4. Should you advise him to take the diphenhydramine and go on his trip as planned? Why or why not?
5. What should your next action be?

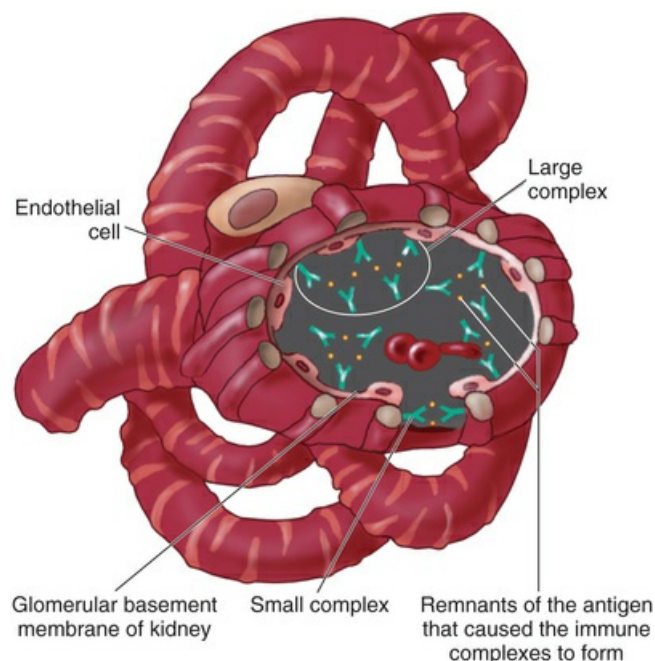

## Type II: Cytotoxic Reactions

In a type II (cytotoxic) reaction the body makes autoantibodies directed against self cells that have some form of foreign protein attached to them. The autoantibody binds to the self cell and forms an immune complex (see Fig. 17-10). The self cell is then destroyed along with the attached protein. Examples of type II reactions include immune hemolytic anemias, immune thrombocytopenic purpura, hemolytic transfusion reactions (when a patient receives the wrong blood type during a transfusion), and drug-induced hemolytic anemia.

Management of type II reactions begins with discontinuing the offending drug or blood product. *Plasmapheresis* (filtration of the plasma to remove specific substances) to remove autoantibodies may be beneficial. Otherwise treatment is symptomatic. Complications such as hemolytic crisis and kidney failure can be life threatening.

## Type III: Immune Complex Reactions

In a type III reaction excess antigens cause immune complexes to form in the blood (Fig. 20-4). These circulating complexes then lodge in small blood vessels of the kidneys, skin, and joints. The complexes trigger inflammation, and tissue or vessel damage results.

**FIG. 20-4** An immune complex in a type III hypersensitivity reaction.

Many immune complex disorders (mostly autoimmune disorders) are caused by type III reactions. For example, the symptoms of rheumatoid arthritis are caused by immune complexes that lodge in joint spaces followed by tissue destruction, scarring, and fibrotic changes. Systemic lupus erythematosus (SLE) has immune complexes lodged in blood vessels (vasculitis), the glomeruli (glomerulonephritis), the joints (arthralgia, arthritis), and other organs and tissues.

*Serum sickness* is a group of symptoms that occurs after receiving serum or certain drugs. Immune complexes are deposited in blood vessel walls of the skin, joints, and kidneys and cause tissue damage. Common causes of serum sickness are penicillin, other antibiotics, and some animal serum-based drugs.

The patient with serum sickness has fever, arthralgia (achy joints), rash, malaise,

lymphadenopathy (enlarged lymph nodes), and possibly polyarthritis and nephritis about 7 to 12 days after receiving the causative agent. Teach him or her about the possibility of serum sickness and what symptoms to look for whenever you give a foreign serum. Also keep emergency equipment and drugs close at hand in case he or she has an anaphylactic reaction.

Serum sickness is usually self-limiting, and symptoms subside after several days. Management is symptomatic; antihistamines are given for itching, and aspirin is given for arthralgias. Prednisone is given for severe symptoms.

## Type IV: Delayed Hypersensitivity Reactions

In a type IV reaction the reactive cell is the T-lymphocyte (T-cell). Antibodies and complement are not involved (Abbas et al., 2015). Sensitized T-cells (from a previous exposure) respond to an antigen by releasing chemical mediators and triggering macrophages to destroy the antigen. A type IV response typically occurs hours to days after exposure. It consists of edema, induration, ischemia, and tissue damage at the site of the exposure.

An example of a small type IV reaction is a positive purified protein derivative (PPD) test for tuberculosis (TB). In a patient previously exposed to TB, an intradermal injection of this agent causes sensitized T-cells to clump at the injection site, release lymphokines, and activate macrophages. Induration and erythema at the injection site appear after about 24 to 72 hours.

Other examples of type IV reactions include contact dermatitis such as poison ivy skin rashes, local response to insect stings, tissue transplant rejections, and sarcoidosis.

The reaction is self-limiting in 5 to 7 days, and the patient is treated symptomatically. Monitor the reaction site and sites distal to the reaction for circulation adequacy. Histamine (H<sub>1</sub>) antagonists such as diphenhydramine (Benadryl) are not useful for type IV reactions because histamine is not the main mediator. Because IgE does not cause this type of reaction, desensitization does not reduce the response. Corticosteroids can reduce the discomfort and help resolve the reaction more quickly.

# Autoimmunity

## ❖ Pathophysiology

Autoimmunity is a process whereby an inappropriate IMMUNITY develops to an adult's own tissues. In this response the body's antibodies or lymphocytes are directed against the body's own healthy normal cells and tissues, not just against invaders. The immune system essentially loses some ability to tolerate self cells and tissues. (Chapter 17 discusses the principles of immunity self-tolerance.) Examples of diseases that have an autoimmune cause are listed in Table 20-2. Some diseases such as type 1 diabetes mellitus may have multiple causes, one of which is autoimmune. Autoimmune diseases are common, chronic, progressive, and self-perpetuating (Abbas et al., 2015).

**TABLE 20-2**  
**Disorders With an Autoimmune Basis**

<ul style="list-style-type: none"> <li>• Ankylosing spondylitis (AS)</li> <li>• Autoimmune hemolytic anemia</li> <li>• Autoimmune thrombocytopenic purpura</li> <li>• Celiac disease (CeD)</li> <li>• Crohn's disease (CD)</li> <li>• Diabetes (type 1)</li> <li>• Dermatomyositis</li> <li>• Erythema nodosum leprosum (ENL)</li> <li>• Glomerulonephritis</li> <li>• Goodpasture's syndrome</li> <li>• Grave's disease</li> <li>• Hashimoto's thyroiditis</li> <li>• Idiopathic Addison's disease</li> </ul>	<ul style="list-style-type: none"> <li>• Irritable bowel disease (IBD)</li> <li>• Multiple sclerosis (MS)</li> <li>• Myasthenia gravis</li> <li>• Pernicious anemia</li> <li>• Psoriasis (PS)</li> <li>• Psoriatic arthritis (PSA)</li> <li>• Rheumatoid arthritis (RA)</li> <li>• Reiter's syndrome</li> <li>• Scleroderma</li> <li>• Sjögren's syndrome (SS)</li> <li>• Systemic lupus erythematosus (SLE)</li> <li>• Ulcerative colitis (UC)</li> <li>• Uveitis</li> <li>• Vasculitis</li> </ul>
--	---

Development of autoimmune disease with failure of some immunity components to tolerate self is complex, involving genetic susceptibility or predisposition and environmental interactions. The incidence of autoimmunity within the general population is about 5% (Abbas et al., 2015; Jorde et al., 2016). However, the incidence is far higher in some families than in others.

## Gender Health Considerations

### Patient-Centered Care QSEN

Virtually all autoimmune disorders, especially rheumatic disorders, occur much more commonly among women than men (McCance et al., 2014). The risk for autoimmune disease among women compared with men ranges from 5 : 1 to 20 : 1 (Abbas et al., 2015).

## Genetics/Genomics Considerations

### Patient-Centered Care QSEN

There is a strong genetic component to autoimmune disease development. Twin studies confirm the link between genetic inheritance and autoimmunity. For dizygotic twins (fraternal twins), when one twin is diagnosed with an autoimmune disease, the incidence of autoimmune disease development in the other twin is about 6%, nearly the same as the general population. For monozygotic twins (identical twins), when one twin is diagnosed with an autoimmune disease, the incidence of autoimmune disease development in the other twin is about 50% (Abbas et al., 2015; Jorde et al., 2016).

Specific tissue types (determined by genetic inheritance) are much more associated with autoimmunity. Susceptible tissue types, known as *human leukocyte antigens (HLAs)*, include DR2, DR3, DRB, DQA, DQB, and Cw6. Ask any patient diagnosed with autoimmune disease whether other family members have an autoimmune disease.

As normal IMMUNITY develops, most immune system cells recognize the body's own cell surface antigens and learn to tolerate them without initiating any immunologic response. Those immune system cells that do not tolerate self cells and become self-reacting are either eliminated early from

the immune system or are held in check by suppressive elements. A variety of immune system cells and cell products regulate these self-reactive IMMUNITY components to prevent attack and damage of normal, healthy self cells. Among these is a substance known as *cytotoxic T lymphocyte-associated protein 4 (CTLA4)*. CTLA4 binds to receptors on T-lymphocytes and helps prevent them from becoming self-reactive.

In some adults, for unknown reasons the immune system regulation of self-reacting cells fails to recognize certain tissues as self, and immune reactions are inappropriately triggered. As a result, both antibody- and cell-mediated responses and products are directed against normal body cells (McCance et al., 2014). (Antibodies directed against self tissues or cells are known as **autoantibodies**.) Immune system cells that cause inflammatory responses can be triggered to continue cell division and continue producing inflammatory mediators through the actions of intracellular enzymes known as *janus kinases (JAKs)*. These enzymes transmit signals from the cells' surfaces to the nucleus so that genes responsible for making inflammatory mediators are expressed and more mediators are produced.

Self-reactions can form against one type of cell and cause problems only for a specific tissue, organ, or system. A classic example of this type of selective autoimmune disease is myasthenia gravis in which the person makes antibodies against the acetylcholine receptor on muscle cells. As a result, transmission of nerve impulses to the skeletal muscles for contraction does not occur. Breathing and movement are impaired, and death can occur if the disease is not continually managed.

Self-reactions can also be directed against a specific tissue component or multiple components that are present in many organs or tissues, resulting in widespread problems or symptoms. An example of this type of autoimmunity is systemic lupus erythematosus (SLE) in which autoantibodies are produced against many cellular proteins and almost all organs are affected to some degree.

All autoimmune diseases have inflammation as part of the reaction that can damage tissues. Unregulated immune system cells and products stimulate the production of pro-inflammatory cytokines, especially interleukins 12, 17, and 23 (IL-12, IL-17, IL-23); gamma interferon; and tumor necrosis factor (TNF). These substances not only cause direct damage to tissues but also increase the cell growth rate for skin cells (inducing the scaling lesions of psoriasis) and inflammatory white blood cells (especially macrophages), which then continue the attack on self-tissues. TNF has several subtypes, and each subtype binds to its specific receptors to induce tissue-damaging actions. In addition to immune system cells producing TNF, some cells within joints such as synovial cells and epithelial cells also produce TNF (Crawford & Harris, 2015b).

### ❖ **Interprofessional Collaborative Care**

*There is no cure for autoimmune diseases.* Management depends on the organ or organs affected. For example, in type 1 diabetes the patient uses insulin to manage the disease and its complications, not drugs that alter IMMUNITY. For other autoimmune diseases, such as rheumatoid arthritis or psoriasis in which controlling the immune response is the best way to manage the disorder, anti-inflammatory drugs and immunosuppressive drugs are commonly used along with symptomatic treatment to suppress the overactive immunity. Drug therapy often involves a combination of general immunosuppressant agents and selective immunosuppressive agents. Patient responses to therapy drive the types and combinations of drugs used. Regardless of the specific agents used, the desired outcomes of drug therapy for autoimmune disease are:

- Self-reacting, immune-mediated tissue-damaging actions slow or stop.
- Symptoms of autoimmune disease are reduced.
- The patient retains enough IMMUNITY to prevent serious infections.

### **General Immunosuppressive Therapy**

The two drug categories of general immunosuppressive therapy for autoimmune diseases are corticosteroids and cytotoxic drugs. These two drug categories have many systemic harmful side effects and can lead to profound general immunosuppression. With the development of more specific immunosuppressant drugs, these less specific agents now have smaller roles in therapy for autoimmune diseases.

### **Corticosteroids.**

*Corticosteroids* are drugs similar to natural cortisol that suppress bone marrow production of all white blood cells (WBCs) and inhibit immune responses, as well as inflammation. Because the corticosteroids cause such a general immunosuppression and can greatly increase the patient's risk for infection, they now are used more sparingly than in years past. [Chapter 62](#) discusses the side effects of corticosteroids and the associated nursing care and patient education.

### Cytotoxic Drugs.

*Cytotoxic drugs* are those with actions that purposely destroy cells. They are used most commonly as cancer chemotherapy with the intent of killing off cancer cells. Because any rapidly dividing cells are more sensitive to the killing effects of these drugs, WBCs are suppressed. For this action cytotoxic drugs such as methotrexate and cyclophosphamide have been used in lower dosages than required for cancer therapy to suppress cell division of WBCs, which then reduces the overactive IMMUNITY experienced by patients with various autoimmune diseases. For some patients these drugs are still used along with selective immunosuppressive therapy to control severe autoimmune diseases. [Chapter 22](#) discusses the side effects of cytotoxic drugs and the associated nursing care and patient education.

### Selective Immunosuppressive Therapy

Selective immunosuppressive therapy with single drugs may be used successfully to control autoimmune diseases for some patients. For others, drugs from more than one category of selective immunosuppressant agents are used along with more general immunosuppressant drugs. Patient responses guide therapy and often are highly individual. The classes for drugs used to manage autoimmune diseases are the antiproliferative agents, calcineurin inhibitors, and disease-modifying antirheumatic drugs (DMARDs).

## Nursing Safety Priority QSEN

### Drug Alert

All selective immunosuppressants reduce protective IMMUNITY to some degree and increase the patient's risk for new infections and reactivation of dormant infections such as tuberculosis. These drugs are not to be started on any patient with a current infection. Tuberculosis testing is usually performed before starting any selective immunosuppressant. Teach patients taking these drugs to avoid crowds and people who are ill. Also teach them to contact their primary health care provider at the first sign of an infection.

### Antiproliferative Drugs.

*Antiproliferative drugs* slow the growth of immune system cells responsible for autoimmune diseases in several ways. Azathioprine, although somewhat less selective than other antiproliferatives, inhibits the metabolism of purines, which are important in DNA synthesis and cell division. It suppresses the actions of the lymphocytes that cause tissue damage in some autoimmune diseases.

Mycophenolate is more selective in suppressing lymphocyte activity than azathioprine. This drug reversibly inhibits an enzyme needed for lymphocyte reproduction. It also prevents T-lymphocytes already present from being active. Both actions selectively suppress the immune responses most associated with autoimmune tissue destruction.

Sirolimus selectively inhibits T-lymphocyte activation and reproduction by blocking the signal transduction pathways, especially mTOR, that promote movement of T-lymphocytes through the cell cycle for cell division. This drug also interferes with the ability of B-lymphocytes to mature into antibody-producing cells. The overall amount of antibodies produced, including autoantibodies, is significantly reduced.

Everolimus acts in a similar way to sirolimus. It also inhibits the mTOR pathway important to cell division and proliferation in lymphocytes. This drug greatly reduces protein synthesis and cell division in immune system cells that attack self cells.

## Nursing Safety Priority QSEN

## Drug Alert

All antiproliferative drugs are associated with poor pregnancy outcomes, and pregnancy is an absolute contraindication for their use. Teach sexually active women in childbearing years to use two reliable methods of contraception during therapy with antiproliferatives and for 12 weeks after they are discontinued. Breast-feeding while taking these drugs is also contraindicated.

### Calcineurin Inhibitors.

*Calcineurin inhibitors* bind to proteins that normally promote T-lymphocyte activation and gene expression that causes increased production of pro-inflammatory cytokines (especially interleukins and tumor necrosis factor) and increased production of macrophages and other white blood cells. The calcineurin inhibitors form a complex with these proteins that suppresses T-lymphocyte activation, resulting in fewer pro-inflammatory cytokines and inflammatory white blood cells. These actions result in less damage to tissues and organs. The two drugs in this class are cyclosporine and tacrolimus. Although these drugs are used more in the prevention of transplant rejection (see [Chapter 17](#)), they are also used in the management of psoriasis and Sjögren syndrome.

### Disease-Modifying Antirheumatic Drugs.

*Disease-modifying antirheumatic drugs (DMARDs)* are drugs that reduce the progression and tissue destruction of the inflammatory disease process largely by inhibiting tumor necrosis factor (TNF) or its receptors. Some also have effects against other substances needed in the inflammatory tissue-destruction pathway(s). There are a variety of drugs in this category with different mechanisms of action. See [Chart 20-4](#) for a listing of DMARDs and the associated nursing implications.

#### Chart 20-4

## Common Examples of Drug Therapy

### Biologic Disease-Modifying Antirheumatic Drugs (DMARDs)

DRUG CATEGORY	NURSING IMPLICATIONS
<b>Monoclonal antibodies to tumor necrosis factor (TNF)</b> Common drug class examples: <ul style="list-style-type: none"> <li>• Adalimumab (Humira)</li> <li>• Certolizumab (Cimzia)</li> <li>• Etanercept (Enbrel)</li> <li>• Golimumab (Simponi)</li> <li>• Infliximab (Remicade)</li> </ul>	Ask the patient whether he or she has ever had tuberculosis (TB), hepatitis B (HVB), or cancer. <i>The immunosuppression caused by these drugs can reactivate TB and HVB and have been associated with cancer recurrence. These conditions are contraindications to the use of these drugs.</i> The first dose of any monoclonal antibody to TNF must be administered in a setting equipped to handle allergic reactions and anaphylaxis. <i>Although these reactions are rare, the antibodies are proteins that can trigger such reactions.</i> After administering the first dose, observe the patient for at least 2 hours to determine whether an adverse reaction, especially a severe allergic reaction, occurs. Indications of an adverse reaction include hypotension; rapid thread pulse, and decreased oxygen saturation. <i>Adverse reactions are most likely to occur within the first 60 to 90 minutes of receiving the drug.</i> Observe the patient for indications of heart failure <i>because these drugs are known to worsen existing heart failure and have caused new-onset heart failure.</i> Monitor subcutaneous injection sites for reactions (e.g., pain, redness, itching swelling), <i>which are common and may be painful but are not indications for stopping the drug because the reactions are localized and mild.</i> Document patient responses to the drug to use as a baseline for assessing future responses. Teach patients the proper technique for subcutaneous injection <i>because many patients will be able to self-inject the drug at home.</i> Ask women of child-bearing age whether they are pregnant. These drugs are not recommended during pregnancy <i>because they do cross the placenta and enter the fetus.</i> No controlled trials of the drugs have been conducted to ascertain the effect of these drugs on pregnancy outcomes. These drugs can be used during breast-feeding. <i>The drugs are large with high molecular weights and are unlikely to enter breast milk. In addition, they are poorly absorbed from the intestinal tract.</i>
<b>Monoclonal antibodies to interleukin-1 (IL-1)</b> Common drug class examples: <ul style="list-style-type: none"> <li>• Anakinra (Kineret)</li> <li>• Canakinumab (Ilaris)</li> </ul>	Ask whether the female patient is pregnant or breast-feeding before starting these drugs. <i>There are insufficient data to know how these drugs affect pregnancy and breast-feeding outcomes, and their use during pregnancy and breast-feeding is not recommended.</i> Ask the patient whether he or she has ever had TB, HVB, or cancer. <i>The immunosuppression caused by these drugs can reactivate TB and HVB and has been associated with cancer recurrence. These conditions are contraindications to the use of these drugs.</i> Just as for the monoclonal antibodies to TNF, monitor for hypersensitivity (anaphylaxis) and injection site reactions. These drugs are not to be administered by the intravenous route; <i>the formulation is for subcutaneous administration only.</i> Observe patients for a decreasing therapeutic effect over time <i>because many patients develop antibodies that neutralize the activity of these drugs.</i>
<b>Monoclonal antibodies to interleukin-6 (IL-6)</b> Common drug class examples: <ul style="list-style-type: none"> <li>• Tocilizumab (Actemra)</li> </ul>	Use during pregnancy and breast-feeding is the same as for monoclonal antibodies to IL-1. Infection and cancer precautions are the same as for monoclonal antibodies to TNF and IL-1. Precautions for hypersensitivity and injection site reactions are the same as for monoclonal antibodies to TNF and IL-1. Observe the patient for yellowing of the eyes and skin. Check results of liver function tests. <i>The drug is associated with hepatic toxicities.</i> May be injected intravenously or subcutaneously <i>because the formulation is approved for both types of administration.</i> Monitor blood pressure and lipid levels <i>because this drug is associated with development of hypertension and hyperlipidemia over time.</i>
<b>Monoclonal antibodies to interleukin 17 (IL-17)</b> Common drug class examples: <ul style="list-style-type: none"> <li>• Secukinumab (Cosentyx)</li> </ul>	Use during pregnancy and breast-feeding is the same as for monoclonal antibodies to IL-1. Infection and cancer precautions are the same as for monoclonal antibodies to TNF and IL-1. Precautions for hypersensitivity and injection site reactions are the same as for monoclonal antibodies to TNF and IL-1. Administer subcutaneously <i>because the formulation is not approved for the intravenous route.</i>
<b>CTLA4 agonist</b> Common drug class examples: <ul style="list-style-type: none"> <li>• Abatacept (Orencia)</li> </ul>	Use during pregnancy and breast-feeding is the same as for monoclonal antibodies to IL-1. Infection and cancer precautions are the same as for monoclonal antibodies to TNF and IL-1. Precautions for hypersensitivity and injection site reactions are the same as for monoclonal antibodies to TNF and IL-1. May be injected intravenously or subcutaneously <i>because the formulation is approved for both types of administration.</i>
<b>Monoclonal antibodies to p40</b> Common drug class examples: <ul style="list-style-type: none"> <li>• Ustekinumab (Stelara)</li> </ul>	Use during pregnancy and breast-feeding is the same as for monoclonal antibodies to IL-1. Infection and cancer precautions are the same as for monoclonal antibodies to TNF and IL-1. Precautions for hypersensitivity and injection site reactions are the same as for monoclonal antibodies to TNF and IL-1. Administer subcutaneously <i>because the formulation is not approved for the intravenous route.</i>

### Biologic DMARDs.

The biologic DMARDs are monoclonal antibodies directed against inflammatory cells or their receptors or products that attack and destroy healthy self cells. The monoclonal antibodies are administered intravenously or subcutaneously.

Some biologic DMARDs are directed against one or more subtypes of TNF, preventing it from binding to its receptors and stimulating tissue-destructive actions. These drugs include adalimumab (Humira), certolizumab (Cimzia), etanercept (Enbrel), golimumab (Simponi), and infliximab (Remicade). Although TNF is the primary target of these drugs, the resulting actions also decrease many other pro-inflammatory cytokines as a secondary response. Most DMARDs with this mechanism of action are approved for management of rheumatoid arthritis (RA), psoriasis, ankylosing spondylitis, Crohn's disease, and ulcerative colitis.

Some DMARDs work by competing with interleukin-1 (IL-1), which is a pro-inflammatory cytokine. These drugs resemble parts of IL-1 and bind to the IL-1 receptor but do not activate it. The response is decrease inflammatory reactions. Drugs in this category include anakinra (Kineret) and canakinumab (Ilaris). Both drug are approved for management of RA.

Tocilizumab (Actemra) is a monoclonal antibody that binds to the interleukin-6 (IL-6) receptor, preventing the pro-inflammatory cytokine IL-6 from binding to it. The response is decreased inflammatory responses. It is approved to manage RA.

Ustekinumab (Stelara) is a monoclonal antibody to a protein (p40) found on the surface of many T-lymphocytes. When the drug binds to p40, the cell is unable to bind with interleukin-12 (IL-12) or interleukin-23 (IL-23). When these substances do not bind to lymphocytes, less TNF and gamma interferon are produced. As a result, inflammation and tissue damage are reduced. This drug is approved to manage psoriasis and psoriatic arthritis.

Secukinumab (Cosentyx) is an antibody that binds to the inflammatory cytokine interleukin-17 (IL-17) and prevents its interaction with receptors on lymphocytes. Lymphocytes are less active and then produce less TNF. This drug is approved to manage psoriasis, psoriatic arthritis, and ankylosing spondylitis.

Abatacept (Orencia) is a DMARD with a different mechanism of action. This drug is a fusion protein like an antibody that is very similar to CTLA4, which is an inhibitor of T-lymphocyte activation. When abatacept is administered, it acts like a synthetic CTLA4, reducing the number of activated T-lymphocytes, which results in less production of TNF, alpha interferon, autoantibodies, and pro-inflammatory interleukins. It is approved to manage RA.

### **Nonbiologic DMARDs.**

Nonbiologic DMARDs are those drugs that interfere with some critical pathway in inflammatory responses but are not monoclonal antibodies. The drugs in this class in current use include thalidomide, apremilast, and tofacitinb.

Thalidomide (Thalomid) is an oral DMARD that inhibits an enzyme important in the activation and expression of the TNF gene. Thus it reduces the amount of TNF produced. Currently its approved use is limited to the management of erythema nodosum leprosum (ENL). Thalidomide is in clinical trials for management of Crohn's disease.

Apremilast (Otezla) is an oral DMARD that reduces pro-inflammatory cytokines by inhibiting the enzyme phosphodiesterase 4 (PPD4). When this enzyme is inhibited, lymphocytes contain more of a substance (cAMP) that inhibits cytokine production. It is currently approved for management of psoriatic arthritis.

Tofacitinib (Xeljanz) is an oral DMARD that inhibits the janus kinase (JAK) enzymes. These enzymes are responsible for transmitting signals from immune system cell surfaces to the nucleus that activate the genes responsible for making some pro-inflammatory cytokines. By inhibiting the JAK enzymes, there is less inflammation and tissue damage. This drug is approved to manage RA.

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Ensure that only latex-free products are used for a patient who has a known latex allergy. **QSEN: Safety**
- Verify that all allergies are documented in a prominent place in the patient's medical record or electronic health record. **QSEN: Safety**
- Keep emergency equipment and drugs (epinephrine, Benadryl, cortisol) in or near the room of a patient with known severe allergies or a history of anaphylaxis. **QSEN: Safety**
- Teach patients to remove common allergens from the home or avoid direct contact with them. **QSEN: Safety**

### Health Promotion and Maintenance

- Urge all patients with severe allergies or those who have a history of anaphylaxis to wear a medical alert bracelet. **QSEN: Patient-Centered Care**
- Teach the patient and family about the symptoms of allergic reactions and when to seek medical help. **QSEN: Patient-Centered Care**
- Teach the patient who has a known drug allergy about which other drugs are likely to stimulate the same reactions. **QSEN: Patient-Centered Care**
- Teach the patient who carries an automatic epinephrine injector how to care for, assemble, and use the device. Obtain a return demonstration. **QSEN: Patient-Centered Care**

### Psychosocial Integrity

- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for tests related to hypersensitivities. **QSEN: Patient-Centered Care**
- Stay with the patient in anaphylaxis. **QSEN: Patient-Centered Care**
- Reassure patients who are in anaphylaxis that the appropriate interventions are being instituted. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Identify patients at risk for hypersensitivity reactions, especially anaphylaxis. **QSEN: Safety**
- Communicate a patient's allergies to all members of the interprofessional health care team. **QSEN: Safety**
- Immediately assess the respiratory status and airway of patients who show any symptoms of an allergic reaction. **QSEN: Evidence-Based Practice**
- Immediately discontinue the IV drug or solution of a patient having an anaphylactic reaction to that drug or solution. **Do not** discontinue the IV, but change the IV tubing and hang normal saline. **QSEN: Evidence-Based Practice**
- Hold the dose of any prescribed drug when a patient develops angioedema. **QSEN: Safety**
- Give oxygen to any patient in anaphylaxis. **QSEN: Evidence-Based Practice**

## CHAPTER 21

# Principles of Cancer Development

---

M. Linda Workman

## PRIORITY AND INTERRELATED CONCEPTS

***The priority concept for this chapter is CELLULAR REGULATION.  
The interrelated concept for this chapter is IMMUNITY.***

## LEARNING OUTCOMES

### **Health Promotion and Maintenance**

1. Help adults identify behaviors that reduce the risk for cancer development.
2. Teach adults the recommended screening practices and schedules for specific cancer types.

### **Physiological Integrity**

3. Apply knowledge of basic biology to understand the factors that allow or cause normal cells to lose CELLULAR REGULATION and become malignant, including the roles of oncogenes and suppressor genes.
4. Distinguish the features of normal cells from those of benign tumors and cancer cells.
5. Interpret cancer grading, ploidy, and staging reports.

Cancer is a common health problem in the United States and Canada. Over 1.8 million people are newly diagnosed with cancer each year ([American Cancer Society \[ACS\], 2017](#); Canadian Cancer Society, 2016). Cancer is a life-threatening disease and without intervention leads to death. Every adult's risk for cancer differs. In addition, some types of cancer can be prevented; many have better cure rates if diagnosed early. As a nurse you can have a vital impact in educating the public about cancer prevention and early detection methods.

## Pathophysiology

During infancy and childhood orderly growth of cells and tissues must occur for body development and maturation. This growth and the continued cell growth needed to replace dead or damaged cells after maturation is complete are normal and controlled through CELLULAR REGULATION. As discussed in Chapter 2, **cellular regulation** is the process to control cellular growth, replication, and *differentiation* (maturation into a specific cell type) to maintain homeostasis. All steps in the process of cellular regulation are the result of gene interactions. Tissues that continue to grow by undergoing mitosis in adulthood include cells of the skin, hair, mucous membranes, bone marrow; and linings of organs such as the lungs, stomach, intestines, bladder, and uterus. These tissues are located in areas in which constant damage or wear is likely and continued cell growth is needed to replace dead tissues. In health this continued growth is controlled by cellular regulation to ensure that the right number of cells is always present in any tissue or organ.

For fully developed tissues and organs that stop growing by mitosis such as heart muscle, skeletal muscle, and neurons, damaged cells are replaced with scar tissue. Thus cardiac muscle cells in the heart do not undergo mitosis in adults, but fibroblastic scar tissue does.

Any new or continued cell growth not needed for normal development or replacement of dead and damaged tissues is called **neoplasia**. This cell growth is abnormal even if it causes no harm (is benign). Whether the new cells are benign or cancerous, neoplastic cells develop from normal cells (*parent cells*). Thus cancer cells were once normal cells but underwent genetic mutations to no longer look, grow, or function normally. The strict processes of CELLULAR REGULATION controlling normal growth and function have been lost (McCance et al., 2014). To understand how cancer cells grow, it is helpful to first understand the regulation and function of normal cells.

## Biology of Normal Cells

Many different normal cells work together to make the whole body function at an optimal level. For optimal function, each cell must perform in a predictable manner. Normal cells have these characteristics:

- *Specific morphology* is the feature in which each normal cell type has a distinct and recognizable appearance, size, and shape, as shown in Fig. 21-1.

**FIG. 21-1** Distinctive morphology of some normal cells.

- A *smaller nuclear-to-cytoplasmic ratio* means that the nucleus of a normal cell occupies a relatively small amount of space inside the cell. As shown in Fig. 21-1, the size of the normal cell nucleus is small compared with the size of the rest of the cell, including the cytoplasm.
- *Differentiated function* means that every normal cell has at least one function it performs to contribute to whole-body function. For example, skin cells make keratin, liver cells make bile, cardiac muscle cells contract, and red blood cells make hemoglobin.
- *Tight adherence* occurs because normal cells make proteins that protrude from the membranes, allowing cells to bind closely and tightly together. One such protein is fibronectin, which keeps most normal tissues bound tightly to each other. Exceptions are blood cells. Red blood cells and white blood cells produce no fibronectin and do not usually adhere together.

- *Nonmigratory* means that normal cells do not wander throughout the body (except for blood cells). This occurs in normal cells because they are tightly bound together, which prevents cells from wandering from one tissue into the next.
- *Orderly and well-regulated growth* or CELLULAR REGULATION is a very important feature of normal cells. They divide (undergo mitosis) for only two reasons: (1) to develop normal tissue or (2) to replace lost or damaged normal tissue. Even when they are capable of mitosis, normal cells divide only when body conditions are just right. Cell division (**mitosis**), occurring in a well-recognized pattern, is described by the cell cycle. Fig. 21-2 shows the phases of the cell cycle. Living cells not actively reproducing are in a reproductive resting state termed  $G_0$ . During the  $G_0$  period, cells actively carry out their functions but do not divide. Normal cells spend most of their lives in the  $G_0$  state rather than in a reproductive state.

Mitosis makes one cell divide into two new cells that are identical to each other and to the cell that began mitosis. The steps of entering and completing the cell cycle are tightly controlled.

Whether a cell enters and completes the cell cycle to form two new cells depends on the presence and absence of specific CELLULAR REGULATION proteins. Proteins that promote cells to enter and complete cell division are produced by oncogenes and are known as *cyclins*. When cyclins are activated by external or internal signaling, they allow a cell to leave  $G_0$  and enter the cycle. These activated cyclins then drive the cell to progress through the different phases of the cell cycle and undergo cell division. Proteins produced by suppressor genes control the amount of cyclins present and ensure that cell division occurs only when it is needed. *Thus cellular regulation of division is a balance between the oncogene protein products that promote cell division (cyclins) and the proteins that limit cell division (suppressor gene products).*

**FIG. 21-2** The cell cycle.

- *Contact inhibition* is CELLULAR REGULATION that stops further rounds of cell division when the dividing cell is completely surrounded and touched (contacted) by other cells. Of the normal cells that can divide, each cell divides only when some of its surface is not in direct contact with another cell. Once a normal cell is in direct contact on all surface areas with other cells, it no longer undergoes mitosis. Thus normal cell division is contact inhibited.
- *Apoptosis* is programmed cell death. Not only do normal cells have to divide only when needed and have to perform their specific differentiated functions, some cells also have to die at the appropriate time to ensure optimum body function. Thus normal cells have a finite life span. With each cell division the telomeric DNA at the ends of the cell's chromosomes shortens (see [Chapter 5](#)). When this DNA is gone, the cell responds to CELLULAR REGULATION signals for apoptosis. This ensures that each organ has an adequate number of cells at their functional peak.
- *Euploidy*, having a complete set of chromosomes, is a feature of most normal human cells. These cells have 23 pairs of chromosomes, the correct number for humans.

## Biology of Abnormal Cells

Body cells are exposed to a variety of conditions that can alter how cells grow or function. When either cell growth or cell function is changed, the cells are considered abnormal. [Table 21-1](#) compares features of normal, benign tumor, and cancer (malignant) cells.

**TABLE 21-1****Characteristics of Normal and Abnormal Cells**

CHARACTERISTIC	NORMAL CELL	BENIGN TUMOR CELL	MALIGNANT CELL
Cell division	None or slow	Continuous or inappropriate	Rapid or continuous
Appearance	Specific morphologic features	Specific morphologic features	Anaplastic
Nuclear-to-cytoplasmic ratio	Smaller	Smaller	Larger
Differentiated functions	Many	Many	Some or none
Adherence	Tight	Tight	Loose
Migratory	No	No	Yes
Growth	Well regulated	Expansion	Invasion
Chromosomes	Diploid (euploid)	Diploid (euploid)	Aneuploid*
Mitotic index	Low	Low	High*

\*Depends on the degree of malignant transformation.

### Features of Benign Tumor Cells

**Benign tumor cells** are normal cells growing in the wrong place or at the wrong time as a result of a problem with CELLULAR REGULATION. Examples include moles, uterine fibroid tumors, skin tags, endometriosis, and nasal polyps. Benign tumor cells have these characteristics:

- *Specific morphology* occurs with benign tumors. They look like the tissues they come from, retaining the specific morphology of parent cells.
- A *smaller nuclear-to-cytoplasmic ratio* is a feature of benign tumors just like completely normal cells.
- *Specific differentiated functions* continue to be performed by benign tumors. For example, in endometriosis, a type of benign tumor, the normal lining of the uterus (endometrium) grows in an abnormal place (e.g., on an ovary or elsewhere in the abdominal or even the chest cavity). This displaced endometrium acts just like normal endometrium by changing each month under the influence of estrogen. When the hormone level drops and the normal endometrium sheds from the uterus, the displaced endometrium, wherever it is, also sheds.
- *Tight adherence* of benign tumor cells to each other occurs because they continue to make fibronectin.
- *No migration* or wandering of benign tissues occurs because they remain tightly bound and do not invade other body tissues.
- *Orderly growth* with normal growth patterns occurs in benign tumor cells even though their growth is not needed. The fact that growth continues beyond an appropriate time or occurs in the wrong place indicates some problem with CELLULAR REGULATION, but the rate of growth is normal. The benign tumor grows by expansion. *It does not invade.*
- *Euploidy* (normal chromosomes) are usually found in benign tumor cells, with a few exceptions. Most of these cells have 23 pairs of chromosomes, the correct number for humans.

### Features of Cancer Cells

Cancer (**malignant**) cells are abnormal, serve no useful function, and are harmful to normal body tissues. Cancers commonly have these features:

- *Anaplasia* is the cancer cells' loss of the specific appearance of their parent cells. As a cancer cell becomes more malignant, it becomes smaller and rounded. Thus many different types of cancer cells look alike under the microscope.
- A *larger nuclear-cytoplasmic ratio* occurs because the cancer cell nucleus is larger than that of a normal cell and the cancer cell is smaller than a normal cell. The nucleus occupies much of the space within the cancer cell, especially during mitosis, creating a large nuclear-to-cytoplasmic ratio.
- *Specific functions are lost* partially or completely in cancer cells. *Cancer cells serve no useful purpose.*
- *Loose adherence* is typical for cancer cells because they do not make fibronectin. As a result, cancer cells easily break off from the main tumor.
- *Migration* occurs because cancer cells do not bind tightly together and have many enzymes on their cell surfaces. These features allow the cells to slip through blood vessel walls and between tissues, spreading from the main tumor site to many other body sites. The ability to spread (**metastasize**) is unique to cancer cells and is a major cause of death. Cancer cells invade other tissues, both close by and more remote from the original tumor. Invasion and persistent growth make untreated cancer deadly.

- *Contact inhibition does not occur* in cancer cells because of lost CELLULAR REGULATION, even when all sides of these cells are in continuous contact with the surfaces of other cells. This persistence of cell division makes the disease difficult to manage.
- *Rapid or continuous cell division* occurs in many types of cancer cells because they do not respond to check-point control of cell division because of gene changes that reduce the effectiveness of CELLULAR REGULATION and re-enter the cell cycle for mitosis almost continuously. In addition, these cells also do not respond to signals for apoptosis. Most cancer cells have a lot of the enzyme *telomerase*, which maintains telomeric DNA. As a result, cancer cells do not respond to apoptotic signals and have an unlimited life span (are “immortal”).
- *Abnormal chromosomes* in which the chromosome number and/or structure is not normal (**aneuploidy**) are common in cancer cells as they become more malignant. Chromosomes are lost, gained, or broken; thus cancer cells can have more than 23 pairs or fewer than 23 pairs. Cancer cells also may have broken and rearranged chromosomes with mutated genes.

## NCLEX Examination Challenge 21-1

### Physiological Integrity

Which tumor features are **most** closely associated with malignant cells rather than benign cells?  
**Select all that apply.**

- A. Aneuploidy
- B. Growth by expansion
- C. Highly differentiated
- D. Large nuclear-to-cytoplasmic ratio
- E. Migratory
- F. Tight adhesion

# Cancer Development

## Carcinogenesis/Oncogenesis

**Carcinogenesis** and **oncogenesis** are other names for cancer development. The process of changing a normal cell into a cancer cell is called **malignant transformation**, occurring through loss of CELLULAR REGULATION leading to the steps of initiation, promotion, progression, and metastasis (Jorde et al., 2016).

*Initiation* is the first step in carcinogenesis. Normal cells can become cancer cells if they lose CELLULAR REGULATION by having their genes promoting cell division (**oncogenes**) turn on excessively (are overexpressed) and produce more cyclins. Initiation is a change in gene expression caused by anything that can damage cellular DNA, leading to loss of cellular regulation. Such changes can activate oncogenes that should have only limited expression and can damage suppressor genes, which normally limit oncogene activity. Thus initiation leads to excessive cell division through DNA damage that results in loss of cellular regulation by either loss of suppressor gene function or enhancement of oncogene function. (Some researchers refer to genes promoting normal cell growth as *proto-oncogenes* and refer to oncogenes as mutated proto-oncogenes that are no longer well controlled. Others do not draw this distinction and refer to all genes promoting cell division as oncogenes.)

Initiation is an irreversible event that can lead to cancer development. After initiation a cell can become a cancer cell if the cellular regulation loss that occurred during initiation continues. *If growth conditions are right, widespread metastatic disease can develop from just one cancer cell.*

Substances that change the activity of a cell's genes so the cell becomes a cancer cell are **carcinogens**. Carcinogens may be chemicals, physical agents, or viruses. More than 56 agents, substances, mixtures, and exposures are known to cause cancer in humans; and about another 187 are suspected to be carcinogens (National Toxicology Program [NTP], 2016). The NTP's website (<http://ntp.niehs.nih.gov/go/roc14/>) lists these substances. Chapters presenting the care of patients with specific cancers discuss specific known carcinogens within the Etiology sections.

*Promotion* is the enhanced growth of an initiated cell by substances known as promoters. Once a normal cell has been initiated by a carcinogen and is a cancer cell, it can become a tumor if its growth is enhanced. Many normal hormones and body proteins, such as insulin and estrogen, can act as promoters and make cells divide more frequently. The time between a cell's initiation and the development of an overt tumor is called the **latency period**, which can range from months to years. Exposure to promoters can shorten the latency period.

*Progression* is the continued change of a cancer, making it more malignant over time. After cancer cells have grown to the point that a detectable tumor is formed (a 1-cm tumor has at least 1 billion cells in it), other events must occur for this tumor to become a health problem. First the tumor must develop its own blood supply. The tumor makes vascular endothelial growth factor (VEGF) that triggers nearby capillaries to grow new branches into the tumor, ensuring the tumor's continued nourishment and growth.

As tumor cells continue to divide, some of the new cells change features from the original, initiated cancer cell and form different groups. Some of the differences provide these cell groups with advantages (*selection advantages*) that allow them to live and divide no matter how the conditions around them change. These tumor changes may allow it to become more malignant. Over time the tumor cells have fewer and fewer normal cell features.

The original tumor is called the **primary tumor**. It is usually identified by the tissue from which it arose (*parent tissue*) such as in breast cancer or lung cancer. When primary tumors are located in vital organs such as the brain or lungs, they can grow and either lethally damage the vital organ or interfere with that organ's ability to perform its vital function. At other times the primary tumor is located in soft tissue that can expand without damage as the tumor grows. One such site is the breast. The breast is not a vital organ and, even with a large tumor, the primary tumor alone would not cause the patient's death. When the tumor spreads from the original site into vital areas, life functions can be disrupted, and death may follow.

*Metastasis* occurs when cancer cells move from the primary location by breaking off from the original group and establishing remote colonies. These additional tumors are called **metastatic** or **secondary tumors**. *Even though the tumor is now in another organ, it is still a cancer from the original altered tissue. For example, when breast cancer spreads to the lung and the bone, it is still breast cancer in the*

lung and bone—not lung cancer and not bone cancer. Metastasis occurs through many steps, as shown in Fig. 21-3.

FIG. 21-3 The steps of metastasis.

Tumors first extend into surrounding tissues by secreting enzymes that open up areas of surrounding tissue. Pressure, created as the tumor increases in size, forces tumor cells to invade new territory.

Spread to distant organs and tissues requires cancer cells to penetrate blood vessels. **Bloodborne metastasis** (tumor cell release into the blood) is the most common cause of cancer spread. Enzymes secreted by tumor cells also make large pores in the patient's blood vessels, allowing tumor cells to enter the blood and circulate. Because tumor cells are loosely held together, clumps of cells break off from the primary tumor into blood vessels for transport.

Tumor cells circulate through the blood and enter tissues at remote sites. Clumps of cancer cells can become trapped in capillaries. These clumps damage the capillary wall and allow cancer cells to leave the capillary and enter the surrounding tissue.

When conditions in the remote site can support tumor cell growth, the cells stop circulating (arrest) and invade the surrounding tissues, creating secondary tumors. Table 21-2 lists the common sites of metastasis for specific tumor types.

**TABLE 21-2**  
**Common Sites of Metastasis for Different Cancer Types**

<b>Breast Cancer</b> <ul style="list-style-type: none"> <li>• Bone*</li> <li>• Lung*</li> <li>• Liver</li> <li>• Brain</li> </ul>	<b>Prostate Cancer</b> <ul style="list-style-type: none"> <li>• Bone (especially spine and legs)*</li> <li>• Pelvic nodes</li> </ul>
<b>Lung Cancer</b> <ul style="list-style-type: none"> <li>• Brain*</li> <li>• Bone</li> <li>• Liver</li> <li>• Lymph nodes</li> <li>• Pancreas</li> </ul>	<b>Melanoma</b> <ul style="list-style-type: none"> <li>• GI tract</li> <li>• Lymph nodes</li> <li>• Lung</li> <li>• Brain</li> </ul>
<b>Colorectal Cancer</b> <ul style="list-style-type: none"> <li>• Liver*</li> <li>• Lymph nodes</li> <li>• Adjacent structures</li> </ul>	<b>Primary Brain Cancer</b> <ul style="list-style-type: none"> <li>• Central nervous system</li> </ul>

\*Most common site of metastasis for the specific malignant neoplasm.

Another way cancers metastasize is by *lymphatic spread*. Lymphatic spread is related to the number, structure, and location of lymph nodes and vessels. Primary sites that are rich in lymphatics have earlier metastatic spread than areas with few lymphatics.

## Cancer Classification

Cancers are classified by the type of tissue from which they arise (e.g., glandular, connective) (McCance et al., 2014), as described in [Table 21-3](#). Other ways to classify cancer include biologic behavior, anatomic site, and degree of differentiation.

**TABLE 21-3**  
**Classification of Tumors by Tissue of Origin**

PREFIX	TISSUE OF ORIGIN	BENIGN TUMOR	MALIGNANT TUMOR*
Adeno	Epithelial glands	Adenoma	Adenocarcinoma
Chondro	Cartilage	Chondroma	Chondrosarcoma
Fibro	Fibrous connective	Fibroma	Fibrosarcoma
Glio	Glial cells (brain)	Glioma	Glioblastoma
Hemangio	Blood vessel	Hemangioma	Hemangiosarcoma
Hepato	Liver	Hepatoma	Hepatocarcinoma Hepatoblastoma
Leiomyo	Smooth muscle	Leiomyoma	Leiomyosarcoma
Lipo	Fat/adipose	Lipoma	Liposarcoma
Lympho	Lymphoid tissues		Malignant lymphomas Hodgkin's lymphoma Non-Hodgkin's lymphoma Burkitt's lymphoma Cutaneous T-cell
Melano	Pigment-producing skin		Melanoma
Meningioma	Meninges	Meningioma	Malignant meningioma Meningioblastoma
Neuro	Nerve tissue	Neuroma Neurofibroma	Neurosarcoma Neuroblastoma
Osteo	Bone	Osteoma	Osteosarcoma
Renal	Kidney		Renal cell carcinoma
Rhabdo	Skeletal muscle	Rhabdomyoma	Rhabdomyosarcoma
Squamous	Epithelial layer of skin, mucous membranes, and organ linings	Papilloma	Squamous cell carcinoma of skin, bladder, lungs, cervix

\*Carcinomas are tumors of glandular tissue; sarcomas are tumors of connective tissue; blastomas are tumors of less differentiated, embryonal tissues.

About 100 different types of cancer arise from various tissues or organs. [Fig. 21-4](#) compares cancer distribution by site and gender. Cancers are either solid or hematologic. Solid tumors develop from specific tissues (e.g., breast cancer and lung cancer). Hematologic cancers arise from blood cell-forming tissues (e.g., leukemias and lymphomas).

## Leading Sites of New Cancer Cases and Deaths for the United States and Canada – 2014 Estimates\*

\*Excludes basal and squamous cell skin cancers and in situ carcinoma except urinary bladder.

Note: Percentages may not total 100% due to rounding.

**FIG. 21-4** Cancer incidence and death by site and sex. (Data from American Cancer Society, 2017, and Canadian Cancer Society, 2016.)

## Cancer Grading, Ploidy, and Staging

Systems of grading and staging have been developed to help standardize cancer diagnosis, prognosis, and treatment. **Grading** of a tumor classifies cellular aspects of the cancer. **Ploidy** classifies the number and structure of tumor chromosomes as normal or abnormal. **Staging** classifies clinical aspects of the cancer.

*Grading* is needed because some cancer cells are “more malignant” than others, varying in their aggressiveness and sensitivity to treatment. Some cancer cells barely resemble the mature tissue from which they arose (are “poorly differentiated”), are aggressive, and spread rapidly. These cells are a “high-grade” cancer. Less malignant cancer cells that are “well differentiated” and more closely resemble the mature tissue from which they arose are less aggressive. On the basis of cell appearance and activity, grading compares the cancer cell with the normal mature parent tissue from which it arose. It is a means of evaluating the patient with cancer for prognosis and appropriate therapy. Grading also allows health care professionals to evaluate the results of management.

Clinical groups have established specific grading systems for different types of cancer cells, but overall they resemble the standard system listed in [Table 21-4](#). This system rates cancer cells with the lowest rating given to those cells that closely resemble normal cells and the highest rating given to cancer cells that barely resemble normal cells. Grading systems for different cancers are presented in the clinical chapters in which care is discussed.

**TABLE 21-4**

### Grading of Malignant Tumors

GRADE	CELLULAR CHARACTERISTICS
G <sub>x</sub>	Grade cannot be determined.
G <sub>1</sub>	Tumor cells are well differentiated and closely resemble the normal cells from which they arose. This grade is considered a low grade of malignant change. These tumors are malignant but are relatively slow growing.
G <sub>2</sub>	Tumor cells are moderately differentiated; they still retain some of the characteristics of normal cells, but also have more malignant characteristics than do G <sub>1</sub> tumor cells.
G <sub>3</sub>	Tumor cells are poorly differentiated, but the tissue of origin can usually be established. The cells have few normal cell characteristics.
G <sub>4</sub>	Tumor cells are poorly differentiated and retain no normal cell characteristics. Determination of the tissue of origin is difficult and perhaps impossible.

*Ploidy* is the description of cancer cells by chromosome number and appearance. Normal human cells have 46 chromosomes (23 pairs), the normal diploid number (**euploidy**). When malignant transformation occurs, changes in the genes and chromosomes also occur. Some cancer cells gain or lose whole chromosomes and may have structural abnormalities of the remaining chromosomes, a condition called **aneuploidy**. The degree of aneuploidy increases with the degree of malignancy. Some chromosome changes are associated with specific cancers, and their presence is used for diagnosis and prognosis. One example is the “Philadelphia” chromosome abnormality often present in chronic myelogenous leukemia cells (see [Chapter 40](#)). Other gene changes in cancerous tumors alter the tumor's susceptibility to specific treatment. Some changes form the basis of “targeted therapy” for cancer (see [Chapter 22](#)).

*Staging* determines the exact location of the cancer and whether metastasis has occurred. Cancer stage influences selection of therapy. Staging is done by clinical staging, surgical staging, and pathologic staging. *Clinical staging* assesses the patient's symptoms and evaluates tumor size and possible spread. *Surgical staging* assesses the tumor size, number, sites, and spread by inspection at surgery. *Pathologic staging* is the most definitive type, determining the tumor size, number, sites, and spread by pathologic examination of tissues obtained at surgery.

The **tumor, node, metastasis (TNM)** system is used to describe the anatomic extent of cancers. The TNM staging systems have specific prognostic value for each solid tumor type. [Table 21-5](#) shows a basic TNM staging system. TNM staging is not useful for leukemia or lymphomas (see [Chapter 40](#)). Additional specific staging systems include Dukes' staging of colon and rectal cancer and Clark's levels method of staging skin cancer.

**TABLE 21-5**  
**Staging of Cancer—TNM Classification**

<b>Primary Tumor (T)</b>	
T <sub>x</sub>	Primary tumor cannot be assessed
T <sub>0</sub>	No evidence of primary tumor
T <sub>is</sub>	Carcinoma in situ
T <sub>1</sub> , T <sub>2</sub> , T <sub>3</sub> , T <sub>4</sub>	Increasing size and/or local extent of the primary tumor
<b>Regional Lymph Nodes (N)</b>	
N <sub>x</sub>	Regional lymph nodes cannot be assessed
N <sub>0</sub>	No regional lymph node metastasis
N <sub>1</sub> , N <sub>2</sub> , N <sub>3</sub>	Increasing involvement of regional lymph nodes
<b>Distant Metastasis (M)</b>	
M <sub>x</sub>	Presence of distant metastasis cannot be assessed
M <sub>0</sub>	No distant metastasis
M <sub>1</sub>	Distant metastasis

Tumor growth is assessed in terms of **doubling time** (the amount of time it takes for a tumor to double in size) and **mitotic index** (the percentage of actively dividing cells within a tumor). The smallest detectable tumor is about 1 cm in diameter and contains 1 billion cells. A tumor with a mitotic index of less than 10% is a slower-growing tumor; a tumor with an index of 85% is faster growing. Different tumor types have a wide range of growth rates.

## Cancer Etiology and Genetic Risk

Carcinogenesis usually takes years and depends on several tumor and patient factors (Boucher et al., 2014). Three interacting factors influence cancer development: exposure to carcinogens, genetic predisposition, and IMMUNITY. These factors account for variation in cancer development from one adult to another, even when each adult is exposed to the same hazards.

*Oncogene activation* is the main mechanism of carcinogenesis regardless of the specific cause. These oncogenes are turned on (expressed) under controlled conditions for CELLULAR REGULATION when cells divide for normal growth and replacement of dead or damaged tissues. At other times they are turned off, controlled, or suppressed by products of “suppressor genes.”

When a normal cell is exposed to any carcinogen (initiator), the normal cell's DNA can be

damaged and mutated. The mutations damage suppressor genes, preventing them from producing proteins that control CELLULAR REGULATION for the expression of oncogenes. As a result, the oncogenes are overexpressed and can cause the cells to change from normal cells to cancer cells. When oncogenes are overexpressed in a cell, excessive amounts of cyclins are produced and upset the balance between cell growth enhancement and cell growth limitation. The effect of the presence of these excessive cyclins is greater than the normal effect of the suppressor gene products, thus cell regulation is lost, allowing uncontrolled cell division.

*Oncogenes are not abnormal genes but are part of every cell's normal makeup.* Oncogenes become a problem only if they are overexpressed as a result of exposure to carcinogenic agents or events with loss of CELLULAR REGULATION. External and personal factors can activate oncogenes.

## External Factors Causing Cancer

External factors, including environmental exposure, are responsible for about 80% of cancer in North America (ACS, 2017). Environmental carcinogens are chemical, physical, or viral agents that cause cancer (NTP, 2016).

*Chemical carcinogenesis* can occur from exposures to many known chemicals, drugs, and other products used in everyday life. Chemicals vary in how carcinogenic they are. For example, tobacco and alcohol appear to be only mildly carcinogenic. For these substances, chronic, long-term exposure to large amounts is required before CELLULAR REGULATION is lost and cancer develops. However, these two substances can act as *co-carcinogens*, meaning that when they are taken together, they enhance each other's carcinogenic activity.

Not all cells are susceptible to carcinogenesis to the same degree. Normal cells that have the ability to divide are at greater risk for cancer development than are normal cells that are not capable of cell division. For example, cancers commonly arise in bone marrow, skin, lining of the GI tract, ductal cells of the breast, and lining of the lungs. All of these cells normally undergo cell division. Cancers of nerve tissue, cardiac muscle, and skeletal muscle are rare. These cells do not normally undergo cell division.

About 30% of cancers diagnosed in North America are related to tobacco use (ACS, 2017; Canadian Cancer Society, 2016). Tobacco is the single most preventable source of carcinogenesis. It contains many carcinogens and co-carcinogens. The risk for cancer development from tobacco use depends on an adult's IMMUNITY, genetic susceptibility, and amount and types of tobacco exposure. Chapter 27 discusses the types of tobacco and tobacco smoke exposure.

Tissues at greatest risk for tobacco-induced cancer are those that have direct contact with tobacco or tobacco smoke such as the lungs and airways. Cigarette smoking and tobacco use also promote the development of pancreatic, oral and laryngeal, bladder, and cervical cancers.

## Veterans' Health Considerations

### Patient-Centered Care QSEN

The incidence of tobacco-related cancers is high among military veterans. One reason is that at one time cigarette smoking was considered “manly” among military personnel. The cost of cigarettes was low in stores on military installations (no state taxes were applied). In addition, military field meals such as “C-rations” or “K-rations” included free cigarettes. Ask patients about their military service and whether cigarette smoking started, continued, or increased during that time.

*Physical carcinogenesis* from physical agents or events also causes cancer by DNA damage. Two physical agents that are known to cause cancer are radiation and chronic irritation.

Even small doses of radiation affect cells. Some effects are temporary and are self-repaired. Other effects cannot be repaired and may induce cancer in the damaged cells. Both ionizing and ultraviolet (UV) radiation can cause cancer. Some ionizing radiation is found naturally in radon, uranium, and radium found in rocks and soil. Other sources of ionizing radiation include x-rays for diagnosis and treatment of disease, as well as cosmic radiation. UV radiation is a type of solar radiation, coming from the sun. Other sources of UV radiation include tanning beds and germicidal lights. UV rays do not penetrate deeply, and the most common cancer type caused by UV exposure is skin cancer. Both ionizing and UV radiation exposure mutates genes.

Chronic irritation and tissue trauma are suspected to cause cancer. The incidence of skin cancer is

higher in the scars of adults with burn scars or other types of severe skin injury. Chronically irritated tissues undergo frequent cell division and thus are at an increased risk for DNA mutation.

*Viral carcinogenesis* occurs when viruses infect body cells and break DNA strands. Viruses then insert their own genetic material into the human DNA. Breaking the DNA, along with viral gene insertion, mutates the cell's DNA and can either activate an oncogene or damage suppressor genes. Viruses that cause cancer are **oncoviruses**. Table 21-6 lists cancers of known viral origin.

**TABLE 21-6**  
**Cancers Associated With a Known Viral Origin**

VIRUS	MALIGNANCIES
Epstein-Barr virus	Burkitt's lymphoma, B-cell lymphoma, nasopharyngeal carcinoma
Hepatitis B virus	Primary liver carcinoma
Hepatitis C virus	Primary liver carcinoma, possibly B-cell lymphomas
Human papilloma virus	Cervical carcinoma, vulvar carcinoma, penile carcinoma, and other anogenital carcinomas
Human lymphotrophic virus type I	Adult T-cell leukemia
Human lymphotrophic virus type II	Hairy cell leukemia

Data from National Toxicology Program. (2016). *Report on carcinogens* (14th ed.). <http://ntp.niehs.nih.gov/go/roc13>.

Dietary factors related to cancer are poorly understood but are suspected to increase cancer risk. Suspected dietary factors include low fiber intake and a high intake of red meat or animal fat. Preservatives, preparation methods, and additives (dyes, flavorings, sweeteners) may have cancer-promoting effects. Chart 21-1 lists dietary habits that may help reduce cancer risk.

### Chart 21-1

## Patient and Family Education: Preparing for Self-Management

### Dietary Habits to Reduce Cancer Risk

- Avoid excessive intake of animal fat.
- Avoid nitrites (prepared lunch meats, sausage, bacon).
- Minimize your intake of red meat.
- Keep your alcohol consumption to no more than one or two drinks per day.
- Eat more bran.
- Eat more cruciferous vegetables such as broccoli, cauliflower, Brussels sprouts, and cabbage.
- Eat foods high in vitamin A (e.g., apricots, carrots, leafy green and yellow vegetables) and vitamin C (e.g., fresh fruits and vegetables, especially citrus fruits).

### Personal Factors and Cancer Development

Personal factors, including IMMUNITY, age, and genetic risk, also affect whether an adult is likely to develop cancer.

*Immunity* protects the body from foreign invaders and non-self cells (see Chapter 17). Non-self cells include cells that are not normal such as cancer cells. Cell-mediated immunity, especially natural killer (NK) cells and helper T-cells, provides immune surveillance (Abbas et al., 2015).

Cancer incidence increases among patients with reduced IMMUNITY. Adults older than 60 years have reduced immunity and a higher incidence of cancer compared with that of the general population. Organ transplant recipients taking immunosuppressive drugs to prevent organ rejection also have a higher incidence of cancer. In patients with acquired immune deficiency syndrome (AIDS), cancer incidence is very high (ACS, 2017).

*Advancing age* is the single most important risk factor for cancer (ACS, 2017). As an adult ages, immunity decreases and external exposures to carcinogens accumulate. Teach older adults to be aware of and report symptoms such as the seven warning signs of cancer (Table 21-7) to health care

providers. Health care providers should investigate all symptoms suggestive of disease. Assessment considerations for the most common cancers that occur among older adult are listed in Chart 21-2.

**TABLE 21-7**  
**The Seven Warning Signs of Cancer**

C	Changes in bowel or bladder habits
A	A sore that does not heal
U	Unusual bleeding or discharge
T	Thickening or lump in the breast or elsewhere
I	Indigestion or difficulty swallowing
O	Obvious change in a wart or mole
N	Nagging cough or hoarseness

## Chart 21-2

# Nursing Focus on the Older Adult

## Cancer Assessment

CANCER TYPE	ASSESSMENT CONSIDERATION
Colorectal cancer	Ask the patient whether bowel habits have changed over the past year (e.g., in consistency, frequency, color). Is there any obvious blood in the stool? Test at least one stool specimen for occult blood during the patient's hospitalization. Encourage the patient to have a baseline colonoscopy. Encourage the patient to reduce dietary intake of animal fats, red meat, and smoked meats. Encourage the patient to increase dietary intake of bran, vegetables, and fruit.
Bladder cancer	Ask the patient about the presence of: Pain on urination Blood in the urine Cloudy urine Increased frequency or urgency
Prostate cancer	Ask the patient about: Hesitancy Change in the size of the urine stream Pain in the back or legs History of urinary tract infections
Skin cancer	Examine skin areas for moles or warts. Ask the patient about changes in moles (e.g., color, edges, sensation).
Leukemia	Observe the skin for color, petechiae, or ecchymosis. Ask the patient about: Fatigue Bruising Bleeding tendency History of infections and illnesses Night sweats Unexplained fevers
Lung cancer	Observe the skin and mucous membranes for color. How many words can the patient say between breaths? Ask the patient about: Cough Hoarseness Smoking history Exposure to inhalation irritants Exposure to asbestos Shortness of breath Activity tolerance Frothy or bloody sputum Pain in the arms or chest Difficulty swallowing

## Genetic/Genomic Considerations

### Patient-Centered Care QSEN

A hereditary genetic risk for cancer occurs only in a small percent of the population; however, adults who have a genetic predisposition are at very high risk for cancer development (Jorde et al., 2016). Mutations in suppressor genes or oncogenes can be inherited when they occur in sperm and ova and are then passed on to one's children, in whom all body cells contain the inherited mutations. Thus for some adults tight CELLULAR REGULATION is lost as a result of a mutation in a suppressor gene, which reduces or halts its function and allows oncogene overexpression. In other adults the suppressor genes are normal, and the oncogene is mutated and does not respond to suppressor gene signals, thus reducing cellular regulation and increasing the risk for cancer development. Table 21-8 lists conditions associated with an increased genetic risk for cancer development. Be sure to include questions about these conditions when performing a family history and develop at least a three-generation pedigree.

**TABLE 21-8****Conditions Associated With a Genetic Predisposition for Cancer**

CONDITION	SPECIFIC CANCER TYPE
Inherited cancers*	Breast cancer Prostate cancer Ovarian cancer
Familial clustering	Breast cancer Melanoma
Bloom syndrome	Leukemia
Familial polyposis	Colorectal cancer
Chromosomal aberrations	
Down syndrome (47 chromosomes)	Leukemia
Klinefelter syndrome (47,XXY)	Breast cancer
Turner's syndrome (45,XO)	Leukemia Gonadal carcinoma Meningioma Colorectal cancer

\*Not all breast, prostate, or ovarian cancers are inherited.

*Genetic testing for cancer predisposition* is available to confirm or rule out an adult's genetic risk for some specific cancer types. (See [Chapter 5](#) for explanation of genetic terminology.) These tests usually are performed on blood and are expensive. Genetic testing should not be performed unless a family history clearly indicates the possibility of increased genetic risk and the patient wants to have the test results. *These tests do not diagnose the presence of cancer; they only provide risk information.* Personal and family history facts that are considered “red flags” suggesting a genetic predisposition for cancer include:

- Cancer of any type appears in multiple members of every generation of a family, especially if an autosomal-dominant pattern of inheritance emerges
- Similar cancers appear in multiple first-degree relatives
- Multiple instances of rare cancer types occur within a family
- Cancer occurs at ages several decades younger than the national average
- Cancer develops in both of paired organs (e.g., bilateral breast cancer)
- Breast cancer is present in a genetic male adult, regardless of gender identity

A variety of issues and potential problems exist with genetic testing for cancer risk. Correct interpretation of the results is critical. Ideally a genetic counselor is involved in giving the patient information *before* as well as after testing is performed. *When a patient tests positive for a known cancer-causing gene mutation, his or her risk for cancer development is greatly increased; however, the cancer still may never develop.* A negative result means that the particular gene mutation tested for is not present. In addition, testing might not find the particular mutation but may indicate a different mutation with an unknown significance. This result is particularly frustrating for patients and health care providers.

Other issues regarding genetic testing include who will have access to the information and whether to share the test results with family members. Genetic testing has implications for the entire family, not just the patient being tested. For more information on genetic testing, see [Chapter 5](#).

## Cultural/Spiritual Considerations

### Patient-Centered Care QSEN

The incidence of cancer varies among races. American Cancer Society (ACS) data (2015b, 2016) show that African Americans have a higher incidence of cancer than whites and the death rate is higher for African Americans. Since 1960 the overall incidence among African Americans has increased 27%, whereas for whites it has increased only 12%. Cancer sites and cancer-related mortality also vary by race. A possible reason for the difference is that more African Americans have less access to health care. They are more often diagnosed with later-stage cancer that is more difficult to cure or control. However, this disparity in access does not explain all differences.

When risks for cancer development are assessed, behavior and socioeconomic factors are assessed along with ethnicity and genetic predisposition. The American Cancer Society (2016) reports that

cancer incidence and survival are often related to socioeconomic factors. These factors include the availability of health care services or the belief that seeking early health care has a positive effect on the outcome of cancer diagnosis.

## **NCLEX Examination Challenge 21-2**

### **Health Promotion and Maintenance**

Which statement by a client who has tested negative for a BRCA1 mutation (while her sister is positive) indicates to the nurse that the client has correct understanding of the results?

- A. "I will continue to perform monthly breast self-examinations."
- B. "It is a relief to know that I have no risk for breast cancer."
- C. "After I have my next child, I will have my ovaries removed."
- D. "I will wear softer bras to avoid putting pressure on or irritating my breasts."

## Cancer Prevention

Cancer prevention activities focus on primary prevention and secondary prevention. **Primary prevention** is the use of strategies to prevent the actual occurrence of cancer. This type of cancer prevention is most effective when there is a known cause for a cancer type. **Secondary prevention** is the use of screening strategies to detect cancer early, at a time when cure or control is more likely.

### Primary Prevention

*Avoidance of known or potential carcinogens* is an effective prevention strategy when a cause of cancer is known and avoidance is easily accomplished. For example, teach adults to use skin protection during sun exposure to avoid skin cancer. Most lung cancer can be avoided by not using tobacco and eliminating exposure to loose asbestos particles. Teach all adults about the dangers of cigarette smoking and other forms of tobacco use (see [the Health Promotion and Maintenance feature in Chapter 27](#)). Teach adults who are exposed to carcinogens in the workplace to use personal protective equipment that reduces direct contact with this substance. As more cancer causes are identified, avoidance may become even more effective.

*Modifying associated factors* appears to help reduce cancer risk. Absolute causes are not known for many cancers, but some conditions appear to increase risk. Examples are the increased incidence of cancer among adults who consume alcohol; the association of a diet high in fat and low in fiber with colon cancer, breast cancer, and ovarian cancer; and a greater incidence of cervical cancer among women who have multiple sexual partners (ACS, 2017). Modifying behavior to reduce the associated factor may decrease the risk for cancer development. Therefore teach all adults to limit their intake of alcohol to no more than one ounce per day and to include more fruits, vegetables, and whole grains in their diets. Instruct women about the importance of limiting the number of sexual partners and to use safer sex practices to avoid exposure to viruses that can increase the risk for cervical cancer (see [Table 21-6](#) for a listing of cancer-causing viruses).

*Removal of "at-risk" tissues* reduces cancer risk for an adult who has a known high risk for developing a specific type of cancer. Examples include removing moles to prevent conversion to skin cancer, removing colon polyps to prevent colon cancer, and removing breasts to prevent breast cancer. Not all "at-risk" tissues can be removed (e.g., those that are part of essential organs).

*Chemoprevention* is a strategy that uses drugs, chemicals, natural nutrients, or other substances to disrupt one or more steps important to cancer development. These agents may be able to reverse existing gene damage or halt the progression of the transformation process. Only a few agents have been found effective for chemoprevention. These include the use of aspirin and celecoxib (Celebrex) to reduce the risk for colon cancer, the use of vitamin D and tamoxifen to reduce the risk for breast cancer, and the use of lycopene to reduce the risk for prostate cancer (ACS, 2017).

*Vaccination* is a newer method of primary cancer prevention. Currently the only vaccines approved for prevention of cancer are related to prevention of infection from several forms of the human papilloma virus (HPV). These vaccines are Gardasil and Cervarix. As more cancer-causing viruses are identified, it is hoped that vaccines will be developed to prevent those viral infections.

### Secondary Prevention

Regular screening for cancer does not reduce cancer incidence but can greatly reduce some types of cancer deaths. Teach all adults the benefits of participating in specific routine screening techniques annually as part of health maintenance. General screening recommendations are listed in chapters discussing cancers by organ system. The age and type of participation in specific screening tests are different for adults who have an identified increased risk for a specific cancer type. In addition, there is some controversy about when the age and frequency for screening has the greatest benefit. Examples of recommended screenings include (ACS, 2017):

- The choice of annual mammography for women 40 to 44 years of age, annual mammography for women 45 to 54 years of age, and annual or biennial mammography for women over 55 years of age
- Annual clinical breast examination for women older than 40 years; every 3 years for women age 20 to 39 years.

- Colonoscopy at age 50 years and then every 10 years
- Annual fecal occult blood for adults of all ages
- Digital rectal examination (DRE) for men older than 50 years

Because cancer development clearly involves gene changes (either inherited gene mutations or acquired damage-induced gene mutations), adults can be screened for some gene mutations that increase the risk for cancer. A few examples of known gene mutations that increase cancer risk are found in the *BRCA1* gene, the *BRCA2* gene, and the *CHEK2* gene (which increase the risk for breast cancer) and mutations in the *APC*, *MLH1*, and *MSH2* genes (which increase the risk for colon cancer).

When a patient has a strong family history of either breast or colon cancer, create a three-generation pedigree to more fully explore the possibility of genetic risk. If a pattern of risk emerges, inform the person about the possible benefits of genetic screening and advise him or her to talk with an oncology health practitioner or genetics professional for more information. Genetic screening can help an adult at increased genetic risk for cancer to alter lifestyle factors, participate in early detection methods, initiate chemoprevention, or even have at-risk tissue removed. Genetic screening has some personal risks, as well as potential benefits (see [Chapter 5](#)).

## NCLEX Examination Challenge 21-3

### Health Promotion and Maintenance

Which actions does the nurse teach a client as **primary** cancer prevention strategies? **Select all that apply.**

- A. Avoiding sun exposure
- B. Having an annual digital rectal examination
- C. Having genetic testing for specific colon cancer-causing genes
- D. Performing monthly breast self-examinations
- E. Quitting cigarette smoking
- F. Having a mole surgically removed

# Get Ready for the NCLEX® Examination

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Health Promotion and Maintenance

- Teach adults to avoid tanning beds and to use sunscreen and wear protective clothing during sun exposure. **QSEN: Patient-Centered Care**
- Encourage patients to participate in the recommended cancer-screening activities for their age-group and cancer risk category. **QSEN: Patient-Centered Care**
- Assist adults interested in smoking cessation to find an appropriate smoking cessation program (see [Chapter 27](#)). **QSEN: Patient-Centered Care**
- Assess the patient's knowledge about causes of cancer and his or her screening/prevention practices. **QSEN: Patient-Centered Care**
- Ask all patients about their exposures to environmental agents that are known or suspected to impair CELLULAR REGULATION and increase the risk for cancer. **QSEN: Evidence-Based Practice**
- Obtain a detailed family history (at least three generations) and use this information to create a pedigree to assess the patient's risk for familial or inherited cancer. **QSEN: Patient-Centered Care**
- Teach anyone, especially older adults, the “seven warning signs of cancer” (see [Table 21-7](#)). **QSEN: Evidence-Based Practice**

### Physiological Integrity

- Be aware of these facts regarding cancer risk and cancer development:
  - Cancer cells originate from normal body cells.
  - Transformation of a normal cell into a cancer cell involves mutation of the genes (DNA) of the normal cell and results in the loss of CELLULAR REGULATION.
  - Oncogenes that are overexpressed can cause a cell to develop into a tumor.
  - Most tumors arise from cells that are capable of cell division.
  - A key feature of cancer cells is the loss of CELLULAR REGULATION and apoptosis. These cells have an “infinite” life span.
  - Tobacco use is a causative factor in 30% of all cancers.
  - Adults with reduced IMMUNITY have a higher risk for cancer development.
  - Tumors that metastasize from the primary site into another organ are still designated as tumors of the originating tissue.
  - Cancer cells that are less differentiated and have a higher mitotic index are “more malignant” and harder to cure.

## CHAPTER 22

# Care of Patients With Cancer

Constance G. Visovsky, Julie Ponto

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is IMMUNITY.**

**The interrelated concepts for this chapter are:**

- CELLULAR REGULATION
- CLOTTING
- GAS EXCHANGE
- SENSORY PERCEPTION

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to coordinate high-quality care to patients receiving cancer therapy.
2. Protect yourself and others from cytotoxic agents and radiation.
3. Teach the patient and caregiver(s) how impaired IMMUNITY, impaired CLOTTING, and other changes caused by cancer or cancer therapy affect home safety.

### Health Promotion and Maintenance

4. Identify community resources for patients with cancer.

### Psychosocial Integrity

5. Implement nursing interventions to help the patient and family cope with the psychosocial impact caused by cancer and cancer therapy.

### Physiological Integrity

6. Apply knowledge of pathophysiology to assess patients with common problems and complications caused by cancer and cancer therapy, including oncologic emergencies.
7. Teach the patient and caregiver(s) about common drugs used for cancer therapy and its complications, including pain, impaired IMMUNITY, and impaired CLOTTING.
8. Prioritize interprofessional collaborative care for patients who experience an oncologic emergency.

With new treatment strategies resulting in more than 68% of people diagnosed with cancer being cured and thousands of others living 5 years or longer, cancer is considered a chronic illness ([American Cancer Society \[ACS\], 2017](#); [Canadian Cancer Society, 2016](#)). Survivors may have exacerbations and remissions of the disease over their lifetimes. *Regardless of the treatment received, cancer has a negative impact on the adult's physical and psychological functioning and quality of life.*

Providing care to patients experiencing cancer and their families is complex, challenging, and best accomplished with an interprofessional team approach. This chapter describes the general interventions for cancer and the problems associated with cancer treatment. For treatments and patient problems that occur with specific cancer types, consult the chapters in which the cancer is described. [Table 22-1](#) lists common cancer types and the specific locations within this text where the

interventions are presented.

---

**TABLE 22-1**  
**Text Location of Specific Cancer Content**

---

CANCER TYPE	CHAPTER
Bladder (urothelial)	66
Brain	45
Breast	70
Cervical	71
Colorectal	56
Esophageal	54
Head and Neck	29
Leukemia	40
Lung	30
Lymphoma	40
Ovarian	71
Prostate	72
Renal cell carcinoma	67
Skin	25
Stomach (gastric)	55

## Impact of Cancer on Physical Function

Cancer can develop in any organ or tissue, reducing the function of that tissue or organ. Cancers that occur in nonvital tissues (such as the breast) can cause death by **metastasizing** (spreading) into vital organs (e.g., brain, liver, bone marrow) and disrupting critical physiologic processes (see [Chapter 21](#)). Advanced cancers often have an impact on:

- IMMUNITY and CLOTTING
- GI function
- Peripheral nerve SENSORY PERCEPTION
- Central motor and sensory function
- Respiratory and cardiac function
- Comfort and quality of life

### Impaired Immunity and Clotting

Impaired IMMUNITY and blood-producing functions can occur when cancer starts in *or* invades the bone marrow, where blood cells are formed. Tumor cells enter the bone marrow and reduce the production and function of healthy white blood cells (WBCs) that are needed for normal immunity. Thus patients who have cancer, especially leukemia, are at an increased risk for infection ([McCance et al., 2014](#)). Some cancer treatments, especially chemotherapy, reduce neutrophil WBC numbers, making the patient more prone to infection.

Bone marrow invasion by cancer cells causes anemia by decreasing the number of red blood cells, and it causes thrombocytopenia (decreased number of platelets), resulting in impaired CLOTTING. These changes may be caused by the disease or by cancer treatment, especially chemotherapy. The patient with anemia usually has fatigue, shortness of breath, and tachycardia.

### Altered GI Function

Tumors of the GI tract increase the metabolic rate and the need for nutrients; however, many patients suffer from disease-related and treatment-related appetite loss, and alterations in taste that have a negative impact on nutrition, leading to weight loss. **Cachexia** (extreme body wasting and malnutrition) develops from an imbalance between food intake and energy use (increased catabolism from cancer) and may occur despite adequate nutrition intake. Some patients experience early satiety or a sense of fullness even when only small volumes are ingested.

Nutrition support for the patient with cancer, especially one undergoing cancer therapy, is complex. There is no one recommended dietary approach to maintaining good nutrition during cancer treatment. Many approaches such as eating smaller, frequent meals, taking nutritional supplemental drinks between meals, and generally eating a healthy diet rich in complex carbohydrates (fiber) and protein are suggested. For patients who cannot take oral nutrition, enteral tube feeding or parenteral nutrition may be recommended. A registered dietitian is part of the interprofessional team and consulted for patients who have nutrition difficulties that accompany cancer and its treatment.

Abdominal tumors may obstruct or compress structures anywhere in the GI tract, reducing the ability to absorb nutrients and eliminate wastes. This problem needs to be addressed promptly to avoid complications such as a bowel obstruction.

Tumors that invade the liver have profound effects on this organ, which has many important metabolic functions. Liver damage has the potential to lead to malnutrition and death.

### Altered Peripheral Nerve Function

Although tumors in the spine can change peripheral nerve function, the more common cause is chemotherapy. Neurotoxic chemotherapy agents injure peripheral nerves, leading to peripheral neuropathy with reduced SENSORY PERCEPTION. Patients with chemotherapy-induced peripheral neuropathy (CIPN) report loss of sensation, especially in the lower extremities. Symptoms include numbness, tingling, neuropathic pain, and changes in gait and balance. Physical assessment of the

degree of sensory perception loss can be performed using monofilaments as described in [Chapter 64](#). Several instruments for self-report of CIPN and severity grading also are available ([Curcio, 2016](#); [Kaplow & Iyer, 2017](#)).

For patients who already have peripheral neuropathy from problems such as diabetes or AIDS, chemotherapy increases its severity. CIPN is a dose-limiting toxicity of cancer chemotherapy treatment. This means that the development or increased severity of CIPN that has a negative impact on ADLs may result in a reduction of the optimum chemotherapy dose, potentially changing the outcome of cancer treatment.

## Motor and Sensory Deficits

Motor and SENSORY PERCEPTION deficits occur when cancers invade bone or the brain or compress nerves. In patients with bone metastasis, the primary cancer started in another organ (e.g., lung, prostate, breast). Bones become thinner, with an increased risk for fractures that can occur with minimal trauma. Bone metastasis causes pain, fractures, spinal cord compression, and hypercalcemia, each of which reduces mobility. Spinal cord compression and hypercalcemia are *oncologic emergencies* and require immediate attention (see discussion of [Oncologic Emergencies](#)).

Patients have sensory perception changes if the spinal cord is damaged or if nerves are compressed. Sensory, motor, and cognitive functions are impaired when cancer spreads to the brain. Any tumor, malignant or benign, growing in the brain can destroy healthy brain tissue and lead to death.

## Cancer Pain

The patient with cancer may have pain, especially chronic pain. Pain does not always accompany cancer, but it can be a major problem. Cancer pain is best managed by an interprofessional team that includes an oncologist, advanced oncology nurse practitioner, certified oncology nurse, interventional radiologist, radiation oncologist, and pain management specialists. Patient education is needed to manage side effects of pain drugs, including constipation. [Chapter 4](#) discusses the causes and management of pain.

## Altered Respiratory and Cardiac Function

Cancer can disrupt respiratory function, capacity, and GAS EXCHANGE and may result in death. Tumors that grow in the airways cause obstruction. If lung tissue is involved, lung capacity is decreased, leading to dyspnea and hypoxemia. Cancer cells thicken the alveolar membrane and damage lung blood vessels, both of which impair gas exchange. Patients are at risk for hypoxemia and hypoxia with either primary or metastatic lung tumors.

Tumors can also press on blood and lymph vessels in the chest, which results in airway compression and dyspnea. Superior vena cava syndrome is an oncologic emergency that results from compression of this vessel.

Both radiation therapy and certain chemotherapy agents can affect cardiac function. Following radiation to the chest, even with appropriate shielding, cardiac events may occur at a younger age in cancer patients compared with the general population. Cardiac conditions from radiation include pericarditis, coronary artery disease, myocardial dysfunction, and valvular heart disease. Higher risk for heart disease has been noted in patients with classic risk factors for cardiac problems such as hypertension, smoking, and hypercholesterolemia. Chemotherapy agents can also contribute to cardiac dysfunction through loss of myocardial muscle mass, leading to heart failure. These late effects of therapy are sometimes reversible but may be permanent.

## Cancer Management

The purpose of cancer management is to cure or control the disease while minimizing the side effects of therapy. For certain cancer types such as leukemia, failure to treat the disease would result in death within weeks to months. Cancer therapy includes surgery, radiation, chemotherapy, immunotherapy (e.g., biological response modifiers, molecularly targeted therapy), photodynamic therapy, and hormonal therapy. These therapies may be used separately or in combination to kill cancer cells. The types of therapy used depend on the specific type of cancer, whether the cancer has spread, and the overall health and functional status of the patient. Treatment regimens (*protocols*) have been established for most types of cancer.

### Surgery

#### Overview

Surgery often plays a part in the diagnosis and/or management of cancer. Typically surgery is only one part of a comprehensive treatment approach for cancer therapy. It is used for prophylaxis, diagnosis, cure, control, palliation, assessment of therapy effectiveness, and tissue reconstruction.

*Prophylactic surgery* removes potentially cancerous tissue as a means of preventing cancer development. It is performed when a patient has either an existing premalignant condition or a strong predisposition for development of a specific cancer. For example, removing a benign polyp from the colon before it can develop into colon cancer is considered prophylactic surgery.

*Diagnostic surgery* (excisional biopsy) is the removal of all or part of a suspected lesion for examination and testing to confirm or rule out a cancer diagnosis. Exploratory surgery is a more extensive approach that may be performed if the suspicion of cancer cannot be confirmed by a less invasive means. Cancer treatment is not initiated without tissue confirmation of a cancer diagnosis.

*Curative surgery* removes all cancer tissue. Surgery alone can result in a cure when all visible and microscopic tumor is removed or destroyed. It is most effective for small localized tumors or noninvasive skin cancers such as basal cell lesions.

*Cancer control* or *cytoreductive surgery* removes part of the tumor when removal of the entire mass is not possible. It is also known as “debulking” surgery and decreases the size of the tumor and the number of cancer cells, which can alleviate symptoms and enhance the success of other types of cancer treatment, as well as increase survival time.

*Palliative surgery* focuses on providing symptom relief and improving the quality of life but is not curative. Examples include removal of tumor tissue that is causing pain, obstruction, or difficulty swallowing, and the treatment of neuropathic pain from bone metastasis (Roos, 2015).

*Reconstructive* or *rehabilitative surgery* increases function, enhances appearance, or both. Examples include breast reconstruction after mastectomy, reconstruction of the esophagus after surgical removal for esophageal cancer, bowel reconstruction, revision of scars, and cosmetic reconstruction in head and neck cancer.

#### Side Effects of Surgical Therapy

Cancer surgery often involves the loss of a body part or its function to ensure removal of all cancerous tissue. Sometimes whole organs are removed such as the kidney, lung, breast, testis, limb, or tongue. *Any organ loss reduces function*. Some cancer surgeries result in scarring or disfigurement. For example, the tongue and part of the mandible or larynx may be removed in patients with head and neck cancers (see Chapter 29). Often patients express the desire to have all cancerous tissue removed, which is not usually possible. Patients may not understand that cancer cells often escape from the original tumor, making cancer a systemic disease. Following some cancer surgeries, the removal of the affected area can cause profound changes in appearance or activity level and can lead to depression, grief, and decreased enjoyment of life.

#### ❖ Interprofessional Collaborative Care

The overall care needs following surgery for cancer are similar to the care required for patients who undergo surgery for other reasons (see Chapters 14, 15, and 16). For cancer surgery, additional priority care needs are psychosocial support and helping the patient achieve maximum functioning.

Often cancer surgery occurs shortly after the diagnosis, before the patient and family have time to adjust to a cancer diagnosis. The stress of the diagnosis can have a significant impact on the patient's and family's ability to understand any teaching provided at this time. Assess the patient's and family's ability to cope with the cancer diagnosis and its treatment and with the potential changes in body image and role. For example, surgery involving the genitals, urinary tract, colon, or rectum may permanently damage these organs, resulting in changes or losses that have an impact on sexual expression or control of elimination.

Coordinate with the interprofessional team to provide support and assistance to the patient and his or her family. Encourage the patient and family to ask questions and express their concerns. Help the patient accept changes in appearance or function by encouraging him or her to look at the surgical site, touch it, and participate in its care, including dressing changes. Provide information about support groups such as those sponsored by the ACS ([www.cancer.org](http://www.cancer.org)) and the Canadian Cancer Society ([www.cancer.ca](http://www.cancer.ca)). Some organizations also have support groups for patients' spouses, caregivers, and children and may provide visits from cancer survivors who have coped with the same cancer or concerns. Such visits can help show the patient that many aspects of life can be the same after cancer treatment. For patients who have persistent anxiety or depression as a result of the cancer experience, initiation of drug therapy and/or inclusion of a mental health professional as part of the interprofessional team is indicated.

Physical rehabilitation to improve physical functioning may be indicated after cancer surgery. For example, a modified radical mastectomy for breast cancer can lead to shoulder muscle weakness and reduced arm function on the affected side. Performing specific exercises after surgery can reduce functional loss. Head and neck cancer surgery often requires therapy to improve swallowing and speech. Teaching patients about the importance of performing the exercises to regain as much function as possible and prevent complications is an important nursing function, even though therapy can be painful and challenging. The patient needs encouragement to perform the expected activities. The physical therapist and occupational therapist coordinate with other members of the interprofessional team to plan strategies individualized to each patient to regain or maintain optimal function.

The role of surgery in cancer care continues to change. Laparoscopic and other minimally invasive approaches with smaller incisions and robotic access to internal body cavities have reduced some risks (see [Chapters 14](#) and [15](#)). Regardless of the surgical approach, nurses have a critical role in the patient's recovery after surgery, such as reinforcing the importance of early mobility, pain management, and prevention of infection.

The use of surgery in combination with other therapies has increased and includes intraoperative radiation therapy, the placement of a radioactive source, or the administration of chemotherapy into a body cavity. Other uses include surgical placement of internal catheters into a specific vessel and placement of electronic pumps for chemotherapy or pain drugs.

## Radiation Therapy

### Overview

Radiation therapy (radiotherapy) uses high-energy radiation from gamma rays, radionuclides, or ionizing radiation beams to kill cancer cells, provide disease control, or relieve symptoms. The delivery of radiation should accomplish these actions with minimal damaging effects on the surrounding normal cells.

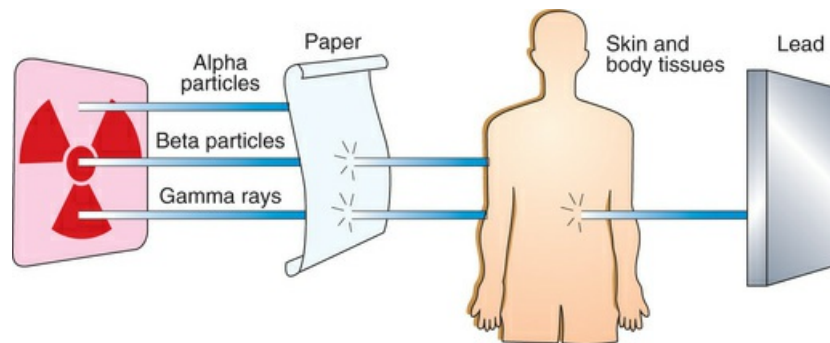

The effects of radiation are seen only in tissues within the radiation field or path; thus this type of therapy is a *local* treatment. For example, radiation to the chest for lung cancer causes skin changes and hair loss only on the chest area that is irradiated. There are no effects seen elsewhere on the body. When total body irradiation (TBI) is used, *all* body areas are affected. Other systemic radiation therapy uses a radioactive substance such as a radiolabeled monoclonal antibody that travels in the blood to tissues throughout the body to target cancerous cells. Radiation therapy has both short- and long-term effects, depending on the area(s) radiated. For example, a short-term effect is redness or desquamation of the skin, whereas a long-term effect can be pulmonary fibrosis from radiation of the chest.

When cancer cells are exposed to ionizing radiation, the cell's DNA is damaged directly, or DNA-damaging charged particles (free radicals) are formed, resulting in a change in CELLULAR REGULATION. These damaged cells usually can no longer reproduce or function, leading to cell death.

However, normal cells in the field of radiation are also affected by radiation. Thus careful planning of the radiation field by a radiation physicist is necessary to minimize damage to normal tissues.

The energy produced by radioactive elements (gamma rays, alpha particles, beta particles) varies in its ability to penetrate tissues and damage cells (Fig. 22-1). *Gamma rays* are used most commonly for radiation therapy because of their ability to deeply penetrate tissues. *Beta particles* are weaker and must be placed within or very close to the cancer cells for cancer therapy (see discussion of brachytherapy in the [Radiation Delivery Methods and Devices](#) section).

**FIG. 22-1** Penetrating capacity of different types of radiation.

The amount of radiation delivered to a tissue is the **exposure**; the amount of radiation absorbed by the tissue is the **radiation dose**. The dose is always less than the exposure because some energy is lost as it travels to the destination. The three factors determining the absorbed dose are the *intensity* of exposure, the *duration* of exposure, and the *closeness* (distance) of the radiation source to the cells. Absorbed radiation doses are described in units called **gray** (Gy). One Gy is equal to one joule of energy absorbed by 1 kg of a material. The total dose of radiation used depends on tumor size and location and on the radiation sensitivity of the tumor and nearby tissues. Some normal tissues are more sensitive than others to radiation. For example, breast tissue tolerates much higher doses of radiation than the liver does. A total dose of 50 to 60 Gy might be prescribed for a breast cancer. However, only 12 Gy might be prescribed for a liver tumor because a higher dose would destroy healthy liver cells as well as the tumor.

Radiation therapy usually is given as a series of divided doses (fractionation) because of the varying responses of all cancer cells within one tumor (Mitchell, 2013). Most often small doses of radiation are given on a daily basis for a set time period to allow greater destruction of cancer cells while reducing the damage to normal tissues.

The intensity of the radiation decreases with the distance from the radiation-emitting source. This factor is known as the *inverse square law*. For example, the radiation dose received at a distance of 2 meters from the radiation source is only one fourth of the dose received at a distance of 1 meter from the radiation source; the dose of radiation received at 3 meters is only one ninth of the dose received at 1 meter.

Cancer radiation therapy does not immediately kill all cells within a tumor because the cells absorb the radiation dose slightly differently and their overall response to the radiation is slightly different (Mitchell, 2013). A few tumor cells die immediately, and more die within the next few days. Some tumor cells are unable to divide as a result of a single treatment. Still other tumor cells repair the radiation-induced damage, recover, and continue to grow.

Radiation may be used as a stand-alone treatment or may be combined with other cancer therapies. Combining therapies requires careful planning of sequencing, timing, and dose of each therapy to maximize tumor kill and limit damage to normal cells. Often combining radiation with chemotherapy or immunotherapy involves first giving agents that radiosensitize to enhance the radiation damage and result in a greater cell kill than either therapy used alone.

### Radiation Delivery Methods and Devices

Radiation cancer treatment can be delivered by external beam (teletherapy) or internal devices (brachytherapy). The type used depends on the patient's general health and on the shape, size, and location of the tumor. The ideal radiation dose is one that kills the cancer cells with an acceptable

level of damage to normal tissues (damage to normal tissues cannot be avoided).

*External beam or teletherapy* is radiation delivered from a source outside of the patient. *Because the source is external, the patient is not radioactive, and there is no hazard to others.* The technique called *intensity-modulated radiation therapy (IMRT)* reduces the amount of normal tissue exposed to radiation by breaking up the single beam into thousands of smaller beams, allowing differing intensities to be delivered to specific areas of the tumor. Stereotactic body radiotherapy (SBRT) uses three-dimensional tumor imaging to identify the exact tumor location, which allows precise delivery of higher radiation doses and spares more of the surrounding tissue. Usually the total dosage is delivered in one to five separate treatment sessions. Other specialized radiation application techniques used in combination with surgery are known as *radiosurgery*. This type of surgery uses ionizing radiation as the surgical instrument instead of a cutting blade. Examples are the gamma knife and the CyberKnife that are used for the treatment of brain tumors by carefully aiming the radiation target point within the brain, sparing normal brain tissue.

Regardless of the delivery method, the exact tumor location is first determined, and the area is fixated and/or the skin marked for therapy precision. The markings may be small, permanent “tattoos”; ink outlines on the skin; or a marked mask laid over the skin. Position-fixing devices include customized external body molds, foam-based body molds, and fiberglass splints. Once the pattern of radiation delivery is decided, the patient must always be in exactly the same position for all treatments. Radiation oncology nurses ensure the patient's ability to get into and maintain this position.

*Brachytherapy*, also known as internal radiotherapy, means “short” (close) therapy. The radiation source comes into direct, continuous contact with the tumor for a specific time period. This method provides a higher dose of radiation in the tumor over a specified time period, limiting the dose in surrounding normal tissues.

Brachytherapy uses radioactive isotopes either in solid form or within body fluids. Isotopes can be delivered to the tumor tissues in several ways. *With all types of brachytherapy, the radiation source is within the patient. Therefore the patient emits radiation for a period of time and is a potential hazard to others.* When the isotopes used are unsealed and suspended in a fluid, they are given by the oral or IV routes or instilled within body cavities. An example of brachytherapy with soluble isotopes is the ingestion or injection of the radionuclide iodine-131 ( $^{131}\text{I}$ ) (an iodine base with a half-life of 8.05 days) to treat some thyroid cancers. The iodine concentrates in the thyroid gland and destroys the thyroid cancer cells.

## Nursing Safety Priority QSEN

### Action Alert

Unsealed isotopes enter body fluids and eventually are eliminated in waste products. These wastes are radioactive, and you must ensure that they are not directly touched by anyone. Handle the wastes according to guidelines established by the institution. During hospitalization for high-dose rate implant radiation, pregnant women and children are not allowed to visit the patient. After the isotope is completely eliminated from the body, neither the patient nor the body wastes are radioactive.

Solid or sealed radiation sources are implanted within or near the tumor. These sources can be temporary or permanent. Most implants emit continuous, low-energy radiation to tumors. Some devices (e.g., seeds or needles) can be placed into the tumor and stay in place by themselves. Seeds are so small and the half-life of the isotope is so short that this device is permanently left in place (often for prostate cancer) and, over time, completely loses its radioactivity. Other devices are removed and reused in other patients. Some sources must be held in place during therapy using special applicators. *While the solid implants are in place, the patient emits radiation but excreta are not radioactive. Thus at this time the patient poses a hazard to others, but the excreta do not.*

Traditional implants deliver “low-dose rates” (LDRs) of radiation continuously, and patients are hospitalized for several days. “High-dose rate” (HDR) implant radiation is another delivery type. The patient comes into the radiation therapy department several times a week, and a stronger radiation implant is placed for only an hour or so each time. The patient is radioactive only when the implant is in place. [Chart 22-1](#) lists the best practices for the safety of the personnel providing

care to the patient with a sealed radiation implant.

### Chart 22-1

## Best Practice for Patient Safety & Quality Care QSEN

### Care of the Patient With Sealed Implants of Radioactive Sources

- Assign the patient to a private room with a private bath.
- Place a “Caution: Radioactive Material” sign on the door of the patient's room.
- If portable lead shields are used, place them between the patient and the door.
- Keep the door to the patient's room closed as much as possible.
- Wear a dosimeter film badge at all times while caring for patients with radioactive implants. The badge offers no protection but measures a person's exposure to radiation. Each person caring for the patient should have a separate dosimeter to calculate his or her specific radiation exposure.
- Wear a lead apron while providing care. Always keep the front of the apron facing the source of radiation (do not turn your back toward the patient).
- If you are attempting to conceive, do not perform direct patient care, regardless of whether you are male or female.
- Pregnant nurses should not care for these patients; do not allow pregnant women or children younger than 16 years to visit.
- Limit each visitor to one-half hour per day. Be sure visitors stay at least 6 feet from the source.
- Never touch the radioactive source with bare hands. In the rare instance that it is dislodged, use a long-handled forceps to retrieve it. Deposit the radioactive source in the lead container kept in the patient's room.
- Save all dressings and bed linens in the patient's room until after the radioactive source is removed. After the source is removed, dispose of dressings and linens in the usual manner. Other equipment can be removed from the room at any time without special precautions and does not pose a hazard to other people.

A recent study examined the effectiveness of a single treatment of CT-guided high-dose brachytherapy applied through a catheter to ablate liver metastases from 20 patients with pancreatic cancer. The rate of local tumor control was 91% for the patients in this study, showing this type of brachytherapy to be safe and effective for treating this type of liver metastases (Wieners et al., 2015).

### Side Effects of Radiation Therapy

Radiation therapy can result in both acute and long-term side effects (Table 22-2). These side effects vary according to the radiation site and largely are limited to the areas exposed to radiation. Changes to the skin, known as *radiation dermatitis*, are the most common side effects of radiotherapy and can range from redness and rash to skin desquamation (Bauer, 2016). Multiple factors, including total radiation dose, duration of radiotherapy, and concurrent chemotherapy, can affect skin response to radiation. These changes may be permanent. Radiation to the head may result in permanent hair loss.

**TABLE 22-2**

### Acute and Late Site-Specific Effects of Radiation Therapy

ACUTE EFFECTS	LATE EFFECTS
<b>Brain</b> <ul style="list-style-type: none"> <li>• Alopecia and radiodermatitis of the scalp</li> <li>• Ear and external auditory canal irritation</li> <li>• Cerebral edema</li> <li>• Nausea and vomiting</li> <li>• Somnolence syndrome</li> </ul> <b>Head and Neck</b> <ul style="list-style-type: none"> <li>• Oral mucositis</li> <li>• Taste changes</li> <li>• Oral candidiasis</li> <li>• Oral herpes</li> <li>• Acute xerostomia</li> <li>• Dental caries</li> <li>• Esophagitis and pharyngitis</li> </ul> <b>Breast and Chest Wall</b> <ul style="list-style-type: none"> <li>• Skin reactions</li> <li>• Esophagitis</li> </ul> <b>Chest and Lung</b> <ul style="list-style-type: none"> <li>• Esophagitis and pharyngitis</li> <li>• Taste changes</li> <li>• Pneumonia</li> </ul> <b>Abdomen and Pelvis</b> <ul style="list-style-type: none"> <li>• Anorexia</li> <li>• Nausea and vomiting</li> <li>• Diarrhea and proctitis</li> <li>• Cystitis</li> <li>• Vaginal dryness/vaginitis</li> </ul> <b>Eye</b> <ul style="list-style-type: none"> <li>• Conjunctival edema and tearing</li> </ul>	<b>Subcutaneous and Soft Tissue</b> <ul style="list-style-type: none"> <li>• Radiation-induced fibrosis</li> </ul> <b>Central Nervous System</b> <ul style="list-style-type: none"> <li>• Brain necrosis</li> <li>• Leukoencephalopathy</li> <li>• Cognitive and emotional dysfunction</li> <li>• Pituitary and hypothalamic dysfunction</li> <li>• Spinal cord myelopathies</li> </ul> <b>Head and Neck</b> <ul style="list-style-type: none"> <li>• Xerostomia and dental caries</li> <li>• Trismus</li> <li>• Osteoradionecrosis</li> <li>• Hypothyroidism</li> </ul> <b>Lung</b> <ul style="list-style-type: none"> <li>• Pulmonary fibrosis</li> </ul> <b>Heart</b> <ul style="list-style-type: none"> <li>• Pericarditis</li> <li>• Cardiomyopathy</li> <li>• Coronary artery disease</li> </ul> <b>Breast/Chest Wall</b> <ul style="list-style-type: none"> <li>• Atrophy, fibrosis of breast tissue</li> <li>• Lymphedema</li> </ul> <b>Abdomen and Pelvis</b> <ul style="list-style-type: none"> <li>• Small and large bowel injury</li> </ul>

Some systemic side effects such as altered taste, fatigue, and bone marrow suppression may also occur. Taste changes are thought to be caused by metabolites released after cell death. Many patients develop an aversion to the taste of red meats. Fatigue may be related to the increased energy demands needed to repair damaged cells. Regardless of the cause, radiation-induced fatigue can be debilitating and may last for months. Some degree of bone marrow suppression and reduced IMMUNITY occurs, regardless of the treatment site. The intensity of marrow suppression is related to the dose, site, and size of the area irradiated.

Radiation damage to normal tissues during therapy can start inflammatory responses that lead to tissue fibrosis and scarring. These effects may appear years after radiation treatment. For example, women who receive HDR therapy for uterine cancer may develop radiation-induced colon changes (which was in the radiation path) years later, resulting in constipation and obstruction. A recent study of 99 patients with gynecologic cancer who received pelvic radiation reported having the following acute GI side effects: diarrhea (64%), proctitis (55%), nausea (33.3%), and vomiting (16.2%) (Hafiz et al., 2015). Because radiation can damage and mutate normal cell DNA, which disrupts CELLULAR REGULATION, radiation therapy increases the risk for development of second malignancies.

Radiation therapy can contribute to the development of cardiovascular disease through effects on collateral blood flow and by increasing the risk for atherosclerosis over time. It is hypothesized that certain areas of the heart may be more susceptible to radiation. For example, women with left-sided breast tumors receiving radiation to the area have a fourfold to sevenfold higher incidence of left anterior descending artery stenosis compared with women who had right-sided tumors (Zagar et al., 2015).

Not all patients experience the same degree of side effects to normal tissues, even when receiving the same dose of radiation therapy. Genetic differences appear to influence how sensitive any person's normal tissues are to radiation damage (Proud, 2014).

### ❖ Interprofessional Collaborative Care

Patients and family members are anxious about radiation and look to the nurse and radiation technician to explain the purpose and side effects of radiation therapy. Accurate information about radiation therapy helps patients cope with the treatment.

Skin in the radiation path becomes dry and may break down. Teaching patients about skin care needs during radiation therapy is a priority intervention. Instruct the patient to not remove temporary ink markings when cleaning the skin until radiation therapy is completed. There are no universal evidence-based interventions for skin care during radiation therapy. It is important to teach patients to avoid skin irritation from clothing.

Good skin hygiene involves washing the irradiated area with mild soap and water and avoiding skin scrubbing. The use of non-aluminum-containing deodorant is recommended. Limited evidence supports the use of any lotion or ointment to decrease radiation dermatitis (Bauer, 2016). Chart 22-2 is an example of an established skin-care protocol during external radiation therapy.

#### Chart 22-2

## Patient and Family Education: Preparing for Self-Management

### Skin Protection During Radiation Therapy

- Wash the irradiated area gently each day with either water or a mild soap and water as prescribed by your radiation therapy team.
- Use your hand rather than a washcloth when cleansing the therapy site to be gentler.
- Rinse soap thoroughly from your skin.
- If ink or dye markings are present to identify exactly where the beam of radiation is to be focused, take care not to remove them.
- Dry the irradiated area with patting rather than rubbing motions; use a clean, soft towel or cloth.
- Use only powders, ointments, lotions, or creams that are prescribed by the radiation oncology department on your skin at the radiation site.
- Wear soft clothing over the skin at the radiation site.
- Avoid wearing belts, buckles, straps, or any type of clothing that binds or rubs the skin at the radiation site.
- Avoid exposure of the irradiated area to the sun:
  - Protect this area by wearing clothing over it.
  - Try to go outdoors in the early morning or evening to avoid the more intense sun rays.
  - When outdoors, stay under awnings, umbrellas, and other forms of shade during the times when the sun's rays are most intense (10 AM to 7 PM).
- Avoid heat exposure.

### Nursing Safety Priority QSEN

#### Action Alert

Skin in the radiation path becomes *photosensitive*, increasing the risk for sunburn and sun damage. Advise against direct skin exposure to the sun during treatment and for at least 1 year after completing radiation therapy.

The normal tissues most sensitive to external radiation are bone marrow cells, skin, mucous membranes, hair follicles, and germ cells (ova and sperm). When possible, these tissues are shielded from radiation during therapy. The long-term problems of radiotherapy vary with the location and dose received (see [Table 22-2](#)). For example, radiation to the throat and upper chest can cause difficulty in swallowing and can lead to reduced nutrition. A registered dietitian is part of the interprofessional oncology team. Head and neck radiation may damage the salivary glands and cause dry mouth (**xerostomia**), which has a negative impact on speaking, chewing, and swallowing, and increases the patient's lifelong risk for tooth decay. Interventions such as saliva-substitute

sprays, lozenges, and mouth rinses may be helpful. Teach patients that regular dental visits are essential. Bone exposed to radiation therapy is less dense and breaks more easily (the cause of pathologic fractures). Fatigue remains a common and often persistent problem during and for some time after radiation therapy. Exercise and sleep interventions have shown some benefit in reducing fatigue. Teach about the symptoms that might be expected from the specific location and dose of radiation (see Table 22-1 for the location of information within this text for different cancer types).

## NCLEX Examination Challenge 22-1

### Safe and Effective Care Environment

Which statements regarding care of the client receiving radiotherapy in the form of unsealed radioactive isotopes guides the nurse's care planning? **Select all that apply.**

- A. The client may have restrictions on who can visit and for how long.
- B. The client must be in total isolation while the isotopes are in place.
- C. When “seeds” are used for prostate cancer therapy, the client must have them removed before leaving the hospital.
- D. The client's urine and stool must be handled as radioactive material.
- E. The nurse must ensure that all personnel entering the client's room use appropriate precautions.
- F. Only female nurses who are past menopause can be assigned to care for this client.

### Cytotoxic Systemic Therapy

Cytotoxic systemic therapy refers to the use of antineoplastic (chemotherapy) drugs that are used to kill cancer cells and disrupt their CELLULAR REGULATION. Chemotherapy may be used as the only cancer treatment received, before or after other treatments, or in combination with other cancer treatments. Unlike surgery or radiation, cytotoxic chemotherapy kills cancer cells (and normal cells) throughout the body. Some areas of the body, such as the blood-brain barrier, are more difficult than others for chemotherapy agents to penetrate. In general chemotherapy agents can be used to shrink a tumor before surgery or radiation. This is called *neoadjuvant chemotherapy*. When chemotherapy is used to kill remaining cancer cells following surgery or radiation, it is known as *adjuvant chemotherapy*.

## Genetic/Genomic Considerations

### Patient-Centered Care QSEN

It is now possible to check the patient's genetic profile to determine the likelihood of experiencing dangerous side effects from some cytotoxic agents. Genomic profiling, known as *pharmacogenomics*, allows a more individualized approach to chemotherapy selection and side effect management. In addition, checking the genetic profile of the tumor can determine its sensitivity to various chemotherapy and targeted therapy agents. This practice individualizes cancer therapy and improves therapy outcomes. Expected future outcomes include an economic advantage for cancer care because decisions for treatment can be based on likelihood of effectiveness for a given patient rather than on a tumor type or stage of disease. Remind patients that assessing genetic sensitivity can result in a selection of therapy that differs from that of other adults with the same cancer type.

Selection of specific agents to use as cytotoxic treatment of cancer is based on cellular kinetic concepts that include cell cycle, growth factors, and tumor burden. Most of the cytotoxic agents are not cancer-cell specific and thus potentially affect all cells in the body. This effect is especially seen on rapidly dividing cells such as those in the bone marrow. The time when bone marrow activity

and white blood cell counts are at their lowest levels after cytotoxic therapy is the **nadir**. It occurs at different times for different drugs. To prevent greatly reduced IMMUNITY and immunosuppression, combination cytotoxic therapy avoids using drugs with nadirs that occur at or near the same time.

## Chemotherapy

### Overview

**Chemotherapy**, the treatment of cancer with chemical agents, is used to cure and to increase survival time. This killing effect on cancer cells is related to the ability of chemotherapy to damage DNA and interfere with cell division and CELLULAR REGULATION. Tumors with rapid growth are often more sensitive to chemotherapy.

As described in [Chapter 21](#), cancer cells can separate from the original tumor, spread to new areas, and establish new cancers at distant sites (**metastasize**). Patients with metastatic cancer will die unless treatment eliminates the metastatic cancer cells along with the original cancer cells. Chemotherapy is useful in treating cancer because its effects are systemic, providing the opportunity to kill metastatic cancer cells that may have escaped local treatment. Drugs used for chemotherapy also exert their cell-damaging (**cytotoxic**) effects on healthy cells. The normal cells most affected by chemotherapy are those that divide rapidly, including skin, hair, intestinal tissues, spermatocytes, and blood-forming cells. These drugs are classified by the specific types of action they exert in the cancer cell ([Table 22-3](#)).

**TABLE 22-3**  
**Categories of Chemotherapeutic Drugs**

### Chemotherapy Drug Categories

*Alkylating agents* cross-link DNA, making the DNA strands bind tightly together. This action prevents proper DNA and ribonucleic acid (RNA) synthesis, which inhibits cell division.

*Antimetabolites* are similar to normal metabolites needed for vital cell processes. Most cell reactions require metabolites to begin or continue the reaction. Antimetabolites closely resemble normal metabolites and act as “counterfeit” metabolites that fool cancer cells into using the antimetabolites in cellular reactions. Because antimetabolites cannot function as proper metabolites, their presence impairs CELLULAR REGULATION, especially cell division.

*Antimitotic agents* (also known as *mitosis inhibitors*) interfere with the formation and actions of microtubules so cells cannot complete mitosis during cell division. As a result the cancer cell either

does not divide at all or divides only once.

*Antitumor antibiotics* are drugs that were originally developed as antibiotics that have effects on cancer cells. These drugs damage the cell's DNA and interrupt DNA or RNA synthesis. The exact mechanism of interruption varies with each agent.

*Topoisomerase inhibitors* disrupt an enzyme (topoisomerase) essential for DNA synthesis and cell division. When drugs disrupt the enzyme, proper DNA maintenance is prevented, resulting in increased DNA breakage and eventual cell death.

*Miscellaneous* chemotherapy drugs are those with mechanisms of action that are either unknown or do not fit those of other drug categories.

### Combination Chemotherapy

Successful cancer chemotherapy often involves giving more than one type of anticancer drug in a timed manner (*combination chemotherapy*). Using more than one drug is more effective in killing cancer cells than using just one drug because of their different mechanisms of action. However, the side effects and damage caused to normal tissues also increase with combination chemotherapy.

### Treatment Issues

Drugs selected for use with a given patient are based on the sensitivity of cancer cells to the drug and the stage or extent of disease. Selected treatment protocols have been developed for many cancers using well-established clinical guidelines for initial treatment and relapsed disease. Dosages for most chemotherapy drugs are calculated according to the patient's size, based on milligrams per square meter of body surface area (BSA), which considers the patient's height and weight at the time of chemotherapy administration.

Chemotherapy drugs are given on a regularly scheduled basis timed to maximize cancer cell kill and minimize damage to normal cells. Regimens vary for the number of days in a row for each round of drug delivery, the number of days or weeks between rounds of therapy, and the total number of rounds. The intent is to allow normal cells time to recover from any injury but prevent cancer cell recovery. **Dose-dense chemotherapy** protocols involve giving chemotherapy rounds closer together, supplemented with bone marrow growth factors to prevent neutropenia. Dose-dense therapy also results in more intense side effects. Maintaining the intended dosage and timing schedule to ensure that the patient receives the maximum recommended doses is a critical factor in the successful response to chemotherapy.

Patient and family education is critical in helping patients adhere to the prescribed schedule for best outcomes, reducing side effects, and preventing therapy complications. Side effects of chemotherapy are generally managed in the home. Therefore comprehensive and consistent patient education efforts by knowledgeable nurses are key to patient safety.

Many chemotherapy drugs are given IV, although other routes may be used. For specific cancer types, the chemotherapy may be infused or instilled into a body cavity. The *intrathecal* route delivers drugs into the spinal canal, and the *intraventricular* route delivers drugs directly into the ventricles of the brain. *Intraperitoneal* instillations place the drugs within the abdominal cavity, most often for ovarian cancer. Drugs for bladder cancer can be instilled directly into the bladder (*intravesicular* route). In some instances drugs may be applied as a *topical* preparation for skin lesions. *Intra-arterial* infusions may be used to deliver a higher dose locally. For example, with liver tumors an interventional radiologist places a catheter into the artery supplying the liver tumor. The concentrated chemotherapy drug, delivered in sponge-like beads, is infused, and the beads become trapped in the small arteries feeding the tumor. The techniques and care needs for different routes are described with the specific cancer type most commonly associated with the specific administration route. Regardless of the route, chemotherapy agents are designated hazardous drugs (HDs) and must be handled as such (Callahan et al., 2016; Crickman & Finnell, 2017).

The IV route is the most common for traditional chemotherapy. The standard of care designated by the Oncology Nursing Society (ONS) and supported by the American Society of Clinical Oncology (ASCO) for safe administration of IV chemotherapy is that giving these drugs requires special education and handling (Callahan et al., 2016; Neuss et al., 2017). *Chemotherapy is to be given only by registered nurses who have completed an approved chemotherapy program and have demonstrated competence in administering these agents. However, responsibility for monitoring the patient during chemotherapy administration rests with all nurses providing patient care.*

Most chemotherapy drugs are absorbed through the skin and mucous membranes. As a result the

interprofessional care workers who prepare or give these drugs (especially nurses and pharmacists) are at risk for absorbing them. Anyone preparing, giving, or disposing of chemotherapy drugs or handling excreta from patients within 48 hours of receiving IV chemotherapy must wear approved personal protective equipment (PPE) (Callahan et al., 2016; Neuss et al., 2017). Such equipment includes eye protection, masks, double gloves or “chemo” gloves, and gown. The Occupational Safety and Health Administration (OSHA) and the Oncology Nursing Society (ONS) have established practice guidelines and protective standards.

A serious complication of IV infusion is **extravasation**, which occurs when drug leaks into the surrounding tissues (also called *infiltration*). When the drugs given are **vesicants** (chemicals that damage tissue on direct contact), the results of extravasation can include pain, infection, and tissue loss (Fig. 22-2). Surgery is sometimes needed for severe tissue damage.

**FIG. 22-2** Appearance of tissue damage and loss after chemotherapy extravasation. (From Weinzweig, J., & Weinzweig, N. [2005]. *The mutilated hand*, St. Louis: Mosby.)

*The most important nursing intervention for extravasation is prevention (Schulmeister, 2014).* Small extravasations resolve without extensive treatment if less than 0.5 mL of the drug has leaked into the tissues. If a larger amount has leaked, extensive tissue damage occurs, and surgery may be needed. *Careful monitoring of blood return and the access site is critical during chemotherapy administration to prevent extravasation.* Institutions have established, evidence-based policies and procedures that are drug specific to guide extravasation management. With some drugs cold compresses to the area are prescribed; for other agents warm compresses are used. Antidotes may be injected into the site of extravasation. Coordinate with the oncologist and pharmacist to determine the specific antidote needed for the extravasated drug. When vesicants are part of therapy, the use of an implanted port or central line to decrease extravasation risk is recommended. Even with these devices, the nurse must observe closely for any indication of leakage and initiate management guidelines immediately.

Some anticancer drugs are available currently as oral agents (Table 22-4), and more are in development. Only a few oral agents are actually oral formulations of classic cytotoxic chemotherapy agents; more are classified as specific types of targeted therapy agents (discussed later). Oral drugs are more convenient for the patient and can be taken at home. However, there are many problems with oral anticancer drugs. One of the biggest problems is the misperception by patients and nononcology nurses that these drugs are less toxic than IV chemotherapy (Spoelstra & Rittenberg, 2015), which is **not** true. *Oral anticancer drugs are just as toxic to the patient taking the drug and to the person handling the drug as are standard chemotherapy drugs.* The responsibility for

administering these drugs often shifts from the oncology clinic to the home or to nononcology acute care settings, and issues of protection, correct administration, adherence, and recognition and management of side effects are major concerns. There is a critical need for patient education and support to self-manage this therapy, including the accidental ingestion by another person. Not all patients are able to accept the responsibility of self-management, and this must be considered during patient selection for oral chemotherapy (Spiegel & Sansoucie, 2015).

**TABLE 22-4**  
**Current Oral Chemotherapeutic Drugs**

AGENT	DRUG CATEGORY	CANCER TYPE
Altretamine (Hexalen)	Alkylating agent	Ovarian cancer
Capecitabine (Xeloda)	Antimetabolite	Breast cancer Colorectal cancer
Chlorambucil (Leukeran)	Alkylating agent	Chronic lymphocytic leukemia; Hodgkin's lymphoma Non-Hodgkin's lymphoma
Dasatinib (Spryvel)	Tyrosine kinase inhibitor	Chronic myelogenous leukemia; acute myelogenous leukemia that is Philadelphia chromosome positive
Erlotinib (Tarceva)	Epidermal growth factor receptor inhibitor	Non-small-cell lung cancer Pancreatic cancer
Everolimus (Afinitor)	Angiogenesis inhibitor	Advanced renal cell carcinoma
Gefitinib (Iressa)	Epidermal growth factor receptor inhibitor	Non-small-cell lung cancer
Hydroxyurea (Droxia, Hydrea)	Miscellaneous agent	Chronic myelogenous leukemia Head and neck cancer Melanoma Ovarian cancer Sickle cell disease
Imatinib (Gleevec)	Tyrosine kinase inhibitor	Chronic myelogenous leukemia that is Philadelphia chromosome positive GI stromal tumors Myelodysplastic syndrome
Lapatinib (Tykerb)	Tyrosine kinase inhibitor	Breast cancer
Lenalidomide (Revlimid)	Angiogenesis inhibitor	Multiple myeloma; myelodysplastic syndrome
Lomustine (CCNU, CeeNU)	Alkylating agent	Hodgkin's lymphoma Malignant glioma
Melphalan (Alkeran)	Alkylating agent	Multiple myeloma Ovarian cancer
Mercaptopurine (Purinethol)	Antimetabolite	Acute lymphocytic leukemia
Nilotinib (Tasigna)	Tyrosine kinase inhibitor	Chronic myelogenous leukemia that is Philadelphia chromosome positive
Pazopanib (Votrient)	Multikinase inhibitor	Advanced renal cell carcinoma
Procarbazine (Matulane, Natulan)	Miscellaneous agent	Hodgkin's lymphoma
Sorafenib (Nexavar)	Multikinase inhibitor	Advanced renal cell carcinoma; hepatocellular carcinoma
Sunitinib (Sutent)	Multikinase inhibitor	Advanced renal cell carcinoma; gastrointestinal stromal tumor
Temozolomide (Temodar)	Alkylating agent	Brain tumors (primary)
Thioguanine (Tabloid)	Antimetabolite	Acute myelogenous leukemia
Topotecan (Hycamtin)	Topoisomerase inhibitor	Small cell lung cancer
Vorinostat (Zolinza)	Histone inhibitor	Cutaneous T-cell lymphoma

Because these oral agents can be absorbed through skin and mucous membranes and exert toxic effects, the person who handles and administers them needs to use PPE in the same way as during IV chemotherapy administration. This becomes a more critical issue when nononcology nurses are administering the drugs. The ONS practice guidelines stress nurse education for competence to administer these drugs. All nurses administering these drugs must know the indications for drug use, dosage ranges, side effects and adverse effects, schedules, and specific precautions (Thompson & Christian, 2016). *Oral agents must not be crushed, split, broken, or chewed.* These drugs are biohazardous and must be discarded in accordance with agency policy.

In the home environment it is important that the patient and family understand the importance of avoiding direct skin contact with oral chemotherapy agents and how to dispose of them properly. Teach patients or whoever prepares the dosages how to avoid touching the drugs. Tablets and capsules in blister packs are pressed into a small paper cup. Those in traditional medication bottles are “poured” first into the bottle cap and then into a paper cup. The patient then “drinks” the tablet/capsule from the cup into his or her mouth. These drugs are to be taken separately from all other drugs. Consult a drug handbook or a pharmacist for timing of the drug in relation to meals and what to do if a dose is missed. For many of these oral drugs, missed doses are **not** taken when remembered. The patient just takes the next scheduled drug dose.

Disposal of expired or discontinued oral chemotherapy agents can be problematic. Just like all other drugs, these agents are not to be flushed down the drain. Unlike many other drugs, disposal needs to consider that the drugs should not be directly touched. Taking them to a community drug disposal event or the police station can be hazardous to others. Instruct patients to (ideally) bring the expired or discontinued drugs back to the oncology clinic in the container in which they were dispensed. If this is not feasible, instruct patients to call the dispensing pharmacist about specific disposal methods.

Adherence to defined oral chemotherapy schedules and dosages is more of a problem than with IV administration (Spiegel & Rittenberg, 2015). Even some highly motivated patients with cancer consider that skipping or reducing doses of oral drugs has only a minor impact. As with teaching other aspects of self-management, nurses have to be certain that patients and caregivers understand

the implications of the decisions they make. Disrupting the schedule or reducing dosages has a negative impact on therapy outcomes and leads to drug resistance among cancer cells, disease progression, and reduced survival. Research on a variety of interventions to increase adherence is ongoing. The [Quality Improvement](#) box describes the effectiveness of an electronic intervention in promoting adherence (Spoelstra et al., 2015).

## Quality Improvement QSEN

### Text Message Reminders Improve Adherence to Oral Anticancer Agents

Spoelstra, S., Given, C., Sikorskii, A., Coursaris, C., Majumder, A., DeKoekkoek, T., et al. (2015). Feasibility of a text-messaging intervention to promote self-management for patients prescribed oral anticancer agents. *Oncology Nursing Forum*, 42(6), 647–657.

Oral anticancer agents are becoming a common form of chemotherapy. They are convenient for the patient and are taken daily in the community environment. This change in delivery shifts responsibility for safe and consistent administration to the patient and family as part of self-management. A major issue with daily oral chemotherapy is consistent adherence to the prescribed schedule. Many patients have the false perception that an oral drug can't be very important to overall cancer therapy. The therapy schedule can be complex, with doses needed more than once daily and cycles changing over the course of a month. For patients who do not take other drugs on a daily or twice-daily basis, remembering to take the oral anticancer agent can be problematic. Whatever the cause, studies have shown that adherence to the prescribed schedule with an oral anticancer agent is less than 80%. Previous research has shown that a telephone reminder has helped some patients improve adherence. However, this intervention has limitations, especially when the telephone used is the patient's landline.

The current study sought to examine the utility of mHealth technology in improving self-management of patients taking oral anticancer agents, including schedule adherence and symptom management. mHealth, which is the use of mobile devices with software applications to provide access to health services, manage patient information, provide specific health knowledge, and assist skill development for health promotion and condition management, is now widely used to promote self-management of a variety of chronic conditions. The use of a text message (texting) has several advantages over a telephone reminder. Because a portable device is used, the patient can receive the message wherever he or she is. The message does not disturb others in the environment. Texting retains the ability of the patient to ask questions and receive responses in a timely manner.

The control group received and used a notebook-based toolkit for information, drug schedules, and symptom management techniques for 3 to 4 weeks. In addition to the toolkit, the intervention group received daily texts for adherence and weekly assessment of symptoms over the same time period.

The intervention group overall had a reduction in the number of symptoms and a higher adherence rate than did the control group. One patient in the intervention group reported that the texts were a burden.

#### Commentary: Implications for Research and Practice

The study design was a 10-week longitudinal, two-group, randomized control with a sample size of 80 adults newly prescribed oral anticancer agents. The methods were appropriate for the purpose of the study.

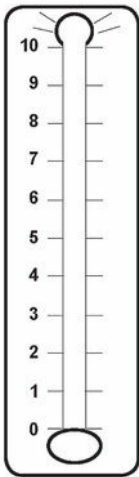

Future research is needed to determine how well the intervention performs and how acceptable it is over long-term therapy. In addition, texts were sent only once daily. More research is needed to determine the effectiveness on adherence when multiple texts per day are used. The increased use of mHealth techniques, even among older adults who may not be as comfortable with mobile devices as younger adults, necessitates ensuring that the techniques are personalized sufficiently and have an ease of use so users perceive them as helpful rather than a nuisance or burden.

### Side Effects of Chemotherapy

Temporary and permanent damage can occur to normal tissues from chemotherapy because it is systemic and exerts its effects on all cells. Some problems include bladder toxicity (hemorrhagic

cystitis), cardiac muscle damage, and loss of bone density. For some cancer drugs, agents that protect specific healthy cells (cytoprotectants or chemoprotectants) are given ahead of or with chemotherapy drugs to decrease the impact of these drugs on normal tissues. For example, amifostine (Ethyol) reduces DNA damage and is used to prevent kidney damage in patients receiving cisplatin; to reduce neutropenia; and to reduce radiation-induced xerostomia for patients receiving radiation therapy for head and neck cancer. Mesna (Mesnex) binds toxic metabolites to decrease bladder toxicity and prevent hemorrhagic cystitis from ifosfamide and high-dose cyclophosphamide use. Agents such as the anthracycline drug doxorubicin can result in cardiotoxicity, leading to heart failure. Loss of bone density is associated with the use of oral aromatase inhibitors for breast cancer treatment.

Serious short-term side effects occur with cytotoxic chemotherapy. The side effects on the hematopoietic (blood-producing) system can be life threatening and are the most common reason for changing the dosage or the treatment plan. The suppressive effects on the bone marrow blood-forming cells cause **anemia** (decreased numbers of red blood cells and hemoglobin); reduced IMMUNITY with **neutropenia** (decreased numbers of neutrophil white blood cells leading to immunosuppression); and **thrombocytopenia** (decreased numbers of platelets), which leads to impaired CLOTTING and bleeding. Common distressing side effects include nausea and vomiting, **alopecia** (hair loss), **mucositis** (open sores on mucous membranes), many skin changes, anxiety, sleep disturbance, altered bowel elimination, and changes in cognitive function. The impact of these side effects is referred to as *cancer therapy symptom distress*, which can vary from patient to patient. Cancer symptom distress is measured using the National Comprehensive Cancer Network® (NCCN®) Distress Thermometer (Fig. 22-3).

NCCN DISTRESS THERMOMETER		PROBLEM LIST	
<p>Instructions: Please circle the number (0–10) that best describes how much distress you have been experiencing in the past week including today.</p>		<p>Please indicate if any of the following has been a problem for you in the past week including today.</p>

**FIG. 22-3** The NCCN Distress Thermometer for patients.

Drug therapy is used to reduce symptom distress from some of these side effects. For other problems such as alopecia, no evidence-based prevention strategies exist, but patients can use techniques to be more comfortable with its presence. Nonpharmacologic interventions for symptom distress include distraction, massage, guided imagery, and complementary therapies.

Psychosocial issues can occur during chemotherapy. For many chemotherapy regimens drugs are

given over a period ranging from 30 minutes to 8 hours or longer. During this time the patient may be confined to a treatment area, which is a constant reminder of the disease and its treatment. Distraction methods such as virtual reality, guided imagery, reading, watching television, and talking with visitors may help reduce the sense of unpleasantness.

## Clinical Judgment Challenge 22-1

### Safety; Evidence-Based Practice; Patient-Centered Care QSEN

Mrs. G is a 67-year-old woman with colorectal cancer who has undergone a surgical resection of the tumor with anastomosis. She has returned for her follow-up visit to the oncologist, who has prescribed the oral chemotherapy agent capecitabine for her.

1. Which teaching concerning the handling of oral chemotherapy agents should be included in the care plan for Mrs. G?
2. Mrs. G calls the oncology clinic and tells you that she has accidentally skipped a dose. What would be your best response?
3. Mrs. G tells you that she dislikes taking pills and finds it easier to chew rather than swallow most medications. What would be your best response?  
Mrs. G's oncologist has discontinued the capecitabine treatment because her disease has progressed.
4. What would be the best way to dispose of oral chemotherapy agents that are no longer needed?

### Interprofessional Collaborative Care

The priority care issues during chemotherapy are protecting the patient from the life-threatening side effects and managing the associated distressing symptoms. For some patients the symptoms are so unpleasant that they choose to stop treatment.

#### Bone Marrow Suppression

In addition to killing cancer cells, chemotherapy also destroys circulating blood cells and further reduces IMMUNITY by suppressing bone marrow replacement of these cells. The numbers of all circulating leukocytes, erythrocytes, and platelets are decreased. Reduced leukocyte numbers, especially neutrophils, greatly increase the risk for infection. Decreased erythrocytes and platelets cause hypoxia, fatigue, and impaired CLOTTING, leading to increased bleeding.

*Infection risk results from reduced IMMUNITY with neutropenia, placing the patient at extreme risk for sepsis. Reduced immunity is the major dose-limiting side effect of cancer chemotherapy and can lead to death during treatment. Many chemotherapy drugs cause myelosuppression to some degree and decrease the patient's protective responses to infection. The severity of the risk is related to drug dosage. Impairment is temporary, and immunity recovers within weeks after therapy completion. However, the seriousness of potential infections makes this problem a major treatment concern. The most common infections are fungal, bacterial, and viral breakthrough (reactivation of dormant virus in the body such as varicella). Most infections during neutropenia result from overgrowth of the patient's own normal flora (microbiome) and entrance of these organisms into the bloodstream.*

Impaired IMMUNITY with increased infection risk can be managed with the use of biological response modifiers (BRMs) and growth factors to stimulate bone marrow production of immune system cells. Although not appropriate for all types of cancer, this supportive treatment can reduce the risk for infection during chemotherapy. This treatment is discussed in the [Immunotherapy](#) section. Actual infections are managed with anti-infective drugs such as antibiotic, antifungal, and antiviral drugs. Just as for any other infection, anti-infective therapy is specific for the organism(s) causing the infection.

## Considerations for Older Adults

### Patient-Centered Care QSEN

Older adults are at even greater risk for chemotherapy-induced neutropenia because of age-related changes in bone marrow function (McCance et al., 2014). Using growth factors such as filgrastim (Neupogen) and pegfilgrastim (Neulasta) before neutropenia occurs rather than later can reduce the severity of neutropenia and the risk for infectious complications. Use frequent handwashing during times of immunosuppression. Be extra vigilant in assessing older adults for early indicators of infection.

## Nursing Safety Priority QSEN

### Action Alert

The priority interventions for the patient with neutropenia are protecting him or her from infection within the health care system and teaching the patient and family how to reduce infection risk in the home. Total patient assessment, including a review of common symptoms associated with infection (e.g., fever, sore throat, urinary frequency or discomfort, purulent drainage), skin and mucous membrane inspection, lung sounds, mouth assessment, and inspection of venous access device insertion sites, must be performed on a scheduled basis by a registered nurse for hospitalized patients. Assessments are performed every 4 hours or as often as agency policy and the patient's condition warrant.

Explain to the patient the importance of reporting signs and symptoms of infection, any change in skin and mucous membranes, or other changes in health status. Instruct him or her to report the presence of pimples, sores, rash, or other open skin areas. Also teach him or her to report a cough, burning on urination, pain around the venous access site, or new drainage from any area of the body. Good handwashing before contact with the patient is essential for infection prevention. Use aseptic technique with any invasive procedure. [Chart 22-3](#) lists the best practices to prevent infection in patients with neutropenia.

### Chart 22-3

## Best Practice for Patient Safety & Quality Care QSEN

### Care of the Patient With Myelosuppression and Neutropenia

- Place the patient in a private room whenever possible.
- Use good handwashing technique or alcohol-based hand rubs before touching the patient or any of the patient's belongings.
- Ensure that the patient's room and bathroom are cleaned at least once each day.
- Do not use supplies from common areas for patients with myelosuppression and neutropenia. For example, keep a dedicated box of disposable gloves in his or her room and do not share this box with any other patient. Provide single-use food products, individually wrapped gauze, and other individually wrapped items.
- Limit the number of health care personnel entering the patient's room.
- Monitor vital signs every 4 hours, including temperature.
- Inspect the patient's mouth at least every 8 hours.
- Inspect the patient's skin and mucous membranes (especially the mouth and anal area) for the presence of fissures and abscesses at least every 8 hours.
- Inspect open areas such as IV sites every 4 hours for indications of infection.

- Change wound dressings daily.
- Obtain specimens of all suspicious areas for culture (as specified by the agency) and promptly notify the primary health care provider.
- Assist the patient in coughing and deep-breathing exercises.
- Encourage activity at a level appropriate for the patient's current health status.
- Change IV tubing daily or according to unit protocol.
- Keep frequently used equipment in the room for use with this patient only (e.g., blood pressure cuff, stethoscope, thermometer).
- Limit visitors to healthy adults.
- Use strict aseptic technique for all invasive procedures.
- Monitor the white blood cell count daily.
- Avoid the use of indwelling urinary catheters.
- Follow agency policy for restriction of fresh flowers and potted plants in the patient's room.

When delegating any nursing care activity to unlicensed assistive personnel (UAP), teach them the importance of protecting the neutropenic patient from infection. Stress the ways that cross-contamination can occur and how to avoid this source of infection. Also ensure that UAP understand that, even when the neutropenic patient is very tired and does not feel well, certain aspects of personal hygiene cannot be deferred. *Teach the importance of mouth care and washing the axillary and perianal regions at least every 12 hours.*

Monitoring for indicators of infection is critical for the hospitalized patient with neutropenia. The reduced numbers of neutrophils can limit the presence of common infection symptoms. Often the patient with neutropenia does not develop a high fever or have purulent drainage even when a severe infection is present. Hospital units specializing in care of patients with impaired IMMUNITY and neutropenia often have standard protocols that nurses initiate as soon as infection is suspected, *before* a primary health care provider examines the patient, because treatment delay can result in sepsis and death. These protocols specify which types of cultures to obtain (e.g., blood, urine, sputum, central line, wound), which diagnostic tests to obtain (e.g., chest x-ray), and which antibiotics to start immediately.

## Nursing Safety Priority QSEN

### Critical Rescue

Monitor patients with reduced IMMUNITY to recognize signs of infection. When any temperature elevation ( $>100^{\circ}\text{F}$  or  $37.8^{\circ}\text{C}$ ) is present, respond by reporting this to the health care provider immediately and implement standard infection protocols. When IV anti-infective drugs are started, the neutropenic patient is admitted to the hospital. The patient with neutropenia but no other symptoms of communicable disease is NOT an infection hazard to other people; however, other people can be an infection hazard to the patient.

Many patients remain at home during periods of neutropenia and are at continuing risk for infection. The focus remains on keeping the patient's own normal flora under control and preventing transmission of organisms from others. Teach patients and families self-care actions to reduce the risk for infection ([Chart 22-4](#)), especially handwashing.

### Chart 22-4

## Patient and Family Education: Preparing for Self-Management

### Prevention of Infection

During the times your white blood cell counts are low:

- Avoid crowds and other large gatherings of people who might be ill.
- Do not share personal toiletries such as toothbrushes, toothpaste, washcloths, or deodorant sticks with others.
- If possible, bathe daily with an antimicrobial soap. If total bathing is not possible, wash the armpits, groin, genitals, and anal area twice a day with an antimicrobial soap.
- Keep your toothbrush dry.
- Wash your hands thoroughly with an antimicrobial soap before you eat and drink, after touching a pet, after shaking hands with anyone, as soon as you come home from any outing, and after using the toilet.
- Follow the cancer center's instructions for eating fresh salads; raw fruits and vegetables; meat, fish and eggs; and pepper and paprika.
- Wash dishes between use with hot, sudsy water or use a dishwasher.
- Do not drink water, milk, juice, or other cold liquids that have been standing at room temperature for longer than an hour.
- Do not reuse cups and glasses without washing.
- Do not change pet litter boxes.
- Take your temperature at least once a day and whenever you do not feel well.
- Report any of these indications of infection to your oncologist immediately:
  - Temperature greater than 100° F (37.8° C)
  - Persistent cough (with or without sputum)
  - Pus or foul-smelling drainage from any open skin area or normal body opening
  - Presence of a boil or abscess
  - Urine that is cloudy or foul smelling or that causes burning on urination
- Take all prescribed drugs.
- Wear clean disposable gloves underneath gardening gloves when working in the garden or with houseplants.
- Wear a condom when having sex. If you are a woman having sex with a male partner, ensure that

he wears a condom.

*Anemia* and *thrombocytopenia* also result from the bone marrow suppression caused by some chemotherapy drugs. Anemia causes patients to feel fatigued from a lack of adequate red blood cells to transport oxygen, and some tissues are hypoxic. Thrombocytopenia increases the risk for excessive bleeding from impaired CLOTTING. When the platelet count is less than  $50,000/\text{mm}^3$  ( $50 \times 10^9/\text{L}$ ), small trauma can lead to prolonged bleeding. With a count lower than  $20,000/\text{mm}^3$  ( $20 \times 10^9/\text{L}$ ), spontaneous and uncontrollable bleeding may occur. Both anemia and thrombocytopenia may require transfusion therapy.

The use of growth factors to stimulate production of red blood cells and platelets to improve CLOTTING is common. Erythropoiesis-stimulating agents (ESAs) such as darbepoetin alfa (Aranesp) and epoetin alfa (Epoen and Procrit) can prevent or improve anemia associated with chemotherapy and reduce the need for transfusions. These drugs increase the production of many blood cell types, not just erythrocytes, increasing the patient's risk for hypertension, blood clots, strokes, and heart attacks, especially among older adults. In addition, certain types of cancer cells, such as head and neck cancer cells, leukemias, and some lymphomas, grow faster in the presence of these ESAs; and their use may be restricted. Dosing is based on each patient's hemoglobin levels to ensure that enough red blood cells are produced to avoid the need for transfusion but not necessarily to bring hemoglobin or hematocrit levels up to normal.

An example of growth factor therapy for thrombocytopenia and reduced CLOTTING is the use of oprelvekin (Neumega). This drug increases the production of platelets. The drug may cause fluid retention and increase the risk for heart failure and pulmonary edema. Other side effects include conjunctival bleeding, hypotension, and tachycardia. Teach patients to weigh themselves daily and keep a record. Remind them to immediately report sudden weight gain or dyspnea to the health care provider.

The priority for nursing care for the patient with thrombocytopenia is to provide a safe environment. [Chart 22-5](#) lists the best practices for Bleeding Precautions for impaired CLOTTING. Teach UAP the importance of using Bleeding Precautions and the need to report any evidence of bleeding immediately. Caregivers at home also need to know these practices.

## Chart 22-5

### Best Practice for Patient Safety & Quality Care

#### Prevention of Injury for the Patient With Thrombocytopenia

- Handle the patient gently.
- Use and teach unlicensed assistive personnel (UAP) to use a lift sheet when moving and positioning the patient in bed.
- Avoid IM injections and venipunctures.
- When injections or venipunctures are necessary, use the smallest-gauge needle for the task.
- Apply firm pressure to the needlestick site for 10 minutes or until the site no longer oozes blood.
- Apply ice to areas of trauma.
- Test all urine and stool for the presence of occult blood.
- Observe IV sites every 4 hours for bleeding.
- Instruct patients to notify nursing personnel immediately if any trauma occurs and if bleeding or bruising is noticed.
- Avoid trauma to rectal tissues:

- Do not administer enemas.
- If suppositories are prescribed, lubricate liberally and administer with caution.
- Instruct the patient and UAP that the patient should use an electric shaver rather than a razor.
- When providing mouth care or supervising others in providing mouth care:
- Use a soft-bristled toothbrush or tooth sponges.
- Do not use water-pressure gum cleaners.
- Make certain that dentures and other dental devices fit and do not irritate the gums.
- Instruct the patient not to blow the nose or insert objects into the nose.
- Instruct UAP and the patient that the patient should wear shoes with firm soles whenever ambulating.
- Practice fall prevention strategies according to the agency's policies.
- Keep pathways and walkways clear and uncluttered.

Teach patients with thrombocytopenia and their families to avoid injury and excessive bleeding when discharge occurs before the platelet count has returned to normal. [Chart 22-6](#) reviews precautions to teach patients to prevent bleeding and what to do if bleeding occurs.

### **Chart 22-6**

## **Patient and Family Education: Preparing for Self-Management**

### **Preventing Injury or Bleeding**

During the time your platelet count is low:

- Use an electric shaver.
- Use a soft-bristled toothbrush.
- Do not have dental work performed without consulting your cancer health care provider.
- Do not take aspirin or any aspirin-containing products. Read the label to be sure that the product does not contain aspirin or salicylates.
- Do not participate in contact sports or any activity likely to result in your being bumped, scratched, or scraped.
- If you are bumped, apply ice to the site for at least 1 hour.
- Avoid hard foods that would scrape the inside of your mouth.
- Eat only warm, cool, or cold foods to avoid burning your mouth. Be especially cautious with

cheese topping on pizza.

- Check your skin and mouth daily for bruises; swelling; or areas with small, reddish-purple marks that may indicate bleeding.
- Notify your cancer health care provider if you:
  - Are injured and persistent bleeding results
  - Have menstrual bleeding that is excessive for you
  - See blood in your vomit, urine, or bowel movement
- Avoid trauma with intercourse.
- Avoid anal intercourse.
- Take a stool softener to prevent straining during a bowel movement.
- Do not use enemas or rectal suppositories.
- Avoid bending over at the waist, which increases pressure in the brain.
- Do not wear clothing or shoes that are tight or that rub.
- Avoid blowing your nose or placing objects in your nose. If you must blow your nose, do so gently without blocking either nasal passage.
- Avoid playing musical instruments that raise the pressure inside your head such as brass wind instruments and woodwinds or reed instruments.

## NCLEX Examination Challenge 22-2

### Health Promotion and Maintenance

The client who received combination chemotherapy 7 days ago for breast cancer calls the oncology clinic to report a temperature of 100.5° F (38.6° C) and has no other symptoms of infection. What is the nurse's **best** response?

- A. "This is a normal immune-related response to the chemotherapy."
- B. "Please go to the nearest emergency room for a full workup for infection."
- C. "You are most likely dehydrated. Come to the clinic now for IV fluids."
- D. "There is no concern at this time but call if your temperature reaches 101.5° F (38.6° C)."

### Chemotherapy-Induced Nausea and Vomiting

Chemotherapy-induced nausea and vomiting (CINV) arises from a variety of GI and neural mechanisms. It may manifest as *anticipatory* (before receiving the chemotherapy, often triggered by thoughts, sights, and sounds related to the anticipated chemotherapy), *acute* (within the first 24 hours after chemotherapy), *delayed* (occurring after the first 24 hours), *breakthrough* (occurring intermittently during therapy for CINV), or a combination. Many cancer drugs are **emetogenic** (vomiting inducing), with some agents causing more nausea and vomiting than others. Although there are advances in prevention and control of CINV, it remains a common and distressing issue. Nausea often persists, even when vomiting is controlled. Current studies examining genetic factors in the metabolism of chemotherapy agents and antiemetics are ongoing to help identify adults at

higher risk for CINV and to allow more precise therapies to manage it (Kiernan, 2016).

Acute CINV is the most common type. It may persist for 1 to 2 days after chemotherapy is given. A few drugs, such as dacarbazine (DTIC), may trigger CINV almost as soon as the drug is started. Other drugs, such as cisplatin (Platinol), induce delayed nausea and vomiting that can continue as long as 5 to 7 days after receiving it. Patients who have CINV during the first round of chemotherapy may begin to experience the same symptoms before the next dose as a result of sheer anticipation. Once considered the single most distressing side effect of chemotherapy, CINV often can be well controlled with appropriate evidence-based antiemetic therapy, especially with serotonin (5-HT<sub>3</sub>) antagonist drugs and the use of standardized protocols for its prevention and management.

### Drug Therapy.

Many antiemetics are available to relieve nausea and vomiting. These drugs vary in the side effects they produce and how well they control CINV. One or more antiemetics are usually given before, during, and after chemotherapy. Drugs commonly used short term to control CINV are listed in Chart 22-7. A new drug, Akynzeo, combines the 5-HT<sub>3</sub> antagonist palonosetron with the drug netupitant to provide greater control of CINV (Aschenbrenner, 2015). Netupitant belongs to a new drug class, P/neurokinin-1 receptor antagonists. *Patient response to antiemetic therapy is variable, and the drug combinations are individualized for best effect (Barak et al., 2013).*

### Chart 22-7

## Common Examples of Drug Therapy

### Chemotherapy-Induced Nausea and Vomiting

DRUG CATEGORIES	NURSING IMPLICATIONS
<b>Serotonin Antagonists</b> —Prevent CINV by blocking the 5-HT <sub>3</sub> receptors of the chemotrigger zones in the brain and intestines. This action prevents serotonin from binding to the receptors and activating the nausea and vomiting centers.	
Ondansetron (Zofran) <i>Oral or IV</i> Granisetron (Kytril) <i>IV</i> Granisetron transdermal (Sancuso) <i>patch</i> Dolasetron (Anzemet) <i>Oral or IV</i> Palonosetron (Aloxi) <i>IV</i>	Teach patient to change positions slowly to avoid falls <i>because these drugs may induce bradycardia, hypotension, and vertigo.</i> Assess the patient for headache, which is a <i>common side effect of drugs from this class.</i>
<b>Neurokinin Receptor Antagonists</b> —Reduce CINV by blocking the substance P neurokinin receptor. When used together with a serotonin antagonist and a corticosteroid, both acute and delayed nausea and vomiting are controlled.	
Aprepitant (Emed) <i>Oral or IV</i>	Teach patients who are also taking warfarin (Coumadin) to have their INR checked before and after the 3 days of this therapy <i>because this drug interferes with warfarin effectiveness.</i> Teach women who are using oral contraceptives to use an additional form of birth control while on this drug <i>because it reduces the effectiveness of oral contraceptives, increasing the risk for an unplanned pregnancy.</i>
<b>Corticosteroids</b> —Reduce CINV by decreasing swelling in the brain's chemotrigger zone.	
Dexamethasone (Decadron) <i>Oral or IV</i>	Teach patients to reduce salt intake to about 4 g daily <i>because these drugs cause fluid retention and hypertension.</i>
<b>Prokinetic Agents</b> —Reduce CINV by blocking dopamine receptors in the brain's chemotrigger zone.	
Metoclopramide (Reglan) <i>IM or IV</i>	Teach the patient to avoid driving or operating heavy machinery <i>because these drugs induce drowsiness.</i>
<b>Benzodiazepines</b> —Reduce CINV by enhancing cholinergic effects and decreasing the patient's awareness.	
Lorazepam (Ativan) <i>Oral or IV</i>	Teach the patient and family that the patient should avoid driving, operating heavy machinery, making legal decisions, and going up and down staircases <i>unassisted because drugs from this class induce amnesia and profound drowsiness.</i>

CINV, Chemotherapy-induced nausea and vomiting; INR, international normalized ratio.

### Nursing Safety Priority QSEN

#### Drug Alert

Do not confuse the antiemetic drug Anzemet (dolasetron) with the diabetes drug Avandamet (a combination of metformin and rosiglitazone). The drugs have similar sounding names but totally different actions.

Regardless of which drugs are being used to prevent or reduce CINV, they are most effective when used in an evidence-based approach on a scheduled basis for prevention and management. Drug therapy for CINV works best when given *before* the nausea and vomiting begin. *The nursing priority is to coordinate with the patient and cancer health care provider to ensure adequate control of CINV. Ensure that antiemetics are given before chemotherapy and are repeated based on the response and duration of CINV.* When patients are receiving dose-dense chemotherapy, the intensity of CINV also increases,

and more aggressive antiemetic therapy is needed. Teach patients to continue the therapy, even when CINV appears controlled. *When the patient stops taking the drug(s), teach him or her to start retaking the drug at the first sign of nausea to prevent it from becoming uncontrollable.*

## Considerations for Older Adults

### Patient-Centered Care QSEN

The older adult can become dehydrated more quickly than a younger adult if CINV is not controlled. Teach older adults to be proactive with taking their prescribed antiemetics and to contact their health care provider if the CINV either does not resolve within 12 hours or becomes worse.

### Mucositis

**Mucositis** (sores in mucous membranes) is a dose-limiting side effect of cancer therapy and a common reason for stopping or delaying treatment. It often develops in the entire GI tract, especially in the mouth (**stomatitis** is a reaction that involves other tissues and structures in the oral cavity). Mucositis is a complex, multiphase process at the cellular level started in response to cytotoxic chemotherapy. Mouth sores cause pain and interfere with eating, nutrition, and quality of life. [Chart 22-8](#) lists patient education for self-management of mucositis.

### Chart 22-8

## Patient and Family Education: Preparing for Self-Management

### Mouth Care for Patients With Mucositis

- Examine your mouth (including the roof, under the tongue, and between the teeth and cheek) every 4 hours for fissures, blisters, sores, or drainage.
- If sores or drainage is present, contact your cancer health care provider to determine whether these areas need to be cultured.
- Brush the teeth and tongue with a soft-bristled brush or sponges every 8 hours and after meals.
- Avoid the use of mouthwashes that contain alcohol or glycerin.
- “Swish and spit” room-temperature tap water, normal saline, or salt and soda water on a regular basis (at least 4 times a day) and as needed according to changes in the oral cavity.
- Drink 2 or more liters of water per day if another health problem does not require limiting fluid intake.
- Take all drugs, including antibiotics and drugs for nausea and vomiting, as prescribed.
- Use topical analgesic drugs as prescribed.
- Take pain medications on schedule as needed.
- Apply a water-based moisturizer to your lips after each episode of mouth care and as needed.
- Use prescribed “artificial saliva” or mouth moisturizers as needed.
- Avoid using tobacco or drinking alcoholic beverages.
- Avoid spicy, salty, acidic, dry, rough, or hard food.

- Cool liquids to prevent burns or irritation.
- If you wear dentures, use them only during meals. When not in place, soak them in an antimicrobial solution. Rinse thoroughly before placing them in your mouth.

Oral cryotherapy using ice water or ice chips can be used for the prevention of mucositis. Instruct patients to suck on ice chips or to hold ice-cold water in their mouths before, during, and after rapid infusions of specific mucositis-causing agents. It is believed that vasoconstriction caused by the cold temperature decreases exposure of the oral mucous membranes to the mucositis-causing agents. Other recommended treatments include low-level laser therapy, sodium bicarbonate rinses, and IV injections of palifermin (Kepivance), which stimulate the growth of mucous membrane cells in the mouth. For multiple mouth lesions, most patients require systemic pain medications.

Frequent mouth assessment and oral hygiene are key in managing mucositis. Stress the importance of good and frequent oral hygiene, including teeth cleaning and mouth rinsing. Because most patients with mucositis also have bone marrow suppression and are at risk for impaired CLOTTING with bleeding, they must take care to avoid traumatizing the oral mucosa. Instruct them to use a soft-bristled toothbrush or disposable mouth sponges. Recommendations include *gentle* flossing once daily. Encourage them to rinse the mouth with plain water or saline at frequent intervals during the day and night when awake. Frequency is guided by the intensity of the mucositis. Initially the rinses start after meals and at bedtime, then every 2 hours, and then progressing to hourly if needed for comfort. Teach patients to avoid mouthwashes that contain alcohol or other drying agents that may further irritate the mucosa.

Oral hygiene equipment must be kept clean. Remind patients not to share toothbrushes. Toothbrushes can be cleaned weekly by using a home dishwasher or by rinsing them with a solution of liquid bleach or hydrogen peroxide and then rinsing with hot water.

### Alopecia

**Alopecia**, hair loss, may occur as whole-body hair loss or may be as mild as only a thinning of the scalp hair. When body hair loss includes pubic hair, patients may struggle with their body image and sexuality. Reassure patients that hair loss is temporary. Regrowth usually begins about 1 month after completion of chemotherapy; however, the new hair may differ from the original hair in color, texture, and thickness. No known evidence-based treatment safely prevents alopecia. The use of cold caps and cyclosporine for the prevention and treatment of chemotherapy-induced alopecia has recently been explored with some promising results; however, further research is needed to fully evaluate these therapies and the incidence of metastasis that may occur as a result of their use. *The priority nursing actions are to teach patients how to avoid scalp injury and to help them cope with this body image change.*

The hairless scalp is at risk for injury. Teach the patient to avoid direct sunlight on the scalp by wearing a hat or other head covering. Sunscreen use is essential to prevent sunburn because many drugs increase sun sensitivity, regardless of skin darkness. This skin can be damaged by helmets, headphones, headsets, wigs, and other items that rub the head. Teach the patient to wear a head covering underneath these items. Head coverings also are needed during cold weather and in cool environments to reduce body heat loss and prevent hypothermia.

Help patients select a type of head covering that suits their income and lifestyle. One recommendation is to coordinate wig purchases with the patient's hairdresser or barber. Having very short hair or a shaved head now is common and socially acceptable for men, and many men choose not to wear a wig during chemotherapy. Cutting the hair very short before chemotherapy begins will allow a better wig fit.

Suggest that patients obtain a wig before therapy begins and have their hairdresser shape it to mimic their usual hairstyle to reduce appearance changes. High-quality wigs are expensive but can look very much like the patient's own hair. Many local units of the ACS offers wigs at no cost that former patients have donated. Patients also can disguise hair loss with caps, scarves, and turbans. The ACS also provides instruction (Look Good–Feel Better) regarding makeup and the use of scarves, for example, to improve appearance and how patients feel about themselves.

### Changes in Cognitive Function

Some patients receiving chemotherapy report changes in cognitive function, most commonly

reduced ability to concentrate, memory loss, and difficulty learning new information during treatment and for months to years after treatment. This problem, termed *chemo brain*, is often reported in women undergoing chemotherapy for breast cancer, although it is not limited either to women or to breast cancer treatment. Cognitive impairment has been reported in up to 75% of patients with breast cancer and in patients with brain tumors and those treated with bone marrow transplantation after high-dose chemotherapy (Armstrong, 2016; Von Ah, 2015). Although most types of chemotherapy drugs do not cross the blood-brain barrier, they can induce inflammation and general biochemical changes that could reduce cognitive function, at least temporarily.

Comparisons of brain structure and cognitive function before, during, and after high-dose chemotherapy show some anatomic changes in brain white matter and gray matter. Most changes are not present at 3 years after completion of therapy. It is not known why all patients receiving high-dose chemotherapy do not develop the problem; however, genetic differences may be partly responsible. Not only is the exact cause of this side effect unclear, so are the personal risk factors. Cognitive training strategies may be effective in improving, maintaining, or restoring mental function through the repeated practicing of tasks that challenge thinking and problem solving (Bail & Meneses, 2016).

*The priorities for nursing care are supporting the patient who reports this side effect and providing resources for cognitive training.* Listen to the patient's concerns and tell him or her that other patients have also reported such problems. Warn patients against participating in other behaviors that could alter cognitive functioning, such as excessive alcohol intake, recreational drug use, and activities that increase the risk for head injury.

### Chemotherapy-Induced Peripheral Neuropathy

**Chemotherapy-induced peripheral neuropathy (CIPN)** is the loss of SENSORY PERCEPTION or motor function of peripheral nerves associated with exposure to certain anticancer drugs (Smith et al., 2014). Some patients undergoing chemotherapy with nerve-damaging drugs (e.g., antimitotics and platinum-based drugs) have rapid onset of severe CIPN. The degree of CIPN is related to the dosage of the nerve-damaging drugs; higher doses lead to greater neuropathy. The results of CIPN on function are widespread, with the most common problems including loss of sensation in the hands and feet, impaired gait and balance, orthostatic hypotension, erectile dysfunction, neuropathic pain, loss of taste discrimination, and severe constipation. CIPN is a long-term consequence and may be permanent in some adults. No known evidence-based interventions are available to prevent CIPN; however, some patients have reduced pain and improved function and quality of life when taking duloxetine.

*The priority for nursing care of patients experiencing CIPN is teaching them to prevent injury.* Loss of SENSORY PERCEPTION increases the patient's risk for injury because he or she may not be aware of excessive heat, cold, or pressure. The risk for injury to the feet is very high. Falls are more likely because of changes in gait and balance, decreased sensation in the feet, and orthostatic hypotension. Chart 22-9 lists teaching priorities for the patient with CIPN.

#### Chart 22-9

## Patient and Family Education: Preparing for Self-Management

### Chemotherapy-Induced Peripheral Neuropathy

- Protect feet and other body areas where sensation is reduced (e.g., do not walk around in bare feet or stocking feet; always wear shoes with a protective sole).
- Be sure that shoes are long enough and wide enough to prevent creating sores or blisters.
- Buy shoes in the afternoon or evening to accommodate any size change needed for foot swelling.
- Provide a long break-in period for new shoes; do not wear new shoes for longer than 2 hours at a time.

- Avoid pointed-toe shoes and shoes with heels higher than 2 inches.
- Inspect your feet daily (with a mirror) for open areas or redness.
- Avoid extremes of temperature; wear warm clothing in the winter, especially over hands, feet, and ears.
- Test water temperature with a thermometer when washing dishes or bathing. Use warm water rather than hot water (less than 105° F or 40.6° C).
- Use potholders when cooking.
- Use gloves when washing dishes or gardening.
- Do not eat foods that are “steaming hot”; allow them to cool before placing them in your mouth.
- Eat foods that are high in fiber (e.g., fruit, whole grain cereals, vegetables).
- Drink 2 to 3 liters of fluid (nonalcoholic) daily unless your health care provider has told you to restrict fluid intake.
- Use the actions for “Falls Prevention” supplied by the cancer center during all activities.
- Get up slowly from a lying or sitting position. If you feel dizzy, sit back down until the dizziness fades before standing; then stand in place for a few seconds before walking or using the stairs.
- To prevent tripping or falling, look at your feet and the floor or ground where you are walking to assess how the ground, floor, or step changes.
- Avoid using area rugs, especially those that slide easily.
- Keep floors free of clutter that could lead to a fall.
- Use handrails when going up or down steps.

Poor gait may be helped with devices such as orthotics and calf braces. Erectile dysfunction may be helped with drug therapy (see [Chapter 72](#) for options for erectile dysfunction). Other issues are not correctable and affect quality of life. The loss of hand sensation may make some activities that require very fine motor skills (i.e., writing, buttoning clothing, playing a musical instrument) difficult or impossible. Assess the patient's ability to cope with these changes. Coordinate with an occupational therapist to help the patient adjust for SENSORY PERCEPTION deficits in performing activities.

### **Immunotherapy: Biological Response Modifiers and Targeted Therapies**

Biological response modifiers (BRMs) enhance or alter the patient's biologic responses to cancer cells. BRMs have a variety of effects. Some have direct antitumor activity (i.e., helping the body recognize cancer cells as foreign so the immune system destroys them). BRMs also can improve IMMUNITY and enhance the repair or replacement of cells damaged by cancer treatment. Targeted therapies used in cancer treatment are drugs that act on specific components needed for cellular function and reproduction. These therapies include monoclonal antibodies and small molecule drugs.

### **BRMs as Cancer Therapy**

As discussed in [Chapter 17](#), cytokines released from immune system cells are not usually cytotoxic alone but influence how immune system cells function. The cytokines include the interferons, interleukins, tumor necrosis factors, and colony-stimulating factors. Some cytokines enhance IMMUNITY, which plays a role in cancer prevention (see [Chapters 17](#) and [21](#)). Cytokines and other BRMs are used as cancer treatment because they stimulate the patient's immune system to recognize cancer cells and take actions to eliminate or destroy them. Some BRMs are used as

supportive therapy during chemotherapy by enhancing recovery of bone marrow function after treatment-induced myelosuppression.

Two common types of BRMs for cancer therapy are interleukins and interferons. Some agents can stimulate specific immune system components to attack and destroy cancer cells; other agents block cancer cell access to an essential function or nutrient needed for cell survival.

*Interleukins* (ILs) are substances the body makes to help regulate inflammation and IMMUNITY. Some ILs are synthesized as anticancer drugs. In particular, ILs have been effective in treating renal cell carcinoma and melanoma. They help different immune cells recognize and destroy abnormal body cells. In particular, IL-1, IL-2, and IL-6 appear to boost IMMUNITY and enhance attacks on cancer cells by macrophages, natural killer (NK) cells.

*Interferons* (IFNs) are cell-produced proteins that have some effect in the treatment of melanoma, hairy cell leukemia, renal cell carcinoma, AIDS-related Kaposi's sarcoma, and lymphoma. IFNs can assist in cancer therapy by:

- Slowing tumor cell division
- Stimulating the growth and activation of NK cells
- Inducing cancer cells to resume a more normal appearance and function
- Inhibiting the expression of oncogenes

### BRMs as Supportive Therapy

BRMs used for supportive therapy during cancer treatment are the colony-stimulating factors or “growth factors” (Table 22-5). These factors affect CELLULAR REGULATION and induce more rapid recovery of bone marrow cells after suppression by chemotherapy. This effect has two benefits. First, when impaired IMMUNITY and CLOTTING are shortened or less severe, patients are less at risk for life-threatening infections and bleeding. Second, because the growth factors allow more rapid bone marrow recovery, patients can receive their chemotherapy regimen as scheduled and may even be able to tolerate higher doses, potentially increasing the likelihood of a remission or cure.

**TABLE 22-5**

**Common Biological Response Modifiers Used as Supportive Cancer Therapy**

AGENT	CELL TYPE AFFECTED	INDICATIONS
Sargramostim (Leukine, Prokine)	All granulocytes Neutrophils Eosinophils Monocytes Macrophages	Chemotherapy-induced leukopenia
Filgrastim (Neupogen) Pegfilgrastim (Neulasta) Tbo-filgrastim (Granix)	Neutrophils	Chemotherapy-induced neutropenia
Epoetin alfa (Epoen, Procrit) Darbepoetin (Aranesp)	Erythrocytes	Chemotherapy-induced anemia Chemotherapy-induced fatigue Anemia induced by renal failure
Oprelvekin (Neumega)	Platelets	Chemotherapy-induced thrombocytopenia
Sipuleucel-T (Provenge) (product is a vaccine)	T-cells; antigen-processing cells (macrophages)	Hormone-refractory prostate cancer

### Side Effects of Biological Response Modifier Therapy

Patients receiving interleukins have generalized and often severe inflammatory reactions. Fluid shifting from the intracellular space and capillary leak syndrome cause widespread edema formation. Tissue swelling affects the function of all organs and can be life threatening. Pulmonary, cardiovascular, and GI reactions can occur. Patients receiving high-dose BRM therapy may need to be in an ICU or on a monitored unit. These inflammatory effects occur during the days of active drug infusion and resolve after therapy completion.

Many BRMs and growth factors induce symptoms of inflammation during and just after receiving the drug, including fever, chills, rigors, and flu-like symptoms (general malaise). Problems are worse when higher doses are given, but they seem to become less severe over time. The nursing priorities for patients receiving BRMs include assessing for complications of systemic inflammation and making patients as comfortable as possible. Fever is treated with acetaminophen. Patients with severe rigors are managed with meperidine (Demerol). Patients may also experience nausea, vomiting, diarrhea, and anorexia. Antiemetics are helpful in the management of nausea and vomiting.

Neurologic symptoms associated with BRM use can be significant. These include confusion, fatigue, somnolence, irritation or agitation, hallucinations, vivid dreams, anxiety, and sleep

disturbances. Some patients have psychosocial reactions of fear, tearfulness, depression, and mood swings. Early identification of these symptoms is an important nursing care activity.

Interferon therapy causes peripheral neuropathy. (See the [Chemotherapy-Induced Peripheral Neuropathy](#) section.)

Skin dryness, itching, and peeling occur with many types of BRM therapy. The skin problems are more severe with higher doses and when more than one type of BRM is used at the same time. Reactions are temporary but cause much discomfort and distress. Advise patients to apply moisturizers (unscented) to the skin and to use mild soap to clean the skin. Involved areas should be protected from the sun with clothing or the use of sunscreen agents. Teach patients to avoid swimming and to not use topical steroid creams on affected areas.

## Monoclonal Antibodies

Monoclonal antibody therapy combines actions from immunotherapy and targeted therapy to help treat specific cancers. The body normally responds to foreign substances by producing antibodies. These proteins are then able to target the antigen when present in the body, attacking and destroying the foreign antigen (non-self cells). In cancer therapy human and/or mouse proteins are used to form antibodies against given targets known to be present in or on certain types of cancer cells.

Monoclonal antibodies bind to their target antigens, which are often specific cell surface membrane proteins. Binding prevents the protein from performing its functions. Some cancer cells express cell membrane surface proteins that are unique to cancer cells and have a role in cancer cell division. So by binding these proteins, monoclonal antibodies change CELLULAR REGULATION and prevent cancer cell division. Some monoclonal antibodies make tumor cells more sensitive to therapy and increase the effectiveness of immune system attacks on the cancer cells. A commonly used monoclonal antibody for targeted therapy is rituximab (Rituxan). It binds to the protein CD20, which is often overexpressed on the surface of non-Hodgkin's lymphoma cell membranes. This protein activates an early step of the cell cycle division process. Binding CD20 with rituximab prevents it from stimulating cell division in the non-Hodgkin's lymphoma cells.

Allergic reactions may occur in patients receiving monoclonal antibodies because of the incorporation of some nonhuman proteins. Most of these antibodies initially were developed in mice and express some mouse proteins. Now many of these antibodies have been "humanized," reducing the risk for allergic reactions. Nursing assessment is key for early recognition of a potentially life-threatening allergic reaction.

The monoclonal antibodies to the epidermal growth factor receptor (EGFR) bind to those specific receptors on normal and cancerous cells. Thus side effects also occur in the skin, mucous membranes, and lining of the GI tract.

## Small Molecule Inhibitor Targeted Therapy

Molecularly targeted therapies are technically biologic agents. However, their unique actions and roles in cancer therapy warrant separate discussion. These agents use the molecular features present in some cancer cells as specific targets, and by acting more specifically they have less of an impact on normal cells. In general, molecularly targeted therapies block the growth and spread of cancer by interfering with the specific cellular growth pathways or molecules involved in the CELLULAR REGULATION of growth and progression of cancer cells. These agents reflect the increased understanding of the biology of cancer cells and are becoming an effective treatment option that provides patients with a new sense of hope against a challenging disease.

As discussed in [Chapter 21](#), normal cells have tightly controlled regulation over when and to what extent a cell divides; cancer cells have altered features that evade this normal control. External events can indicate to a cell that cell division is needed (i.e., tissue loss, injury). However, these external events must be communicated to the cell's nucleus to activate the genes that promote cell division (oncogenes) and turn off the genes that normally suppress cell division (suppressor genes). The key to communicating the need for cell division is the presence and activation of signal transduction pathways. [Fig. 22-4](#) shows a segment of a cell with one signal transduction pathway. When this pathway is activated at the cell surface by binding growth factors to their receptors, having certain drugs interact with the cell's plasma membrane, or by the binding of certain adhesion factors, the first result is an increase in the cell's production of a family of enzymes known as *tyrosine kinases* (TKs). With increased TKs present, the pro-cell division signal activates

transcription factors within the pathway. When the pro-cell division transcription factors reach the cell's nucleus, oncogenes are activated, suppressor genes are inactivated, and a variety of proteins are produced to make cell division occur.

**FIG. 22-4** Pro-cell division signal transduction pathway. (From Workman, M. L., & LaCharity, L. [2011]. *Understanding pharmacology: Essentials for medication safety*. St. Louis: Saunders.)

When cell division is not needed, external signals such as growth factor inhibitors and the direct contact of a cell's plasma membrane with other cells send signals that inhibit activation of TKs and the signal transduction pathway. As a result, fewer transcription factors are produced, suppressor genes are expressed, and oncogenes are suppressed. The proteins needed for cell division are not produced, and cell division does not occur.

Overall cancer cells have more active signal transduction pathways and transcription factors that ultimately lead to excessive division of the cancer cells. Often the signaling pathways and receptors are overexpressed in cancer cells. Targeted therapies take advantage of differences in CELLULAR REGULATION for one or more parts of the signal transduction pathway to block it. Targeted therapies can disrupt the pathway and slow or stop cell division. They may work by blocking a growth factor receptor, by preventing the activation of tyrosine kinases, by limiting the production of transcription factors, and by other mechanisms that are not yet fully understood. Regardless of how a targeted therapy works, it will work only with cancer cells that have the actual target. The result is that the signal for turning on cell division genes (oncogenes) does not get through to the cell's nucleus (Fig. 22-5) (Santos et al., 2013).

**FIG. 22-5** Sites of action for targeted therapies that inhibit a signal transduction pathway and greatly reduce cell division. (From McCuiston, L., Kee, J., Hayes, E. [2015]. *Pharmacology: A nursing process approach* [8th ed.]. St. Louis: Saunders.)

Drugs for targeted therapy of some cancers are classified based on the mechanism of action, and some have more than one action (Table 22-6). *It is important to remember that these drugs will not work unless the cancer cell overexpresses the actual target substance. Thus not all patients with the same cancer type would benefit from the use of targeted therapy.* Each patient's cancer cells are evaluated to determine whether the cells have enough of a target to be affected by targeted therapy. Because of the varying mechanisms of action, a priority nursing action is careful assessment for adverse reactions to therapy.

**TABLE 22-6**  
**Common Targeted Therapy Agents**

CLASSIFICATION	AGENT
Tyrosine kinase inhibitors	Dasatinib (Sprycel) Erlotinib (Tarceva) Imatinib mesylate (Gleevec) Lapatinib (Tykerb) Nilotinib (Tasigna)
Epidermal growth factor/receptor inhibitors (EGFRIs)	Cetuximab (Erbix) Gefitinib (Iressa) Panitumumab (Vectibix) Trastuzumab (Herceptin)
Vascular endothelial growth factor/receptor inhibitors (VEGFRIs)	Bevacizumab (Avastin) Axitinib (Inlyta)
Multikinase inhibitors	Sorafenib (Nexavar) Sunitinib (Sutent) Pazopanib (Votrient) Crizotinib (Xalkori)
Proteasome inhibitors	Bortezomib (Velcade)
Angiogenesis/mTOR kinase inhibitors	Everolimus (Afinitor) Lenalidomide (Revlimid) Polamidonide (Pomlyst) Temsilimus (Torisel)
Monoclonal antibodies	Alemtuzumab (Campath) Ibritumomab (Zevalin) Rituximab (Rituxan) <sup>131</sup> I tositumomab (Bexxar)

## Nursing Safety Priority QSEN

### Drug Alert

Many targeted therapies, the small molecule therapies in particular, are administered as oral agents. Some patients minimize the potential effects of the drug because it is “just a pill.” Emphasize with patients and their family members and caregivers the importance of taking the drugs as prescribed and using safe handling techniques. Teach them that only the patient should handle the oral chemotherapy and that, if the patient is unable, the family member or caregiver needs to wear gloves when handling the chemotherapy drug.

Targeted therapy agents are classified based on their action. The first application of these agents was against estrogen in breast cancer (discussed in the [Hormonal Manipulation](#) section). Selective estrogen receptor modulators (SERMs) and aromatase inhibitors (AIs) have been developed to interfere with estrogen's ability to promote the growth of estrogen receptor–positive breast cancers. Discussion in this section focuses on the tyrosine kinase inhibitors (TKIs), epidermal growth factor/receptor inhibitors (EGFRIs), vascular endothelial growth factor/receptor inhibitors (VEGFRIs), multikinase inhibitors (MKIs), proteasome inhibitors, and angiogenesis inhibitors.

### Tyrosine Kinase Inhibitors

Drugs with the main action of inhibiting activation of tyrosine kinases (TKs) are **tyrosine kinase inhibitors (TKIs)**. There are many different TKs. Some are unique to the cell type; others may be present only in cancer cells that express a specific gene mutation. As a result, the different TKI drugs are effective in disrupting the CELLULAR REGULATION and growth of some cancer cell types and not others. An example of a TKI is imatinib mesylate (Gleevec, TEVA-Imatinib 🍀). This drug binds to the energy site of the enzyme TK and prevents its activation. The drug is useful in cancers that overexpress the *ABL1* oncogene such as most types of chronic myeloid leukemia (CML) and metastatic GI stromal tumors (GISTs).

Side effects common to most TKIs include nausea, vomiting, fluid retention, electrolyte imbalances, and bone marrow suppression that reduces IMMUNITY with neutropenia, anemia, and thrombocytopenia. The problems associated with bone marrow suppression are further increased when the patient also receives traditional chemotherapy with drugs that suppress bone marrow.

### Epidermal Growth Factor/Receptor Inhibitors

The epidermal growth factor/receptor inhibitors (EGFRIs) block epidermal growth factor from binding to its cell surface receptor. As shown in [Fig. 22-5](#), when this receptor is blocked, it cannot activate tyrosine kinase. As a result, the signal transduction pathway for promotion of cell division is inhibited.

An example of an EGFR drug is trastuzumab (Herceptin), which binds the excessive amounts of a certain type of EGFR produced by some breast and colon cancers in response to the activation of the *HER2/neu* gene. Binding this receptor prevents cancer cell division and increases the sensitivity to chemotherapy and immune system actions.

The most common side effects of EGFRIs include hypersensitivity reactions and a variety of skin reactions because skin cells also have EGFRs. These side effects may be as mild as a rash or result in excessive skin peeling and fissures ([Wallner et al., 2016](#)). Trastuzumab has been found to have adverse effects on the heart.

### Vascular Endothelial Growth Factor/Receptor Inhibitors

An example of a vascular endothelial growth factor/receptor inhibitor drug is bevacizumab (Avastin). It binds to vascular endothelial growth factor (VEGF) and prevents the binding of VEGF with its receptors on the surfaces of endothelial cells present in blood vessels. This inhibits formation of new blood vessels within a tumor. As a result, tumor cells are poorly nourished and growth is inhibited. This drug is used with standard chemotherapy for many cancers that overexpress the receptor, such as colon, rectal, lung, and renal cell cancers.

The most common side effects are hypertension and impaired wound healing. Bone marrow suppression with reduced IMMUNITY and neutropenia and thrombocytopenia also occur, especially when the drug is used in combination with chemotherapy drugs that cause bone marrow suppression.

### Multikinase Inhibitors

The multikinase inhibitors (MKIs) inhibit the activity of specific kinases in cancer cells and tumor blood vessels. An example of an MKI is sunitinib (Sutent). These drugs are most effective in preventing the activation of tyrosine kinases that have a specific gene mutation found most often in some renal cell carcinomas, GI stromal tumors, and pancreatic cancers.

A common side effect of this class of drugs is hypertension. Other side effects include nausea and vomiting, diarrhea, constipation, mucositis, erythematous rash on the hands and feet (palmar-plantar erythrodysesthesia), and mild neutropenia and thrombocytopenia.

### Proteasome Inhibitors

Proteasome inhibitors prevent the formation of a large complex of proteins (a proteasome) in cells. The proteasome helps regulate the genes that promote cell division and prevent cell death. Proteasome inhibitors limit the amount of proteasome present, impairing the tumor's CELLULAR REGULATION and making its cells less likely to divide and more likely to respond to signals for cell death. The proteasome inhibitor bortezomib (Velcade) is used in the treatment of multiple myeloma. Proteasomes are present in normal and cancer cells, but cancer cells are much more sensitive to the effects of proteasome inhibition than are normal cells.

The most common side effects of bortezomib are nausea, vomiting, anorexia, abdominal pain, bowel changes, decreased taste sensation, and peripheral neuropathy. Other side effects include headache, rash, pruritus, back and bone pain, muscle aches, and tumor lysis syndrome.

### Angiogenesis Inhibitors

Angiogenesis inhibitors target a specific protein kinase known as the *mammalian target of rapamycin* (mTOR). An example of an angiogenesis inhibitor is temsirolimus (Torisel) used for renal cell cancer. When the drug binds to an intracellular protein, a protein-drug complex forms that inhibits the activity of mTOR. When mTOR is inhibited, the concentrations of vascular endothelial growth factor (VEGF) are greatly reduced, and many pro-cell division signal transduction pathways are disrupted.

Hyperglycemia and hypersensitivity reactions to these drugs are common. Bone marrow suppression is moderate to severe with anemia, neutropenia, and thrombocytopenia. Other general side effects include headache, nausea and vomiting, back pain, muscle and joint pain, mucositis, diarrhea, and skin problems.

## Clinical Judgment Challenge 22-2

### Safety; Evidence-Based Practice QSEN

A 70-year-old was diagnosed with colon cancer 3 years ago. At that time he underwent IV combination chemotherapy. He responded to the chemotherapy regimen until about 6 months ago when his colon cancer returned. His oncologist has now prescribed an oral chemotherapy, which has been effective for some colon cancers. When you talk with the patient, his comment to you is that “this new drug will be a breeze. I’ll just take it like my other pills. My wife puts those out for me to take.”

1. What concerns do you have about this man's response to his oral chemotherapy and why?
2. How will you respond to the man's comments about his oral chemotherapy drug?

### Photodynamic Therapy

#### Overview

Photodynamic therapy (PDT) is the selective destruction of cancer cells through a chemical reaction triggered by high energy laser light. It can be used to destroy some cancers, reduce the size of tumors to allow subsequent complete surgical removal, and shrink tumors in airways or the esophagus to relieve obstruction. PDT is used most often for nonmelanoma skin cancers, ocular tumors, GI tumors, and cancers located in the upper airways. PDT use in patients with noninvasive bladder cancer is being explored.

An agent that sensitizes cells to light is injected IV along with a dye to achieve cell death with exposure to specific wavelengths of laser light administered later. These agents enter all cells but leave normal cells more rapidly than cancer cells. Usually within 48 to 72 hours, most of the drug has collected in high concentrations in cancer cells. At this time a laser light is focused on the tumor. The light activates a chemical reaction, inducing irreversible cell damage in the cells retaining the sensitizing drug. Some cells die and slough immediately; others continue to slough for several days. Some lesions require only one exposure to the laser, and others must be re-exposed several days after the first treatment.

### ❖ Interprofessional Collaborative Care

PDT is typically performed in the outpatient setting, but at times the patient may require short-term ICU monitoring for airway management when the upper airways are treated. The photosensitizer dose, laser light exposure, and depth of tissue penetration by the light are items to be considered depending on the tumor type. Laser light exposure following photosensitizer administration leads to multiple chemical reactions that result in death of malignant tumor cells and the ultimate destruction of the vascular bed that fed the tumor. The application of PDT is contraindicated in patients with known tumor involvement of a major blood vessel because of the triggering of a severe or fatal episode of bleeding.

The risks associated with PDT are increased in patients who have had prior radiation or a history of coagulation disorders. The patient may be instructed to avoid sunlight exposure for 24 to 48 hours or longer, depending on the type and dose of photosensitizing agent. Patient and family teaching regarding sun and other types of light exposure are important for safety.

### Hormonal Manipulation

*Hormonal manipulation* involves changing the body's usual hormone responses. Hormones are chemicals secreted by endocrine glands and taken up by capillaries where they then circulate to all areas of the body. Hormones exert their effects only on their specific target tissues. Some hormones cause hormone-sensitive tumors to grow more rapidly, thus decreasing the amount of these hormones that reach hormone-sensitive tumors can slow cancer growth.

Hormonal manipulation may include the use of steroids, steroid analogues, and enzyme inhibitors (aromatase inhibitors, gonadotropin-releasing hormone analogues, anti-androgens, and antiestrogens). Many of these agents are used to block receptors and thus affect CELLULAR REGULATION by preventing the cancer cells from receiving normal hormonal growth stimulation. Hormonal manipulation can help control or slow the growth of some cancers for years but does not cure the disease. If a tumor depends on hormone A for growth and a large quantity of hormone B (similar to A) is given to the patient, hormone B will interfere with the tumor's uptake of hormone A or will limit the amount produced. As a result, tumor growth is slowed, and survival time increases. Table 22-7 lists drugs used in hormonal manipulation for cancer therapy.

**TABLE 22-7**  
**Common Agents Used for Hormonal Manipulation of Cancer**

TYPE OF AGENT	EXAMPLE
<b>Hormone Agonists</b>	
Androgen	Fluoxymesterone (Halotestin) Testolactone (Teslac)
Estrogen	Chlorotrianisene (Tace) Conjugated equine estrogen (Premarin) Diethylstilbestrol (DES, Stilphostrol) Ethinyl estradiol (Estinyl)
Progestin	Medroxyprogesterone (Amen, Provera) Megestrol (Megace)
Luteinizing hormone-releasing hormone (LHRH)	Leuprolide (Eligard, Lupron, Viadur) Goserelin (Zoladex)
<b>Hormone Antagonists</b>	
Antiandrogens	Bicalutamide (Casodex) Flutamide (Eulexin)
Antiestrogens	Fulvestrant (Faslodex) Raloxifene (Evista) Tamoxifen (Nolvadex) Toremifene (Fareston)
<b>Hormone Inhibitors</b>	
	Aminoglutethimide (Cytadren, Elipten) Anastrozole (Arimidex) Exemestane (Aromasin) Letrozole (Femara)

Some drugs are *hormone antagonists* that compete with natural hormones at the receptors. When

hormone antagonists are given, they bind to the specific hormone receptors on or in the tumor cell and prevent the needed hormone from binding to its receptors. If a tumor needs a certain hormone to grow and the hormone can enter or activate the cell only through receptors, hormone antagonists can alter CELLULAR REGULATION and slow tumor growth.

The hormone inhibitors also are used for hormonal therapy. These drugs inhibit the normal organ production of some specific hormones. For example, the aromatase inhibitor anastrozole (Arimidex) prevents the production of estrogen in the adrenal gland and reduces the blood level of estrogen, which results in slower growth of some breast cancers.

*Side effects* of hormonal manipulation are different from those of other types of chemotherapy. Androgens and the antiestrogen receptor drugs cause masculinizing effects in women. Chest and facial hair may develop, menstrual periods stop, and breast tissue shrinks. Patients may have some fluid retention. For men and women receiving androgens, acne and hypercalcemia are common, and liver dysfunction may occur with prolonged therapy. Women receiving estrogens or progestins may have irregular menses, fluid retention, and breast tenderness. All patients who take estrogen or progestins are at increased risk for venous thromboembolism (VTE).

Feminine manifestations appear in men who take estrogens, progestins, or antiandrogen receptor drugs. Facial hair thins, facial skin is smoother, body fat is redistributed, and breast development (**gynecomastia**) can occur. Bone loss is common, which increases the risk for osteoporosis and pathologic bone fractures (Limburg et al., 2014). Testicular and penile atrophy also occur to some degree. Teach patients and families about expected side effects. Encourage them to express their feelings about body changes. Refer them for counseling if needed.

## Oncologic Emergencies

With improvements in cancer treatments, many cancers have become a chronic disease. However, acute complications from the cancer or its treatment can occur at any time. This chapter presents select acute complications of cancer or cancer therapy, including sepsis and disseminated intravascular coagulation, syndrome of inappropriate antidiuretic hormone, spinal cord compression, hypercalcemia, superior vena cava syndrome, and tumor lysis syndrome as emergencies. Early diagnosis and immediate intervention of these emergency conditions are essential to avoid life-threatening situations. The role of the nurse is to implement interventions to prevent and detect these complications early for immediate treatment.

### Sepsis and Disseminated Intravascular Coagulation

*Sepsis*, or *septicemia*, is a condition in which organisms enter the bloodstream (bloodstream infection [BSI]) and can result in septic shock, a life-threatening condition. Adults with cancer who have low white blood cell counts (WBCs) (neutropenia) and impaired IMMUNITY from cancer therapy are at risk for infection and sepsis. [Chapter 37](#) describes the pathophysiology of sepsis and septic shock. Adults with neutropenia do not have enough WBCs to always produce the typical signs and symptoms of infection (i.e., erythema, swelling, warmth, high fever). Often a low-grade fever (100.4° F or 38° C) is the only sign of infection. Infection and sepsis have a high mortality rate in adults with neutropenia ([Shelton et al., 2016](#)).

*Disseminated intravascular coagulation* (DIC) is a problem with the blood-CLOTTING process. DIC is triggered by many severe illnesses, including cancer. In patients with cancer DIC often is caused by gram-negative sepsis, although viral and other bacterial infections can trigger it. A patient's normal bacterial flora enter the bloodstream through any site of skin breakdown and cause a severe infection, especially when neutropenia is present. Other causes of sepsis include liver disease, intravascular hemolysis, prosthetic devices, or metabolic acidosis.

Extensive, abnormal CLOTTING occurs throughout the small blood vessels of patients with DIC. This widespread clotting depletes circulating clotting factors and platelets. As this happens, extensive bleeding occurs. Bleeding from many sites is the most common problem and ranges from oozing to fatal hemorrhage. Clots block blood vessels and decrease blood flow to major body organs and result in pain, ischemia, strokelike symptoms, dyspnea, tachycardia, reduced kidney function, and bowel necrosis.

### Nursing Safety Alert QSEN

#### Critical Rescue

DIC is a life-threatening problem with a high mortality rate, even when proper therapies are instituted. *Thus the best management of sepsis and DIC is prevention. Identify patients at greatest risk for sepsis and DIC. Practice strict adherence to aseptic technique during invasive procedures and during contact with nonintact skin and mucous membranes. Teach patients and families the early indicators of infection and to seek prompt assistance.*

When sepsis is present and DIC is likely, management focuses on reducing the infection and halting the DIC process. IV antibiotic therapy is initiated. During the early phase of DIC, anticoagulants (especially heparin) are given to limit CLOTTING and prevent the rapid consumption of circulating clotting factors. When DIC has progressed and hemorrhage is the primary problem, clotting factors are given. See [Chapter 37](#) for a detailed discussion of DIC.

### NCLEX Examination Challenge 22-3

#### Safe and Effective Care Environment

Which assessment findings in a client who has neutropenia from cancer chemotherapy indicate to

the nurse that severe disseminated intravascular coagulation (DIC) is present? **Select all that apply.**

- A. The client is bleeding from the nose, IV sites, and rectum.
- B. The client's temperature is 99° F (37.2° C).
- C. The client's pulse rate is 130 beats per minute.
- D. The client's respiratory rate is 24 breaths per minute.
- E. The client's white blood cell count is 3200/mm<sup>3</sup> ( $3.2 \times 10^9/L$ )
- F. The client's hourly urine output is 100 mL.

## Syndrome of Inappropriate Antidiuretic Hormone

In healthy adults antidiuretic hormone (ADH) is secreted by the posterior pituitary gland only when more fluid (water) is needed in the body, such as when plasma volume is decreased. Certain conditions induce ADH secretion when not needed by the body, which leads to syndrome of inappropriate antidiuretic hormone (SIADH).

Cancer is a common cause of SIADH, especially small cell lung cancer. SIADH also may occur with other cancers, including head and neck, melanoma, GI, prostate, and hematologic malignancies, especially when metastatic tumors are present in the brain. Some cancers make and secrete ADH, whereas others stimulate the posterior pituitary to secrete ADH. Drugs used for cancer therapy or supportive therapy also can cause SIADH (e.g., cyclophosphamide, morphine sulfate).

In SIADH water is reabsorbed in excess by the kidneys and put into systemic circulation. The retained water dilutes blood sodium levels, causing hyponatremia. Mild symptoms include weakness, muscle cramps, loss of appetite, and fatigue. Serum sodium levels range from 115 to 120 mEq/L (mmol/L) or lower (normal range is 135 to 145 mEq/L [mmol/L]). With greater fluid retention, weight gain, nervous system changes, personality changes, confusion, and extreme muscle weakness occur. As the sodium level drops toward 110 mEq/L (mmol/L), seizures, coma, and death may follow depending on how rapidly hyponatremia occurs.

SIADH is managed by treating the condition and the cause. Nursing priorities focus on patient safety, restoring normal fluid balance, and providing supportive care. Management includes fluid restriction, increased sodium intake, and drug therapy. Immediate cancer therapy with radiation or chemotherapy may cause enough tumor regression that ADH production returns to normal. Effective treatment of the cancer triggering the syndrome is the only cure for SIADH. See [Chapter 62](#) for a detailed discussion of SIADH management.

## Nursing Safety Priority QSEN

### Critical Rescue

Monitor patients at least every 2 hours to recognize signs and symptoms of increasing fluid overload (bounding pulse, increasing neck vein distention (jugular venous distention [JVD]), presence of crackles in lungs, increasing peripheral edema, reduced urine output) because pulmonary edema can occur very quickly and lead to death. When symptoms indicate that the fluid overload from SIADH either is not responding to therapy or is becoming worse, respond by notifying the health care provider immediately.

## Spinal Cord Compression

Spinal cord compression (SCC) is an oncologic emergency that requires immediate intervention to relieve pain and prevent neurologic damage. Damage from SCC occurs either when a tumor directly enters the spinal cord or spinal column or when the vertebrae collapse from tumor degradation of the bone. Tumors metastasizing from the lung, prostate, breast, and colon account

for most SCC. Primary tumors of the spinal cord causing compression are less common. The most frequent area for SCC is the thoracic spine.

The symptoms of SCC can vary depending on the severity and location of the compression. Back pain is a common first symptom and occurs before other problems or nerve deficits. Other symptoms include weakness, loss of sensation, urinary retention, and constipation. Loss of or reduced deep tendon reflexes along with reduced pinprick and vibratory sensations are other findings that may be present on physical assessment. Neurologic problems are specific to the level of spinal compression and can lead to paralysis, which is usually permanent if the compression is not alleviated promptly.

Early recognition and treatment of spinal cord compression are key to a positive outcome. Assess for back pain that worsens over time; neurologic changes; muscle weakness or a sensation of heaviness in the arms or legs; numbness or tingling in the hands or feet; inability to distinguish pinprick, touch, or hot and cold sensation; and an unsteady gait. Depending on how low the compression occurs, constipation, incontinence, and difficulty starting or stopping urination also may be present. Teach patients and families to recognize and report the symptoms of early SCC, and instruct them to seek help immediately.

An MRI is used to confirm a diagnosis of SCC; however, if SCC is suspected by clinical symptoms, treatment should begin immediately to preserve function. Treatment is often palliative, with high-dose corticosteroids given first as an IV bolus to reduce swelling around the spinal cord and relieve symptoms, followed by a tapered dose over time. High-dose radiation may be used to reduce the size of the tumor in the area and relieve compression. Surgery may be performed to remove the tumor and trim the bony tissue so less pressure is placed on the spinal cord or to repair the spine if the spinal column is unstable. External back or neck braces may be used to reduce the weight borne by the spinal column and to reduce pressure on the spinal cord or spinal nerves.

## Hypercalcemia

Hypercalcemia (increased serum calcium level) occurs in up to a third of patients with cancer. It is a metabolic emergency and can lead to death. Breast, lung, and renal cell carcinomas; multiple myeloma; and adult T-cell leukemia and lymphoma are the most common causes among cancer patients. These cancers can secrete parathyroid hormone, causing bone to release calcium. Bone metastasis can stimulate bone breakdown (osteoclast activity) and bone resorption, which releases more calcium from bone and leads to hypercalcemia. In addition, systemic secretion of vitamin D analogues by the tumor can also cause elevated calcium levels in the bloodstream. Dehydration worsens hypercalcemia.

Early symptoms of hypercalcemia are nonspecific. Common symptoms include skeletal pain, kidney stones, abdominal discomfort, and altered cognition that can range from lethargy to coma. Additional symptoms include fatigue, loss of appetite, nausea, vomiting, constipation, and increased urine output. More serious problems include severe muscle weakness, loss of deep tendon reflexes, paralytic ileus, dehydration, and electrocardiographic (ECG) changes. Symptom severity depends on how high the calcium level is and how quickly it rose (see [Chapter 11](#)).

Cancer-induced hypercalcemia often develops slowly for many patients, which allows the body time to adapt to this electrolyte change. As a result, symptoms of hypercalcemia may not be evident until the serum calcium level is greatly elevated.

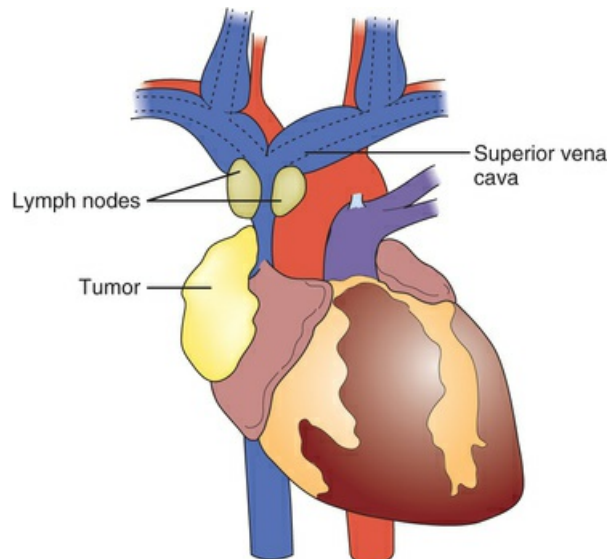

For patients who have elevated serum calcium levels and symptoms of hypercalcemia, vigorous IV hydration with normal saline at an infusion rate for 500 mL/hour (if cardiovascular function is normal) is used. Correcting the dehydration that often accompanies hypercalcemia restores urine output. Loop diuretics can promote calcium loss in urine. Thiazide diuretics are avoided because they can increase calcium reabsorption from urine. Many drugs such as bisphosphonates (which block bone resorption of calcium), calcitonin, and oral glucocorticoids can temporarily lower serum calcium levels. Treatment of the cancer is needed for long-term calcium control. When cancer-induced hypercalcemia is life threatening or occurs with kidney disease, dialysis can temporarily reduce serum calcium levels.

## Superior Vena Cava Syndrome

The superior vena cava (SVC), which returns all blood from the head, neck, and upper extremities to the heart, has thin walls, and compression or obstruction by tumor growth or by clots in the

vessel leads to congestion of the blood (Fig. 22-6). This is known as *superior vena cava syndrome* (SVCS) and can occur quickly or develop gradually over time. With gradual development physiologic adaptation occurs that allows the development of collateral circulation to handle the blood flow. SVCS occurs most often in patients with lymphomas (especially with tumors in the mediastinum), thymoma, right-sided lung cancer, and breast cancer.

**FIG. 22-6** Compression of the superior vena cava by lymph nodes and tumors in superior vena cava syndrome.

Compression of the SVC is painful and can be life threatening. Symptoms result from the blockage of venous return from the head, neck, and upper trunk. Early signs and symptoms include edema of the face, especially around the eyes (periorbital edema) on arising in the morning, and tightness of the collar. As the compression worsens, the patient develops engorged blood vessels and erythema of the upper body (Fig. 22-7), edema in the arms and hands, and dyspnea. The development of stridor (a high-pitched crowing sound) indicates narrowing of the pharynx or larynx and is an alarming sign of rapid SVCS progression. Symptoms are more apparent when the patient is in the supine position. Late symptoms include hemorrhage, cyanosis, mental status changes, decreased cardiac output, and hypotension. Imaging with CT or MRI is essential for diagnosis and treatment planning. Death results if compression is not relieved.

**FIG. 22-7** Appearance of the face, neck, upper arms, and chest in a patient with superior vena cava syndrome. (From Forbes, C. D., & Jackson, W. F. [2003]. *Colour atlas and text of clinical medicine* [3rd ed.]. London: Mosby.)

SVC syndrome is often associated with late-stage disease when the tumor is widespread. Occasionally SVCS occurs with obstruction in an indwelling vascular device by a blood clot. This

type of obstruction can be treated successfully with fibrinolytic drugs. High-dose radiation therapy to the upper chest area may be used to provide temporary relief of airway obstruction. Chemotherapy may be the only option for long-term control of the cancer causing the compression. Surgery is rarely performed for this condition. A metal stent can be placed in the vena cava in an interventional radiology department to relieve swelling. Follow-up angioplasty can keep this stent open for a longer period.

## NCLEX Examination Challenge 22-4

### Safe and Effective Care Environment

Which client report indicates to the nurse that spinal cord compression may be present?

- A. The client reports having a headache for the past 7 hours.
- B. The client has reduced breath sounds in the left lung.
- C. The client has worsening mid-thoracic back pain.
- D. Pedal edema is now present bilaterally.

### Tumor Lysis Syndrome

In tumor lysis syndrome (TLS) large numbers of tumor cells are destroyed rapidly. The intracellular contents of damaged cancer cells, including potassium and purines (DNA components), are released into the bloodstream faster than the body can eliminate them (Fig. 22-8). Unlike other oncologic emergencies, TLS is a positive sign that cancer treatment is effective in destroying cancer cells.

FIG. 22-8 Pathway of tumor lysis syndrome.

Severe or untreated TLS can cause tissue damage, acute kidney injury (AKI), and death (Wang et al., 2015). Serum potassium levels can increase to the point of hyperkalemia, causing cardiac dysfunction (see Chapter 11). The large amounts of purines form uric acid, causing hyperuricemia. These uric acid crystals precipitate in the kidney, blocking kidney tubules and leading to AKI. Sudden development of hyperkalemia, hyperuricemia, and hyperphosphatemia has life-threatening

effects on the heart muscle, kidneys, and central nervous system.

TLS is usually seen in patients with high-grade cancers that are growing quickly and in extensive cancers that are very responsive to treatment (Kaplow & Iyere, 2016). Adults receiving radiation or chemotherapy for cancers that are very sensitive to these therapies are at risk for TLS. Common cancers likely to cause TLS include acute leukemia, high-grade lymphomas, small cell lung cancer, germ cell tumors, inflammatory breast cancer, melanoma, and multiple myeloma. Chemotherapy drugs most likely to cause TLS include paclitaxel, fludarabine, etoposide, thalidomide, bortezomib, zoledronic acid, and hydroxyurea. In addition, TLS is more likely to occur in older adults undergoing cancer treatment (Sleutel et al., 2016). Early symptoms of TLS include lethargy, nausea, vomiting, anorexia, flank pain, muscle weakness, cramps, seizures, edema, and altered mental status.

Hydration prevents and manages TLS by diluting the serum potassium level and increasing the kidney flow rates. These actions prevent the precipitation of uric acid crystals, increase the excretion of potassium, and flush any kidney precipitates.

With tumors known to be very sensitive to cancer therapy, instruct patients to drink at least 3000 mL (5000 mL is more desirable) of fluid the day before, the day of, and for 3 days after treatment. Some fluids should be alkaline (e.g., sodium bicarbonate) to help prevent uric acid precipitation. Stress the importance of keeping fluid intake consistent throughout the 24-hour day, and help patients draw up a schedule of fluid intake.

Because some patients have nausea and vomiting after cancer therapy and may not feel like drinking fluids, stress the importance of following the antiemetic regimen. Instruct patients to contact the oncologist immediately if nausea prevents adequate fluid intake so parenteral fluids can be started.

Prophylaxis is essential for high-risk patients receiving cancer therapy that is expected to reduce tumor burden quickly. Monitor daily weights and serum electrolyte values. Management becomes more aggressive for patients who become hyperkalemic or hyperuricemic. In addition to fluids, diuretics (especially osmotic types) are given to increase urine flow through the kidney. These agents are used cautiously to avoid dehydration. Drugs that promote purine excretion, such as allopurinol (Aloprim, Zyloprim), rasburicase (Elitek), or febuxostat (Uloric) are given. To reduce serum potassium levels for mild-to-moderate hyperkalemia, sodium polystyrene sulfonate can be given orally or as a retention enema. For more severe hyperkalemia IV infusions containing glucose and insulin may be given. Patients who have severe hyperkalemia and hyperuricemia may need dialysis and intensive care.

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Use aseptic technique during care for open skin areas or any invasive procedure to prevent infection. **QSEN: Safety**
- Perform good handwashing before providing any care to patients with neutropenia. **QSEN: Evidence-Based Practice**
- Assess the venous access device at least every 30 to 60 minutes during chemotherapy administration. **QSEN: Safety**
- During chemotherapy administration, verify the blood return after every 2 to 5 mL for IV push drugs and every 5 to 10 minutes for short continuous infusions. **QSEN: Safety**
- Use Bleeding Precautions for any patient with thrombocytopenia and impaired CLOTTING (see [Chart 22-5](#)). **QSEN: Safety**
- Use appropriate personal protection equipment (gowns, gloves, masks, eye protection) when handling the excreta of a patient receiving chemotherapy and for 48 hours afterward. **QSEN: Safety**
- Inspect the oral mucosa of patients with neutropenia at least every 8 hours. **QSEN: Safety**
- Report any temperature over 100° F (37.8° C) in a patient with neutropenia. **QSEN: Evidence-Based Practice**
- Ensure proper shielding and waste disposal when patients in inpatient settings are receiving brachytherapy. **QSEN: Safety**
- Teach patients receiving radiation therapy how to care for the skin in the radiation path (see [Chart 22-2](#)). **QSEN: Safety**
- Teach the patient and family about symptoms of infection and when to seek medical advice. **QSEN: Safety**
- Teach patients at risk for bleeding from impaired CLOTTING the precautions to avoid injury (see [Chart 22-6](#)). **QSEN: Safety**
- Instruct patients to contact the oncologic pharmacist or oncology clinic to determine the proper disposal of expired or discontinued oral chemotherapy agents. **QSEN: Safety**

### Health Promotion and Maintenance

- Assist patients and families experiencing cancer to find appropriate community resources such as the American Cancer Society and the Canadian Cancer Society for support, supplies, care, and other assistance. **QSEN: Patient-Centered Care**

### Psychosocial Integrity

- Allow the patient and family the opportunity to express concerns regarding the diagnosis of cancer or the treatment regimen. **QSEN: Patient-Centered Care**
- Encourage the patient to verbalize feelings about changes in appearance resulting from cancer therapy. **QSEN: Patient-Centered Care**
- Encourage patients to use strategies to improve their appearance when alopecia occurs. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Perform a total assessment each time the patient with cancer is seen to determine the level of

cancer treatment side effects and whether an oncologic emergency exists. **QSEN: Patient-Centered Care**

- Assess the patient's pain level on a regular basis. **QSEN: Patient-Centered Care**
- Use pharmacologic and nonpharmacologic therapies to reduce pain for the patient with cancer. **QSEN: Patient-Centered Care**
- Explain all procedures, restrictions, drugs, and follow-up care to the patient and family. **QSEN: Patient-Centered Care**
- Instruct patients to use prescribed antiemetic drugs on a schedule for maximum relief of nausea and vomiting. **QSEN: Evidence-Based Practice**
- Work with other members of the interprofessional oncology care team to ensure the implementation of a personalized pain management and symptom control regimen. **QSEN: Teamwork and Collaboration**
- Assess the patient receiving chemotherapy for infection at least every 8 hours. **QSEN: Patient-Centered Care**
- Assess the patient with thrombocytopenia and impaired CLOTTING for bleeding. **QSEN: Patient-Centered Care**
- Assess the patient receiving hormonal therapy for evidence of inappropriate CLOTTING and blood clot formation. **QSEN: Patient-Centered Care**
- Closely monitor patients receiving any type of targeted therapy for severe side effects or adverse drug reactions. **QSEN: Patient-Centered Care**
- Stress the importance of adhering to the prescribed schedule for oral chemotherapy agents. **QSEN: Evidence-Based Practice**
- Demonstrate to the patient and whomever prepares oral chemotherapy agents at home how to do so without touching the tablets or capsules. **QSEN: Patient-Centered Care**
- Teach patients and families the symptoms of oncologic emergencies and when to notify the health care provider. **QSEN: Patient-Centered Care**

## CHAPTER 23

# Care of Patients With Infection

Donna D. Ignatavicius

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is IMMUNITY.**

✚ The IMMUNITY concept exemplar for this chapter is Infection, below.

**The interrelated concept for this chapter is TISSUE INTEGRITY.**

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Use clinical judgment to determine infection control measures, such as hand hygiene and Transmission-Based Precautions.
2. Apply current principles of infection prevention and control to ensure safe, patient-centered care.

### Health Promotion and Maintenance

3. Outline health teaching for patients, families, and staff about infection control measures.

### Psychosocial Integrity

4. Explain the importance of assessing the patient's emotional response to having an infection.

### Physiological Integrity

5. Determine patients most at risk for infection, including older adults and others with impaired IMMUNITY.
  6. Teach the patient and family about drug therapy for infections, including the need for adherence.
  7. Describe common causes of infection, including impaired TISSUE INTEGRITY.
  8. Identify common signs and symptoms of infection.
  9. Interpret laboratory test findings related to infections.
0. Evaluate evidence-based interprofessional collaborative interventions for management of the patient with an infection.
    1. Explain why multidrug-resistant organisms are increasing and how genetic/genomic research is helping to fight them.
    2. Identify examples of common emerging diseases and bioterrorism agents.
    3. Discuss nursing implications for the patient having a fecal microbiota transplantation (FMT) for recurrent *C. difficile* infections.

The human body has many systems that promote homeostasis. Physiologic mechanisms are the structural and functional defenses that maintain IMMUNITY and protect people from stressors such as infection. When these mechanisms fail to work properly or are overcome with microbes, infection can result.

Infections and infectious diseases have been the major cause of millions of deaths worldwide for centuries. Threats of bioterrorism have been added to the concerns about multidrug-resistant and emerging infections. Global travel and migration have increased exposure to a wider variety of infectious agents than in the past.

Advancing technology and invasive procedures also introduce microorganisms into the body, often resulting in infection. In other environments these microorganisms are harmless. This chapter

provides an overview of infection and general principles for prevention and management. Specific infections and their management are described elsewhere in this text.

## Immunity Exemplar Infection

A **pathogen** is any microorganism (also called an *agent*) capable of producing disease. Infections can be **communicable** (transmitted from person to person [e.g., influenza]) or not communicable (e.g., peritonitis). Microorganisms with differing levels of **pathogenicity** (ability to cause disease) surround everyone. **Virulence** is a term for pathogenicity. However, virulence is related more to the frequency with which a pathogen causes disease (degree of communicability) and its ability to invade and damage a host. It can also indicate the severity of the disease.

## Genetic/Genomic Considerations

### Patient-Centered Care QSEN

A current related issue in IMMUNITY and genomics is the microbiome. As described in Chapter 5, the **microbiome** for an adult is genomes of all the microorganisms that coexist in and on him or her. Many microorganisms live in or on the human host without causing disease and may be beneficial. These include the organisms that live in the mouth, the rest of the GI tract, the nose and sinuses, the vagina, and on the skin. Most of these organisms are part of our normal flora, which differ somewhat from person to person. **Normal flora** are mostly nonpathogenic (non-disease causing) when they remain confined to the expected area. However, when they manage to escape their normal human habitat and move elsewhere, they may be pathogenic in the new environment. For example, when GI organisms get into the urinary tract or the blood, serious infections can result. In some instances microorganisms that are often pathogenic may be present in the tissues of the host and yet not cause symptomatic disease because of normal flora; this process is called **colonization**.

In the United States, the Centers for Disease Control and Prevention (CDC) collects information about the occurrence and nature of infections and infectious diseases. It then recommends guidelines to health care agencies for infection control and prevention. Certain diseases such as tuberculosis must be reported to health departments and the CDC. In Canada the Public Health Agency of Canada also provides guidelines for infection control and for prevention of common infections. The infection control practitioner (ICP) for each health care organization is responsible for tracking infections (**surveillance**) and ensuring compliance with federal, provincial, and local requirements and accreditation standards.

## Transmission of Infectious Agents

Transmission of infection requires three factors:

- Reservoir (or source) of infectious agents
- Susceptible host with a portal of entry
- Mode of transmission

Reservoirs (sources of infectious agents) are numerous. Animate reservoirs include people, animals, and insects. Inanimate reservoirs include soil, water, handheld mobile devices (especially cell phones), and medical equipment (e.g., IV solutions, urine collection devices). Stethoscopes used for auscultation by many health care professionals carry *Staphylococcus aureus* from the skin of one patient to another. These devices should be cleaned with an antibacterial solution between patients ([Alspach, 2014](#)). The host's body can be a reservoir; pathogens colonize skin and body substances (e.g., feces, sputum, saliva, wound drainage). A person with an active infection or an asymptomatic **carrier** (one who harbors an infectious agent without active disease) is a reservoir. Examples of *community* reservoirs include sewage, stagnant or contaminated water, and improperly handled foods.

Bacteria such as *Neisseria meningitidis* can exist in the respiratory tract while causing no illness. If the bacteria invade the bloodstream or cerebrospinal fluid, they become extremely pathogenic. Another example is *Enterococcus*, which lives as normal flora in the GI system, where it is nonpathogenic and assists in the digestive process. If it enters the bloodstream, *Enterococcus* can

cause disease.

Continued multiplication of a pathogen is sometimes accompanied by toxin production. **Toxins** are protein molecules released by bacteria to affect host cells at a distant site. *Exotoxins* are produced and released by certain bacteria into the surrounding environment. Botulism, tetanus, diphtheria, and *Escherichia coli* 0157:H7–related systemic diseases are attributed to exotoxins. *Endotoxins* are produced in the cell walls of certain bacteria and released only with cell lysis. For example, typhoid and meningococcal diseases are caused by endotoxins.

Host factors influence the development of infection (Table 23-1). Host defenses provide the body with an efficient system for IMMUNITY against pathogens. Breakdown of these defense mechanisms may increase the **susceptibility** (risk) of the host for infection.

**TABLE 23-1**  
**Host Factors That Influence the Development of Infection**

HOST FACTOR	INCREASED RISK FOR INFECTION
Natural immunity	Congenital or acquired immune deficiencies
Normal flora	Alteration of normal flora by antibiotic therapy
Age	Infants and older adults
Hormonal factors	Diabetes mellitus, corticosteroid therapy, and adrenal insufficiency
Phagocytosis	Defective phagocytic function, circulatory disturbances, and neutropenia
Skin/mucous membranes/normal excretory secretions	Break in skin or mucous membrane integrity; interference with flow of urine, tears, or saliva; interference with cough reflex or ciliary action; changes in gastric secretions
Nutrition	Malnutrition or dehydration
Environmental factors	Tobacco and alcohol consumption and inhalation of toxic chemicals
Medical interventions	Invasive therapy such as endoscopy, urinary catheters, IVs; chemotherapy, radiation therapy, and steroid therapy (suppress immune system); surgery

The patient's *immune status* plays a large role in determining risk for infection. Congenital abnormalities and acquired health problems (e.g., renal failure, steroid dependence, cancer, acquired immune deficiency syndrome [AIDS]) can result in numerous immunologic deficiencies. Depression of IMMUNITY may make the host more susceptible to infection or impair the ability to combat organisms that have gained entry.

**Immunity** is resistance to infection; it is usually associated with the presence of antibodies or cells that act on specific microorganisms. **Passive immunity** is of short duration (days or months) and either natural by transplacental transfer from the mother or artificial by injection of antibodies (e.g., immunoglobulin). **Active immunity** lasts for years and is natural by infection or artificial by stimulation of the body's immune defenses (e.g., vaccination). Chapter 17 discusses the immune system and IMMUNITY in detail.

Environmental factors can also influence patients' immune status and thus their susceptibility to or ability to fight infection. Examples include alcohol consumption, nicotine use, inhalation of bone marrow–suppressing toxic chemicals, and certain vitamin deficiencies. Malnutrition, especially protein-calorie malnutrition and obesity, places patients at increased risk for infection. Diseases such as diabetes mellitus also predispose a patient to infection. Older adults have decreased IMMUNITY and other physiologic changes that make them very susceptible to infection (Chart 23-1).

### Chart 23-1

## Nursing Focus on the Older-Adult

### Factors That May Increase Risk for Infection in the Older Patient

FACTOR	AGING-ASSOCIATED CHANGES OR CONDITIONS
Immune system	Decreased antibody production, lymphocytes, and fever response
Integumentary system	Thinning skin, decreased subcutaneous tissue, decreased vascularity, slower wound healing
Respiratory system	Decreased cough and gag reflexes
GI system	Decreased gastric acid and intestinal motility
Chronic illness	Diabetes mellitus, chronic obstructive pulmonary disease, neurologic impairments
Functional/cognitive impairments	Immobility, incontinence, dementia
Invasive devices	Urinary catheters, feeding tubes, IV devices, tracheostomy tubes
Institutionalization	Increased person-to-person contact and transmission

Medical and surgical interventions may impair normal immune response. Steroid therapy, chemotherapy, and anti-rejection drugs increase the risk for infection. Medical devices (e.g., intravascular or urinary catheters, endotracheal tubes, synthetic implants) may also interfere with normal host defense mechanisms. Surgery, trauma, radiation therapy, and burns result in impaired TISSUE INTEGRITY. *The body's skin is one of the best barriers or defenses against infection.* When this barrier

is broken, infection often results. Microorganisms may enter the body in a variety of ways, including the respiratory tract, GI tract, genitourinary tract, skin and mucous membranes, and bloodstream.

### Routes of Transmission

Pathogens may enter the body through the *respiratory tract*. Microbes in droplets are sprayed into the air when people with infected oral or nasal tissues talk, cough, or sneeze. A susceptible host then inhales droplets, and pathogens localize in the lungs or are distributed via the lymphatic system or bloodstream to other areas of the body. Microorganisms that enter the body by the respiratory tract and produce distant infection include influenza virus, *Mycobacterium tuberculosis*, and *Streptococcus pneumoniae*.

Other pathogens enter the body through the *GI tract*. Some stay there and produce disease (e.g., *Shigella* causing self-limited disease). Others invade the GI tract to produce local and distant infection (e.g., *Salmonella enteritidis*). Some produce limited GI symptoms, causing systemic infection (e.g., *Salmonella typhi*) or profound involvement of other organs (e.g., hepatitis A virus). Millions of foodborne illness cases occur each year in the United States. This type of illness results in many hospitalizations and deaths.

Microorganisms also enter through the *genitourinary tract*. *Urinary tract infection (UTI)* is one of the most common health care–associated infections (HAIs). Indwelling urinary catheters are a primary cause of catheter-associated urinary tract infections (CAUTIs), especially in older adults. CAUTIs can increase hospital costs by prolonging the patient's length of stay and complicating his or her recovery. In many settings nurse-driven protocols have helped decrease the use of urinary catheters and associated infections (see [the Quality Improvement box](#)).

## Quality Improvement QSEN

### Reducing Catheter-Associated Urinary Tract Infections

Mori, C. (2014). A-voiding catastrophe: Implementing a nurse-driven protocol. *Medsurg Nursing*, 23(1), 15–21, 28.

In spite of the move to decrease the use of indwelling urinary catheters (e.g., Foley catheters), catheter-associated urinary tract infections (CAUTIs) remain a major cause of sepsis and increased hospital costs. The Centers for Medicare and Medicaid Services (CMS) recently began to link health care reimbursement to quality improvement efforts to prevent CAUTIs.

An interdisciplinary team led by a clinical nurse specialist in a Midwestern community hospital implemented a protocol that decreased the use of urinary catheters and ensured best practices for patients for whom the catheters were indicated. Using a screening checklist, each patient was assessed to determine the need for a Foley catheter. If certain criteria were not met, the catheter was removed by a nurse using a specific protocol during and after removal. For patients who had to have a Foley catheter, the nurse provided care to minimize the chance for urinary infection, including checking that the:

- Catheter was secure
- Tamper-evident seal was intact
- Catheter tubing was not twisted or had a dependent loop
- Catheter bag was positioned lower than the bladder level
- Drainage bag did not touch the floor or was not overfilled

### Commentary: Implications for Practice and Research

Research demonstrates that decreasing the use of indwelling urinary catheters is the most important intervention to prevent hospital-acquired CAUTIs. This project used this research and showed how an interdisciplinary team led by a Clinical Nurse Specialist (CNS) in a community hospital could improve the quality of care by decreasing urinary tract infections. In addition,

nurses provided evidence-based care for patients who needed urinary catheters to ensure adequate urinary flow.

A limitation of the project was that incremental changes or strategies to maintain the positive changes were not discussed. More quality improvement activities at a unit or health care agency are needed to use current research, sustain a change in nursing practice, and achieve positive patient outcomes.

Although intact skin is the best barrier to prevent most infections, some pathogens such as *Treponema pallidum* can enter the body through intact *skin* or *mucous membranes*. However, most pathogens enter through breaks in these normally effective surface barriers. Sometimes a medical procedure causes impaired TISSUE INTEGRITY or a break in mucous membranes, as in catheter-acquired **bacteremia** (bacteria in the bloodstream) and surgical-site infections (SSIs). *Fragile skin of older patients and of those receiving prolonged steroid therapy increases infection risk.*

Microorganisms can gain direct access to the *bloodstream*, especially when invasive devices or tubes are used. The incidence of bloodstream infections (BSIs) continues to increase in hospitals throughout the United States. Central venous catheters (CVCs) are a primary cause of these infections (see [Chapter 13](#) for more discussion of CVC-related BSIs). In the community setting biting insects can inject organisms into the bloodstream, causing infection (e.g., Lyme disease, West Nile viral encephalitis).

## Methods of Transmission

For infection to be transmitted from an infected source to a susceptible host, a transport mechanism is required. Microorganisms are transmitted by several routes:

- Contact transmission (indirect and direct)
- Droplet transmission
- Airborne transmission

*Contact transmission* is the usual mode of transmission of most infections. Many infections are spread by direct or indirect contact. With *direct contact* the source and host have physical contact. Microorganisms are transferred directly from skin to skin or from mucous membrane to mucous membrane. Often called *person-to-person transmission*, direct contact is best illustrated by the spread of the “common cold.”

*Indirect contact* transmission involves the transfer of microorganisms from a source to a host by passive transfer from a contaminated object. Contaminated articles or hands may be sources of infection. For example, patient-care devices such as glucometers and electronic thermometers may transmit pathogens if they are contaminated with blood or body fluids. Uniforms, laboratory coats, and isolation gowns used as part of personal protective equipment (PPE) may be contaminated as well.

Indirect transmission may involve contact with infected secretions or *droplets*. Droplets are produced when a person talks or sneezes; the droplets travel short distances. Susceptible hosts may acquire infection by contact with droplets deposited on the nasal, oral, or conjunctival membranes. Therefore the CDC recommends that staff stay at least 3 feet (1 m) away from a patient with droplet infection. An example of droplet-spread infection is influenza.

*Airborne transmission* occurs when small airborne particles containing pathogens leave the infected source and enter a susceptible host. These pathogens can be suspended in the air for a prolonged time. The particles carrying pathogens are usually contained in droplet nuclei or dust; they are usually propelled from the respiratory tract by coughing or sneezing. A susceptible person then inhales the particles directly into the respiratory tract. For example, tuberculosis is spread via airborne transmission.

Preventing the spread of microbes that are transmitted by the airborne route requires the use of special air handling and ventilation systems in an airborne infection isolation room (AIIR). *M. tuberculosis* and the varicella-zoster virus (chickenpox) are examples of airborne agents that require one of these systems. In addition to the AIIR, respiratory protection using a certified **powered air-purifying respirator (PAPR)** is recommended for health care personnel entering the patient's room. This device has a high-efficiency particulate air (HEPA) filter and battery to promote positive-pressure airflow and is more effective than N95 respirators.

Other sources of infectious agents include the environment such as contaminated food, water, or

vectors. *Vectors* are insects that carry pathogens between two or more hosts such as the deer tick that causes Lyme disease and, a more current concern, the mosquito that carries the Zika virus.

The **Zika virus** has affected people in over a dozen countries, including the United States, and can cause microcephaly (abnormally small heads) in newborns and Guillain-Barré syndrome and other neurologic diseases in adults (Simon & Carpenetti, 2016). In addition to vector transmission, the virus can be transmitted via sexual transmission, blood transmission, and prenatal transmission from mother to fetus. Teach patients to apply liberal amounts of insect repellent to prevent getting bitten by insects. One in five people with the virus have mild, self-limiting flu-like symptoms such as muscle and joint pain, fever, headaches, and fatigue. Treatment is supportive with rest, hydration, and acetaminophen (Simon & Carpenetti, 2016).

The *portal of exit* completes the chain of infection. Exit of the microbe from the host often occurs through the portal of entry. An organism such as *M. tuberculosis* enters the respiratory tract and then exits the same tract as the infected host coughs. Some organisms can exit from the infected host by several routes. For example, varicella-zoster virus can spread through direct contact with infective fluid in vesicles and by airborne transmission.

## Physiologic Defenses for Infection

Strong and intact host defenses can prevent microbes from entering the body or destroy a pathogen that has entered. Impaired host defenses may be unable to defend against microbial invasion, allowing entry of organisms that can destroy cells and cause infection. Common defense mechanisms include:

- Body tissues
- Phagocytosis
- Inflammation
- Immune systems

*Intact skin forms the first and most important physical barrier to the entry of microorganisms.* In addition to providing a mechanical barrier, the skin's slightly acidic pH (resulting from breakdown of lipids into fatty acids), together with normal skin flora, creates an unfriendly environment for many bacteria.

Mucous membranes' mucociliary action provides some mechanical protection against pathogenic invasion. More important, however, mucous membranes are bathed in secretions that inactivate many microorganisms. Lysozymes, which dissolve the cell walls of some bacteria, are present in large quantities in many body secretions, particularly in tears and nasal mucus.

Other body systems provide natural barriers to infection. For instance, the healthy respiratory tract clears most of all inhaled material by upper airway filtration, humidification, mucociliary transport, and coughing. Peristaltic action mechanically empties the GI tract of pathogenic organisms. Stomach acid, intestinal secretions, pancreatic enzymes, and bile, together with the competition from normal bowel flora, provide an environment that protects the GI tract from invasion by harmful organisms. In the genitourinary tract, the flushing action of urine eliminates pathogenic organisms. The low pH of urine also maintains a sterile environment, although some microorganisms, such as *E. coli*, can thrive in an acid medium.

**Phagocytosis** occurs when a foreign substance evades the first-line mechanical barriers and enters the body. Various leukocyte types function differently in the immune reaction, but neutrophils bear primary responsibility for phagocytosis. This process of engulfing, ingesting, killing, and disposing of an invading organism is an essential mechanism in host defense. Phagocytic dysfunction dramatically increases a patient's risk for infection.

*Inflammation* is another important nonspecific defense mechanism for preventing the spread of infection. It occurs when tissue becomes damaged or impaired. Damaged cells release enzymes, and polymorphonuclear (PMN) leukocytes (neutrophils) are attracted to the infected site from the bloodstream. One important substance, histamine, increases the permeability of the capillaries in inflamed tissues, thus allowing fluid, proteins, and white blood cells to enter an inflamed area. Other enzymes activate fibrinogen, which causes leaked fluid to clot and prevents its flow away from the damaged site into unaffected tissue, essentially "walling off" the inflamed tissue. The process of phagocytosis disposes of the invading microorganism and often dead tissue. If inflammation is caused by infection, the end products of inflammation form pus, which is then absorbed or exits the body through a break in the skin. [Chapter 17](#) discusses the process of

inflammation in more detail.

Specific defense responses to specific microorganisms are provided by antibody- and cell-mediated IMMUNITY. The **antibody-mediated immune system** produces antibodies directed against certain pathogens. These antibodies inactivate or destroy invading microorganisms and protect against future infection from that microorganism. Resistance to other microorganisms is mediated by the action of specifically sensitized T-lymphocytes and is called **cell-mediated immunity**. The components of the immune system work both independently and together to protect against infection. [Chapter 17](#) describes the function of the immune system in detail.

## Health Promotion and Maintenance

Infections occur most often in high-risk patients such as older adults and those who have inadequate or impaired IMMUNITY (immunocompromised). Implement interventions to prevent infection and detect signs and symptoms as early as possible. [Chart 23-2](#) summarizes nursing interventions for infection prevention and control.

### Chart 23-2

## Best Practice for Patient Safety & Quality Care

### Nursing Interventions for the Patient at Risk for Infection

- Assess patients for risk for infections.
- Monitor for signs and symptoms of infection.
- Monitor laboratory tests results such as cultures and white blood cell (WBC) count and differential.
- Screen all visitors for infections or infectious disease.
- Inspect skin and mucous membranes for redness, heat, pain, swelling, and drainage.
- Promote sufficient nutritional intake, especially protein for healing.
- Encourage fluid intake to treat fever.
- Teach the patient and family the signs and symptoms of infections and when to report them to the primary health care provider.
- Teach the patient and family how to avoid infections in health care agencies and the community.

## Infection Control in Health Care Settings

Infection acquired in the inpatient health care setting (not present or incubating at admission) is termed a **health care–associated infection (HAI)**. When occurring in a hospital setting, it is sometimes referred to as a *hospital-acquired infection*, but the former term is more accurate. HAIs can be *endogenous* (from a patient's flora) or *exogenous* (from outside the patient, often from the hands of health care workers, tubes, or implants). HAIs, including surgical site infections (SSIs), cause increased health care costs and many deaths (see discussion in [Chapter 16](#)). These infections tend to occur most often because health care workers do not follow basic infection control principles.

**Infection control within a health care facility is designed to reduce the risk for HAIs and thus reduce morbidity and mortality, as recommended in The Joint Commission's National Patient Safety Goals (NPSGs). This expected outcome is consistent with the desire for health care facilities to create a culture of safety within their environments (see [Chapter 1](#)).** Infection control and prevention are interprofessional efforts and include:

- Health organization–specific and department-specific infection control policies and procedures
- Surveillance and analysis

- Patient and staff education
- Community and interprofessional collaboration
- Product evaluation with an emphasis on quality and cost savings
- Bioengineering for designing health care facilities that help control the spread of infections

The infection control program of a hospital is coordinated and implemented by a health care professional certified in infection control (CIC) who has clinical and administrative experience. The Centers for Disease Control and Prevention (CDC) recommends one person with CIC credentials for every 100 occupied acute care beds. Long-term care facilities may not have a practitioner who specializes in infection control. However, every facility must designate a health care professional to be responsible for coordinating and implementing an infection prevention and control program.

Long-term care facilities are unique in that they have a large group of older adults who are together in one setting for weeks to years. Nursing homes in particular are required to provide a homelike environment in which residents can move and interact freely. Therefore infection control in these settings can be challenging. As a result, many infectious outbreaks may occur such as pneumonia, *Clostridium difficile*, and multidrug-resistant organisms (discussed in the [Multidrug-Resistant Organism Infections and Colonizations](#) section).

Ambulatory and home health care are the fastest-growing segments of the health care system. Infection remains a common cause of death for dialysis patients. Little information is available about acquired infections in home health settings because data are not systematically collected, surveillance programs are not established, and best practices for infection prevention and control do not yet exist.

## Methods of Infection Control and Prevention

All health care workers who come in contact with patients or care areas are involved in some aspect of the infection control program of the agency. According to the CDC, infections can be prevented or controlled in several ways:

- Hand hygiene
- Disinfection/sterilization
- Standard Precautions
- Transmission-Based Precautions
- Staff and patient placement and cohorting

### Hand Hygiene

*Health care workers' hands are the primary way in which infection is transmitted from patient to patient or staff to patient. Hand hygiene refers to both handwashing and alcohol-based hand rubs (ABHRs) ("hand sanitizers").*

In 2002 the U.S. CDC released the classic document entitled "CDC Hand Hygiene Recommendations." These recommendations are summarized in [Chart 23-3](#). *Handwashing is still an important part of hand hygiene, but it is recognized that in some health care settings, sinks may not be readily available. Despite years of education, health care workers do not wash their hands or perform hand hygiene on a consistent basis.*

#### Chart 23-3

### Best Practice for Patient Safety & Quality Care QSEN

#### Hand Hygiene

- When hands are visibly soiled or contaminated with proteinaceous material or visibly soiled with blood or other body fluids, wash hands with soap and water.
- If hands are not visibly soiled, use an alcohol-based hand rub (ABHR) for decontaminating hands or wash hands with soap and water.
- Use either ABHR or wash with soap and water (decontaminate hands) before having direct

contact with patients.

- Decontaminate hands before donning sterile gloves to perform a procedure such as inserting an invasive device (e.g., indwelling urinary catheter).
- Decontaminate hands after contact with a patient's intact skin (e.g., taking a pulse) or with body fluids or excretions/secretions.
- Decontaminate hands after removing gloves.
- Decontaminate hands after contact with inanimate objects (including medical equipment) in the immediate vicinity of the patient.

Effective handwashing includes wetting, soaping, lathering, applying friction under running water for at least 15 seconds, rinsing, and adequate drying. Friction is essential to remove skin oils and disperse transient bacteria and soil from hand surfaces. Performing adequate handwashing takes time that health care workers (HCWs) may not think they have. Handwashing can also cause dry skin; therefore hand moisturizers are essential to maintain good hand health and hygiene.

*Alcohol-based hand rubs (ABHRs)* allow care providers to spend less time seeking sinks and more time delivering care. However, these hand rubs have their limitations.

## Nursing Safety Priority QSEN

### Action Alert

If your hands are visibly dirty or soiled or feel sticky or if you have just toileted, *wash your hands instead of using ABHRs*. Keep in mind that ABHRs are also ineffective against spore-forming organisms such as *Clostridium difficile*, a common cause of health care–associated diarrhea, especially in older adults. Do not use an ABHR before inserting eyedrops, ointments, or contact lenses because alcohol can irritate the patient's eyes, causing burning and redness. The Joint Commission's National Patient Safety Goals require that health care agencies monitor handwashing practices and the use of ABHRs to make sure that HCWs are performing hand hygiene on a regular basis.

The CDC recommends using antiseptic solutions such as chlorhexidine for handwashing in caring for patients who are at high risk for infection (e.g., those with impaired IMMUNITY).

The classic CDC guidelines (CDC, 2002) also address the issue of artificial fingernails, which have been linked to a number of outbreaks because of poor fingernail health and hygiene. The guidelines recommend that artificial fingernails and extenders not be worn while caring for patients at high risk for infections, such as those in ICUs or operating suites. Most health care agencies have banned artificial nails for all health care workers providing direct patient care and require that natural nails be short. Some agencies also ban the use of nail polish or gel.

## Sterilization and Disinfection

Sterilization and disinfection have helped invasive procedures become much more common and safe. **Sterilization** means destroying all living organisms and bacterial spores. Many invasive procedures, such as inserting vascular access devices (VADs) and urinary catheters, require sterile technique. Sterile technique in the operating suite is discussed in detail in [Chapter 15](#).

All items that invade human tissue where bacteria are not commonly found should be sterilized. **Disinfection** does not kill spores and only ensures a reduction in the level of disease-causing organisms. High-level disinfection is adequate when an item is going inside the body where the patient has resident bacteria or normal flora (e.g., GI and respiratory tracts). As with sterilization, no high-level disinfection can occur without first cleaning the item. This can be especially difficult with items that have narrow lumens in which organic debris can become trapped and is not easily visible. For example, endoscopes have been especially challenging to clean and have been linked to a number of infectious outbreaks.

## Standard Precautions

The classic 2007 guidelines from the CDC focus on transmission mechanisms and the precautions needed to prevent the spread of infection. Included in these guidelines are Standard Precautions and Transmission-Based Precautions, including Airborne, Droplet, and Contact Precautions (Tables 23-2 and 23-3).

**TABLE 23-2**  
**Recommendations for Application of Standard Precautions for the Care of All Patients in All Health Care Settings**

COMPONENT	RECOMMENDATIONS
Hand hygiene	Perform hand hygiene after touching blood, body fluids, secretions, excretions, contaminated items; immediately after removing gloves; between patient contacts
Personal protective equipment (PPE)	Use appropriate PPE, including:
• Gloves	• For touching blood, body fluids, secretions, excretions, contaminated items; for touching mucous membranes and nonintact skin
• Gown	• During procedures and patient-care activities when contact of clothing/exposed skin with blood/body fluids, secretions, and excretions is anticipated
• Mask, eye protection (goggles), face shield*	• During procedures and patient-care activities likely to generate splashes or sprays of blood, body fluids, secretions, especially suctioning, endotracheal intubation
Soiled patient-care equipment	Handle in a manner that prevents transfer of microorganisms to others and to the environment; wear gloves if visibly contaminated; perform hand hygiene
Environmental control	Develop procedures for routine care, cleaning, and disinfection of environmental surfaces, especially frequently touched surfaces in patient-care areas
Textiles and laundry	Handle in a manner that prevents transfer of microorganisms to others and to the environment
Needles and other sharps	Do not recap, bend, break, or hand manipulate used needles; use safety features such as needleless systems when available; place used sharps in puncture-resistant container
Patient resuscitation	Use mouthpiece, resuscitation bag, other ventilation devices to prevent contact with mouth and oral secretions
Patient placement	Prioritize for single-patient room if patient is at increased risk for transmission, is likely to contaminate the environment, does not maintain appropriate hygiene, or is at increased risk for acquiring infection or developing adverse outcome following infection
Respiratory hygiene/cough etiquette (source containment of infectious respiratory secretions in symptomatic patients, beginning at initial point of encounter [e.g., triage and reception areas in emergency departments and physician offices])	Instruct symptomatic people to cover mouth/nose when sneezing/coughing; use tissues and dispose in no-touch receptacle; observe hand hygiene after soiling of hands with respiratory secretions; wear surgical mask if tolerated or maintain spatial separation, >3 feet if possible

\*During aerosol-generating procedures on patients with suspected or proven infections transmitted by respiratory aerosols, wear a powered air-purifying respirator (PAPR) (most effective) or N95 mask in addition to gloves, gown, and face/eye protection.

**TABLE 23-3**  
**Transmission-Based Infection Control Precautions**

PRECAUTIONS (IN ADDITION TO STANDARD PRECAUTIONS)	EXAMPLES OF DISEASES IN CATEGORY
<b>Airborne Precautions</b> 1. Private room required with monitored negative airflow (with appropriate number of air exchanges and air discharge to outside or through HEPA filter); keep door(s) closed 2. Special respiratory protection: • Wear PAPR for known or suspected TB • Susceptible people not to enter room of patient with known or suspected measles or varicella unless immune caregivers are not available • Susceptible people who must enter room must wear PAPR or N95 HEPA filter* 3. Transport: patient to leave room only for essential clinical reasons, wearing surgical mask	Diseases that are known or suspected to be transmitted by air: • Measles (rubeola) • <i>Mycobacterium tuberculosis</i> , including multidrug-resistant TB (MDR-TB) • Varicella (chickenpox)†; disseminated zoster (shingles)†
<b>Droplet Precautions</b> 1. Private room preferred; if not available, may cohort with patient with same active infection with same microorganisms if no other infection present; maintain distance of at least 3 feet from other patients if private room not available 2. Mask: required when working within 3 feet of patient 3. Transport: as for Airborne Precautions	Diseases that are known or suspected to be transmitted by droplets: • Diphtheria (pharyngeal) • Streptococcal pharyngitis • Pneumonia • Influenza • Rubella • Invasive disease (meningitis, pneumonia, sepsis) caused by <i>Haemophilus influenzae</i> type B or <i>Neisseria meningitidis</i> • Mumps • Pertussis
<b>Contact Precautions</b> 1. Private room preferred; if not available, may cohort with patient with same active infection with same microorganisms if no other infection present 2. Wear gloves when entering room 3. Wash hands with antimicrobial soap before leaving patient's room 4. Wear gown to prevent contact with patient or contaminated items or if patient has uncontrolled body fluids; remove gown before leaving room 5. Transport: patient to leave room only for essential clinical reasons; during transport, use needed precautions to prevent disease transmission 6. Dedicated equipment for this patient only (or disinfect after use before taking from room)	Diseases that are known or suspected to be transmitted by direct contact: • <i>Clostridium difficile</i> • Colonization or infection caused by multidrug-resistant organisms (e.g., MRSA, VRE) • Pediculosis • Respiratory syncytial virus • Scabies

\*Before use: training and fit testing required for personnel.

†Add Contact Precautions for draining lesions.

HEPA, High-efficiency particulate air; MRSA, methicillin-resistant *Staphylococcus aureus*; PAPR, powered air-purifying respirator; TB, tuberculosis; VRE, vancomycin-resistant *Enterococcus*.

**Standard Precautions** are based on the belief that all body excretions, secretions, and moist membranes and tissues, excluding perspiration, are potentially infectious. As barriers to potential or actual infections, **personal protective equipment (PPE)** is used. PPE refers to gloves, isolation gowns, face protection (masks, goggles, face shields), and powered air-purifying respirators (PAPRs) or N95 respirators (Fig. 23-1).

**FIG. 23-1** A, Nurse in personal protective equipment (PPE) caring for a patient in a private room. B, Powered air-purifying respirator (PAPR). (A From deWit, S. C. [2014]. *Fundamental concepts and skills for nursing* [4th ed.]. Philadelphia: Saunders; B from Curran, P. [2006]. *Medical response to weapons of mass destruction*. Philadelphia: Mosby/JEMS.)

## Nursing Safety Priority QSEN

### Action Alert

Remember that gloves are an essential part of infection control and should always be worn as part of Standard Precautions. Either handwashing or use of alcohol-based hand rubs should be done before donning and after removing gloves. The combination of hand hygiene and wearing gloves is the most effective strategy for preventing infection transmission!

Health care settings in the United States and Canada have switched from latex to nonlatex gloves. The U.S. National Institute for Occupational Safety and Health (NIOSH) issued a public warning about potential allergic reactions to those exposed to latex in gloves and other medical products. Reactions include rashes, nasal or eye symptoms, asthma, and (rarely) shock. People with **latex allergy** usually have an allergy to foods such as bananas, kiwis, and avocados. Health care workers (HCWs) have not been as strict with wearing gloves as they should because of poor fit or skin dryness, irritation, and dermatitis. One possible solution to dry skin is the use of aloe vera–coated gloves or moisturizers such as Eucerin or AmLactin products.

The *respiratory hygiene/cough etiquette (RH/CE)* requirement is directed at patients and visitors with signs of respiratory illness such as sinus or chest congestion, cough, or rhinorrhea (“runny nose”). The elements for RH/CE include:

- Patient, staff, and visitor education
- Posted signs
- Hand hygiene
- Covering the nose and mouth with a tissue and prompt tissue disposal or using surgical masks (or sneezing/coughing into a shirt sleeve rather than the hand)
- Separation from the person with respiratory infection by more than 3 feet (1 m)

### Transmission-Based Precautions

Transmission-Based Precautions may also be referred to as *Isolation Precautions*. But the word *isolation* implies that the patient is physically separated from everyone, which is not always the case.

**Airborne Precautions** are used for patients known or suspected to have INFECTIONS transmitted by the airborne transmission route. These infections are caused by organisms that can be suspended in air for prolonged periods. Negative-airflow rooms are required to prevent airborne spread of microbes. Enclosed booths with high-efficiency particulate air (HEPA) filtration or ultraviolet light may be used for sputum induction procedures. Tuberculosis, measles (rubeola), and chickenpox (varicella) are examples of airborne diseases.

**Droplet Precautions** are used for patients known or suspected to have INFECTIONS transmitted by the droplet transmission route. Such infections are caused by organisms in droplets that may travel 3 feet but are not suspended for long periods. Examples of infectious conditions requiring Droplet

Precautions include influenza, mumps, pertussis, and meningitis caused by either *Neisseria meningitidis* or *Haemophilus influenzae* type B.

**Contact Precautions** are used for patients known or suspected to have INFECTIONS transmitted by direct contact or contact with items in the environment. Patients with significant multidrug-resistant organism (MDRO) infection or colonization, such as methicillin-resistant *Staphylococcus aureus* (MRSA) or vancomycin-resistant *Enterococcus* (VRE), are placed on Contact Precautions. Other infections requiring Contact Precautions include pediculosis (lice), scabies, respiratory syncytial virus (RSV), and *C. difficile*.

### Staff and Patient Placement and Cohorting

*Adequate staffing* of nurses is an essential method for preventing infection. In addition to a ratio of one infection control practitioner to 100 occupied acute care beds, nurse staffing is critical. When possible, bedside nurse staffing should consist of full-time nurses assigned regularly to the unit to ensure consistent practices.

*Patient placement* has been used as a way to reduce the spread of infection. The CDC does not mandate that all patients with infections have a private room. It does recommend that private rooms always be used for patients on Airborne Precautions and those in a protective environment (PE). A PE is architecturally designed and structured to prevent infection from occurring in patients who are at extremely high risk, such as those having stem cell therapy. The CDC also prefers private rooms for patients who are on Contact and Droplet Precautions. If private rooms are not available, keep these patients at least 3 feet apart. Many hospitals are becoming totally private-room facilities. Large health care systems have biomedical engineers to assist in designing the best environment to reduce the spread of infection, including ventilation systems and physical layout.

Cohorting is another method of patient placement. **Cohorting** is the practice of grouping patients who are colonized or infected with the same pathogen. This method has been used the most with patients who have an outbreak of a multidrug-resistant organism such as methicillin-resistant *Staphylococcus aureus* (MRSA). It is particularly effective in long-term care settings.

Infection control principles for *patient transport* include limiting movement to other areas of the facility, using appropriate barriers such as covering infected wounds, and notifying other departments or agencies who are receiving the patient about the necessary precautions. **Accurate hand-off communication between agencies is also very important to prevent the spread of infection, according to The Joint Commission's National Patient Safety Goals.**

### Protection of Visitors of Patients on Transmission-Based Precautions

Many agencies have policies regarding visitors of patients who are on Transmission-Based Precautions. However, visitors are seldom monitored to ensure that they are following these policies. [Munoz-Price et al. \(2015\)](#) made the following recent recommendations for visitors:

- Use proper hand hygiene before and after the patient visit. (Health care organizations should provide conveniently located alcohol-based rub stations.)
- Wear gowns and gloves (Contact Precautions) to prevent the spread of enteric pathogens or drug-resistant organisms.
- Wear a surgical mask if visiting a patient on Droplet or Airborne Precautions.
- Do not visit patients if you have an active cough or fever.

## NCLEX Examination Challenge 23-1

### Safe and Effective Care Environment

Which statements by a nursing student indicate a need for further teaching by the nurse regarding infection control measures needed to care for a client who has possible tuberculosis? **Select all that apply.**

- A. "I'll wear an isolation gown when providing direct care."
- B. "I'll wear gloves when emptying the bed pan."

- C. "I'll wear a mask each time I enter the client's room."
- D. "I'll use a hand sanitizer when I can't wash my hands."
- E. "I'll wear goggles to protect my eyes."

## Multidrug-Resistant Organism Infections and Colonizations

Antibiotics have been available for many years. Unfortunately these drugs were commonly prescribed for conditions that did not need them or were given at higher doses and for longer periods of time than were necessary. As a result, a number of microorganisms have become resistant to certain antibiotics; that is, drugs that were once useful no longer control these infectious agents (multidrug-resistant organisms [MDROs]). New antibiotics are not keeping up with preventing antimicrobial-resistant infection (ARI); therefore patients are at risk for increased morbidity and mortality because of health care–associated infections (HCAIs) (Plavskin, 2016). For this reason, a culture of safety related to infection control has been mandated by the CDC, the Institute for Healthcare Improvement (IHI), and The Joint Commission. Standard Precautions must be strictly followed today in all health care settings to prevent more of these difficult and deadly infections.

One of the newest discoveries to explain the increase in HCAIs, especially the rise in drug-resistant infections, is the formation of biofilms. A **biofilm**, also called *glycocalyx*, is a complex group of microorganisms that functions within a “slimy” gel coating on medical devices such as urinary catheters, orthopedic implants, and enteral feeding tubes; on parts of the body such as the teeth (plaque) and tonsils; and in chronic wounds. These reservoirs become sources of infection for which antibiotics and disinfection are not effective. Antibiotic therapy may increase the growth of microbes within biofilms.

Biofilms are extremely difficult to treat, and mechanical disruption strategies are the mainstay of management and research. Studies on biofilms that cause the most common HCAIs, such as catheter-associated urinary tract infections (CAUTIs) and wound infections, continue to be conducted. Many specific biofilms have been identified, and methods to remove or disrupt them are being researched.

### Genetic/Genomic Considerations

#### Evidence-Based Practice QSEN

A new area of research is the study of genetics and genomics of pathogens to help fight drug-resistant organisms and reduce ARIs. For example, genomic bacterial analysis can provide information about sources of infection and how they can be controlled. Population genetic studies can track pathogen transmission and identify infection prevalence and incidence. Transmission mapping can help identify the characteristics of infectious agents, how they are spread, and where carriers of infections are likely to occur within an institution. Research in the genetics and genomics of pathogens is ongoing and can help the interprofessional team promote patient safety by preventing and treating ARIs (Plavskin, 2016).

The most common MDROs are methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant *Enterococcus*, and carbapenem-resistant *Enterococcus*. Other infections such as vancomycin-intermediate *S. aureus* (VISA) and vancomycin-resistant *S. aureus* (VRSA) may also occur, which may be effectively treated with antibiotics such as linezolid (Zyvox) and quinupristin-dalfopristin (Synercid). In 2014 the *Shigella sonnei* bacterium showed signs of becoming more resistant to ciprofloxacin (Cipro) and other antibiotics. As a result, shigellosis has become another public health concern in the United States.

### Methicillin-Resistant *Staphylococcus aureus* (MRSA)

*Staphylococcus aureus* (*S. aureus*) is a common bacterium found on the skin and perineum and in the nose of many people. It is usually not infectious when in these areas because the number of bacteria is controlled by good hygiene measures. However, when skin or mucous membranes are not intact, localized infection such as boils or conjunctivitis may occur. If the organism enters into deep wounds, surgical incisions, the lungs, or bloodstream, more serious or systemic infections occur that

require strong antibiotics such as methicillin.

Within the past 40 years, more and more *S. aureus* infections have not responded to methicillin or other penicillin-based drugs. Known as MRSA, these infections are one of the fastest growing and most common in health care today. This type of infection is called *health care-associated MRSA*, or HA-MRSA. Patients who have HA-MRSA have increased hospital stays at a very high cost. To add to this problem, some patients may be colonized with the organism. Health care staff members may also colonize. Patients who develop HA-MRSA pneumonia, abscesses, or bacteremia (bloodstream infection [BSI]) can quickly progress to sepsis and death.

MRSA is spread by direct contact and invades hospitalized patients through indwelling urinary catheters, vascular access devices, open wounds, and endotracheal tubes. It is susceptible to only a few antibiotics, such as IV vancomycin (Lyphocin, Vancocin) and oral linezolid (Zyvox). A newer IV antibiotic, ceftaroline fosamil (Teflaro), is the first cephalosporin approved to treat MRSA.

Studies show that bathing hospitalized patients with premoistened cloths or warm water containing chlorhexidine gluconate (CHG) solution can significantly reduce MRSA infection by 23% to 32% (Kassakian et al., 2011; Powers et al., 2012). In 2013 the American Association of Critical Care published a recommendation that nurses use CHG to bathe patients in critical care settings as a way to reduce MRSA and other multidrug-resistant organisms.

## Nursing Safety Priority QSEN

### Action Alert

Patients most at risk for HA-MRSA are older adults and those who have suppressed IMMUNITY, have a long history of antibiotic therapy, or have invasive tubes or lines. ICU patients are especially at risk. Check with your agency policy regarding specific MRSA preventive measures. Examples include bathing patients with chlorhexidine wipes and administering nasal mupirocin ointment.

Although controversial, some health care facilities have a MRSA-surveillance program in which each patient's nose is swabbed and cultured for MRSA. Staff may also be cultured. All patients with HA-MRSA infection or colonization should be placed on Contact Precautions.

*Community-associated MRSA*, or CA-MRSA, causes infections in healthy, nonhospitalized people, especially those living in college housing and prisons. It is easily transmitted among family members and can cause serious skin and soft-tissue infections, including abscesses, boils, and blisters. The best way to decrease the incidence of this growing problem is health teaching, including:

- Performing frequent hand hygiene, including using hand sanitizers
- Avoiding close contact with people who have infectious wounds
- Avoiding large crowds
- Avoiding contaminated surfaces
- Using good overall hygiene

Minocycline (Minocin, Apo-Minocycline) and doxycycline (Doryx, Apo-Doxy) are usually effective in treating CA-MRSA.

## NCLEX Examination Challenge 23-2

### Safe and Effective Care Environment

A client is diagnosed with a foot ulcer infected with methicillin-resistant *Staphylococcus aureus* (MRSA) infection. Which personal protective equipment is appropriate when providing **direct** client care? **Select all that apply.**

- A. Mask
- B. Gloves

- C. Shoe covers
- D. Goggles
- E. Gown

## Vancomycin-Resistant *Enterococcus* (VRE)

Enterococci are bacteria that live in the intestinal tract and are important for digestion. When they move to another area of the body, such as during surgery, they can cause an infection, which is usually treatable with vancomycin. However, in recent years many of these infections have become resistant to the drug, and VRE results. Risk factors for this infection include prolonged hospital stays, severe illness, abdominal surgery, enteral nutrition, and immunosuppression. Place patients with VRE infections on Contact Precautions to prevent contamination from body fluids.

Unfortunately VRE can live on almost any surface for days or weeks and still be able to cause an infection. Contamination of toilet seats, door handles, and other objects is very likely for a lengthy period.

## Carbapenem-Resistant *Enterobacteriaceae* (CRE)

Carbapenem antibiotics, most often given for abdominal infections such as peritonitis, have been used extensively for the past 15 years. Examples of this class of antibiotics include imipenem (Cilastin) and meropenem (Merrem IV).

*Klebsiella* and *Escherichia coli* (*E. coli*) are types of *Enterobacteriaceae* that are located within the intestinal tract. Carbapenem-resistant *Enterobacteriaceae* (CRE) is a family of pathogens that are difficult to treat because they have a high level of resistance to carbapenems caused by enzymes that break down the antibiotics. *Klebsiella pneumoniae* (KPC) and New Delhi metallo-beta-lactamase are examples of these enzymes. Patients who are high risk for CRE include those in ICUs or nursing homes and patients who are immunosuppressed, including older adults.

To prevent the transmission of this infection, place patients who are high risk on Contact Precautions. The [CDC \(2013\)](#) also recommends chlorhexidine (2% dilution) bathing to prevent CRE or decrease colonization and other types of infections from MDROs.

## Occupational and Environmental Exposure to Sources of Infection

The U.S. Occupational Safety and Health Administration (OSHA) is a federal agency that protects workers from injury or illness at their place of employment. Unlike the voluntary guidelines developed by the CDC, OSHA regulations are law. Employers can be fined or disciplined for noncompliance with OSHA regulations. The regulation for prevention of exposure to bloodborne pathogens, such as hepatitis B and hepatitis C or the human immune deficiency virus (HIV), is one example of an OSHA regulation.

Reduction of skin and soft-tissue injuries (e.g., needlesticks) is essential to reduce bloodborne pathogen transmission to health care personnel. *OSHA mandates that sharp objects (“sharps”) and needles be handled with care.* Many contaminated sharp-object exposures involve nurses. Needleless devices have helped decrease these exposures, especially when caring for patients receiving infusion therapy (see [Chapter 13](#)).

Other infection control concerns that nurses and other HCWs have are the possibilities of pandemic influenza or biologic agent exposure. A large outbreak of one of the MDROs is also worrisome, especially if no drug is sensitive enough for successful management. Nurses may fear that they will accidentally bring the infectious agent to their homes and families.

### Nursing Safety Priority QSEN

#### Action Alert

To help prevent the transmission of an MDRO, wear scrubs and change clothes before leaving work. Keep work clothes separate from personal clothes. Take a shower when you get home, if possible, to rid your body of any unwanted pathogens. Be careful not to contaminate equipment that is commonly used such as your stethoscope.

Another environmental source for infection is animals or insects. For example, *hantaviruses* are caused by exposure to rodent-infested areas such as old sheds or cabins. Lyme disease can be caused by deer ticks (see [Chapter 18](#)).

Saliva and excrement from mice and rats living in the southwestern part of the United States are the primary sources of hantaviruses. While not a common infection, patients can die from complications such as *hantavirus pulmonary syndrome*, a severe and potentially lethal respiratory disease. Teach patients to avoid exposure to potential hantaviruses by avoiding rodent-infested areas. If infested areas need to be cleaned, teach patients to wear rubber or nonlatex gloves and either a tight-seal negative-pressure respirator or a positive-pressure powered air-purifying respirator equipped with N100 or P100 filters ([Ly, 2013](#)).

## Problems Resulting From Inadequate Antimicrobial Therapy

Inadequate antimicrobial therapy may range from an incorrect choice of drug to inadequate drug dosing. Drug regimen **noncompliance** (deliberate failure to take the drug) or **nonadherence** (accidental failure to take the drug) also contributes to resistant-organism development.

Some diseases such as tuberculosis (TB) have legal sanctions that require that a patient complete treatment. Patients who are at risk for noncompliance or nonadherence with an anti-TB drug regimen may be placed on *directly observed therapy (DOT)*. This means that a health care worker must observe and validate patient compliance with the drug regimen. DOT has been very effective at reducing the spread of multidrug-resistant TB.

Serious complications of infection may also result from incomplete or inadequate antibiotic therapy. Local infections that could be cured without complications such as cellulitis and pneumonia may progress to abscess formation or systemic infection if appropriate drug therapy is not continued. Although drug therapy does not always prevent abscess, early therapy may prevent or limit the size of an abscess.

In addition to abscess formation, inadequate therapy or a missed diagnosis may lead to systemic spread, or sepsis. *Sepsis is the number one cause of hospitalized patient deaths (Lopez-Bushnell et al., 2014; Plavskin, 2016)*. If the infection is not resolved or if it is treated with drugs that are ineffective for the offending microorganism, the pathogen may enter the bloodstream (referred to as septicemia or bloodstream infection [BSI]). Inadequately treated local infections may also lead to widespread sepsis with leukocytosis (increased white blood cell count) and inflammation (systemic inflammatory response syndrome [SIRS]). In severe or advanced cases, leukopenia (decreased white blood cell count) and life-threatening disseminated intravascular coagulation (DIC) may occur. After pathogens invade the bloodstream, no site is protected from invasion.

BSI may progress to **septic shock**, more accurately called *sepsis-induced distributive shock*. In septic shock, insufficient cardiac output is compounded by hypovolemia. Inadequate blood supply to vital organs leads to hypoxia (lack of oxygen) and multiple organ failure. [Chapter 37](#) describes sepsis, septic shock, and management in detail.

### ❖ Interprofessional Collaborative Care

#### ◆ Assessment: Noticing

##### History.

The patient's age, history of tobacco or alcohol use, current illness or disease (e.g., diabetes), past and current drug use (e.g., steroids), and poor nutritional status may place him or her at increased risk for infection. Patients with impaired IMMUNITY as a result of disease or therapies such as chemotherapy and radiation are also at a high risk for infection. Ask the patient about previous vaccinations or immunizations, including the dates of administration.

Ask the patient if he or she has recently been in a hospital or nursing home as a patient or visitor. Inquire about any invasive testing, such as a colonoscopy, or recent surgery. Ask if the patient had an indwelling urinary catheter or IV line. These invasive treatments often are the source of infections.

Determine whether the patient has been exposed to infectious agents. A history of recent exposure to someone with similar clinical symptoms or to contaminated food or water, as well as the time of exposure, helps to identify a possible source of infection. This information helps determine the incubation period for the disease and thus provides a clue to its cause.

Contact with animals, including pets, may increase exposure to infection. Question the patient about recent animal contact at home or work or in leisure activities (e.g., hiking). Insect bites should be documented.

Obtain a travel history. Travel to areas both within and outside the patient's home country may expose a susceptible person to infectious organisms not encountered in the local community.

A thorough sexual history may reveal behavior associated with an increased risk for sexually transmitted diseases. Obtain a history of IV drug use and a transfusion history to assess the

patient's risk for hepatitis B, hepatitis C, and HIV infections.

Identifying the type and location of symptoms may point to affected organ systems. The onset order of symptoms gives clues to the specific problem. Gathering a history of past infection or colonization with multidrug-resistant organisms will help determine which type of Transmission-Based Precautions is needed.

### Physical Assessment/Signs and Symptoms.

Disorders caused by pathogens vary depending on the infection cause and site. Common signs and symptoms are associated with specific sites of infection. Carefully inspect the skin for symptoms of local infection at any site (*pain, swelling, heat, redness, pus*). Wounds can easily become infected when TISSUE INTEGRITY is impaired (also see [Chapter 2](#)).

## Considerations for Older Adults

### Patient-Centered Care QSEN

Fever (generally a temperature above 101° F [38.3° C]), chills, and malaise are primary indicators of a systemic infection. Fever may accompany other noninfectious disorders; and infection can be present without fever, especially in patients who have impaired IMMUNITY. The older adult, whose normal temperature may be 1° to 2° lower than the normal temperature in younger adults, may have a fever at 99° F (37.2° C). In most patients with an infection, fever (**hyperthermia**) is a normal immune response that can help destroy the pathogen. Assess the patient for these signs and symptoms and carefully ask about their history and pattern.

**Lymphadenopathy** (enlarged lymph nodes), pharyngitis, and GI disturbance (usually diarrhea or vomiting) are often associated with infection. To detect enlargement, palpate the cervical, axillary, and other lymph nodes; examine the throat for redness. Ask about changes in stool and if the patient has had any nausea or vomiting.

### Psychosocial Assessment.

The patient with an infectious disease often has psychosocial concerns. Delay in diagnosis because of the need to await clinical test results produces anxiety. Assess the patient's and family's level of understanding about various diagnostic procedures and the time required to obtain test results. Plan education on infection risk reduction at a time when they are ready to learn.

Feelings of malaise and fatigue often accompany infection. Assess the patient's current level of activity and the impact of these symptoms on family, occupational, and recreational activities.

The potential spread of infection to others is an additional stress associated with the diagnosis. The patient may curtail family and social interactions for fear of spreading the illness. Determine the patient's and family's understanding of the infection, the mode of transmission, and mechanisms that may limit or prevent transmission. Special precautions, although sometimes necessary for preventing transmission of the organism, can be emotionally difficult for the patient and family.

A number of transmissible infectious diseases, especially those identified with social stigmas (e.g., IV drug abuse), are associated with labeling. The patient may feel socially isolated or have guilt related to behavior that increased the risk for infection. Observe carefully for the patient's reaction to labels and how these feelings further affect socialization.

### Laboratory Assessment.

The definitive diagnosis of an infectious disease requires identification of a microorganism in the tissues of an infected patient. Direct examination of blood, body fluids (such as urine), and tissues under a microscope may not yield a definitive identification. However, laboratory assessment usually provides helpful information about organisms, such as amount, shape, motility, and reaction to staining agents. Even when direct microscopy does not provide a conclusive specific diagnosis, often enough information is obtained for starting appropriate antimicrobial therapy.

*The best procedure for identifying a microorganism is **culture**, or isolation of the pathogen by cultivation in tissue cultures or artificial media. Specimens for culture can be obtained from almost*

any body fluid or tissue. The health care provider usually decides when and where the specimen for culture is taken.

*Proper collection and handling of specimens for culture, using Standard Precautions, are essential for obtaining accurate results.* Specimens collected must be appropriate for the suspected infection. Be sure that the specimen is of adequate quantity and is freshly obtained and placed in a sterile container to preserve the specimen and microorganism. Label the specimen properly, including the date and time it was collected. Follow your health care organization's policy if you have any questions about how to perform a culture.

After isolation of a microorganism in culture, antimicrobial **sensitivity** testing is performed to determine the effects of various drugs on that particular microorganism. For example, an agent that is killed by acceptable levels of an antibiotic is considered sensitive to that drug. An organism that is not killed by tolerable levels of an antibiotic is considered resistant to that drug. Preliminary results are usually available in 24 to 48 hours, but the final results generally take 72 hours. *Antimicrobial therapy should not begin until after the culture specimen is obtained.*

Rapid cultures or assays are used in ambulatory care settings to provide quicker assessments of infections. The most popular is the rapid antigen detection test for group A streptococci to rule out “strep throat” in patients who present with pharyngitis (sore, inflamed throat). Other examples of rapid testing are those for tuberculosis (TB) and influenza (“flu”), discussed in [Chapter 31](#).

A *white blood cell (WBC) count with differential* is often done for the patient with a suspected infection. Five types of leukocytes (WBCs) are measured as part of the results:

- Neutrophils
- Lymphocytes
- Monocytes
- Eosinophils
- Basophils

In most active infections, especially those caused by bacteria, the total leukocyte count is elevated. Various infections are characterized by changes in the percentages of the different types of leukocytes. The differential count usually shows an increased number of immature neutrophils, or a **shift to the left** (“left shift”). However, a few infectious diseases such as malaria and infectious mononucleosis are associated with neutropenia (decreased neutrophils). See [Chapter 17](#) for further discussion.

The *erythrocyte sedimentation rate (ESR)* measures the rate at which red blood cells fall through plasma. This rate is most significantly affected by an increased number of acute-phase reactants, which occurs with inflammation. Thus an elevated ESR (>20 mm/hr) indicates inflammation or infection somewhere in the body. Chronic infection, especially osteomyelitis and chronic abscesses, is commonly associated with an elevated ESR. The ESR is chronically elevated with inflammatory arthritis and other connective tissue diseases as well (see [Chapter 18](#)). The effectiveness of therapy is often determined by a decrease in this value.

**Serologic testing** is performed to identify pathogens by detecting antibodies to the organism. The antibody titer tends to *increase* during the acute phase of infectious diseases such as hepatitis B. The titer *decreases* as the patient improves. Other examples of testing for viruses include the enzyme-linked immunosorbent assay (ELISA) and the reverse transcriptase-polymerase chain reaction (RT-PCR).

### **Imaging Assessment.**

X-ray films may be obtained to determine activity or destruction by an infectious microorganism. Radiologic studies (e.g., chest films, sinus films, joint films, GI studies) are available for diagnosis of infection in a specific body site.

More sophisticated techniques for infection diagnosis include computed tomography (CT) scans and magnetic resonance imaging (MRI). CT and ultrasonography are helpful in assessing for abscesses. CT scans help identify suspected osteomyelitis and fluid collections that point to possible infection. MRI scans provide a cross-sectional assessment for infection.

Another diagnostic tool for the evaluation of a patient with an infectious disease is ultrasonography. This noninvasive procedure is particularly helpful in detecting infection involving the heart valves.

Scanning techniques using radioactive substances such as gallium can determine the presence of

inflammation caused by infection. Inflammatory tissue is identified by its increased uptake of the injected radioactive material.

### ◆Analysis: Interpreting

The priority collaborative problem for patients with an infection is *fever due to the immune response triggered by the pathogen*. In addition, the patient has a potential for developing severe sepsis, systemic inflammatory response syndrome (SIRS), and septic shock, which are discussed in detail in [Chapter 37](#).

### ◆Planning and Implementation: Responding

#### Managing Fever

##### Planning: Expected Outcomes.

Patients with an infection are expected to have a body temperature within normal limits as a result of effective interprofessional collaborative care.

##### Interventions.

The primary concern is to provide measures to eliminate the underlying cause of fever (also known as *hyperthermia*) and to destroy the causative microorganism. In collaboration with the interprofessional health care team, nurses use a variety of methods to manage fever.

Drug therapy plays a major role in interprofessional collaborative care of patients with infection. *Antimicrobials*, also called *anti-infective agents*, are the cornerstone of drug therapy. Antipyretics are used to decrease patient discomfort and reduce fever.

Antibiotics, antiviral agents, and antifungals are common types of antimicrobial drugs that are given for infection, depending on its type. Effective antibiotics are available to treat nearly all bacterial infections, but misuse of antibiotics has contributed to the development of multidrug-resistant organisms (MDROs) discussed earlier in this chapter. A few effective antifungal agents have been developed, but these drugs generally cause more toxicity than antibacterial agents.

Effective antimicrobial therapy requires delivery of an appropriate drug, sufficient dosage, proper administration route, and sufficient therapy duration. These four requirements ensure delivery of a concentration of drug sufficient to inhibit or kill infecting microorganisms. To ensure effectiveness of antibiotic therapy such as vancomycin, health care providers may require serum trough and peak levels to be drawn. A specimen for a *trough level* (lowest serum drug concentration) is drawn about 30 minutes before the next scheduled vancomycin dose. A specimen for a *peak level* (highest serum drug concentration) is drawn 30 to 60 minutes after medication administration ([Rosini & Srivastava, 2013](#)).

Primary health care providers collaborate on selecting drugs and dosing. Antimicrobials act on susceptible pathogens by:

- Inhibiting cell wall synthesis (e.g., penicillins and cephalosporins)
- Injuring the cytoplasmic membrane (e.g., antifungal agents)
- Inhibiting biosynthesis, or reproduction (e.g., erythromycin and gentamicin)
- Inhibiting nucleic acid synthesis (e.g., actinomycin)

## 📌Nursing Safety Priority QSEN

### Drug Alert

Before administering an antimicrobial drug, check to see that the patient is not allergic to it. Be sure to take an accurate allergy history before drug therapy begins to prevent possible life-threatening reactions, such as anaphylaxis!

Teach the drug's actions, side effects, and toxic effects to patients and their families. Observe and report side effects and adverse events. These reactions vary according to the specific classification of the drug. Most antibiotics can cause nausea, vomiting, diarrhea, and rashes. Stress the importance

of completing the entire course of drug therapy, even if symptoms have improved or disappeared.

## Considerations for Older Adults

### Patient-Centered Care QSEN

For older adults, be sure to teach the need to drink additional fluids if diarrhea occurs as result of antibiotic therapy. Observe older adults in inpatient facilities carefully for signs and symptoms of dehydration as described in Chapter 11. Acute confusion, hypotension, and tachycardia are common indicators of dehydration and require interventions such as IV fluids. Serum electrolyte levels may increase, causing additional risks to the older adult.

*Antipyretic drugs* such as acetaminophen (Tylenol, Ace-Tabs) are often given to reduce fever. Because these drugs mask fever, monitoring the course of the disease may be difficult. Therefore, unless the patient is very uncomfortable or if fever presents a significant risk (e.g., in the patient with heart failure, febrile seizures, or head injury), antipyretics are not always prescribed.

Teach patients that they may have waves of sweating after each dose. Sweating may be accompanied by a fall in blood pressure followed by return of fever. These unpleasant side effects of antipyretic therapy can often be alleviated by increasing fluid intake and regular scheduling of drug administration.

Other interventions to reduce fever may include external cooling and fluid administration. Perform a thorough assessment before and after interventions are implemented.

*External cooling* by hypothermia blankets or ice bags or packs can be effective mechanisms for reducing a high fever. Alternative cooling methods may be used. Sponging the patient's body with tepid water or applying cool compresses to the skin and pulse points to reduce body temperature is sometimes helpful. Ice packs and cooling blankets may be used for patients with extremely high temperatures. *Teach unlicensed assistive personnel (UAP) to observe for and report shivering during any form of external cooling. Shivering may indicate that the patient is being cooled too quickly.*

The use of fans is discouraged because they can disperse airborne- or droplet-transmitted pathogens. Fans can also disturb air balance in negative-pressure rooms, making them positive-pressure rooms and allowing possible transmission of the agent to those outside the room.

In patients with fever, fluid volume loss is increased from rapid evaporation of body fluids and increased perspiration. As body temperature increases, fluid volume loss increases.

### Care Coordination and Transition Management

Patients with infections may be cared for in the home (group or individual), hospital, nursing home, or ambulatory care setting, depending on the type and severity of the infection. Infections among older adults in nursing homes and assisted-living facilities are common. Residents often have meals together in a communal dining room and participate in group activities. Confused residents may not wash their hands or may enter other resident rooms. Immunizing them against respiratory infections is highly recommended because these illnesses can cause severe complications or death in older adults.

### Home Care Management.

The patient with an infectious disease such as osteomyelitis may require continued, long-term antibiotic therapy at home or in a long-term care facility. Emphasize the importance of a clean home environment, especially for the patient who continues to have compromised IMMUNITY or who is uniquely susceptible to **superinfection** (i.e., reinfection or a second infection of the same kind) to reduce the chance of infection. Drugs often need to be refrigerated. Ensure that the patient has access to proper storage facilities, and teach him or her to check for signs of improper storage, such as discoloration of the drug.

Ask about the availability of handwashing facilities in the home and check that supplies and instructions are provided as needed. Most people do not know how to wash hands correctly. Demonstrate the procedure with the patient and family and request a repeat demonstration.

### Self-Management Education.

Explaining the disease and making certain that the patient understands what is causing the illness are the primary purposes of health teaching. Discuss whether the pathogen causing the infection can be spread to others and the modes of transmission.

If the patient has an infection that is potentially transmissible, teach the patient, family, and other home caregivers about precautions. Explain whether any special household cleaning is necessary and, if so, what those special steps include. If syringes with needles are used to administer drug therapy, explain how to dispose safely and legally of needles in the community. Clothing soiled with blood or other body fluids can be washed with bleach or disinfectant (e.g., Lysol). Recommended cleaning measures should be based on actual available equipment and facilities.

For the patient who is discharged to the home setting to complete a course of antimicrobial therapy, the importance of adherence to the planned drug regimen needs to be stressed. Explain the importance of both the timing of doses and the completion of the planned number of days of therapy. Teach the patient (and family as appropriate) how the agents need to be taken (e.g., before meals, with meals, without other agents) and the possible side effects. Side effects include those that are expected (e.g., gastric distress) and adverse reactions that are more severe (e.g., rash, fever, other systemic signs and symptoms). Teach the patient about allergic manifestations and the need to notify a primary health care provider if an adverse reaction occurs. Also discuss what to do if a drug dose is missed (e.g., doubling the dosage, waiting until the next dose time).

Many patients are discharged with an infusion device to continue drug therapy at home or in other inpatient facilities. The patient, family member, or home care nurse administers the drugs. Home care services are often used to teach appropriate administration of drug therapy in the patient's home. Health teaching and wound care may also be needed. These services have proven to be efficient, effective, psychologically supportive, and less expensive than hospitalization or skilled nursing facilities (SNFs).

The patient is often anxious and fearful that the infection will be transmitted to family members or friends. Teaching the patient and the family ways of preventing the spread of disease allays these fears. Pay careful attention to the patient's and family's concerns. Making concrete suggestions (e.g., "Your partner can wear gloves when changing your dressing") to address specific concerns may reduce these fears.

The patient with an infection associated with lifestyle behaviors such as sexual activity or IV drug abuse may have guilt related to the disease. Encourage discussion of feelings associated with the illness, and assist in locating support systems that may help alleviate these feelings, such as clergy or other spiritual or cultural leaders.

### Health Care Resources.

At times a patient who has been hospitalized for an infection may not be able to return to the home setting because of lack of caregiver support. In such cases temporary placement in an SNF may be needed. Document care requirements, patient history of infection or colonization with multidrug-resistant organisms, medication schedules, and personal needs and preferences on transfer forms. **Hand-off communication such as the SBAR between the two facilities is required to facilitate a smooth transition from the hospital to the intermediate care setting, according to The Joint Commission's National Patient Safety Goals.**

### ◆Evaluation: Reflecting

Evaluating the care of the patient with an infection on the basis of the identified priority problems is important. The expected outcomes include that the patient:

- Has body temperature and other vital signs within baseline
- Adheres to drug therapy regimen

## Critical Issues: Emerging Infections and Global Bioterrorism

Additional current concerns related to infection and infection control are the risk for emerging infectious diseases and global bioterrorism. As for any pathogen, strict infection control measures can prevent transmission of these microbes to you and your patients. Some of the most serious infections are briefly described here.

The 2014 Ebola epidemic was labeled as the largest in history, with many West African countries affected (CDC, 2016). An epidemic occurs when new cases of a certain disease substantially exceed expectation during a given period. The ongoing struggle with the Ebola virus outbreak in West Africa became a concern within the United States when an individual who flew back from Liberia was diagnosed, although after initial discharge, at a Dallas hospital. That individual later died. Symptoms of Ebola, which can present from 2 to 21 days after exposure (with an average of 8 to 10 days), include fever greater than 101.5° F (38.6° C), severe headache, muscle pain, weakness, diarrhea, vomiting, abdominal pain, and unexplained hemorrhage (bleeding or bruising) (CDC, 2016). The virus is most commonly spread through exposure to bodily fluids of the infected individual and through needlesticks in which the needle has been contaminated with the virus. Recovery from this virus is contingent on appropriate clinical care and the immune response of the patient. Patients who recover from Ebola infection develop antibodies that can last for 10 years (CDC, 2016) (Table 23-4).

**TABLE 23-4**  
**Care for Patients With Ebola Virus Disease**

TRANSMISSION OF DISEASE	PREVENTION OF DISEASE	ASSESSMENT	PATIENT-CENTERED COLLABORATIVE CARE
<p>The primary source of the Ebola virus is most likely contaminated bats or primates (apes and monkeys) in West Africa. Information that is known about transmission includes:</p> <ul style="list-style-type: none"> <li>• The Ebola virus cannot be transmitted unless a person is sick and has signs and symptoms of the disease.</li> <li>• The Ebola virus is not spread via air, water, or food.</li> <li>• Nurses can help identify people at high risk for having or transmitting the disease by taking a complete history, including asking about travel to West Africa or exposure to family and friends who have Ebola.</li> <li>• The disease can be transmitted by unprotected contact with people infected with the Ebola virus or with people who have died from Ebola.</li> <li>• Teach patients who recover from Ebola and their partners that the virus is present in semen for up to 3 months. Using a condom may prevent transmission.</li> </ul>	<p>Take special training <i>before</i> caring for patients with the Ebola virus. Use these precautions:</p> <ul style="list-style-type: none"> <li>• Avoid direct contact with body fluids (blood, feces, saliva, urine, vomit, and semen).</li> <li>• Use Standard, Contact, and Droplet Precautions, including appropriate PPE.</li> <li>• Isolate patient with Ebola in a single room.</li> <li>• Use dedicated or disposable medical equipment and supplies.</li> <li>• Practice proper sterilization measures.</li> </ul>	<p>Signs and symptoms occur 2-21 days after exposure to the Ebola virus. Assess for:</p> <ul style="list-style-type: none"> <li>• Fever</li> <li>• Severe headache</li> <li>• Muscle pain</li> <li>• Weakness</li> <li>• Fatigue</li> <li>• Diarrhea</li> <li>• Vomiting</li> <li>• Abdominal pain</li> <li>• Unexplained hemorrhage (bleeding and bruising)</li> </ul>	<p>No drug therapy or vaccine is yet FDA approved for Ebola. Remember that the virus can enter the body through broken skin or unprotected mucous membranes such as the eyes, nose, and mouth. Supportive care includes:</p> <ul style="list-style-type: none"> <li>• IV fluid and electrolyte replacement</li> <li>• Oxygen and ventilation support</li> <li>• Blood pressure support</li> <li>• Treatment of other infections</li> <li>• Care and comfort measures</li> <li>• Symptomatic care</li> <li>• Emotional support</li> <li>• Possible end-of-life care</li> </ul>

FDA, Food and Drug Administration; PPE, personal protective equipment.

Data from Centers for Disease Control and Prevention. (2014). *Ebola (Ebola virus disease)*. [www.cdc.gov/vhf/ebola/index/html](http://www.cdc.gov/vhf/ebola/index/html).

With the Dallas Ebola incident, there was reported to be a communication concern within the electronic medical record (EMR) in which the physician was unable to view the nurse's notes and see that the nurse had recorded the patient's recent return from West Africa. It is of vital importance that the nurse and primary health care provider be sure to communicate pertinent historical information both verbally and in the EMR so appropriate interventions for both the individual and the general public can be undertaken immediately.

Pandemic infections such as influenza are another threat to the population. As recently as the early 1900s, the "Spanish flu" killed millions of people throughout the world. Health care workers are encouraged to have annual influenza vaccines to prevent infection with common strains of the virus. The federal government and health care agencies around the United States include the risk for pandemic disease in their disaster planning (see Chapter 10).

Contaminated food is another source of infection. The incidence of foodborne infections has risen in the United States as contaminated fresh spinach, ground beef, and other foods were found to contain *E. coli* 0157:H7 and other pathogens. Major restaurant chains such as Chipotle have been the source of GI infections for many of their customers. Multiple illnesses and deaths in the United States have been caused by these infections. Safer food preparation practices and increased monitoring by federal agencies have resulted from demand for public safety, but more oversight is needed to prevent large outbreaks.

Another pathogen, *Clostridium difficile*, is associated with antibiotic therapy use, especially in older adults. Associated problems have led to the development of the diagnosis of *C. difficile*-associated disease (CDAD). A new, more virulent strain of this pathogen has developed in the past decade as a result of the use of fluoroquinolone antibiotics such as ciprofloxacin (Cipro).

*C. difficile* is spread by indirect contact with inanimate objects such as medical equipment and commodes, and its toxins cause colon dysfunction and cell death from sepsis. CDAD is confirmed by stool culture. Patients who have three or more liquid stools per day for two or more days are suspected of having the infection. Fever and abdominal pain and cramping commonly occur with diarrheal stools. Oral metronidazole (Flagyl) and vancomycin have been the drugs of choice to treat CDAD. However, some patients experience recurrence of infection after treatment with these drugs. A new oral antibacterial drug available for specifically managing *C. difficile* is fidaxomicin (Dificid).

A recently approved treatment for CDAD is **fecal microbiota transplantation (FMT)** to place healthy normal flora into the lower GI system of the infected patient who does not respond to antibiotic therapy or has recurrent disease. Potential donors of fecal material should not have impaired IMMUNITY, history of drug abuse, chronic GI disorders, or recent exposure to potential pathogens such as those that could be present from tattooing or travel to endemic areas. Before the FMT, the donor is screened using a variety of blood and stool tests to rule out active or chronic infections such as hepatitis A, B, or C.

Fecal transplantation is most commonly performed by colonoscopy. Therefore the pre-procedure and follow-up care are the same as for any patient having a colonoscopy (see Chapter 52). FMT has been very successful for many patients with *C. difficile*. It is being investigated for use in patients who have other lower GI diseases such as inflammatory bowel disease and irritable bowel syndrome (Kelly et al., 2015).

In addition to concerns about emerging infections, preparation for and education about *bioterrorism* have been major focuses of the U.S. government since September 11, 2001 (Table 23-5). In some cases vaccines are no longer given for biologic agents such as smallpox. Many people in the United States have never been vaccinated, and those who had vaccinations many years ago are not guaranteed to have lifelong immunity. Anthrax, usually seen in animals, may be spread to the skin or inhaled. These infections have a high fatality rate in humans. Plague, once seen centuries ago, is one of the biggest threats because the survival rate is low. Vaccines are being researched and stockpiled by the U.S. government for some of the common biologic agents.

**TABLE 23-5**

**Centers for Disease Control and Prevention\* Examples of Bioterrorism Agents and General Clinical Management**

PATHOGEN OR AGENT AND DISEASE INFORMATION	CLINICAL MANAGEMENT
<p><b>Anthrax (<i>Bacillus anthracis</i>)</b>  <b>Cutaneous:</b> 1-7 days after contact; exposed skin itching, progressing to papular and vesicular lesions, eschar, edema, ulceration, and sloughing. If untreated, may spread to lymph nodes and bloodstream. Fatality 5%-20%.  <b>Inhalation:</b> 48 hr after organism or spore inhalation; flu-like illness with possible brief improvement. 2-4 days from initial symptoms, abrupt onset of severe cardiopulmonary illness (dyspnea, tachycardia, fever, diaphoresis, thoracic edema, shock, and respiratory failure). If antibiotics delayed until onset of cardiopulmonary symptoms, mortality high. May be confused with common upper respiratory infection (URI).  <b>Other forms:</b> GI, meningial, and sepsis.</p>	<p>For cutaneous and inhaled anthrax: No person-to-person spread.            Contact Precautions not needed unless patient presents directly from exposure.            Standard Precautions for:            • Prescribed wound cleansing and management of lesions            • Ventilator support for respiratory failure            • Postmortem care</p>
<p><b>Botulism (<i>Clostridium botulinum</i> and Neurotoxin)</b>            Toxin ingestion results in dysphasia, dry mouth, drooping eyelids, and blurred or double vision. Vomiting and constipation or diarrhea may be present initially, extending to symmetric flaccid paralysis in an alert person. Acute bilateral cranial nerve impairment and descending weakness or paralysis follow.            Neurologic symptoms after 12-36 hr for foodborne botulism and 24-72 hr after aerosol exposure. Case fatality up to 10%. Recovery may take months.</p>	<p>Standard Precautions: decontamination of patient is not required. No person-to-person spread.            Consider outbreak with suspicion of a single case. Consult with CDC and health departments.            Advise careful cleanup and disposal of suspected contaminated food source <i>after</i> consultation with health department about any needed laboratory sampling.            Interdisciplinary planning for nutrition and rehabilitation support during lengthy neuromuscular and respiratory recovery.</p>
<p><b>Plague (<i>Yersinia pestis</i>)</b>  <b>Lymphatic infection:</b> 2-8 days after bites from fleas of an infected rodent (rarely after infected tissue or body fluid contact), onset of fever and chills, painful lymphadenopathy (or bubo—usually inguinal, axillary, or cervical lymph nodes), headache, GI symptoms, and rapidly progressive weakness. 50%-60% fatality if untreated.  <b>Pneumonic:</b> 1-3 days after aerosolized organism inhalation, fever and chills, productive cough, hemoptysis, rapidly progressive weakness, GI symptoms, and bronchopneumonia. Survival unlikely if not treated within 18 hr of symptom onset.  <b>Other forms:</b> Sepsis with coagulopathy, rarely meningitis.</p>	<p>Droplet Precautions: required for pneumonic plague (until 72 hr of antibiotic therapy).            Contact Precautions until decontamination is complete:            • For any suspected gross contamination. See documentation information listed under Anthrax.            • For prescribed management of bubo(s) if incised to drain.            Community and other environmental modifications:            • Apply insecticide to infested environment and pets (to kill fleas).            • Reduce food and water supply for rodents.            • Avoid sick or dead animals.</p>
<p><b>Smallpox (<i>Variola Virus</i>) (Variola Major and Minor)</b>            10-17 days after droplet or airborne virus inhalation or contact with bleeding lesions, onset of severe myalgias, headache, and high fever. 2-3 days later, a papular rash appears on face and spreads to extremities (and palms and soles). The rash quickly (simultaneously) becomes vesicular and then painful and pustular (contrasted to varicella rash that crops and concentrates more on trunk with various stages of macules to vesicles seen at one time). Patients are infectious at onset of rash until scabs separate (3 weeks). Historically variola major kills 20%. May be confused with varicella.</p>	<p>Standard, Contact, and Airborne Precautions for patients with vesicular rash pending diagnosis. Same for varicella and variola.            Also avoid contact with organism while handling contaminated clothes and bedding. Wear protective attire (gloves, gown, and N95 respirator).</p>

	<p>One case is a public health emergency—highly communicable. Consult CDC and health departments at earliest suspicion.  Vaccine does not give reliable lifelong immunity. Previously vaccinated people are considered susceptible.  <i>Following exposure:</i> Initiate Airborne Precautions and observe for unprotected contacts (from days 10-17).  Vaccinate within 2-3 days of exposure.</p>
<p><b>Other Key Points</b>  <b>Assessment:</b> Include account of symptoms, patient's incident (what, where, when, how, others exposed or ill, and officials aware).  <b>Treatment:</b> Antibiotic-resistance possible. Vaccine and postexposure prophylaxis are subject to change. If any of the above diseases are suspected, consult infection control practitioner for coordination with community health officials and CDC about current recommendations and specimen collection. <i>If bioterrorism suspected</i>, Federal Bureau of Investigation (FBI) will coordinate evidence collection and delivery.  <b>Multiple exposures planning:</b> Emergency and critical care managers must address availability and acquisition of stocks of medications, vaccines, equipment (e.g., ventilators), and communications with officials, as well as public information needs.</p>	

Data from the CDC.

CDC, Centers for Disease Control and Prevention.

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Handwashing and alcohol-based hand rubs are two methods of hand hygiene to prevent infection (see [Chart 23-3](#)). **QSEN: Safety; Quality Improvement**
- The Centers for Disease Control and Prevention (CDC) recommends a ban on artificial fingernails for health care professionals when they are caring for patients at high risk for infection. **QSEN: Evidence-Based Practice**
- Use clinical judgment to prevent or control infection through hand hygiene, disinfection/sterilization, personal protective equipment (PPE), patient placement, and adequate staffing. Proper hand hygiene and gloves are the most important interventions because health care workers' hands are the primary way in which disease is transmitted from patient to patient. **Clinical Judgment; QSEN: Evidence-Based Practice**
- Standard Precautions are used with all patients in health care settings, assuming that all body excretions and secretions are potentially infectious (see [Table 23-2](#)). **QSEN: Safety**
- Airborne Precautions are used for patients who have infections transmitted through the air such as tuberculosis.
- Droplet Precautions are used for patients who have infections transmitted by droplets such as influenza and certain types of meningitis.
- Contact Precautions are used for patients who have infections transmitted by direct contact or contact with items in the patient's environment.

### Health Promotion and Maintenance

- Health teaching about signs and symptoms of infection and drug therapy is important for the patient with an infection being managed at home; some patients may need health care nursing services for IV antimicrobial therapy.
- Teach patients about antimicrobial therapy and protective measures to prevent infection transmission. **QSEN: Safety**
- Teach patients how to avoid community-acquired MRSA by performing frequent hand hygiene and by avoiding crowds and direct contact with others who have infections. **QSEN: Safety**
- Teach patients about how to prevent vector transmission of infection (e.g., using insect repellent to prevent tick and mosquito bites).

### Psychosocial Integrity

- Help patients cope with feelings about having an infection through verbalization and collaboration with the health care team. **QSEN: Teamwork and Collaboration**

### Physiological Integrity

- Patients at the highest risk for infection include older adults, health care professionals at risk for needlesticks, and patients who have chronic disease (e.g., diabetes) or impaired IMMUNITY. Patients who take long-term steroid therapy or have had invasive procedures or impaired TISSUE INTEGRITY are also at a high risk for infection.
- Multidrug-resistant organisms (MDROs) are the result of the overuse of antibiotic therapy and include methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococcus* (VRE), and carbapenem-resistant *Enterobacteriaceae* (CRE).
- A biofilm, also called *glycocalyx*, is a complex group of microorganisms that function within a

“slimy” gel coating on medical devices such as urinary catheters, orthopedic implants, and enteral feeding tubes; on parts of the body such as the teeth (plaque) and tonsils; and in chronic wounds.

- Common signs and symptoms of infection include fever and lymphadenopathy. If infections are not treated or are inadequately treated by the interprofessional health care team, systemic sepsis (septicemia), septic shock, and disseminated intravascular coagulation (DIC) may result.
- A culture is the most definitive way to confirm and identify microorganisms; sensitivity testing determines which antibiotics will destroy the identified microbes. **QSEN: Evidence-Based Practice**
- The white blood cell differential count usually shows a shift to the left (increased number of immature neutrophils) during active infections.
- Antimicrobials and antipyretics are the most common types of drugs used when infection is accompanied by fever.
- Antipyretics are used only when the fever presents a significant risk or the patient is very uncomfortable because antipyretics may mask the disease. **QSEN: Evidence-Based Practice**
- Critical issues for the next decade include bioterrorism, emerging infectious diseases (such as Ebola), and multidrug-resistant organisms (MDROs).
- Foodborne infections are becoming increasingly common as a result of contaminated food consumed by restaurant customers.
- Fecal microbiota transplantation (FMT) is a recent therapy for managing chronic *Clostridium difficile*-associated disease (CDAD). Fecal transplantation restores normal flora to the infected patient. **QSEN: Evidence-Based Practice**

## UNIT VI

# Interprofessional Collaboration for Patients With Problems of the Skin, Hair, and Nails

### OUTLINE

---

Chapter 24 Assessment of the Skin, Hair, and Nails

Chapter 25 Care of Patients With Skin Problems

Chapter 26 Care of Patients With Burns

## CHAPTER 24

# Assessment of the Skin, Hair, and Nails

Janice Cuzzell

## PRIORITY AND INTERRELATED CONCEPTS

*The priority concept for this chapter is TISSUE INTEGRITY.*

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Protect patients from skin injury and loss of TISSUE INTEGRITY.

### Health Promotion and Maintenance

2. Teach adults how to protect the skin from damage and cancer development.

### Psychosocial Integrity

3. Implement nursing interventions to minimize stressors for the patient undergoing assessment and testing of the integumentary system.

### Physiological Integrity

4. Apply knowledge of anatomy and physiology, genetic risk, and principles of aging to perform a focused assessment of the skin, hair, and nails.

The integumentary system is made of the skin, hair, and nails. Intact skin, the largest organ of the body, has barrier, alarm, and combat functions. Skin TISSUE INTEGRITY plays a major role in protection by protecting the body against invasion of pathogenic organisms by providing first, second, and third lines of defense. The normal flora on the surfaces of skin and mucous membranes repels some of the more harmful microorganisms. Specialized cells in the skin engulf foreign substances (antigens) that invade the body when TISSUE INTEGRITY is lost and then alert the immune system to the presence of the invader. Localized tissue inflammation and swelling work to contain the invading pathogen until white blood cells can respond and remove this threat.

Intact skin helps regulate body temperature and maintains fluid and electrolyte balance. Emotional stress, systemic disease, some drugs, and skin injury or disease can alter skin function, appearance, and texture. The skin's sensory function allows the use of touch as an intervention to provide comfort, relieve pain, and communicate caring.

## Anatomy and Physiology Review

### Structure of the Skin

There are three skin layers: subcutaneous tissue (fat), dermis, and epidermis (Fig. 24-1). Each layer has unique properties that help the skin maintain its complex functions.

**FIG. 24-1** Anatomy of the skin. (From Kumar, V et al: *Robbins & Cotran pathologic basis of disease* [8th ed.], St. Louis, 2009, Saunders.)

*Subcutaneous fat (adipose tissue [fat])* is the innermost layer of the skin, lying over muscle and bone. Fat distribution varies with body area, age, and gender. Fat cells insulate the body and absorb shock, padding internal structures. Blood vessels go through the fatty layer and extend into the dermis, forming capillary networks that supply nutrients and remove wastes.

*The dermis (corium)* is the layer above the fat layer and contains no skin cells but does contain some protective mast cells and macrophages (see [Chapter 17](#)). The dermis is composed of interwoven collagen and elastic fibers that give the skin flexibility and strength.

Collagen, the main component of dermal tissue, is a protein produced by fibroblast cells. Its production increases in areas of tissue injury and helps form scar tissue. Fibroblasts also produce **ground substance**, a gel-like substance that fills the spaces between cells and contributes to skin suppleness and turgor. Skin elasticity depends on the amount and quality of the dermal elastic fibers, which are primarily composed of elastin.

The dermis has capillaries and lymph vessels for the exchange of oxygen and heat. It is rich in sensory nerves that transmit the sensations of touch, pressure, temperature, pain, and itch.

*The epidermis* is the outermost skin layer. It is anchored to the dermis by fingerlike projections (**rete pegs**) that interlock with dermal structures called **dermal papillae**. Less than 1 mm thick, the epidermal layer is the first line of defense between the body and the environment.

The epidermis (Fig. 24-2) does not have its own blood supply. Instead it receives nutrients by diffusion from the blood vessels in the dermal layer. Attached to the basement membrane of the epidermis are the basal **keratinocytes**—skin cells that undergo cell division and differentiation to continuously renew skin TISSUE INTEGRITY and maintain optimal barrier function. As basal cells divide, keratinocytes are pushed upward and form the *spinous layer (stratum spinosum)*. Together the basal layer and the spinous layer are referred to as the *germinative layer (stratum germinativum)* because these layers are responsible for new skin growth ([McCance et al., 2014](#)). The keratinocytes continue to enlarge and flatten as they move upward to form the outermost horny skin layer (**stratum corneum**). When these cells reach the stratum corneum (in 28 to 45 days), they are no longer living cells and are shed from the skin surface. **Keratin**, a protein produced by keratinocytes, makes the horny layer waterproof.

**FIG. 24-2** Anatomy of the epidermis. (From Gawkrödger D., & Arden-Jones, MR [2012]: *Dermatology*. (5th ed.). Philadelphia: Churchill Livingstone.)

On the palms of the hands and soles of the feet an additional thick, clear layer of epidermis forms, known as the *stratum lucidum*. This layer of nonliving cells pads and protects the underlying dermal and epidermal structures in these vulnerable areas.

Vitamin D is activated in the epidermis by ultraviolet (UV) light, such as sunlight. Once activated, it is distributed by the blood to the GI tract to promote uptake of dietary calcium.

Melanocytes are pigment-producing cells found at the basement membrane. These cells give color to the skin and account for the ethnic differences in skin tone. Darker skin tones are not caused by increased numbers of melanocytes; rather, the size of the pigment granules (*melanin*) contained in each cell determines the color. Melanin protects the skin from damage by UV light, which stimulates melanin production. For this reason, people with dark skin (and thus more melanin) are less likely to develop sunburn than lighter-skinned people. Freckles, birthmarks, and age spots are lesions caused by patches of increased melanin production. Melanin production also increases in areas that have endocrine changes or inflammation.

## Structure of the Skin Appendages

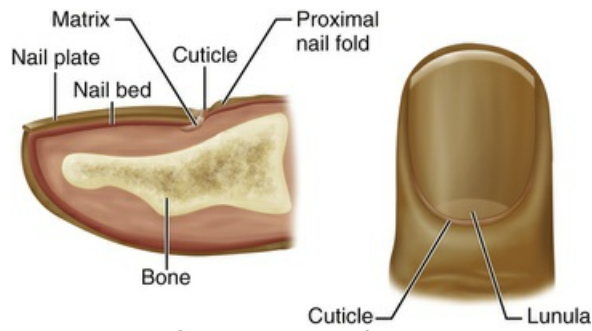

*Hair* differs in type and function in various body areas. Hair growth varies with race, gender, age, and genetic predisposition. Individual hairs can differ in both structure and rate of growth, depending on body location.

Hair follicles are located in the dermal layer of the skin but are actually extensions of the epidermal layer (see Fig. 24-1). Within each hair follicle, a round column of keratin forms the hair shaft. Hair color is genetically determined by an individual's rate of melanin production.

Hair growth occurs in cycles of a growth phase followed by a resting phase. Growth is dependent on a good blood supply and adequate nutrition. Stressors can alter the growth cycle and result in temporary hair loss. Permanent baldness, such as male pattern baldness, is inherited.

*Nails* protect and enhance sensation of the fingertips and toe tips, have cosmetic value, and are useful for grasping and scraping. Like hair follicles, the nails are extensions of the keratin-producing epidermal layers of the skin.

The white, crescent-shaped part of the nail at the lower end of the nail plate is the **lunula** and is where nail keratin is formed and nail growth begins (Fig. 24-3). Nail growth is a continuous but slow process. Fingernail replacement requires 3 to 4 months. Toenail replacement may take up to 12 months.

**FIG. 24-3** Anatomy of the nail.

The cuticle attaches the nail plate to the soft tissue of the nail fold. The nail body is translucent, and the pinkish hue reflects a rich blood supply beneath the nail surface. Nail growth and appearance are often altered during systemic disease or serious illness.

*Sebaceous glands* are distributed over the entire skin surface except for the palms of the hands and soles of the feet. Most of these glands are connected directly to the hair follicles (see Fig. 24-1).

Sebaceous glands produce **sebum**, a mildly bacteriostatic, fat-containing substance. Sebum lubricates the skin and reduces water loss from the skin surface.

*Sweat glands* of the skin are of two types: eccrine and apocrine. Eccrine sweat glands arise from the epithelial cells. They are found over the entire skin surface and are not associated with the hair follicle. The odorless, colorless secretions of these glands are important in body temperature regulation. This sweat and the resultant water evaporation can cause the body to lose up to 10 to 12 L of fluid in a single day.

Apocrine sweat glands are in direct contact with the hair follicle and are found mostly in the axillae, nipple, umbilical, and perineal body areas. The interaction of skin bacteria with the secretions of these glands causes body odor.

## Functions of the Skin

The skin is a complex organ responsible for the regulation of many body functions throughout the life span (Table 24-1) (McCance et al., 2014). In addition to the skin's protective and regulatory functions, its location on the outside of the body makes it an important way to communicate a patient's state of health and body image.

**TABLE 24-1**  
**Functions of the Skin**

EPIDERMIS	DERMIS	SUBCUTANEOUS TISSUE
<b>Protection</b>		
Keratin provides protection from injury by corrosive materials Inhibits proliferation of microorganisms because of dry external surface Mechanical strength through intercellular bonds	Provides cells for wound healing Provides mechanical strength: Collagen fibers Elastic fibers Ground substance Sensory nerve receptors signal skin injury and inflammation	Mechanical shock absorber Energy reserve Insulation
<b>Homeostasis (Water Balance)</b>		
Low permeability to water and electrolytes prevents systemic dehydration and electrolyte loss	Lymphatic and vascular tissues respond to inflammation, injury, and infection	No real function in water balance
<b>Temperature Regulation</b>		
Eccrine sweat glands allow dissipation of heat through evaporation of sweat secreted onto the skin surface	Cutaneous vasculature promotes or inhibits heat loss from the skin surface	Fat cells insulate and assist in retention of body heat
<b>Sensory Organ</b>		
Transmits a variety of sensations through the neuroreceptor system	Has many nerve receptors for relaying sensations to the brain	Contains large pressure receptors
<b>Vitamin Synthesis</b>		
Allows photo conversion of 7-dehydrocholesterol to active vitamin D	No function	No function
<b>Psychosocial</b>		
Body image alterations occur with many epidermal diseases	Body image alterations occur with many dermal diseases	Body image alterations may result from changes in body fat stores

## Skin Changes Associated With Aging

The process of aging begins at birth. As changes in physiology progress with aging, the skin also undergoes age-related changes in structure and function (Chart 24-1). Figures 24-4 through 24-7 show age-related skin changes.

**Chart 24-1**

## Nursing Focus on the Older Adult

### Changes in the Integumentary System Related to Aging

PHYSICAL CHANGES	CLINICAL FINDINGS	NURSING ACTIONS
<b>Epidermis</b>		
Decreased epidermal thickness	Skin transparency and fragility	Handle patients carefully to reduce skin friction and shear. Assess for excessive dryness or moisture. Avoid taping the skin.
Decreased cell division	Delayed wound healing	Avoid skin trauma and protect open areas.
Decreased epidermal mitotic homeostasis	Skin hyperplasia and skin cancers (especially in sun-exposed areas)	Assess non-sun-exposed areas for baseline skin features. Assess exposed skin areas for sun-induced changes.
Increased epidermal permeability	Increased risk for irritation	Teach patients how to avoid exposure to skin irritants.
Decreased immune system cells	Decreased skin inflammatory response	Do not rely on degree of redness and swelling to correlate with the severity of skin injury or localized infection.
Decreased melanocyte activity	Increased risk for sunburn	Teach patients to wear hats, sunscreen, and protective clothing. Teach patients to avoid sun exposure from 10 AM to 4 PM.
Hyperplasia of melanocyte activity (especially in sun-exposed areas)	Changes in pigmentation (e.g., liver spots, age spots)	Teach patients to keep track of pigmented lesions. Teach them which changes should be evaluated for malignancy.
Decreased vitamin D production	Increased risk for osteomalacia	Urge patients to take a multiple vitamin or a calcium supplement with vitamin D.
Flattening of the dermal-epidermal junction	Increased risk for shearing forces, resulting in blisters, purpura, skin tears, and pressure-related problems	Avoid pulling or dragging patients. Help patients confined to bed or chairs change positions at least every 2 hours. Avoid or use care when removing adhesive wound dressings.
<b>Dermis</b>		
Decreased dermal blood flow	Increased susceptibility to dry skin	Teach patients to apply moisturizers when the skin is still moist and to avoid agents that promote skin dryness.
Decreased vasomotor responsiveness	Increased risk for heat stroke and hypothermia	Teach patients to dress for the environmental temperatures.
Decreased dermal thickness	Paper-thin, transparent skin with an increased susceptibility to trauma	Handle patients gently and avoid the use of tape or tight dressings. Use lift sheets when positioning patients.
Degeneration of elastic fibers	Decreased tone and elasticity	Check skin turgor on the forehead or chest.
Benign proliferation of capillaries	Cherry hemangiomas	Teach patients that these are benign.
Reduced number and function of nerve endings	Reduced sensory perception	Tell patients to use bath thermometer and lower the water heater temperature to prevent scalds.
<b>Subcutaneous Layer</b>		
Thinning subcutaneous layer	Increased risk for hypothermia	Teach patients to dress warmly in cold weather.
	Increased risk for pressure injury	Help patients confined to bed or chairs change positions at least every 2 hours.
<b>Hair</b>		
Decreased number of hair follicles and rate of growth	Increased hair thinning	Suggest wearing hats to prevent heat loss in cold weather and to prevent sunburn.
Decreased number of active melanocytes in follicle	Gradual loss of hair color (graying)	Inform patients that hair color loss can occur at any age.
<b>Nails</b>		
Decreased rate of growth	Increased risk for fungal infections	Inspect the nails of all older adults. Teach patients to keep feet clean and dry.
Decreased nail bed blood flow	Longitudinal nail ridges	Use the oral mucosa to assess for cyanosis.
Thickening of the nail	Toenails thicken and may overhang the toes	Use fingernails to assess capillary refill. Cut toenails straight across. Do not use nail appearance alone to assess for a fungal infection. Assess skin next to the nail to determine whether the thick nail is irritating it.
<b>Glands</b>		
Decreased sebum production	Increased size of nasal pores; large comedones	Teach patients not to squeeze the pores or comedones to prevent skin trauma.
Decreased eccrine and apocrine gland activity	Increased susceptibility to dry skin	Urge patients to use soaps with a high fat content. Teach patients to avoid frequent bathing with hot water. Teach patients to apply moisturizers after bathing while skin is moist.
	Decreased perspiration with decreased cooling effect	Do not use sweat production as an indicator of hyperthermia.

**FIG. 24-4** Arcus senilis of the iris.

**FIG. 24-5** Nail changes, longitudinal ridges and thickening.

**FIG. 24-6** Paper thin, transparent skin with actinic lentigo (liver spots).

**FIG. 24-7** Eyelid eversion, deepening of the eye orbit, and "bags" under the eye.

Individual differences exist in how quickly and to what degree the skin ages (Touhy & Jett, 2015). Although genetic factors, hormonal changes, and disease may change skin appearance over time, chronic sun exposure is the single most important factor leading to degeneration of the skin components.

## Assessment: Noticing and Interpreting

### Patient History

Take an accurate history from the patient so skin problems can be readily identified. [Chart 24-2](#) highlights specific questions to ask during a skin assessment.

#### **Chart 24-2**

### Best Practice for Patient Safety & Quality Care QSEN

#### Questions to Obtain an Accurate Nursing History of the Patient With a Skin Problem

##### Medical-Surgical History

- Do you have any current or previous medical problems?
- Have you undergone any recent or previous surgical procedures?

##### Family History

- Is there any family tendency toward chronic skin problems?
- Do any members of your immediate family have skin problems?

##### Medication History

- Are you allergic to any drugs? If so, describe the reaction.
- What prescription drugs have you taken recently? When was the drug started? What is the dose or frequency of administration? When was the last dose taken?
- What over-the-counter drugs have you taken recently? When was the drug started? What is the dose or frequency of administration? When was the last dose taken?

##### Social History

- What is your occupation?
- What recreational activities do you enjoy?
- Have you traveled recently? If so, where?
- What is your nutrition status?
- Do you use tobacco or recreational drugs or drink alcohol?

##### Current Health Problem

- When did you first notice the skin problem?
- Where on the body did the problem begin?
- Has the problem gotten better or worse?
- Has a similar skin condition ever occurred before? If so, what was the course, and how was it treated?
- Is the problem associated with any itching, burning, stinging, numbness, pain, fever, nausea and

vomiting, diarrhea, sore throat, cold, stiff neck, new foods, new soaps or cosmetics, new clothing or bed linens, or stressful situations?

- What seems to make the problem worse?
- What seems to make the problem better?

*Demographic data* include age, race, occupation, and hobbies or recreational activities. This information can help identify causative or aggravating factors for skin problems. Age is important because many changes in the skin, hair, and nails are normal for the aging process.

Ethnicity can also be important. Some variations in skin appearance are normal for patients of some ethnicities but are abnormal for those of other races or ethnicities.

Information about occupation and hobbies can provide clues to chronic skin exposure to chemicals, irritants, and other substances that can contribute to skin problems.

*Socioeconomic status* data can help identify environmental factors that might contribute to skin disease. Unhealthy or crowded living conditions promote the spread of contagious skin pathogens. Recent or frequent travel to tropical climates may be a source of unusual skin infections or infestations.

Regardless of skin color or ethnicity, always ask patients about the amount of time spent in the sun and tanning booths and identify skin problems caused by sun overexposure. Use this time to teach the patient about the harmful aspects of sun exposure and how to reduce risk by avoiding time in the sun and wearing sunscreen. Because one in five Americans is expected to develop skin cancer in their lifetime, simple actions such as these can make an impact in preventing this diagnosis (Roebuck et al., 2015). Also determine whether he or she regularly assesses the skin for lesion development or changes.

Skin problems caused by poor hygiene are common. Ask about living conditions and bathing practices. Teach individuals that keeping the skin and hair clean by bathing and shampooing regularly helps maintain the skin's health.

*Information about drug use* is important because prescribed drugs, over-the-counter (OTC) drugs, herbal preparations or remedies, and tobacco use can cause skin reactions or affect skin function. Ask about any recent use of prescription drugs, OTC drugs (e.g., laxatives, antacids, cold remedies), and herbal preparations or remedies. Determine when each drug was started, the dose and frequency of the drug, and the time the last dose was taken. Ask the patient whether skin changes began after starting a new drug. A drug history also helps identify skin changes that result from management of other health problems, such as the changes that occur with long-term steroid or anticoagulant therapy.

*Allergies* to environmental substances, whether a new onset or history thereof, often have skin implications. Ask about the use of any new personal care product (e.g., shaving products, perfumes, soap, shampoo, lotion, makeup, hair gel), laundry detergents and softeners, and home cleaning products. Ask whether the patient wears gloves to avoid direct contact with cleaning solutions. New clothing may contain chemicals that irritate the skin. Noting the body location(s) of the skin problem can help determine its cause.

## Nutrition Status

Document the patient's weight, height, body build and fat distribution, and food preferences. Protein deficiencies, vitamin deficiencies, and obesity can increase the risk for skin lesions and delay wound healing. Fat-free diets and chronic alcoholism can lead to vitamin deficiencies and related skin changes. Skin problems such as chronic urticaria and acne may be worsened by certain foods or food additives.

Hydration influences overall skin health, and the skin reflects hydration status. Reduced fluid intake can lead to dry skin. Symptoms of severe fluid losses are seen as loose skin that tents when pinched together. Fluid overload with edema can stretch the skin, masking wrinkles and allowing the formation of skin "pits" (i.e., pitting edema) when pressure is applied to it.

## Family History and Genetic Risk

Many skin problems (e.g., psoriasis, keloid formation, eczema) have a familial predisposition.

Explore any family tendency of chronic skin problems. Ask about immediate family members' current health to identify a transmittable disorder (e.g., ringworm, scabies).

## Current Health Problems

Begin by gathering information about skin changes and skin care practices (see [Chart 24-2](#)).

If a skin problem is identified, obtain more information about the specific problem, such as when the patient first noticed the rash or skin change, where the rash began, and whether the problem has improved or become worse.

If the problem has occurred before, ask the patient to describe the course of the skin lesion and how it was treated. Try to link the problem with symptoms, such as itching, burning, numbness, pain, fever, sore throat, stiff neck, or nausea and vomiting. Ask the patient to identify anything that seems to make the problem better or worse.

## Skin Assessment

### Inspection

A thorough assessment of the skin is best performed with the patient undressed. (Always provide privacy to maintain the patient's dignity.) Incorporate skin examination as a routine part of daily care during the bath or when assisting with hygiene.

Inspect the patient's skin surfaces in a well-lighted room; natural or bright fluorescent lighting makes subtle skin changes more visible. Use a penlight to closely inspect lesions and to illuminate the mouth.

Assess each skin surface systematically, including the scalp, hair, nails, and mucous membranes. Give particular attention to the skinfold areas. The moist, warm environment of skinfolds can harbor organisms such as yeast or bacteria. Observe and document obvious changes in color and vascularity, moisture presence or absence, edema, skin lesions, and skin integrity. Check the cleanliness of the various body areas to determine whether the patient's self-care activities need to be evaluated.

*Skin color* is affected by blood flow, gas exchange, body temperature, and pigmentation. The wide variation in skin tones requires different techniques for patients who have darker skin. (See the [Cultural/Spiritual Considerations](#) box for tips for assessing patients with darker skin.)

Describe and document changes in skin color by their appearance ([Table 24-2](#)). Include in your description whether the changes are general or confined to one body region. Color changes are more visible in the areas of least pigmentation, such as the oral mucosa, sclera, nail beds, and palms and soles. Inspect these areas to help confirm more subtle color changes of general body areas.

**TABLE 24-2**

**Common Alterations in Skin Color**

ALTERATION	UNDERLYING CAUSE	LOCATION	SIGNIFICANCE
White (pallor)	Decreased hemoglobin level	Conjunctivae	Anemia
	Decreased blood flow to the skin (vasoconstriction)	Mucous membranes Nail beds Palms and soles Lips	Shock or blood loss Chronic vascular compromise Sudden emotional upset Edema
	Genetically determined defect of the melanocyte (decreased pigmentation)	Generalized	Albinism
Yellow-orange	Acquired patchy loss of pigmentation	Localized	Vitiligo, tinea versicolor
	Increased total serum bilirubin level (jaundice)	Generalized Mucous membranes Sclera	Hemolysis of red blood cells Liver disorders
	Increased serum carotene level (carotenemia)	Perioral Palms and soles Ears and nose Absent in sclera and mucous membranes	Increased ingestion of carotene-containing foods (carrots) Pregnancy Thyroid deficiency Diabetes
	Increased urochrome level	Generalized Absent in sclera and mucous membranes	Chronic kidney disease (uremia)
Red (erythema)	Increased blood flow to the skin (vasodilation)	Generalized	Generalized inflammation (e.g., erythroderma)
		Localized (to area of involvement)	Localized inflammation (e.g., sunburn, cellulitis, trauma, rashes)
		Face, cheeks, nose, upper chest Area of exposure	Fever, increased alcohol intake Exposure to cold
Blue	Increase in deoxygenated blood (cyanosis)	Nail beds Mucous membranes Generalized	Cardiopulmonary disease Methemoglobinemia
		Bleeding from vessels into tissue:	
		Petechiae (1-3 mm) Ecchymosis (>3 mm)	Localized Localized
Reddish blue	Increased overall amount of hemoglobin	Generalized	Polycythemia vera
		Decreased peripheral circulation	Distal extremities, nose

Brown	Increased melanin production	Localized (to area of involvement)	Chronic inflammation
		Pressure points, areolae, palmar creases, and genitalia	Exposure to sunlight Addison's disease
	Café au lait spots (tan-brown patches):	Face, areolae, vulva, linea nigra	Pregnancy; oral contraceptives (melasma)
	<6 spots	Localized	Nonpathogenic
	>6 spots	Generalized	Possible neurofibromatosis
	Melanin and hemosiderin deposits (bronze or grayish tan color)	Distal lower extremities	Chronic venous stasis
		Exposed areas or generalized	Hemochromatosis

Lesions in skin disease are clinically described in terms of primary and secondary lesions (Fig. 24-8). **Primary lesions** develop as a direct result of a disease process. **Secondary lesions** evolve from primary lesions or develop as a consequence of the patient's activities. These changes occur with progression of an underlying disease or in response to a topical or systemic therapeutic intervention. For example, acute dermatitis often occurs as primary vesicles with associated **pruritus** (itching). Secondary lesions in the form of crusts occur as the patient scratches, the vesicles are opened, and the exudate dries. With chronic dermatitis, the skin often becomes **lichenified** (thickened) because of the patient's continual rubbing of the area to relieve itching.

### Primary lesions

### Secondary lesions

FIG. 24-8 Classification of skin ulcers.

Describe lesions by color, size, location, and shape. Note whether they are isolated or are grouped and form a distinct pattern. Table 24-3 defines terms used to describe lesions. Research continues on tools such as the WoundVision Scout, an imaging device designed to photograph and measure area of a wound (Langemo et al., 2015), and on other methods of digitized tracing and digital wound photography (Gabison et al., 2015). Methods such as these may increase accuracy of measurement as a wound is assessed over time.

**TABLE 24-3**  
**Terms Commonly Used to Describe Skin Lesion Configurations**

<b>annular</b>	Ringlike with raised borders around flat, clear centers of normal skin
<b>circinate</b>	Circular
<b>circumscribed</b>	Well-defined with sharp borders
<b>clustered</b>	Several lesions grouped together
<b>coalesced</b>	Lesions that merge with one another and appear confluent
<b>diffuse</b>	Widespread, involving most of the body with intervening areas of normal skin; generalized
<b>linear</b>	Occurring in a straight line
<b>serpiginous</b>	With wavy borders, resembling a snake
<b>universal</b>	All areas of the body involved, with no areas of normal-appearing skin

Assess each lesion for these ABCDE features that are associated with skin cancer (The Skin Cancer Foundation, 2016):

- Asymmetry of shape
- Border irregularity
- Color variation within one lesion
- Diameter greater than 6 mm
- Evolving or changing in any feature (shape, size, color, elevation, itching, bleeding, or crusting)

Because of the continued rise of incidence of melanoma (Masterson, 2015), routinely teach patients signs of skin cancer and encourage them to perform skin self-examination on a monthly basis (American Cancer Society, 2015). High-risk patients may benefit from taking The Brief Skin Cancer Assessment Tool (BRAT) to self-assess their relative risk for developing melanoma (Gordon, 2014). *A patient who has a lesion with one or more of the ABCDE features should be evaluated by a dermatologist or surgeon.*

In describing location, determine whether lesions are generalized or localized. If the lesions are localized, identify the specific body areas involved. This information is important because some diseases have a specific pattern of skin lesions. For example, involvement of only the sun-exposed areas of the body is important when considering possible causes. Rashes limited to the skinfold areas (e.g., on the axillae, beneath the breasts, in the groin) may reflect problems related to friction, heat, and excessive moisture.

*Edema* causes the skin to appear shiny, **taut** (tightly stretched), and paler than uninvolved surrounding skin. During skin inspection, document the location, distribution, and color of areas of edema.

Skin elasticity is affected by edema. Using moderate pressure, place the tip of a finger against edematous tissue to determine the degree of indentation, or pitting (see Chapter 11).

*Moisture content* is assessed by noting the thickness and consistency of secretions. Normally increased moisture in the form of sweat occurs with increased activity or elevated environmental temperatures. Dampness of skinfold areas occurs with reduced air circulation where the skin surfaces touch. Excess moisture can cause impaired TISSUE INTEGRITY with skin breakdown in bedridden and debilitated patients.

Overly dry skin is caused by a dry environment, poor skin lubrication, inadequate fluid intake, and the normal aging process. Dry skin usually has scaling and flaking and may be especially marked in areas of limited circulation such as the feet and lower legs. It is a common problem during the winter months when the air contains less moisture, for those living in geographic areas with little humidity, and in the hospital environment where humidity is often low.

*Vascular changes or markings* may be normal or abnormal, depending on the cause. Normal vascular markings include birthmarks, cherry angiomas (Fig. 24-9), spider angiomas, and venous stars. Bleeding into the skin is abnormal and results in **purpura** (bleeding under the skin that may progress from red to purple to brownish-yellow), petechiae, and ecchymosis.

**FIG. 24-9** Senile (cherry) angiomas.

**Petechiae** are small, reddish-purple lesions (<0.5 mm in diameter) that do not fade or blanch when pressure is applied (Fig. 24-10). They often indicate increased capillary fragility. Petechiae of the lower extremities often occur with stasis dermatitis, a condition usually seen with chronic venous insufficiency. Petechiae found below the nipple line may be indicative of a serious underlying medication problem such as disseminated intravascular coagulation (DIC).

**FIG. 24-10** Petechiae. (Modified from Marks, J., & Miller, J. [2013]. *Lookingbill and Marks' Principles of dermatology* (5th ed.). Philadelphia: Saunders.)

**Ecchymoses** (bruises) are larger areas of hemorrhage. In older adults, bruising is common after minor trauma to the skin. Certain drugs (e.g., aspirin, warfarin, corticosteroids) and low platelet counts lead to easy or excessive bruising. Anticoagulants and decreased numbers of platelets disrupt clotting action, resulting in ecchymosis.

Skin **TISSUE INTEGRITY** is assessed by first examining areas with actual breaks or open areas. For example, skin tears are a common finding in older adults as a result of aging. The thin, fragile skin is easily damaged by friction or shearing forces, especially if bruising is already present. Look for skin tears where clothing rubs against the skin, on upper extremities where skin is grasped to assist in ambulation, and where adhesive tapes or dressings have been applied and removed. Check for the presence of multiple abrasions or early pressure-related skin changes. These changes may indicate unrecognized problems in mobility or sensory perception.

Document breaks in skin **TISSUE INTEGRITY** by describing their location, size, color, and distribution and by the presence and characteristics of drainage or infection. The evaluation of partial- and full-thickness wounds, including objective criteria that describe progress toward healing, is discussed in [Chapter 25](#). A model such as the Skin Safety Model (SSM) or the Pathway to Assessment/Treatment of Skin Tears can help you thoroughly evaluate potential for skin injury and associated outcomes, especially for older adults ([Campbell et al., 2016](#); [LeBlanc et al., 2014](#)).

*Cleanliness* of the skin is evaluated to learn about self-care needs. Inspect the hair, nails, and skin closely for excessive soiling and offensive odor. Depending on a patient's degree of self-care deficit,

hard-to-reach areas (e.g., perirectal and inguinal skinfolds, axillae, feet) may be less clean than other skin surface areas.

Patients who have cognitive problems may not observe hygiene measures. Assess the cognition of any patient whose hygiene of the skin, hair, or nails appears inadequate.

*Tattoos and piercings* can cause or mask skin problems and must be examined carefully. Bruises and rashes may be difficult to see in tattooed areas. Examine newly pierced areas for inflammation or infection. Scars may be present in old tattoos or pierced areas and should be documented. Closely examine any areas where tattoos have been removed. Skin cancer is more likely to occur in these areas.

## NCLEX Examination Challenge 24-1

### Physiological Integrity

While performing skin assessment on an elderly client, the nurse observes an isolated brownish-purple lesion with irregular borders on the anterior chest wall. The lesion feels slightly raised on palpation, and crusted blood is visible at the lower edge. Which is the appropriate nursing intervention?

- A. Wash the lesion gently with warm water to remove the crusts and teach not to pick it.
- B. Document lesion's location, size, and characteristics and request a dermatology consult.
- C. Reassure that the lesion is a common occurrence with aging, especially in sun-exposed areas.
- D. Ask the patient about exposure to new lotions or perfumes that could cause an allergic reaction.

### Palpation

Skin inspection can be misleading in areas of color changes, tattoos, and piercings. Use palpation to gather additional information about skin lesions, moisture, temperature, texture, and turgor (Table 24-4). Wash hands thoroughly before and after palpating a patient's skin. Use gloves to examine nonintact skin, and use Standard Precautions when skin areas are draining.

**TABLE 24-4**  
**Common Clinical Findings in Skin Palpation**

CLINICAL FINDINGS	CAUSE	LOCATION	EXAMPLES OF PREDISPOSING CONDITIONS
<b>Edema</b>			
Localized	Inflammatory response	Area of involvement	Trauma
Dependent or pitting	Fluid and electrolyte imbalance Venous and cardiac insufficiency	Ambulatory: dorsum of foot and medial ankle Bedridden: buttocks, sacrum, and lower back	Congestive heart failure Kidney disease Liver cirrhosis Venous thrombosis or stasis
Nonpitting	Endocrine imbalance	Generalized, but more easily seen over the tibia	Hypothyroidism (myxedema)
<b>Moisture</b>			
Increased	Autonomic nervous system stimulation	Face, axillae, skinfolds, palms, and soles	Fever, anxiety, activity Hyperthyroidism
Decreased	Dehydration Endocrine imbalance	Buccal mucous membranes with progressive involvement of other skin surfaces	Fluid loss Postmenopausal status Hypothyroidism Normal aging
<b>Temperature</b>			
Increased	Increased blood flow to the skin	Generalized	Fever, hypermetabolic states Neurotrauma
		Localized	Inflammation
Decreased	Decreased blood flow to the skin	Generalized	Impending shock, sepsis, anxiety Hypothyroidism
		Localized	Interference with vascular flow
<b>Turgor</b>			
Decreased	Decreased elasticity of the dermis (tenting when pinched)	Abdomen, forehead, or radial aspect of the wrist	Severe dehydration Sudden, severe weight loss Normal aging
<b>Texture</b>			
Roughness or thickness	Irritation, friction	Pressure points (e.g., soles, palms, elbows) Localized areas of pruritus	Calluses Chronic eczema Atopic skin diseases
	Sun damage	Areas of sun exposure	Normal aging
	Excessive collagen production	Localized or generalized	Scleroderma Scars and keloids
Softness or smoothness	Endocrine disturbances	Generalized	Hyperthyroidism

Palpation confirms lesion size and whether the lesions are flat or slightly raised. Consistency of

larger lesions can vary from soft and pliable to firm and solid. Subtle changes, such as the difference between a fine **macular** (flat) rash and a **papular** (raised) rash, are best determined by palpating with your eyes closed. Ask the patient if skin palpation causes pain or tenderness.

In areas of excess dryness, rub your finger against the skin surface to determine the degree of flaking or scaling. Changes in skin temperature are detected by placing the back of your hand on the skin surface. First, make certain to have warm hands. Cold hands interfere with accurate assessment and are uncomfortable for the patient.

Palpate skin surfaces to assess texture, which differs according to body area and exposure to irritants. For example, areas of long-term sun exposure have a rougher texture than protected skin surfaces. The patient who has repeated exposure to harsh soaps or chemicals may show skin changes related to this exposure. Increased skin thickness from scarring, lichenification, or edema usually decreases elasticity.

**Turgor** indicates the amount of skin elasticity. Skin turgor can be altered by water content and aging. Gently pinch the patient's skin between your thumb and forefinger and then release. If skin turgor is normal, the skin immediately returns to its original state when released. Poor skin turgor is seen as “tenting” of the skin, with a gradual return to the original state (see [Chapter 11](#)). Loss of elasticity with aging makes the assessment of skin turgor difficult in an older-adult patient. Although usually checked on the back of the hand, you may also check for turgor on the abdomen, forehead, or radial aspect of the wrist.

## Nursing Safety Priority QSEN

### Action Alert

To avoid mistaking dehydration for dry skin in an older adult, always assess skin turgor on the forehead or chest.

## Hair Assessment

During the skin assessment, inspect and palpate the hair for general appearance, cleanliness, distribution, quantity, and quality. Hair is normally found in an even distribution over most of the body surfaces. The hair on the scalp, in the pubic region, and in the axillary folds is thicker and coarser than hair on the trunk, arms, and legs. Although color and growth patterns vary, sudden changes in hair characteristics may reflect an underlying disease. Check any abnormal findings by obtaining a detailed history of the change.

How well the hair is groomed, including the cleanliness of areas of thicker hair growth, can provide information about a patient's health care needs. If the patient has intense itching or scratches continually, examine the scalp and pubis for lice and **nits** (lice eggs). Inspect the scalp for scaling, redness, open areas, crusting, and tenderness.

**Dandruff**, a collection of patchy or diffuse white or gray scales on the surface of the scalp, is common. The flaking that occurs with dandruff causes many adults to mistakenly think the scalp is too dry; however, it is a problem of excessive oil production. Dandruff is a cosmetic problem, but a very oily scalp can induce inflammatory changes with redness and itching. Severe inflammatory dandruff can extend to the eyebrows and the skin of the face and neck. *If severe dandruff is not treated, alopecia (hair loss) can occur.* Teach the patient that dandruff is not caused by dryness and should be treated to prevent hair loss.

Although gradual hair loss occurs with aging, sudden asymmetric or patchy hair loss at any age is of concern. Assess the scalp for hair distribution and thickness, and document variations. Body hair loss, especially on the feet or lower legs, may occur with decreased blood flow to the area and also is a part of aging.

**Hirsutism** is excessive growth of body hair or hair growth in abnormal body areas. Increased hair growth across the face and chest in women is a sign of hirsutism. It may occur on the face of a woman as part of aging, is one sign of hormonal imbalance, and can also occur as a side effect of drug therapy. If hirsutism is present, look for changes in fat distribution and capillary fragility, which can occur in Cushing's disease, and for clitoral enlargement and deepening of the voice, which may indicate ovarian dysfunction.

## Nail Assessment

**Dystrophic** (abnormal-appearing) nails may occur with a serious systemic illness or local skin disease involving the epidermal keratinocytes. Assess the fingernails and toenails for color, shape, thickness, texture, and the presence of lesions.

Many variations in color, texture, and grooming of the nails are influenced by factors unrelated to disease, such as occupation. When assessing the older adult, observe for minor variations associated with the aging process, such as a gradual thickening of the nail plate, the presence of longitudinal ridges, or a yellowish-gray discoloration.

*Color* of the nail plate depends on nail thickness and transparency, amount of red blood cells, arterial blood flow, and pigment deposits (Table 24-5). Fig. 24-11 shows normal variations in nail pigmentation. Changes in color can be caused by chemical damage that occurs with some occupations and with the long-term use of nail polish. Regardless of skin color, the healthy nail blanches (lightens) with pressure.

**TABLE 24-5**  
**Common Alterations in Nail Color**

ALTERATION	CLINICAL FINDINGS	SIGNIFICANCE
White	Horizontal white banding or areas of opacity	Chronic liver or kidney disease (hypoalbuminemia)
	Generalized pallor of nail beds	Shock Anemia Early arteriosclerotic changes (toenails) Myocardial infarction
Yellow-brown	Diffuse yellow-to-brown discoloration	Jaundice
		Peripheral lymphedema
		Bacterial or fungal infections of the nail
		Psoriasis
		Diabetes
		Cardiac failure
		Staining from tobacco, nail polish, or dyes
		Long-term tetracycline therapy
		Normal aging (yellow-gray color)
		Vertical brown banding extending from the proximal nail fold distally
Red	Thin, dark red vertical lines 1-3 mm long (splinter hemorrhages)	Bacterial endocarditis
		Trichinosis
		Trauma to the nail bed
		Normal finding in some patients
		Red discoloration of the lunula
Blue	Diffuse blue discoloration that blanches with pressure	Polycythemia vera
		Respiratory failure Methemoglobinuria Venous stasis disease (toenails)

**FIG. 24-11** A, Diffuse nail pigmentation. B, Linear nail pigmentation.

During examination, the patient's fingers and toes should be free of any surface pressure that interferes with local blood flow or alters the appearance of the digits. To differentiate between color changes from the underlying blood supply and those from pigment deposits, blanch the nail bed to see whether the color changes with pressure. Gently squeeze the end of the finger or toe, exerting downward pressure on the nail bed, and then release the pressure. Color caused by blood flow changes as pressure is applied and returns to the original state when pressure is released. Color caused by pigment deposits remains unchanged.

*Nail shape changes* may be related to systemic disease. For example, fingernail clubbing occurs

with impaired gas exchange (see Fig. 30-10).

Assess nail shape by examining the curve of the nail plate and surrounding tissue from all angles. Palpate the fingertips to assess for sponginess, tenderness, or edema. Table 24-6 describes common variations in nail shape.

**TABLE 24-6**  
**Common Variations in Nail Shape**

NAIL SHAPE	CLINICAL FINDINGS		SIGNIFICANCE
Normal	Angle of 160 degrees between the nail plate and the proximal nail fold Nail surface slightly convex Nail base firm when palpated		Normal finding
Clubbing			
Early clubbing	Straightening of angle between the nail plate and the proximal nail fold to 180 degrees Nail base spongy when palpated		Hypoxia Lung cancer
Late clubbing	Angle between the nail plate and the proximal nail fold exceeds 180 degrees Nail base visibly edematous and spongy when palpated Enlargement of the soft tissue of the fingertips gives a "drumstick" appearance when viewed from above		Prolonged hypoxia Emphysema Chronic obstructive pulmonary disease Advanced lung cancer Cystic fibrosis Chronic heart disease
Spoon nails (koilonychia)			
Early koilonychia	Flattening of the nail plate with an increased smoothness of the nail surface		Iron deficiency (with or without anemia) Poorly controlled diabetes >15 yr in duration Local injury
Late koilonychia	Concave curvature of the nail plate		Psoriasis Chemical irritants Developmental abnormality
Beau's grooves	1-mm-wide horizontal depressions in the nail plates caused by growth arrest (involves all nails)		Acute, severe illness Prolonged febrile state Isolated periods of severe malnutrition
Pitting	Small, multiple pits in the nail plate May be associated with plate thickening and onycholysis Most often involves the fingernails (several or all)		Psoriasis Alopecia areata

Thickness of the nail plate varies with age, trauma, dermatologic disease, or decreased arterial blood flow. In older patients, look for a "heaped-up" appearance of the toenails, which occurs with fungal infection (*onychomycosis*).

Consistency of the nail is described as hard, soft, or brittle. Nail plates become hard, with thickening. A warm-water soak is required to soften the nail plates before they can be trimmed. Soft nail plates, which are thin and bend easily with pressure, are associated with malnutrition, chronic arthritis, myxedema, and peripheral neuritis.

Brittle nails can split, as with onychomycosis or advanced psoriasis involving the fingers or toes.

Splitting of the nail plate is caused by repeated exposure to water and detergents, which damage the plate over time.

*Lesions* can occur around, on, within, or under the nail. Separation of the nail plate from the nail bed (*onycholysis*) creates an air pocket beneath the plate. The pocket first appears as a grayish-white opacity. The color changes as dirt and keratin collect in the pocket, and the area begins to have a bad odor. This problem occurs with fungal infections and after trauma. Separation of the nail plate may also occur with psoriasis or with prolonged chemical contact.

Inspect the tissue folds around the nail plate for redness, heat, swelling, and tenderness. **Acute paronychia** (inflammation of the skin around the nail) often occurs with a torn cuticle or an ingrown toenail.

**Chronic paronychia** is common and is an inflammation that persists for months. Adults at risk for chronic paronychia are those with frequent exposure to water, such as homemakers, bartenders, laundry workers, and nurses.

## Cultural/Spiritual Considerations

### Patient-Centered Care OSEN

Pallor, erythema, cyanosis, and other skin color changes are less visible in patients with naturally dark skin tones. Although physiologic processes are the same for both light-skinned and dark-skinned patients, the amount of skin pigmentation alters how the skin appears in response to physiologic alterations. Different assessment skills are needed to detect the more subtle color changes. Become familiar with the normal appearance of a dark-skinned patient's mucous membranes, nail beds, and skin tone so variations from baseline can be identified. Chart 24-3 lists assessment techniques to assess skin changes in people with dark skin.

### Chart 24-3

## Best Practice for Patient Safety & Quality Care OSEN

### Assessing Changes in Dark Skin

#### Cyanosis

- Examine lips and tongue for gray color.
- Examine nail beds, palms, and soles for blue tinge.
- Examine conjunctiva for pallor.

#### Inflammation

- Compare affected area with nonaffected area for increased warmth.
- Examine the skin of the affected area to determine whether it is shiny or taut or pits with pressure.
- Compare the skin color of affected area with the same area on the opposite side of the body.
- Palpate the affected area and compare it with unaffected area to determine whether texture is different (affected area may feel hard or “woody”).

#### Jaundice

- Check for yellow tinge to oral mucous membranes, especially the hard palate.
- Examine the sclera nearest to the iris rather than the corners of the eye.

## Bleeding

- Compare the affected area with the same area on the unaffected body side for swelling or skin darkening.
- If the patient has thrombocytopenia, petechiae may be present on the oral mucosa or conjunctiva.

## Skin Assessment Techniques for Patients With Darker Skin

*Pallor* can be detected in people with dark skin by first inspecting the mucous membranes for an ash-gray color (Jarvis, 2016). If the lips and the nail beds are not heavily pigmented, they appear paler than normal for that patient. Use good lighting to assess for the absence of the underlying red tones that normally give heavily pigmented skin a healthy glow. With decreased blood flow to the skin, brown skin appears yellow-brown, and very dark brown skin is ash gray.

*Cyanosis* can be present when gas exchange is impaired. Examine the lips, tongue, nail beds, conjunctivae, and palms and soles for subtle color changes (Jarvis, 2016). In a patient with cyanosis, the lips and tongue are gray; and the palms, soles, conjunctivae, and nail beds have a bluish tinge. To support these findings, assess for other indicators of hypoxia, including tachycardia, hypotension, changes in respiratory rate, decreased breath sounds, and changes in cognition.

*Inflammation* in dark-skinned patients appears as excessive warmth and changes in skin consistency or texture (Jarvis, 2016). Use the back of your hand to palpate areas of suspected inflammation for increased warmth. With the fingertips, palpate for hardened areas deep in the tissue, which may give the skin a “woody” feeling. Inflamed skin is tender and edematous. If edema is extensive, the skin is taut and shiny.

Skin areas where inflammation has recently resolved appear *darker* than the patient's normal skin tone. This change is caused by stimulation of the melanocytes during the inflammatory process and the increased pigment production that continues after inflammation subsides. Deep skin injury with destruction of melanocytes (e.g., deep ulcer, full-thickness burn) may heal with color changes that are *lighter* than the normal skin tone. Chronic inflammatory changes are not tender. Scarred skin feels less supple, especially over the joints. If chronic inflammatory changes are suspected, ask the patient about a history of skin problems in that area.

*Jaundice* in a patient with dark skin is best assessed by inspecting the oral mucosa, especially the hard palate, for yellow discoloration. Yellowness of the conjunctivae and adjacent sclera may be misleading because normal deposits of fat produce a yellowish hue that is visible in contrast to the dark skin around the eyes (Jarvis, 2016). Examine the sclera closest to the cornea for a more accurate determination of jaundice. The palms and soles of dark-skinned patients may appear yellow if they are calloused, even when jaundice is not present.

*Skin bleeding* with purpuric lesions may not be visible with deep pigmentation. Areas of ecchymoses appear darker than normal skin; they may be tender and easily palpable, depending on whether hematoma is present. Often the patient relates a history of trauma to the area that confirms the assessment. Petechiae are rarely visible in dark skin and may be seen only in the oral mucosa and conjunctiva.

## Psychosocial Assessment

Skin changes, especially of the face, hair, and hands, often affect body image. Encourage the patient to express feelings about a change in appearance. Assess body language for clues indicating a disturbance in self-concept. The avoidance of eye contact or the use of clothing to cover the affected areas may suggest concern about appearance. Patients with chronic skin diseases often become socially isolated related to a fear of rejection by others or a belief that the skin problem is contagious.

Skin changes linked to poor hygiene are common among homeless individuals and those who have reduced cognitive functioning. Assess the patient's overall appearance for excessive soiling, matted hair, body odor, or other self-care deficits. Confirm unsanitary living conditions by obtaining a social history. Patients may relate similar skin problems among family members, friends, and sexual contacts.

If skin problems related to poor hygiene are identified in older patients, also evaluate any physical limitations that might interfere with grooming. For example, visual or mobility problems

can make it difficult for them to see or reach skin surfaces to clean them.

## Clinical Judgment Challenge 24-1

### Patient-Centered Care QSEN

You are a home health care nurse caring for an African-American patient following hospital discharge for an acute exacerbation of congestive heart failure. During your initial assessment, you observe that the patient's pulse is slightly elevated and mild dyspnea on exertion is noted. Both lower extremities are edematous and cool to the touch.

1. What skin changes suggest that the patient is hypoxic?
2. What other assessment findings may you notice that could indicate hypoxia?
3. How do you differentiate between tissue edema caused by altered cardiac perfusion and deep tissue inflammation?
4. What action(s) should you take at this time?

## Diagnostic Assessment

### Laboratory Tests

When a fungal, bacterial, or viral infection of the skin is suspected, confirmation by microscopic examination is necessary. *Always wear gloves (use Standard Precautions) when examining skin that is not intact.*

*Cultures for fungal infection* are obtained by using a tongue blade and gently scraping scales from skin lesions into a clean container. Collect fingernail clippings and hair in a similar manner. Waiting for culture results can delay treatment of a superficial fungal infection. For this reason, the specimen is also treated with a potassium hydroxide (KOH) solution and examined microscopically. A positive fungal infection shows branched hyphae when viewed under a microscope after treatment with KOH and may eliminate the need for a culture.

For deeper fungal infections, a piece of tissue is obtained for culture. The health care provider obtains the specimen by punch biopsy (see [Skin Biopsy](#) section). Check with the laboratory for any specific instructions related to specimen handling.

*Cultures for bacterial infection* are obtained from intact primary lesions (abscess, bullae, vesicles, or pustules), if possible. Express material from the lesion, collect it with a cotton-tipped applicator, and place it in a bacterial culture medium specified by the laboratory. For intact lesions, *unroofing* (lifting or puncturing of the outer surface) may be needed using a sterile small-gauge needle before the material can be easily expressed. If crusts are present, the nurse or other health care professional removes them with normal saline and swabs the underlying exudate to obtain a specimen for culture ([Cross, 2014](#)).

A biopsy of deep bacterial infections may be needed to obtain a specimen for culture. If bacterial cellulitis is suspected, the health care provider can inject nonbacteriostatic saline deep into the tissue and then aspirate it back; the aspirant is sent for culture.

*Cultures for viral infection* are indicated if a herpes virus infection is suspected. A cotton-tipped applicator is used to obtain vesicle fluid from intact lesions. Viral culture specimen tubes must be placed on ice immediately after specimens are obtained and are transported to the laboratory as soon as possible.

The presence of a viral infection can be confirmed by *Tzanck smear*, although the exact virus is not identified. A smear is obtained from the base of the lesion and examined under a microscope. The presence of multinucleated giant cells confirms a viral infection.

### Other Diagnostic Tests

Other tests for diagnosis of skin problems include biopsy, special noninvasive examination techniques, and skin testing for allergy (discussed in [Chapter 20](#)).

## Skin Biopsy.

A small piece of skin tissue may be obtained for diagnosis or to assess the effectiveness of an intervention. Check with the health care provider to determine the number, location, and type of skin biopsies to be performed. Depending on the size, depth, and location of the skin changes, the health care provider may perform a punch biopsy, shave biopsy, or scalpel excision (excisional biopsy).

*Punch biopsy* is the most common technique. A small circular cutting instrument, or “punch,” ranging in diameter from 2 to 6 mm, is used. After the site is injected with a local anesthetic, a small plug of tissue is cut and removed. The site may be closed with sutures or may be allowed to heal without suturing.

*Shave biopsies* remove only the part of the skin that rises above the surrounding tissue when injected with a local anesthetic. A scalpel or razor blade is moved parallel to the skin surface to remove the tissue specimen. Shave biopsies are usually indicated for superficial or raised lesions. Suturing is not needed.

*Excisional biopsy* is rarely used for skin problems. When needed, larger or deeper specimens are obtained by deep excision with a scalpel followed by closure with sutures. Excisional biopsies are more uncomfortable than punch or shave biopsies while healing.

## NCLEX Examination Challenge 24-2

### Safe and Effective Care Environment

What is the appropriate nursing response when a client asks, “What is a punch biopsy?”

- A. “The health care provider will use a scalpel to remove a portion of the skin.”
- B. “A circular cutting instrument will be used to remove a small plug of tissue.”
- C. “A deep specimen of skin will be taken, and then the health care provider will suture this area closed.”
- D. “A local anesthetic will be injected before a razor blade is moved parallel to the skin's surface to obtain a sample.”

### Patient Preparation.

Explain to the patient what to expect and that a biopsy is a minor procedure with few anticipated complications. Obtain informed consent. If a punch or shave biopsy is planned, reassure the patient that only a small amount of skin is removed and scarring is minimal. For an excisional biopsy, teach that a scar similar to that of a healed surgical incision will result.

### Procedure.

Establish a sterile field and assemble all needed supplies and instruments. Local anesthesia is provided by local infiltration using a small-gauge (25-gauge) needle to reduce discomfort during injection. Preparation of the biopsy site differs by health care provider preference, but usually the skin is simply wiped with alcohol.

The injection of a local anesthetic agent, which produces a burning or stinging sensation, may be uncomfortable. Reassure the patient that the discomfort will subside as the anesthetic takes effect. Talking the patient through the procedure with a quiet voice along with a gentle touch may have a calming effect.

After removal, tissue specimens for pathologic study are placed in 10% formalin for fixation. Specimens for culture are placed in sterile saline solution. Bleeding of the site may be controlled by applying localized pressure, applying a topical hemostatic agent, or suturing.

### Follow-up Care.

After bleeding is controlled and any sutures are placed, the site is covered with an adhesive bandage or a dry gauze dressing. Instruct the patient to keep the dressing dry and in place for at least 8 hours. Teach him or her to clean the site daily after the dressing is removed. Tap water or

saline is used to remove any dried blood or crusts. An antibiotic ointment may be prescribed to reduce the risk for infection. The site may be left open or covered for cosmetic reasons or because the site is an area often soiled. Instruct the patient to report any redness or excessive drainage. Sutures are usually removed 7 to 10 days after biopsy.

### Wood's Light Examination.

A handheld, long-wavelength ultraviolet (black) light or Wood's light may be used during physical examination. Exposure of some skin infections with this light produces a specific color, such as blue-green or red, that can be used to identify the infection. Hypopigmented skin is more prominent when it is viewed under black light, making evaluation of pigment changes in lighter skin easier. This examination is carried out in a darkened room and does not cause discomfort.

### Diascopy.

Diascopy is a painless technique to eliminate erythema caused by increased blood flow to the skin, thereby easing the inspection of skin lesions. A glass slide or lens is pressed down over the area to be examined, blanching the skin and revealing the shape of the lesions.

## NCLEX Examination Challenge 24-3

### Safe and Effective Care Environment

Which are appropriate nursing interventions for a client who has poor personal hygiene? **Select all that apply.**

- A. Obtain a social history.
- B. Assist the client with bathing.
- C. Tell the client that he or she smells bad.
- D. Consult social services to assess the client's living conditions.
- E. Teach client and family members how to help with personal hygiene.
- F. Notify the health care provider of any suspected drug or alcohol addiction.
- G. Assess for poor cognitive function or physical limitations that might interfere with grooming.
- H. Instruct the client and family to use rubbing alcohol to cleanse skin areas with most visible amount of dirt.

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Assist patients with limited mobility to change positions at least every 2 hours, noting any areas of compromised TISSUE INTEGRITY. **QSEN: Safety**
- Wash your hands before and after touching any areas of impaired skin TISSUE INTEGRITY. **QSEN: Safety**
- Use Standard Precautions when providing care to a patient who has areas of impaired skin TISSUE INTEGRITY or skin with an abnormal appearance. **QSEN: Safety**
- Use lift sheets when moving patients with fragile skin to avoid shearing. **QSEN: Safety**
- Position patients who are confined to bed to promote air circulation to skinfold areas and minimize pressure over bony prominences. **QSEN: Safety**

### Health Promotion and Maintenance

- Teach adults to reduce sun exposure and exposure to ultraviolet (UV) light and to regularly use sunscreen. **QSEN: Safety**
- Teach adults to examine all skin areas on a monthly basis for new lesions and changes to existing lesions using the ABCDE method of checking lesions for signs of melanoma. **QSEN: Evidence-Based Practice**
- Teach and encourage patients to bathe, shampoo the hair, and keep fingernails clean and trimmed. **QSEN: Patient-Centered Care**

### Psychosocial Integrity

- Use effective communication when teaching patients and family members about what to expect during tests and procedures associated with skin assessment. **QSEN: Patient-Centered Care**
- Reassure patients who have skin changes that are variations of normal. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Assess the cognitive function of any patient whose hygiene of the skin, hair, and nail hygiene appears inadequate.
- Modify techniques to assess skin changes in patients with dark skin. **QSEN: Evidence-Based Practice**
- Be aware of specific allergies that have skin indications. **QSEN: Patient-Centered Care**
- Ask any patient who has started taking a newly prescribed or over-the-counter drug whether skin changes have occurred since starting the drug. **QSEN: Patient-Centered Care**
- Distinguish between normal variations and abnormal skin signs and symptoms regarding skin color, texture, warmth, elastic turgor, and moisture. **Clinical Judgment**
- Use the ABCDE method of assessing skin lesions for cancer. **QSEN: Evidence-Based Practice**

## CHAPTER 25

# Care of Patients With Skin Problems

Janice Cuzzell

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is TISSUE INTEGRITY.**

✚ The TISSUE INTEGRITY concept exemplar for this chapter is Pressure Injuries, below.

**The interrelated concept for this chapter is CELLULAR REGULATION.**

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to coordinate high-quality care for patients with skin problems.
2. Protect patients from skin injury, loss of TISSUE INTEGRITY, and infection.

### Health Promotion and Maintenance

3. Teach adults how to protect the skin from damage and cancer development.

### Psychosocial Integrity

4. Implement nursing interventions to minimize stressors for the patient with changes in appearance or function of the integumentary system.

### Physiological Integrity

5. Apply knowledge of anatomy and physiology to assess skin changes, lesions, and open wounds.
6. Prioritize nursing care for the patient with skin problems.

Skin TISSUE INTEGRITY helps to protect the entire body by providing a strong barrier, especially to invasion by harmful microorganisms and other foreign proteins (antigens). Problems associated with the skin are common, especially in older adults. Skin TISSUE INTEGRITY changes reduce protective function, and the cause of the change is often difficult to determine. The skin also reflects underlying medical conditions, so skin symptoms may indicate injury or underlying systemic disease.

Interventions and medications for any health problem can trigger a skin response. Skin problems can interfere with the management of other conditions. Age-related changes and problems caused by immobility, chronic disease, debility, and reduced immune function increase the older patient's risk for skin damage and loss of tissue integrity. Pressure injuries reflect one of the most concerning skin conditions with tissue integrity loss for which nurses provide care. Nurses coordinate the activities of an interprofessional team comprised of health care providers, wound care nurses, registered dietitians, and therapists to provide high-quality care for patients with skin concerns.

## Tissue Integrity Concept Exemplar Pressure Injuries

### ❖ Pathophysiology

A **pressure injury** (PrI) is a loss of TISSUE INTEGRITY caused when the skin and underlying soft tissue are compressed between a bony prominence and an external surface for an extended period. Although they commonly occur over the sacrum, hips, and ankles, *pressure injuries can occur on any body surface*. For example, nasal cannula tubing that is too tight can cause pressure injuries behind the ears or in the nares (Ambutas et al., 2014).

*Tissue compression from pressure restricts blood flow to the skin, resulting in reduced tissue perfusion and gas exchange, which eventually leads to cell death.* Ulcers occur most often in adults with limited mobility because they cannot change their position to relieve pressure. Patients who cannot feel or communicate the pain that occurs with unrelieved pressure are more likely to develop pressure injuries. Once formed, these chronic wounds are slow to heal, resulting in increased morbidity and health care costs. Complications include sepsis, kidney failure, infectious arthritis, and osteomyelitis.

Friction and shear are mechanical forces that impair skin TISSUE INTEGRITY and cause skin tears, which set the stage for skin breakdown (LeBlanc & Baranoski, 2014). Excessive skin moisture, such as urinary or fecal incontinence, also increases the risk for skin damage. Nutrition status is an important concern. Protein malnutrition makes normal tissue more prone to breakdown and also delays healing (Posthauer et al., 2015).

### Mechanical Forces

*Pressure* occurs as a result of gravity. Dependent tissues in contact with a fixed surface experience varying degrees of pressure. Pressure is determined by the amount and distribution of weight exerted at the point of contact and the density of the contacting surface. Excessive or prolonged pressure compresses blood vessels at the point of contact, such as over bony prominences. Pressure occurs when the patient is positioned on a hard surface that does not redistribute the weight, such as when lying on a hard floor for hours after a fall or when remaining in the same position too long. Unrelieved pressure leads to ischemia, inflammation, and tissue necrosis.

*Friction* occurs when surfaces rub the skin and irritate or tear fragile epithelial tissue. Such forces are generated when the patient is dragged or pulled across bed linen.

*Shearing forces* are generated when the skin itself is stationary and the tissues below the skin (e.g., fat, muscle) shift or move (Fig. 25-1). The movement of the deeper tissue layers reduces the blood supply to the skin, leading to skin hypoxia, anoxia, ischemia, inflammation, and necrosis.

**FIG. 25-1** Shearing forces pulling skin layers away from deeper tissue. The skin is "bunched up" against the back of the mattress while the rest of the bone and muscle in the area presses downward on the lower part of the mattress. Blood vessels become kinked, obstructing circulation and leading to tissue death.

A shear ulcer usually occurs when a patient is in a wheelchair or in bed in a semi-sitting position and gradually slides downward. The skin over the sacrum may not slide down at the same pace as

the deeper tissues, mechanically “shearing” the skin, causing blood vessels to stretch and break. Shearing leads to soft-tissue ischemia and deep-tissue ulcer, even though no external break in skin integrity is observed.

## Considerations for Older Adults

### Patient-Centered Care QSEN

Older adults are at higher risk for skin tears and pressure injuries because of age-related skin changes. Flattening of cells at the dermal-epidermal junction predisposes older adults to skin tears from mechanical shearing forces such as tape removal and minor trauma. Skin moisture and irritation from incontinence combined with friction over bony prominences can lead to skin destruction with loss of TISSUE INTEGRITY and pressure injury formation. Patients with cognitive impairments may not readily report discomfort from inadequate pressure relief. **If pressure is unrelieved, tissue destruction progresses to full-thickness ulcer.** Assess patients with cognitive impairments more frequently for loss of skin tissue integrity.

### Incidence/Prevalence

Pressure injury development is a problem found among patients in any care setting, including the home. Although new products are available for prevention and treatment, many hospitalized patients still experience pressure injury formation, which contributes significantly to morbidity and mortality in this patient population (Paul et al., 2014; Roe & Williams, 2014).

### Health Promotion and Maintenance

Pressure injuries can be prevented if the risk is recognized and intervention begins early (Chart 25-1) (National Pressure Ulcer Advisory Panel, 2016). Pressure injury prevention does not just happen, even with conscientious nursing care. Deliberate and consistent interventions, as described in the Evidence-Based Practice box, are needed to prevent pressure injuries across the health care continuum, particularly for critically ill patients. Key health care team members for pressure injury prevention and management are the certified wound care specialist and the dietitian. Involving unlicensed assistive personnel (UAP) in pressure injury prevention also enhances prevention program effectiveness.

## Chart 25-1

### Best Practice for Patient Safety & Quality Care QSEN

#### Preventing Pressure Injuries

##### Positioning

- Pad contact surfaces with foam, silicone gel, air pads, or other materials with pressure-redistribution properties.
- Do not keep the head of the bed elevated above 30 degrees to prevent shearing.
- Use a lift sheet to move a patient in the bed. Avoid dragging or sliding him or her.
- When positioning a patient on his or her side, position at a 30-degree tilt.
- Re-position an immobile patient at a frequency consistent with assessed needs.
- Do not place a rubber ring or donut under the patient's sacral area.
- When moving an immobile patient from a bed to another surface, use a designated slide board well lubricated with talc or use a mechanical lift.

- Place pillows or foam wedges between two bony surfaces.
- Keep the patient's skin directly off plastic surfaces.
- Keep the patient's heels off the bed surface using bed pillow under ankles or a heel-suspension device.

### Nutrition

- Ensure a fluid intake between 2000 and 3000 mL/day.
- Help the patient maintain an adequate intake of protein and calories.

### Skin Care

- Perform a daily inspection of the patient's entire skin.
- Document and report any manifestations of skin infection.
- Use moisturizers daily on dry skin and apply when skin is damp.
- Keep moisture from prolonged contact with skin:
  - Dry areas where two skin surfaces touch, such as the axillae and under the breasts.
  - Place absorbent pads under areas where perspiration collects.
  - Use moisture barriers on skin areas where wound drainage or incontinence occurs.
- *Do not massage bony prominences.*
- Humidify the room.

### Skin Cleaning

- Clean the skin as soon as possible after soiling occurs and at routine intervals.
- Use a mild, heavily fatted soap or gentle commercial cleanser for incontinence.
- Use tepid rather than hot water.
- In the perineal area, use a disposable cleaning cloth that contains a skin-barrier agent.
- While cleaning, use the minimum scrubbing force necessary to remove soil.
- Gently pat rather than rub the skin dry.
- Do not use powders or talc directly on the perineum.
- After cleaning, apply a commercial skin barrier to areas in frequent contact with urine or feces.

## Evidence-Based Practice QSEN

### Using a Skin Integrity Care Bundle to Reduce Pressure Injuries

Coyer, F., et al. (2015). Reducing pressure injuries in critically ill patients by using a patient skin integrity care bundle (InSPiRE). *American Journal of Critical Care*, 24(3), 199-210.

This study sought to determine whether using a skin integrity bundle, the InSPiRE protocol, would reduce the incidence of pressure injuries in critically ill patients.

The sample included 207 patients in an Australian intensive care unit. Of the 207, 105 were part of the intervention group, and 102 were in the control group. Both groups had an average age of 55, a comparable average length of stay in intensive care, and similar Sequential Organ Failure Assessment (SOFA) scores. The InSPiRE protocol, used with the intervention group, included a bundle of processes, including ongoing skin assessment; intervention attention to hygiene, repositioning, and use of devices intended to lower pressure and friction; and focus on nutrition, mobility, and documentation. Within the intervention group, cumulative incidence of pressure injuries (skin and mucous) was significantly lower than that of the control group. Patients in the intervention group also developed significantly fewer pressure injuries over time than those in the control group.

### Level of Evidence: 2

This research was designed as a prospective comparative study.

### Commentary: Implications for Practice and Research

A significant reduction in the incidence of pressure injuries between the groups, from 30% in the control group to 18% in the intervention group, was noted. Use of protocols such as InSPiRE draws attention to the importance of diligence in ongoing interventions to prevent development of pressure injuries throughout the length of the patient's stay. As noted by the authors, nurses and all members of the interdisciplinary team benefit the patient by continually being aware of, and implementing, evidence-based strategies on a continual basis.

A pressure injury prevention program consists of two steps: (1) early identification of high-risk patients, and (2) implementation of aggressive intervention for prevention with the use of pressure-relief or pressure-reduction devices. Pressure mapping with a computerized tool that measures pressure distribution during sitting or lying can identify specific body areas at risk for breakdown and can help plan interventions for patients who are bedridden or wheelchair bound. The map is displayed in colors on the computer screen based on temperature differences. Red indicates areas of greater heat production and increased pressure loads. Blue indicates cooler areas under lower pressure. When used in combination with risk assessment tools, pressure mapping helps identify problem areas before skin changes can be seen and allows for more targeted prevention strategies.

Effective risk identification and prevention measures include patient and caregiver education. Documentation of risk assessment, implementation of prevention measures, and education of all adults involved in the care of the patient at risk for pressure injury formation are key to the plan's success. Continuing evaluation and risk assessment are critical, especially when the patient's condition changes.

### Identification of High-Risk Patients

As suggested by The Joint Commission's National Patient Safety Goals (NPSGs), all patients admitted to a health care facility or home care agency are to be assessed for pressure injury risk. The use of a risk assessment tool increases the chances of identifying patients at greater risk for skin breakdown. The Braden scale (Fig. 25-2) is a commonly used valid skin risk assessment tool. Using it helps the nurse assess and document risk categories for pressure injury formation (e.g., mental status, activity and mobility, nutritional status, incontinence).

Patient's name _____	Evaluator's name _____				Date of assessment _____
<b>Sensory perception</b> Ability to respond meaningfully to pressure-related discomfort	<b>1. Completely limited</b> Unresponsive to painful stimuli; cannot communicate (flinch, or grasp) because of diminished level of consciousness or sedation OR limited ability to feel pain over most of body surface	<b>2. Very limited</b> Responds only to painful stimuli; cannot communicate discomfort except by moaning or restlessness OR has a sensory impairment that limits the ability to feel pain or discomfort over half of the body	<b>3. Slightly limited</b> Responds to verbal commands but cannot always communicate discomfort or need to be turned OR has some sensory impairment that limits ability to feel pain or discomfort in one or two extremities	<b>4. No impairment</b> Responds to verbal commands; has no sensory deficit that would limit ability to feel or voice pain or discomfort	
<b>Moisture</b> Degree to which skin is exposed to moisture	<b>1. Constantly moist</b> Skin is kept moist almost constantly by perspiration, urine, dampness is detected every time the client is moved or turned	<b>2. Very Moist</b> Skin is often but not always moist; linen must be changed at least once a shift	<b>3. Occasionally moist</b> Skin is occasionally moist, requiring an extra linen change approximately once a day	<b>4. Rarely moist</b> Skin is usually dry; linen requires changing only at routine intervals	
<b>Activity</b> Degree of physical activity	<b>1. Bedfast</b> Confined to bed	<b>2. Chairfast</b> Ability to walk severely limited or nonexistent; cannot bear own weight and must be assisted into chair or wheelchair	<b>3. Walks occasionally</b> Walks occasionally during the day but for very short distances, with or without assistance; spends the majority of each shift in bed or chair	<b>4. Walks frequently</b> Walks outside the room at least twice a day and inside the room at least once every 2 hours during waking hours	
<b>Mobility</b> Ability to change or control body position	<b>1. Completely immobile</b> Does not make even slight changes in body or extremity position without assistance	<b>2. Very limited</b> Makes occasional slight changes in body or extremity position but unable to make frequent or significant changes independently	<b>3. Slightly limited</b> Makes frequent though slight changes in body or extremity position independently	<b>4. No limitations</b> Makes major and frequent changes in position without assistance	
<b>Nutrition</b> Usual food intake pattern	<b>1. Very poor</b> Never eats a complete meal; rarely eats more than a third of any food offered; eats two servings or less of protein (meat or dairy products) per day; takes fluids poorly; does not take a liquid dietary supplement OR is NPO or maintained on clear liquids or IV for more than 5 days	<b>2. Probably inadequate</b> Rarely eats a complete meal and generally eats only about half of any food offered; protein intake includes only three servings of meat or dairy products per day; occasionally will take a dietary supplement OR receives less than optimal amount of liquid diet or tube feeding	<b>3. Adequate</b> Eats over half of most meals; eats a total of four servings of protein (meat, dairy products) each day; occasionally will refuse a meal, but will usually take a supplement if offered OR is receiving tube feeding or total parenteral nutrition, which probably meets most nutritional needs	<b>4. Excellent</b> Eats most of every meal; never refuses a meal; usually eats a total of four or more servings of meat and dairy products; occasionally eats between meals; does not require supplementation	
<b>Friction and shear</b>	<b>1. Problem</b> Requires moderate to maximum assistance in moving; complete lifting without sliding against sheets is impossible; frequently slides down in bed or chair, requiring frequent repositioning with maximum assistance; spasticity, contractures, or agitation leads to almost constant friction	<b>2. Potential problem</b> Moves feebly or requires minimum assistance during a move; skin probably slides to some extent against sheets, chair, restraints, or other devices; maintains relatively good position in chair or bed most of the time but occasionally slides down	<b>3. No apparent problem</b> Moves in bed and in chair independently and has sufficient muscle strength to lift up completely during move; maintains good position in bed or chair at all times		
Scoring system: 15-16 = mild risk, 12-14 = moderate risk, <11 = severe risk					Total score _____

**FIG. 25-2** The Braden scale for predicting pressure ulcer risk. *IV*, Intravenous; *NPO*, nothing by mouth.  
(From Barbara Braden & Nancy Bergstrom. ©1988. Reprinted with permission.)

*Mental status* changes and decreased sensation determine whether the patient is a partner in pressure injury prevention. When the patient understands that turning and shifting of weight prevent tissue damage, the risk for pressure injuries decreases. Stroke, head injury, organic brain disease, Alzheimer's disease, sedation, or other cognitive problems increase the risk for pressure injuries.

*Impaired mobility* is a factor in the risk for pressure injury formation. Patients who have unimpaired mobility and can respond to pain are at lower risk for pressure injuries. *Regardless of age, any patient who requires assistance with turning and positioning or who is unable to verbalize discomfort is at higher risk for pressure injuries.* Those confined to bed or a chair also are at higher risk than a patient who requires assistance only with ambulation.

*Nutrition status* is a critical risk factor for pressure injury development and for successful healing (Posthauer et al., 2015). TISSUE INTEGRITY and wound healing depend on a positive nitrogen balance and adequate serum protein levels. The patient in negative nitrogen balance not only heals more slowly but also is at risk for accelerated tissue destruction. Draining wounds contribute to protein loss and require aggressive intervention.

Nutrition assessment includes laboratory studies; evaluation of weight and weight change; ability of the patient to consume an adequate diet; and the need for vitamin, mineral, or protein supplementation. Serum prealbumin levels are often used to monitor nutrition status. *Nutrition is considered inadequate when the serum prealbumin level is less than 19.5 g/dL, albumin level is less than 3.5 g/dL, or the lymphocyte count is less than 1800/mm<sup>3</sup>.* Because serum protein levels are affected by a number of other factors, laboratory values are useful only when supported by additional assessment information. Other indicators of inadequate nutrition include poor daily intake of food and fluids with a weight loss greater than 5% change in 30 days or greater than 10% change in 180 days (Posthauer et al., 2015).

A positive nitrogen balance requires an intake of 30 to 35 calories per kilogram of body weight daily with a protein intake of 1.25 to 1.5 g/kg/day. Up to 2 g/kg/day of protein may be needed when nutritional deficits are severe or protein loss is ongoing. Vitamin and mineral supplementations are based on the patient's nutrition status. Collaborate with a dietitian for all patients at risk for a pressure injury to perform a thorough nutrition assessment and plan interventions for nutrition deficits (National Pressure Ulcer Advisory Panel, European Pressure Ulcer Advisory Panel, & Pan Pacific Pressure Injury Alliance, 2014).

*Incontinence* results in prolonged contact of the skin with substances that irritate the skin, destroy

TISSUE INTEGRITY, and predispose to skin breakdown (e.g., urea, bacteria, yeast, and enzymes in urine and feces). Excessive moisture macerates skin, further increasing the risk for breakdown. Daily inspection of the skin for any areas of redness, maceration, or loss of skin TISSUE INTEGRITY is a major part of pressure injury prevention. Maintenance of clean, dry, intact skin also assists in ulcer prevention. Wash the skin with a pH-balanced soap to maintain the normal acid level. Use creams or lotions to lubricate and moisturize the skin. Barrier ointments and zinc oxide–based creams help protect intact skin from urine and feces when incontinence is present. Change absorbent pads or garments immediately after each incontinence episode and avoid using adult briefs when patients are unable to communicate their needs to avoid prolonged skin contact with urine or feces.

## Nursing Safety Priority QSEN

### Action Alert

Teach all nursing care personnel and family members not to massage reddened skin areas directly or use donut-shaped pillows for pressure relief. These actions can damage capillary beds and increase tissue necrosis.

## Pressure-Redistribution Techniques

### Support Surfaces and Devices.

The cornerstone in the prevention and management of pressure injuries is maintaining adequate pressure redistribution so pressure over bony prominences remains below the **capillary closing pressure**. Capillary closing pressure is the pressure needed to occlude skin capillary blood flow and normally ranges from 12 to 32 mm Hg. An effective pressure-redistribution surface or device keeps tissue interface pressure *below* the capillary closing pressure, thus promoting adequate tissue perfusion and gas exchange. *Most support surfaces and devices have a standardized guaranteed pressure-redistribution reading; however, these readings do not ensure that capillary blood flow for any given patient is adequate. Observe skin color, capillary refill, tissue integrity, and temperature directly to determine capillary flow adequacy.*

Products that redistribute tissue load are available in several forms: specialty bed replacements, mattress replacements, mattress overlays, seat cushion replacements, seat cushion overlays, and heel-suspension devices (McInnes et al., 2015). Choosing the correct product is important to the success of any prevention or treatment plan. Factors to consider when selecting a product include:

- Number and severity of existing pressure injuries
- Risk for developing new pressure injuries
- Patient's ability to reposition self to relieve pressure-related discomfort
- Need for microclimate control to help manage skin temperature and moisture
- Need to reduce shearing forces
- Compatibility of product with care setting

Support surfaces are classified as either nonpowered (*static*) or powered (*dynamic*). Static devices use gel, water, foam, or air to increase the body surface area that comes in contact with the surface and reduce interface pressure. A static high-specification reactive foam mattress with frequent repositioning is recommended for patients at high risk for pressure injury development and for management of those with existing Stage 1 or Stage 2 pressure injuries.

Dynamic systems are comprised of cells that inflate and deflate to continuously alter the area of the body that is bearing the load. Alternating pressure surfaces with small air cells are considered to be less effective than those with air compartments >10 cm. Consider the use of a dynamic support surface for immobile patients when manual repositioning is medically contraindicated; when the number and severity of existing pressure injuries limit turning options; for management of Stage 3, Stage 4, and unstageable pressure injuries (as in [Chart 25-2](#)); and for suspected deep-tissue injury when repositioning is ineffective.

### Chart 25-2

## Key Features

### Pressure Injuries

#### Suspected Deep-Tissue Injury

- The intact skin area appears purple or maroon.
- Blood-filled blisters may be present.
- Before the previously listed changes appeared, the tissue in this area may first have been painful.
- Other changes that may have preceded the discoloration include that the area may have felt more firm, boggy, mushy, warmer, or cooler than the surrounding tissue.

#### Stage 1

- Skin is intact.
- Area, usually over a bony prominence, is red and does not blanch with external pressure.
- For patients with darker skin that does not blanch, observe pressure-related alteration of intact skin; changes are compared with an adjacent or opposite area and include one or more of these:
  - Skin color (darker or lighted than the comparison area)
  - Skin temperature (warmth or coolness)
  - Tissue consistency (firm or boggy)
  - Sensation (pain, itching)
- The ulcer appears as a defined area of persistent redness in lightly pigmented skin, whereas in darker skin tones, the ulcer may appear with persistent red, blue, or purple hues.

#### Stage 2

- Skin is not intact.
- There is partial-thickness skin loss of the epidermis or dermis.
- Ulcer is superficial and may be characterized as an abrasion, a blister (open or fluid-filled), or a shallow crater.
- Bruising is *not* present.

#### Stage 3

- Skin loss is full thickness.
- Subcutaneous tissues may be damaged or necrotic.

- Damage extends down to but not through the underlying fascia; bone, tendon, and muscle are *not* exposed.
- The depth can vary with anatomic location; areas of thin skin (e.g., the bridge of the nose) may show only a shallow crater, whereas thicker tissue areas with larger amounts of subcutaneous fat may show a deep, crater-like appearance.
- Undermining and tunneling may or may not be present.

#### Stage 4

- Skin loss is full thickness with exposed or palpable muscle, tendon, or bone.
- Often includes undermining and tunneling.
- Sinus tracts may develop.
- Slough and eschar are often present on at least part of the wound.

#### Unstageable

Skin loss is full thickness; and the base is completely covered with slough or eschar, obscuring the true depth of the wound.

Data from National Pressure Ulcer Advisory Panel. (2016). *NPUAP pressure injury stages*. Retrieved from <http://www.npuap.org/resources/educational-and-clinical-resources/npuap-pressure-injury-stages/>.

Evaluate the surface daily for effectiveness in redistributing pressure, reducing discomfort, managing the microclimate and shear, and eliminating “bottoming out.” Bottoming out occurs when the product is not providing adequate pressure redistribution for the patient's size and weight and the patient's bony prominences sink into the mattress or cushion. If the patient has a pressure injury involving the heel, use a heel-suspension device to elevate the heel and offload pressure completely without placing pressure on the Achilles tendon. Check heel-suspension devices periodically to assess skin integrity ([National Pressure Ulcer Advisory Panel, European Pressure Ulcer Advisory Panel, & Pan Pacific Pressure Injury Alliance, 2014](#)).

Pressure-redistribution devices lower pressure below that of a standard hospital mattress or chair surface but do not reduce pressure consistently below the capillary closing pressure. These devices are effective for preventing pressure injuries only when used together with a turning schedule and other preventive skin-care measures.

#### Positioning.

*Frequent repositioning* of bedbound patients, as described in [Chart 25-1](#), is critical in reducing pressure over bony prominences. A good plan for positioning is the 30-degree rule. This plan ensures that the patient is positioned and propped so whatever part of the body is elevated is tilted back to no more than a 30-degree angle to the mattress rather than resting directly on a dependent bony prominence. This rule applies to side-lying and head-of-bed elevation positions. The patient who requires greater head elevation because of respiratory difficulties should be tilted up above 30 degrees with pillows behind the back to keep pressure off of the sacral/coccyx area. Often positioning is delegated to UAP. Teach UAP the importance of proper positioning, demonstrate how to perform it, and provide appropriate supervision. Also teach family members to use these techniques in the home.

The patient at risk for pressure injuries in bed is also at risk while sitting. Assess for proper chair cushioning. Collaborate with physical therapists and rehabilitation specialists for selection of these products. Periodically assist high-risk patients who are chair bound to a standing position to promote perfusion and prevent breakdown over the sacral area.

Even with an appropriate mattress or cushion, the patient needs to change or be helped to change positions periodically to prevent loss of skin TISSUE INTEGRITY. Many facilities require turning and positioning every 2 hours. *However, pressure can occur in less time, and the actual turning or repositioning schedule for each patient must be individualized.* When this action is delegated to UAP,

teach them the importance of maintaining a repositioning schedule and supervise appropriately.

Use pillows and other positioning or heel-suspension devices to keep heels pressure free at all times for high-risk patients. Assess heel positioning every 4 hours to ensure that pressure is not redistributed to other high-risk areas, such as the ankles or side of the feet. Check heels even more often when devices that hide the feet (e.g., boots, heel protectors) are used, especially if the patient has a vascular problem. Also check knees and elbows regularly, especially when the patient is in a side-lying position.

### ❖ **Interprofessional Collaborative Care**

Care of the patient with a pressure injury, depending on stage and associated health issues, can take place in a variety of settings: the hospital, long-term care center, or home. Members of the interprofessional team who collaborate most closely to care for the patient with pressure injury include the primary health care provider, who continually assesses the wound condition and prescribes treatment; the nurse; and the dietitian, who assesses nutrition status and recommends dietary modification to speed wound healing.

### ◆ **Assessment: Noticing**

#### **History.**

When a patient already has a pressure injury, identify the cause of skin TISSUE INTEGRITY loss and factors that may impair healing. Ask about the circumstances of the skin loss. Patients with chronic pressure injuries may have a history of delayed healing or recurrence of the ulcer after healing has occurred. Assess for any of these contributing factors:

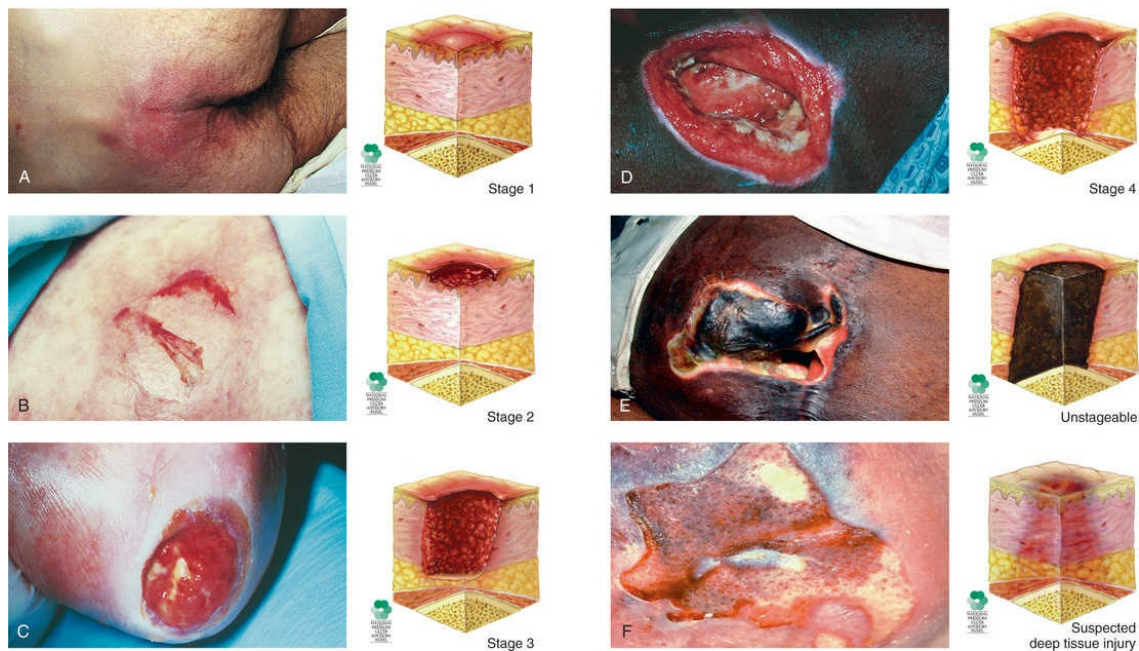

- Prolonged bedrest
- Immobility
- Incontinence
- Diabetes mellitus
- Inadequate nutrition or hydration
- Decreased sensory perception or cognitive problems
- Peripheral vascular disease

#### **Physical Assessment/Signs and Symptoms.**

Inspect the entire body, including the back of the head, for areas of skin TISSUE INTEGRITY loss or pressure. Give special attention to bony prominences (e.g., the heels, sacrum, elbows, knees, trochanters, and posterior and anterior iliac spines) and areas with excessive moisture. Make sure that tubing and other medical devices are not under the patient, producing a pressure point. Assess the patient's general appearance for issues related to skin health, such as the proportion of weight to height. Obese and thin patients are at increased risk for malnutrition and pressure injuries. Check overall cleanliness of the skin, hair, and nails. Determine whether any loss of mobility or range of joint motion has occurred. *Do not delegate this assessment to UAP because it is beyond their scope of practice.*

#### **Wound Assessment.**

The appearance of pressure injuries changes with the depth of the ulcer. [Chart 25-2](#) lists the features of the six categories or stages of pressure ulceration, and [Fig. 25-3](#) shows examples.

**FIG. 25-3** Various stages of pressure injuries. **A**, Stage 1 pressure injury. **B**, Stage 2 pressure injury. **C**, Stage 3 pressure injury. **D**, Stage 4 pressure injury. **E**, Unstageable pressure injury. **F**, Suspected deep-tissue injury. (Illustrations from the National Pressure Ulcer Advisory Panel and European Pressure Ulcer Advisory Panel. [2009]. *Pressure ulcer prevention and treatment: Clinical practice guideline*. Washington, DC: NPUAP. Used with permission.)

Assess wounds for location, size, color, extent of tissue involvement, cell types in the wound base and margins, exudate, condition of surrounding tissue, and presence of foreign bodies. Document this initial assessment to serve as a starting point for determining the intervention plan and its effectiveness. How often a wound is assessed is determined by the policies and procedures at the facility or agency. Weekly documented assessment is standard in many long-term care facilities. Daily assessment is needed when the patient is in an acute care setting. *Also assess the wound at each dressing change, comparing the existing wound features with those documented previously to determine the current state of healing or deterioration.*

Blanchable erythema of intact skin over a bony prominence is an early sign of pressure-related complications. In light-skinned patients, assess whether blanching is present by pressing the reddened area firmly with a gloved finger and releasing the pressure. An area that blanches (lightens) when pressure is briefly applied and reddens again when pressure is released suggests adequate capillary blood flow to the tissue. A reddened area that does not blanch indicates absence of capillary blood flow and early tissue damage (Stage 1 pressure injury). Redness and blanching may be difficult to detect in darker-skinned patients. Look for more subtle differences in the skin color and texture over the pressure point compared with the surrounding area. In addition to being painful, the skin may feel firmer, softer, warmer, or cooler than adjacent areas (Steven et al., 2015).

First record the location and size of the wound. Wounds are sized by length, width, and depth using millimeters or centimeters. For standardization in documentation, assess the wound as a clock face with the 12 o'clock position in the direction of the patient's head and the 6 o'clock position in the direction of the patient's feet (van Rijswijk, 2013). Using a disposable measuring device, always measure the length from the 12 o'clock position to the 6 o'clock position and the width between the 9 o'clock position and the 3 o'clock position. Measure depth as the distance from the deepest portion of the wound base to the skin level. Touch the bottom of the wound with a cotton-tipped applicator or swab and mark the place on the swab that is level with the skin surface to obtain wound depth. Then measure the area of the swab between the tip and the mark. When everyone uses this format, measurement is accurate, and progress can be determined.

Inspect the wound margins for *cellulitis* (inflammation of the skin and subcutaneous tissue) extending beyond the area of injury. Progressive tissue destruction, seen as an increase in the size or depth of the ulcer and increased wound drainage, may indicate an increased risk for infection if proper measures have not been taken to relieve pressure.

Inspect the wound for the presence or absence of necrotic tissue. Because of the depth of tissue destruction, a full-thickness pressure injury is often covered by a layer of black, gray, or brown

collagen called wound **eschar**.

In the early stages of wound healing, the eschar is dry, leathery, and firmly attached to the wound. As the inflammatory phase of wound healing begins and removal of wound debris progresses, the eschar starts to lift and separate from the tissue beneath. This nonliving eschar is a good breeding ground for any bacteria on the skin surface. As bacteria increase, they release enzymes that cause the eschar to soften and become more yellow or tan in appearance. With bacterial colonization, wound exudate increases substantially; the color and odor of wound exudate indicate the major organism present. The features of wound exudate are listed in [Table 25-1](#).

**TABLE 25-1**  
**Types of Wound Exudate**

CHARACTERISTICS	SIGNIFICANCE
<b>Serosanguineous Exudate</b>	
Blood-tinged amber fluid consisting of serum and red blood cells	Normal for first 48 hr after injury Sudden increase in amount precedes wound dehiscence in wounds closed by first intention
<b>Purulent Exudate</b>	
Creamy yellow pus	Colonization with <i>Staphylococcus</i>
Greenish-blue pus causing staining of dressings and accompanied by a "fruity" odor	Colonization with <i>Pseudomonas</i>
Beige pus with a "fishy" odor	Colonization with <i>Proteus</i>
Brownish pus with a "fecal" odor	Colonization with aerobic coliform and <i>Bacteroides</i> (usually occurs after intestinal surgery)

Beneath the dead tissue, granulation tissue appears. Early granulation is pale pink, progressing to a beefy red color as it grows and fills the wound. Palpate the wound to determine the granulation texture. Healthy granulation tissue is moist and has a slightly spongy texture. Wounds with a poor arterial blood supply or that have stopped healing appear dry with hard (fibrotic) granulation tissue on palpation. Venous obstruction causes a very moist ulcer surface with a deep reddish-purple color from the deoxygenated blood beneath the surface.

Pressure injuries may have more tissue destruction than is first seen on inspection. Deep, extensive tissue damage may be present under normal-appearing skin surrounding the wound, with separation of the skin layers from the underlying granulation tissue. This problem is known as **undermining**. Inspect undermined areas for gradual filling with healthy granulations and for wound-healing progress. Palpate the bony prominences for deep hardening of the surrounding soft tissue, which often occurs with deep-tissue ischemia.

After ischemia has occurred, continued pressure over the area increases tissue destruction from the deep-tissue layers toward the surface, resulting in the formation of tunnels. This "hidden" wound may have a small opening in the skin with purulent drainage. If such an opening is observed, use a cotton-tipped applicator to probe gently for a much larger tunnel or pocket of necrotic tissue beneath the opening. Additional tunnels may occur along the main wound. Check all wounds for tunneling and, if present, document the location and length of each tunnel.

In addition to recording regular wound assessments, serial photographs of the wound help document changes in wound appearance and progress toward healing. Policies on photographic documentation vary from facility to facility and require informed consent from the patient or responsible family member. New ways of assessing and managing wounds are emerging with advancing technology. For example, in rural or long-term care settings, facilities can use bidirectional video to consult with a wound specialist at the bedside and get recommendations on how to better manage nonhealing wounds ([Chanussot-Deprez & Contreras-Ruiz, 2013](#)).

### Psychosocial Assessment.

The patient with pressure injuries may have an altered body image. Many changes in lifestyle are needed for healing. Chronic injuries are often painful and costly to treat.

Assess the patient's and family's knowledge of the desired treatment outcomes during the healing process and adherence to the prescribed treatment regimen. Also assess the patient's skills in cleaning and dressing the wound. Poor adherence to pressure injury care procedures may reflect an inability to cope with the pain, cost, or potential scarring associated with prolonged healing. Depending on the patient's activity level and the ulcer location, family assistance or a home care nurse may be needed to provide pressure injury care at home.

Teach the patient and family specific changes in ADLs to relieve pressure and promote healing. Encourage increased activity whenever possible to enhance circulation to the affected tissue. Leg position changes may be needed for chronic leg ulcers, depending on whether vascular problems are present. For patients who have arterial insufficiency, keeping the legs and feet in a dependent

position helps ensure adequate blood flow to the lower legs. When arterial blood flow is adequate but venous return is impaired, elevation of the legs may be needed for healing. When the patient is bedridden, frequent repositioning to relieve pressure can be labor intensive. In the home, repositioning, incontinence management, and dressing changes are often needed around the clock, not only increasing patient discomfort but also disrupting family routines and causing added stress.

### Laboratory Assessment.

An exposed chronic wound is always *colonized with microorganisms* but is not always *infected*. *Colonization* is the presence of one or more communities of organisms that attach to the wound surface in the form of a wound biofilm. Polymicrobial biofilms are composed of nonpathogenic, microbiome organisms that impede normal wound healing by producing a state of chronic inflammation without clinical infection (Cowan et al., 2014). Pathogenic organisms form biofilms that lead to wound infection. *Wound infection* is a state of critical colonization with pathogenic organisms to the degree that organism growth and spread cannot be controlled by the body's immune defenses. Wounds that are red and indurated with moderate-to-heavy exudate and an odor should be cultured to identify the organism and determine antibiotic sensitivity. *The presence of purulent exudate alone does not indicate an infection because pus forms whenever necrotic tissue liquefies and separates.*

If wounds are extensive, if the patient is severely immunocompromised, or if local blood supply to the wound is impaired, bacterial growth exceeds the body's defenses against invasion into deeper tissues. The result is deep wound infection and eventually bacteremia and sepsis.

Swab cultures are helpful only in identifying the types of bacteria present on the ulcer surface and may not identify bacteria encapsulated within a mature biofilm or invading deeper tissues (Cross, 2014). Wound biopsies allow the numbers of bacteria to be analyzed, but these tests are time consuming, costly, and not always available. Clinical indicators of infection (cellulitis, progressive increase in ulcer size or depth, changes in the quantity and quality of exudate) and systemic signs of bacteremia (e.g., fever, elevated white blood cell [WBC] count) are used to diagnose an infection.

### Other Diagnostic Assessments.

Additional laboratory studies are performed based on the suspected cause of the wound. For example, noninvasive and invasive arterial blood flow studies are indicated if arterial occlusion is suspected in delayed healing of a pressure injury on the heel or ankle. Blood tests to determine nutritional deficiencies (e.g., prealbumin, albumin, total protein) are helpful in managing the debilitated, malnourished patient with a pressure injury.

## Clinical Judgment Challenge 25-1

### Evidence-Based Practice QSEN

A 78-year-old man with hypertension, hyperlipidemia, osteoporosis, and urge incontinence is admitted to a long-term care facility after having an ischemic stroke. His wife tells you that, over the past 6 months, the patient has become progressively dependent on her to assist with ADLs. You observe the patient to be a slender, frail elderly male who appears alert and cooperative. He has significant left-sided weakness and requires assistance to transfer from the wheelchair to the bed. While helping him change clothes, you notice a large reddened area on his left hip that doesn't change color when you press it with your index finger.

1. What is the most probable cause of his reddened hip?
2. How would you stage this skin change?
3. Which risk factors does this patient have for pressure injury formation?
4. What other body areas do you need to inspect for skin breakdown?
5. Which support surface would be appropriate for this patient?

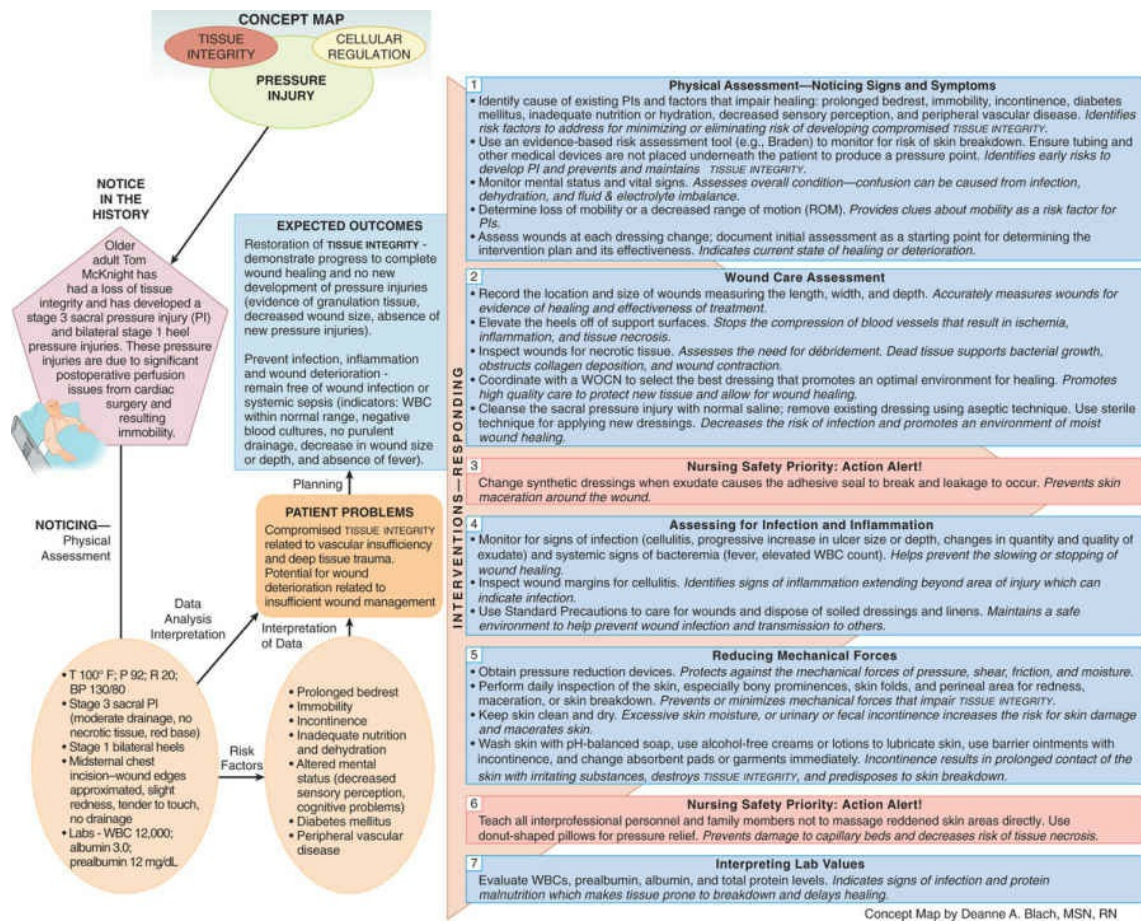

## ◆Analysis: Interpreting

The priority collaborative problems for patients with pressure injuries include:

1. Compromised TISSUE INTEGRITY due to vascular insufficiency and trauma
2. Potential for wound deterioration due to insufficient wound management

## ◆Planning and Implementation: Responding

The Concept Map addresses care issues related to patients who have or are at risk for pressure injuries.

## Managing Wounds

### Planning: Expected Outcomes.

The patient with a pressure injury is expected to progress to complete wound healing and not develop new pressure injuries. Indicators include:

- Presence of granulation, re-epithelialization, and scar tissue formation
- Decreased wound size
- Absence of new pressure injuries

### Interventions.

Wound care for pressure injuries varies according to each patient's needs and the health care provider's preferences. Surgery may be indicated for some patients, whereas a nonsurgical approach to ulcer débridement is preferred for a patient who has adequate defenses but is too ill or debilitated for surgery.

## Nonsurgical Management.

General interventions for wound management of pressure injuries are listed in [Chart 25-3](#). Nonsurgical intervention of pressure injuries is often left to the discretion of the nurse, who coordinates with the primary health care provider and certified wound care specialist (if available) to select an appropriate method of wound dressing and management. Many agencies have guidelines for wound dressings based on wound size and depth and presence of drainage.

### Chart 25-3

## Best Practice for Patient Safety & Quality Care QSEN

### Wound Management of Pressure Injuries

- If injury is covered, change dressing according to manufacturer's instructions, when dressing seal is compromised, when drainage is visible on the outer layer (gauze), or when the dressing becomes contaminated with body fluids.
- Measure wound size at greatest length and width using a disposable paper tape measure or, for asymmetric injuries, by tracing the wound onto a piece of plastic film or sheeting (plastic template) at least weekly or more often if the wound shows signs of deterioration.
- Compare all subsequent measurements against the initial measurement.
- Assess the injury for presence of necrotic tissue and amount of exudate.
- Assess and document the condition of the skin surrounding the pressure injury in terms of color, temperature, texture, moisture, and appearance.
- Remove or trim loose bits of tissue (may be done by a certified wound care specialist, physical therapist, advanced practice nurse, or other as specified by the agency and the state nurse practice act).
- Cleanse the injury with saline, nontoxic wound cleanser or a prescribed solution (after diluting it per manufacturer's directions or prescriber's instructions).
- Rinse and dry the injury surface.
- In collaboration with the certified wound care specialist, select and apply the dressing materials most appropriate for the volume of wound drainage.
- If possible, avoid positioning the patient on the pressure injury.
- Re-position frequently to prevent injury extension or generation of additional pressure injuries.
- Use prescribed pressure redistribution devices and techniques as described in [Chart 27-2](#).

### Dressings.

A well-designed dressing helps healing by removing surface debris, protecting exposed healthy tissues, and creating a barrier until the ulcer is closed. *For a draining, necrotic ulcer, the dressing must also remove excessive exudate and loose debris without damaging healthy epithelial cells or new granulation tissue. Extensive necrosis and thick eschar require sharp surgical or chemical removal before débridement with dressings can be effective.* Different dressing materials help remove debris by **mechanical débridement** (mechanical entrapment and detachment of dead tissue), **topical chemical débridement** (topical enzyme preparations to loosen necrotic tissue), or **natural chemical débridement** (promoting self-digestion of dead tissues by naturally occurring bacterial enzymes [autolysis]) ([Table 25-2](#)).

### TABLE 25-2

## Common Dressing Techniques for Wound Débridement

TECHNIQUE	MECHANISM OF ACTION
Wet-to-damp saline-moistened gauze	As with the wet-to-dry technique, necrotic debris is mechanically removed but with less trauma to healing tissue.
Continuous wet gauze	The wound surface is continually bathed with a wetting agent of choice, promoting dilution of viscous exudate and softening of dry eschar.
Topical enzyme preparations	Proteolytic action on thick, adherent eschar causes breakdown of denatured protein and more rapid separation of necrotic tissue.
Moisture-retentive dressing	Spontaneous separation of necrotic tissue is promoted by autolysis.

After all the dead tissue has been removed, protection of exposed healthy tissues is critical to pressure injury care. The ideal healing environment is a clean, *slightly* moist ulcer surface with minimal bacterial colonization as evidenced by the absence of a wound biofilm, a shiny gel-like film on the surface of the wound. Heavy moisture from an excessively draining ulcer or a dressing that is too wet promotes the growth of organisms and causes maceration (mushiness) of healthy tissue. Likewise, if a clean ulcer surface is exposed to air or if highly absorbent dressing materials are used for prolonged periods, overdrying can dehydrate surface cells, form scabs, and convert the wound to a deeper injury. The right balance of moisture is the key to maintaining a healing environment. The type of dressing should change as wound features change with healing (Ayello & Baranoski, 2014; Krasner et al., 2014).

Assess the ulcer for necrotic tissue and amount of exudate. Coordinate with a wound care specialist to select a dressing material that promotes an optimal environment for healing. For example, a material that does not stick to the wound surface and does not remove new epithelial cells when it is changed is used for protecting new tissue. Depending on the amount of drainage, select either a hydrophobic or a hydrophilic material:

- A **hydrophobic** (nonabsorbent, waterproof) material is useful when the wound has little drainage and needs to be protected from external contamination.
- A **hydrophilic** (absorbent) material draws excessive drainage away from the injury surface, preventing maceration.

A variety of synthetic materials with different absorbent and antimicrobial properties are available. Unlike cotton gauze dressings, these may be left intact for extended periods. Biologic and synthetic skin substitutes are the newest materials being researched. Although useful, these “smart” dressings may be cost prohibitive for many patients.

The frequency of dressing changes depends on the amount of necrotic material or exudate. Dry gauze dressings are changed when “strike through” occurs (i.e., when the outer layer of the dressing first becomes saturated with exudate). Gauze dressings used for débridement of a wet wound (allowed to become damp and then removed) are changed often enough to take off any loose debris or exudate, usually every 4 to 6 hours.

### Nursing Safety Priority QSEN

#### Action Alert

Change synthetic dressings when exudate causes the adhesive seal to break and leakage to occur.

Before reapplying any dressing, gently clean the ulcer surface with saline or another wound cleanser as prescribed. If an antibacterial cleanser is prescribed, dilute the agent to reduce tissue toxicity and then rinse with tap water and dry the surface before applying the dressing.

#### Physical Therapy.

Physical therapists are a valuable resource on the wound care team. Consult them to help plan and implement therapeutic strategies to redistribute and off-load pressure, maximize overall function, and improve quality of life for patients with chronic wounds. In addition to recommending assistive devices and facilitating ADLs, physical therapists typically administer modalities to promote healing, such as electrical stimulation and ultrasound (Aviles, 2014).

#### Drug Therapy.

Clean, healthy granulation tissue has a blood supply and is capable of providing white blood cells and antibodies to the ulcer to combat infection. If extensive necrosis is present or if local tissue defenses are impaired, topical antibacterial agents or dressing materials are often needed to control bacterial growth (see Chart 26-5 for a list of topical antibacterial agents). Antibiotic use is avoided in

the absence of infection to reduce the development of resistant bacterial strains.

### **Nutrition Therapy.**

Successful healing of pressure injuries depends on adequate intake of calories, protein, vitamins, minerals, and water. Nutrition deficiencies are common among chronically ill patients and increase the risk for skin breakdown and delayed wound healing. Severe protein deficiency inhibits healing and impairs host infection defenses.

Coordinate with the dietitian to help the patient eat a well-balanced diet, emphasizing protein, vegetables, fruits, whole grains, and vitamins. Fats also are needed to ensure formation of cell membranes. (See [Chapter 60](#) for interventions to ensure adequate nutrition.) If the patient cannot eat sufficient amounts of food, other types of feedings may be needed to increase protein and caloric intake (see [Chapter 60](#)). Vitamin and mineral supplements are also indicated.

### **Technology-Based Therapies.**

For chronic injuries that remain open for months, new technologies have had some success. These include electrical stimulation, negative-pressure wound therapy, hyperbaric oxygen therapy, low-frequency ultrasound, topical growth factors, and skin substitutes.

*Electrical stimulation* is the application of a low-voltage current to a wound area to increase blood vessel growth and promote granulation. This treatment is usually performed by a physical therapist or certified wound care specialist. The voltage is delivered in “pulses” that may cause a “tingling” sensation. Usually this technique is performed for 1 hour a day, 5 to 7 days a week. It is not used with patients who have a pacemaker, a wound over the heart, or a skin cancer involving the wound or periwound skin.

*Negative-pressure wound therapy (NPWT)* can reduce or even close chronic injuries by removing fluids or infectious materials from the wound and enhancing granulation. This technique requires that a suction tube be covered by a special sponge and sealed in place. Per manufacturer's instructions, the foam dressing is changed every 48 to 72 hours (or at least three times weekly). Continuous low-level negative pressure is applied through the suction tube. Duration of the treatment is determined by the wound's response. It should not be used in areas of skin cancer. Failure of NPWT is often caused by the inability to maintain an adequate dressing seal ([Rock, 2014](#)).

Current evidence does not support greater effectiveness of NPWT in closing chronic wounds than more traditional methods. Serious bleeding and even deaths have occurred with NPWT, and these devices have received a warning from the Food and Drug Administration (FDA) to exclude high-risk patients from its use. Any patient who is receiving this therapy must be monitored at least every 2 hours for bleeding at or near the wound site.

## **Nursing Safety Priority** QSEN

### **Critical Rescue**

Recognize that you do not use a continuous negative-pressure wound therapy device with any patient who is on anticoagulant therapy; has reduced tissue health near the wound (e.g., with radiation therapy or poor nutrition); or has any exposed blood vessels, nerves, or organs in the wound area. Respond by consulting with members of the interprofessional team, such as the primary health care provider and wound nurse, for appropriate methods of treatment.

*Hyperbaric oxygen therapy (HBOT)* is the administration of oxygen under high pressure, raising the tissue oxygen concentration. This type of therapy is usually reserved for life- or limb-threatening wounds such as burns, necrotizing infections, brown recluse spider bites, osteomyelitis, and diabetic ulcers. The patient is enclosed in a large chamber and exposed to 100% oxygen at pressures greater than normal atmospheric pressure. Systemic oxygen enhances the ability of white blood cells to kill bacteria and reduce swelling. Treatment usually lasts from 60 to 90 minutes. Smaller topical oxygen-delivery devices are also available. These devices are applied directly over an open wound to promote local tissue gas exchange; however, their effectiveness in promoting wound healing requires further study.

*Topical growth factors* are normal body substances that stimulate cell movement and growth. These factors are deficient in chronic wounds, and topical application is used to stimulate wound healing.

For example, platelet-derived growth factor (PDGF) stimulates the movement of fibroblasts into the wound space. Use of this and other growth factors has been effective for healing of some clean granulating chronic wounds, but further study is needed (Cowan et al., 2014).

*Skin substitutes* are engineered products that aid in the closure of different types of wounds. These products vary widely in design and application and are used mainly for surgically débrided wounds before reconstruction with grafts or muscle flaps (Daugherty & Spear, 2015).

*Ultrasound-assisted wound therapy (USWT)* uses energy produced by low frequency (40 kHz) sound waves to cleanse and débride necrotic tissue over time, thus reducing microbial bioburden. USWT is administered with a disposable applicator, which is moved over the wound without coming in direct contact with tissue. Atomized saline mist serves as a conduit for delivery of the ultrasound energy. Additional benefits of noncontact low-frequency ultrasound therapy may include pain reduction, stimulation of granulation, and reduced rates of infection (Hakim & Heitzman, 2013).

The use of exogenous *electrical stimulation (ES)* has been shown to promote healing of chronic wounds that are stalled in the healing process. ES works by restoring the natural electric impulses found in healthy tissue and promoting more normal cellular function. Potential benefits include increased fibroblast activity to stimulate granulation, increased epithelial cell migration, enhanced macrophage activity, and reduced pain. Since electrical stimulation can also increase the activity of cancer cells, contraindications for use include basal or squamous cell carcinoma in the wound or periwound tissues or melanoma.

### Surgical Management.

Surgical management of a pressure injury includes removal of necrotic tissue and skin grafting or use of muscle flaps to close wounds that do not heal by re-epithelialization and contraction. Not all wounds are candidates for grafting. Those with poor blood flow are unlikely to have successful graft take and heal. The procedures are very similar to the surgical management of burn wounds. See the Surgical Interventions section of Managing Wound Care in Chapter 26.

### Preventing Infection and Wound Deterioration

#### Planning: Expected Outcomes.

The patient with a pressure injury is expected to remain free of wound infection or sepsis. Indicators include that the patient will have mild or no:

- White blood cell (WBC) elevation
- Positive blood culture
- Purulent or malodorous drainage
- Increase in wound size or depth
- Fever

#### Interventions.

Priority nursing interventions focus on preventing wound infection and identifying it early to prevent complications.

*Monitoring* the ulcer's appearance using objective criteria allows evaluation of the response to treatment and early recognition of infection. If an ulcer shows no progress toward healing within 7 to 10 days or worsens, the treatment plan is re-evaluated. Chart 25-4 outlines objectives of monitoring wounds with and without tissue loss. Patients who are at highest risk for infection are those who are older, have diabetes, have WBC disorders, are receiving steroid therapy, or have wounds with a compromised blood supply.

### Chart 25-4

## Best Practice for Patient Safety & Quality Care QSEN

### Monitoring the Wound

VARIABLE	FREQUENCY OF ASSESSMENT	RATIONALE
Wounds Without Tissue Loss		

<i>Examples</i>		
Surgical incisions and clean lacerations closed primarily by sutures or staples		
<i>Observations (Using First Postoperative Dressing Change as Baseline)</i>		
Check for the presence or absence of increased: • Localized tenderness • Swelling of the incision line • Erythema of the incision line >1 cm on each side of wound • Localized heat	At least every 24 hr until sutures or staples are removed	To detect cellulitis (bacterial infections)*
Check for the presence or absence of: • Purulent drainage from any portion of the incision site • Localized fluctuance (from fluid accumulation) and tenderness beneath a <i>portion</i> of the wound when palpated	At least every 24 hr until sutures or staples are removed	To detect abscess formation related to presence of foreign body (suture material) or deeper wound infection*
Check for the presence or absence of: • Approximation (sealing) of wound edges with or without serosanguinous drainage • Necrosis of skin edges	At least every 24 hr until sutures or staples are removed	To detect potential for wound dehiscence
<b>Wounds With Tissue Loss</b>		
<i>Examples</i>		
Partial- or full-thickness skin loss caused by pressure necrosis, vascular disease, trauma, etc., and allowed to heal by secondary intention		
<i>Observations</i>		
<b>Wound Size</b>		
Measure wound size at greatest length and width using a disposable paper tape measure or, for asymmetric ulcers, by tracing the wound onto a piece of plastic film or sheeting (plastic template) Measure depth of full-thickness wounds using cotton-tipped applicator Compare all subsequent measurements against the initial measurement	Once per week	To detect increase in wound size and depth secondary to infectious process (Expect an increase in wound size after débridement of necrotic tissue in deep wounds.)
<b>Ulcer Base</b>		
Check for the presence or absence of: • Necrotic tissue (loose or adherent) • Foul odor from wound when dressing is changed Note the frequency of dressing changes or dressing reinforcements owing to drainage	At least every 24 hr	To detect the need for débridement or the response to treatment (necrotic tissue) and to detect local wound infection (frequent dressing changes and foul odor)
<b>Wound Margins</b>		
Check for the presence or absence of: • Erythema and swelling extending outward >1 cm from wound margins • Increased tenderness at wound margins	At least every 24 hr or at each dressing change	To detect wound infection*
<b>Systemic Response</b>		
Check for the presence or absence of elevated body temperature or WBCs or positive blood culture	Check temperature daily; if elevated, check WBCs and blood culture	To detect bacteremia

The wounds of patients who are severely immunosuppressed or wounds with compromised blood supply may not exhibit a typical inflammatory response to local wound infection.

WBCs, White blood cells.

*Preventing infection* and its complications starts with monitoring the ulcer's progress. Routinely check for signs and symptoms of wound infection: increased pain, tenderness, and redness at the wound margins, edema, and purulent and malodorous drainage. Report these changes to the primary health care provider:

- Sudden deterioration of the ulcer, with an increase in the size or depth of the lesion
- Changes in the color or texture of the granulation tissue
- Changes in the quantity, color, or odor of exudate

These changes may occur with or without signs and symptoms of bacteremia, such as fever, an elevated WBC count, and positive blood cultures. Use the previously described interventions to prevent the formation of new pressure injuries and to prevent early-stage injuries from progressing to deeper wounds (see [Chart 25-1](#)).

*Maintaining a safe environment* can help prevent wound infection. Because of the variety of organisms in the hospital environment, keeping an ulcer totally free of bacteria is impossible. Optimal ulcer management is based on maintaining acceptably low levels of organisms through meticulous wound care and reducing contamination with pathogenic organisms that could lead to sepsis and death. *Teach all personnel to use Standard Precautions and to properly dispose of soiled dressings and linens.*

## Clinical Judgment Challenge 25-2

### Patient-Centered Care; Teamwork and Collaboration QSEN

An unlicensed assistive personnel (UAP) reports to you that an 86-year-old resident of the nursing home has what appears to be a large early-stage pressure injury over her “bum.” Skin changes are evident on the buttocks, inner upper thighs, and labia. The patient has hemiparesis and urinary incontinence from a series of strokes and wears adult diapers for continence care. When you assess the client, you find the whole area to be bright red with a few small blisters on the very edges and an area on her upper, outer thigh to be brown and peeling. The reddened area appears slightly edematous and blanches when you touch it, and the client tells you that her “bum hurts and burns.” The UAP asks whether the physical therapist should be called to obtain an air cushion to

prevent the pressure injury from getting worse.

1. What is the most likely cause of the patient's skin problems?
2. Does this skin problem meet the criteria of any stage of pressure injury? Explain your rationale.
3. Should the physical therapist be asked to order a pressure-relieving device for the patient's wheelchair? Provide a rationale for your answer.
4. Which interventions are most likely to address this patient's skin problems?
5. Which other interprofessional team members would be helpful for this situation?

## Care Coordination and Transition Management

Patients with pressure injuries may be in acute care, subacute care, long-term care, or home care settings. If pressure injury therapy requires hospitalization, most patients are discharged before complete wound closure is achieved. Discharge may be to the home setting or to a long-term care facility, depending on the degree of debilitation and other patient factors.

### Home Care Management.

Ulcer care in the patient's home is similar to care in the hospital. Most dressing supplies and pressure-relief devices can be obtained at a pharmacy or medical supply store. If ulcer débridement is needed, a handheld shower device or forceful irrigation of the wound with a 35-mL syringe and 19-gauge angiocatheter can be substituted for whirlpool therapy.

Many patients cannot change their own dressings because of wound location, distress over an altered body image, or the pain of dressing removal. Others depend on family members or support personnel because of limited physical mobility.

For some patients, drastic changes in daily activities are needed to promote healing. Patients with leg ulcers may need frequent rest periods with leg elevation to avoid or reduce edema. Immobile patients with pressure injuries require around-the-clock repositioning to prevent further breakdown, which takes its toll on caregivers. Explain the rationale for activity changes to the patient and family and explore ways of coping with these changes.

Some patients may need to continue the use of special beds or mattress overlays at home. Although these items can be expensive, home use can keep the patient out of more costly health care settings. Consider both the space and power supply when choosing a pressure-relief device for home use. Coordinate with the case manager to work with the insurance company in providing these important aids for quality patient care.

### Self-Management Education.

Before the patient is discharged, have the patient or caregiver demonstrate competence in removing the dressing, cleaning the wound, and applying the dressing. When choosing a dressing to be used at home, consider the patient's or caregiver's ability to apply the dressing properly. If the patient's finances are limited, address the cost of the dressing material. At times, the more expensive dressing materials that require less frequent changing may be preferred. Explain the signs and symptoms of wound infection and remind the patient and family to report their presence to the primary health care provider or wound care clinic.

Encourage the patient to eat a balanced diet, including high-protein snacks. Discuss diet preferences with the patient and consult a dietitian as needed to design a food plan to promote wound healing. Vitamin and mineral supplements may be needed to prevent or treat deficiencies.

If the patient is incontinent, emphasize the need to keep the skin clean and dry. If bowel and bladder training are not possible, discuss the use of absorbent underpads, briefs, and topical moisture barrier creams and ointments as methods to reduce skin exposure to urine and feces.

### Health Care Resources.

A home health nurse may be needed to follow wound progress after discharge. As indicated by The Joint Commission's NPSGs, the hospital nurse provides details of ulcer size and appearance and any special wound care needs in a hand-off report to the home care nurse, who can then accurately judge changes in ulcer appearance. [Chart 25-5](#) is a guideline for a focused assessment of the patient

with risk for pressure injuries.

### **Chart 25-5**

## **Focused Assessment**

### **The Patient at Risk for Pressure Injuries**

Assess cardiovascular status:

- Presence or absence of peripheral edema
- Hand-vein filling in the dependent position
- Neck-vein filling in the recumbent and sitting positions
- Weight gain or loss

Assess cognition and mental status:

- Level of consciousness
- Orientation to time, place, and person
- Can the patient accurately read a seven-word sentence containing words of three syllables or fewer?

Assess condition of skin:

- Assess general skin cleanliness
- Observe all skin areas, paying particular attention to bony prominences and areas in greatest contact with the bed and other firm surfaces
- Measure and record any areas of redness or loss of integrity
- If possible, photograph areas of concern
- Note the presence or absence of skin tenting over the sternum or the forehead
- Note the moistness of skin and mucous membranes
- If wounds are present, remove dressings (noting condition of dressings), cleanse the wound, and compare with previous

notations of wound condition:

- Presence, amount, and nature of exudate
- Use a disposable paper tape measure to measure wound diameter and depth
- Amount (%) and type of necrotic tissue
- Presence of granulation/epithelium
- Presence or absence of cellulitis
- Presence or absence of odor
- Take patient's temperature to assess for fever

Assess the patient's understanding of illness and compliance with treatment:

- Signs and symptoms to report to primary health care provider
- Drug therapy plan (correct timing and dose)
- Ambulation or positioning schedule
- Dressing changes/skin care
- Nutrition modifications (24-hr diet recall)

Assess the patient's nutritional status:

- Change in muscle mass
- Lackluster nails, sparse hair
- Recent weight loss of more than 5% of usual weight
- Impaired oral intake
- Difficulty swallowing
- Generalized edema

To help decrease the cost of treatment, emphasize proper use of dressing materials. Clean tap water and nonsterile supplies are used for home management of chronic wounds and are less costly

than sterile products. Stress the importance of properly cleaning reused items and of handwashing before touching any supplies.

The patient with activity restrictions may need daily assistance from a home health aide. Collaborate with a physical therapist or occupational therapist to help the patient and family continue rehabilitation efforts in the home.

#### ◆ **Evaluation: Reflecting**

Evaluate the care of the patient with a pressure injury on the basis of the identified priority patient problems. The expected outcomes include that the patient will:

- Experience progress toward wound healing by second intention as evidenced by granulation, epithelialization, contraction, and reduction or resolution of wound size
- Re-establish skin TISSUE INTEGRITY and restore skin barrier function
- Remain infection free

## Minor Skin Irritations

### Pruritus

#### ❖ Pathophysiology

Irritation of the skin is often associated with **pruritus** (itching), a distressing and often debilitating condition caused by stimulation of itch-specific nerve fibers. Physical or chemical agents either activate nerve fibers directly or stimulate the release of chemical mediators (i.e., histamine), which then act on itch receptors.

Itching can be localized or generalized and occur with or without a skin rash. It is estimated that over 50% of elderly patients have **xerosis** (dry skin), a condition often described generalized discomfort in the absence of skin lesions. Comorbid medical conditions such as diabetes can also lead to generalized pruritus. Certain localized pruritic skin diseases are more common among the older population, including scabies and bullous pemphigoid.

Itching is a subjective condition similar to pain, and severity of the sensation varies among patients. Regardless of the cause, patients often report that itching is worse at night when there are fewer distractions. Other conditions that make itching worse include skin dryness, increased temperature, perspiration, and emotional stress.

#### ❖ Interprofessional Collaborative Care

Care of the patient with minor skin irritations usually takes place in the outpatient setting. Members of the interprofessional team who collaborate most closely to care for this patient include the primary health care provider, who continually assesses the skin condition and prescribes treatment, and the nurse.

The priority nursing interventions focus on increasing patient comfort and preventing skin injury with loss of TISSUE INTEGRITY. Patients usually try to relieve itching by scratching or rubbing the skin, a response that further stimulates the itch receptors and causes the “itch-scratch-itch” cycle (McCance et al., 2014). Itching with skin lesions can often be relieved by treating the underlying skin disorder with topical or systemic drugs. Systemic diseases, such as liver and venous disorders, can also cause itching without skin lesions. Liver disease often increases the buildup of bilirubin in the skin, which stimulates itch receptors. Pruritus can also be caused by too little or too much blood flow to an area (especially the feet and legs).

Plan care to promote comfort and prevent disruption of skin tissue integrity from vigorous scratching. Because dry skin worsens itching, emphasize interventions to prevent it (Chart 25-6). Encourage patients to keep the fingernails trimmed short, with rough edges filed to reduce damage from scratching and secondary infection. Wearing mittens or splints at night can help prevent scratching during sleep. If the patient cannot perform self-care, teach the family (for home care) and unlicensed assistive personnel (UAP) to trim the patient's fingernails and apply mittens or gloves. Stress the importance of not breaking the skin or digging into nail corners when trimming the nails of patients with diabetes.

#### Chart 25-6

### 🏠 Patient and Family Education: Preparing for Self-Management

#### Prevention of Dry Skin

- Use a room humidifier during the winter months or whenever the furnace is in use.
- Take a complete bath or shower only every other day (wash face, axillae, perineum, and any soiled areas with soap daily).
- Use tepid water.
- Use a superfatted, nonalkaline soap instead of deodorant soap.

- Rinse the soap thoroughly from your skin.
- If you like bath oil, add the oil to the water at the end of the bath.
- Take care to avoid falls; oil makes the tub slippery.
- Pat rather than rub skin surfaces dry.
- Avoid clothing that continuously rubs the skin, such as tight belts, nylon stockings, or pantyhose.
- Maintain a daily fluid intake of 3000 mL unless contraindicated for another medical condition.
- Do not apply rubbing alcohol, astringents, or other drying agents to the skin.
- Avoid caffeine and alcohol ingestion.

A cool sleeping environment and comfort measures (e.g., cool shower, moisturizers) may help promote sleep. Using sleep-promoting herbal teas or sedating antihistamines at bedtime (when the side effect of drowsiness is welcome) may provide an uninterrupted night's sleep for some patients. Colloidal oatmeal or tar extract baths provide temporary relief.

If antihistamines are prescribed, monitor the patient's response so the dosage can be adjusted as needed. The effectiveness of topical steroid preparations and other topical agents is improved if the drug is applied to slightly damp skin. Using topical drugs under an occlusive dressing increases the dose being delivered. Avoid occluding treated areas unless specifically prescribed by the primary health care provider.

## Urticaria

**Urticaria** (hives) is a rash of white or red edematous papules or plaques of various sizes. This problem is usually caused by exposure to allergens, which releases histamine into the skin. Blood vessel dilation and plasma protein leakage lead to formation of lesions or wheals. Some common causes of urticaria include drugs, temperature extremes, foods, infection, diseases, cancer, and insect bites.

Management focuses on removal of the triggering substance and relief of symptoms. Because the skin reaction is caused by histamine release, antihistamines such as diphenhydramine (Benadryl) are helpful. Teach the patient to avoid overexertion, alcohol consumption, and warm environments, which further dilate blood vessels and make urticaria worse. Alcohol increases sedating effect of antihistamines, increasing the risk for falls.

# Common Inflammations

## ❖ Pathophysiology

Skin inflammation can have many nonspecific signs and symptoms, including severe itching, lesions with indistinct borders, and different distribution patterns. The cause may not be identified. Rashes from inflammation can evolve from acute to chronic conditions.

Most skin inflammations are related to allergic immune responses. The responses may be triggered by external skin exposure to allergens or internal exposure to allergens and irritants. The result is tissue destruction or skin changes induced by the immune system. (A more detailed description of these immune mechanisms is presented in [Chapter 17](#).)

The specific cause of skin inflammation is not always known. When this is the case, the catch-all diagnosis of *nonspecific eczematous dermatitis*, or *eczema*, is often used.

*Contact dermatitis* is an acute or chronic rash caused by direct contact with either an irritant or an allergen. Irritants cause a toxic injury to the skin. Allergens result in a cell-mediated immune reaction in the skin.

*Atopic dermatitis* is a chronic rash that occurs with allergies and atopic skin disease. It is made worse by dry or irritated skin, food allergies, chemicals, or stress. (Atopic reactions are described in [Chapter 20](#).)

## ❖ Interprofessional Collaborative Care

Because all skin eruptions from inflammation appear similar, personal data are needed to identify the cause. Inflammatory skin problems differ from eczematous dermatitis in chronicity, lesion distribution, and associated signs and symptoms. [Chart 25-7](#) lists the symptoms of many types of inflammatory skin conditions.

**Chart 25-7**

### Key Features

#### Common Inflammatory Skin Conditions

SIGNS AND SYMPTOMS	DISTRIBUTION
<b>Nonspecific Eczematous Dermatitis</b> Evolution of lesions from vesicles to weeping papules and plaques. Lichenification occurs in chronic disease. Oozing, crusting, fissuring, excoriation, or scaling may be present. Itching is common.	Anywhere on the body; localized eczema commonly involves the hands or feet
<b>Contact Dermatitis</b> Localized eczematous eruption with well-defined, geometric margins that are consistent with contact by an irritant or allergen. Usually seen in the acute form but may become chronic if exposure is repeated. Allergy to plants (e.g., poison ivy or oak) classically occurs as linear streaks of vesicles or papules.	Cosmetic/perfume allergy: head and neck Hair product allergy: scalp Shoe/rubber allergy: dorsum of feet Nickel allergy: earlobes Mouthwash/toothpaste allergy: perioral region Airborne contact allergy (e.g., paint, ragweed): generalized
<b>Atopic Dermatitis</b> Hallmark in adults is lichenification with scaling and excoriation. Extremely itchy. Face involvement is seen as dry skin with mild-to-moderate erythema, perioral pallor, and skinfolds beneath the eyes (Dennie-Morgan lines). Associated with linear markings on the palms.	Face, neck, upper chest, and antecubital and popliteal fossae
<b>Drug Eruption</b> Bright red erythematous macules and papules are found. Skin blisters in extreme cases. Lesions tend to be confluent in large areas. Moderately itchy. Fever is rare. Dehydration and hypothermia can occur with extensive involvement. Condition clears only after offending drug has been discontinued.	Generalized Involvement begins on trunk, proceeds distally (legs are the last to be involved)

If the cause of the rash is identified, avoidance therapy is used to reverse the reaction and clear the rash. For example, if a new soap for handwashing causes contact dermatitis of the hands, teach the patient to avoid that substance. Even when the cause is unclear, certain irritants may worsen the rash and increase discomfort. Additional interventions promote comfort through suppression of inflammation.

*Steroid therapy* with topical, intralesional, or systemic steroids is prescribed to suppress inflammation. Because a side effect of oral corticosteroids (e.g., prednisone) is adrenal suppression, patients receiving long-term systemic therapy must taper their drug dosages rather than stop them abruptly.

*Remember that corticosteroids never cure the inflammation.* During active disease, these drugs reduce symptoms and relieve discomfort. Moisten dressings with warm tap water and place them over topical steroids for short periods to increase absorption. Avoid applying topical steroids under occlusive dressings unless prescribed by the primary health care provider.

Avoid applying oil-based ointments and pastes to the sweaty skinfold areas to prevent blocking of pores and folliculitis. Water-soluble creams are better for these areas. Lotions and gels prevent matting of the hair and are more appropriate for the scalp and other hairy areas. Thick, stiff ointments or pastes (e.g., zinc oxide pastes) are applied to localized areas because they cling to the skin where applied and resist spreading to uninvolved skin.

*Antihistamines* provide some relief of itching but may not keep the patient totally comfortable. The sedative effects of these drugs may be better tolerated if most of the daily dose is taken near bedtime. Teach patients to avoid driving or operating heavy machinery if these drugs are taken during the day.

## Nursing Safety Priority QSEN

### Drug Alert

Polypharmacy combined with the sedating effects of H<sup>1</sup>-antihistamines [diphenhydramine (Benadryl), carbinoxamine (Clistin), clemastine (Tavist), chlorpheniramine (Chlor-Trimeton), and brompheniramine (Dimetane)] place older adults at increased risk for falls.

*Comfort measures* such as cool, moist compresses and lukewarm baths with bath additives have a soothing effect, decrease inflammation, and help débride crusts and scales. Colloidal oatmeal, tar extracts, cornstarch, or oils added to baths may relieve itching.

# Psoriasis

## ❖ Pathophysiology

**Psoriasis** is a chronic autoimmune disorder affecting the skin with exacerbations and remissions. It results from overstimulation of the immune system (Langerhans' cells) in the skin that activates T-lymphocytes. These cells then target the keratinocytes, causing increased cell division (because some degree of CELLULAR REGULATION is lost) and plaque formation. Even though psoriasis cannot be cured, patients can often achieve control of symptoms with proper management.

Psoriasis lesions are scaled with underlying dermal inflammation from an abnormality in the growth of epidermal cells. Normally basal cells take about 28 days to reach the outermost layer where they are shed. In a person with psoriasis, the rate of cell division is speeded up so cells are shed every 4 to 5 days.

## ❖ Genetic/Genomic Considerations

### Patient-Centered Care QSEN

A genetic predisposition is associated with psoriasis as indicated by the fact that, when one identical (monozygotic) twin develops the disease, the second twin also develops it about 70% of the time. Variation in many gene sequences, labeled PSORS1 through PSORS13, influences the development of this autoimmune disorder. It is likely that different variations of these gene loci also influence individual patient responses to therapy. Always ask about a family history of the disorder when assessing the patient with psoriasis (OMIM, 2017).

Many environmental factors lead to outbreaks and influence the severity of symptoms, but these vary from person to person. Triggering factors may be local or systemic. A psoriatic lesion may appear after skin trauma (i.e., Koebner's phenomenon, in which a previously injured area is more susceptible to development of cancer or chronic skin problems) such as surgery, sunburn, or excoriation.

Patients with psoriasis often improve with more exposure to sunlight. Systemic factors that can aggravate the disease include infection (severe streptococcal throat infection, *Candida* infection, upper respiratory infections), hormonal changes (e.g., puberty, menopause), stress, drugs (lithium, beta-blocking agents, indomethacin), obesity, and the presence of other diseases.

Some patients with psoriasis also develop debilitating *psoriatic arthritis*. This arthritis may lead to severe joint changes similar to those seen in rheumatoid arthritis and indicates that psoriasis is a systemic disorder (McCance et al., 2014). See Chapter 18 for more discussion of arthritis.

## ❖ Interprofessional Collaborative Care

Care of the patient with psoriasis most often takes place in an outpatient setting. When a patient with psoriasis is hospitalized for another health problem, psoriasis therapy may continue in this setting. Members of the interprofessional team who collaborate most closely to care for the patient with psoriasis include the primary health care provider, who continually assesses the patient's condition and prescribes treatment, and the nurse.

## ◆ Assessment: Noticing

### History.

Ask the patient about any family history of psoriasis, including the age at onset, a description of the disease progression, and the pattern of recurrences. Have the patient describe the current flare-up of psoriasis, including whether the onset was gradual or sudden, where the lesions first appeared, whether there have been any changes in severity over time, and whether fever and itching are present. Explore possible precipitating factors and ask about the effectiveness of any previous interventions.

### Physical Assessment/Signs and Symptoms.

The appearance of psoriasis and its course vary among patients. Typically during flare-ups of the disease, lesions thicken and extend into new body areas. As psoriasis responds to treatment, lesions become thinner with less scaling.

*Psoriasis vulgaris* is the most common type of psoriasis, with thick, reddened papules or plaques covered by silvery white scales (Fig. 25-4). Borders between the lesions and normal skin are sharply defined. Patches are less red and moister in skinfold areas. Lesions are usually present in the same areas on both sides of the body (bilateral distribution). Common sites include the scalp, elbows, trunk, knees, sacrum, and outside surfaces of the limbs. Facial skin is rarely affected. The patient may have only a few lesions, or the entire skin surface may be affected.

**FIG. 25-4** A, Psoriasis vulgaris in a white patient. B, Psoriasis vulgaris in a patient with dark skin.

*Exfoliative psoriasis* (erythrodermic psoriasis) is an explosively eruptive and inflammatory form with generalized erythema and scaling but no obvious lesions. Fluid loss with this severe inflammatory reaction can lead to dehydration and hypothermia or hyperthermia.

*Palmoplantar pustulosis (PPP)* is a type of psoriasis that forms pustules on the palms of the hands and soles of the feet along with reddened hyperkeratotic plaques. The course of the disease is cyclic, with new outbreaks of pustules occurring after older lesions have resolved. PPP is difficult to treat, and patients often have social and physical problems.

### ◆Planning and Implementation: Responding

The three different approaches to therapy are based on the extent of disease, the patient's distress, and the response of the psoriasis to treatment. Patients must understand that no cure for psoriasis exists yet. Therapy is aimed at reducing cell proliferation and inflammation. *Priority nursing strategies include teaching the patient about the disease and its treatment and providing emotional support for the changes in body image often experienced with psoriasis.*

### Topical Therapy.

The topical agents used to treat moderate-to-severe psoriasis are topical steroids, topical tar and anthralin preparations, and ultraviolet (UV) light.

*Corticosteroids* have anti-inflammatory actions. When applied to psoriatic lesions, they suppress cell division. The effectiveness of a topical steroid depends on its potency and ability to be absorbed into the skin. The more potent agents are used as therapy for patients with psoriasis. Examples of commonly prescribed topical corticosteroids include clobetasol (Temovate, Dermovate 🍀), triamcinolone (Aristocort, Triaderm 🍀), fluocinonide (Synalar, Fluoderm 🍀), and betamethasone (Diprolene).

Teach patients to enhance the skin penetration of these drugs by applying the steroid directly to the skin. When prescribed, using warm, moist dressings and an occlusive outer wrap of plastic (film, gloves, booties, or similar garments) may enhance absorption. Avoid using high potency steroids on the face, scalp, or skinfold areas because of the potential for increased absorption and side effects.

*Tar preparations* applied to the skin suppress cell division from impaired CELLULAR REGULATION and reduce inflammation. These drugs are available as solutions, ointments, lotions, gels, and shampoos. The ointments are messy, cause staining, and have an unpleasant odor.

Topical therapy with anthralin (Zithranol, Anthraforte ✱, Drithocrema, Psoriatec), a hydrocarbon similar in action to tar, also relieves chronic psoriasis. These drugs can be used alone or in combination with coal tar baths and ultraviolet (UV) light.

Teach the patient to apply the high-potency anthralin, suspended in a stiff paste, to each lesion for short periods of time as directed by the physician. The drug is a strong irritant and can cause chemical burns if left on lesions too long or not washed off completely after each treatment. Remind the patient to check for local tissue reaction and to take care to prevent this drug from coming into contact with uninvolved skin.

*Other topical therapies* can be effective for many patients with mild-to-moderate psoriasis. These drugs include calcipotriene (Dovonex), a synthetic form of vitamin D that regulates skin cell division, and tazarotene (Avage, Tazorac), a derivative of vitamin A that slows cell division and reduces inflammatory responses. In some cases calcitriol (Vectical ointment) has been helpful but is very expensive.

## Nursing Safety Priority QSEN

### Drug Alert

Tazorac is **teratogenic** (can cause birth defects) even when used topically. Teach sexually active women of childbearing age using this drug to adhere to strict contraceptive measures.

### Light Therapy.

UV radiation is a physical agent commonly used as a topical therapy in many skin conditions, including psoriasis. Ultraviolet B (UVB) light, which produces more energy, is responsible for the obvious biologic effects of the sun such as burning. Although the sun is an inexpensive source of UV radiation, better availability and intensity control occur with the use of artificial light sources. These sources include lamps or cabinets containing UV tubes. *The use of commercial tanning beds is not recommended for the patient with psoriasis.*

UV therapy is limited by exposure time and effects on the surrounding normal skin. The time of exposure is gradually increased to achieve a mild suntan effect without burning or tenderness. The patient's skin pigmentation determines the exposure times. Because of the extremely high intensity of most artificial UVB light sources, therapy is measured in seconds of exposure, and patients must wear eye protection during treatment. Narrow-band UVB light therapy, although intense, can shorten the time to effectiveness and reduce the number of exposures needed to maintain the response.

Light therapy with lasers can be effective in controlling mild-to-moderate psoriasis. Laser sources, whether administered in a continuous or pulsed exposure, allow for better focus on the lesions and reduce exposure to the surrounding normal skin.

Teach patients to inspect the skin carefully each day for signs of overexposure. If tenderness on palpation occurs and severe erythema or blister formation develops, notify the primary health care provider before therapy is resumed.

Psoralen and ultraviolet A (UVA) (PUVA) therapy involves the ingestion of a photosensitizing agent (psoralen) 45 to 60 minutes before exposure to UVA light. Therapy sessions are limited to two or three times a week and are not given on consecutive days. Exposure is gradually increased until tanning occurs. Dosages are adjusted according to the erythema reaction of normal skin and the response of psoriatic lesions.

Teach the patient to check for redness with edema and tenderness. If these are present, treatment must be interrupted until they subside. Because psoralen is a strong photosensitizer, patients must wear dark glasses during treatment and for the rest of the day.

### Systemic Therapy.

Oral systemic agents are often prescribed when psoriasis fails to respond to topical treatment. Agents commonly used include acitretin (Soriatane), a vitamin A derivative, and apremilast (Otezla), a small molecule inhibitor that inhibits the spontaneous production of tumor necrosis

factor alpha (TNF- $\alpha$ ).

## Nursing Safety Priority QSEN

### Drug Alert

Both acitretin and bexarotene are teratogenic. Teach sexually active women of childbearing age using this drug to adhere to strict contraceptive measures.

A variety of biologic (immunomodulating) agents that alter the immune response and prevent overstimulation of keratinocytes from impaired CELLULAR REGULATION are now being used to manage moderate-to-severe plaque psoriasis. These agents may be prescribed when other drugs are not effective and when psoriatic arthritis is also present. Most of these drugs are given by IV infusion, IM injection, or subcutaneous injection. All of these agents induce some degree of immunosuppression, and patients are at an increased risk for serious infection.

## Nursing Safety Priority QSEN

### Drug Alert

Instruct patients to discontinue the biologic agent and notify the primary health care provider immediately if signs and symptoms of an active infection occur.

Biologics currently approved for the treatment of psoriasis are listed in [Chart 25-8](#). These drugs should NOT be used by patients who are pregnant or breast-feeding.

## Chart 25-8

### Common Examples of Drug Therapy

#### Plaque Psoriasis

DRUG	NURSING IMPLICATIONS
Adalimumab (Humira)	Given subcutaneously After loading dose given as two injections, maintenance dose given every other week starting week 1 after the loading dose for 16 weeks Black Box warning: active infections, risk of lymphomas/leukemias, tuberculosis
Etanercept (Enbrel)	Given subcutaneously Given twice weekly for 3 months Black Box warning: Should not be given to patients with hypersensitivity to product, latex needle cap, benzyl alcohol; can cause infection, lymphoma, neoplastic disease; patients on immunosuppressive therapy, corticosteroids, and/or methotrexate at greater risk
Infliximab (Remicade, Inflectra)	Given IV Given at 0, 2, and 6 weeks; then every 8 weeks Black Box warning: infection, neoplastic disease, tuberculosis
Secukinumab (Cosentyx)	Given subcutaneously Given at weeks 0, 1, 2, 3, and 4, followed by maintenance dose every 4 weeks Although no Black Box warning, the nurse should monitor for signs of infection
Ustekinumab (Stelara)	Given subcutaneously Initial dose given, followed by a dose 4 weeks later and then every 12 weeks Although no Black Box warning, the nurse should monitor for signs of infection

Other less commonly used systemic drugs for the patient whose disease is resistant to topical therapy include methotrexate (Folex, Mexate), cyclosporine (Sandimmune), and azathioprine (Imuran). The many health risks associated with these therapies must be considered along with the potential benefits, especially in older adults.

#### Emotional Support.

Often patients' self-esteem suffers because of the presence of skin lesions. Encourage the patient and family members to express their feelings about having an incurable skin problem that can alter appearance. Support groups for individuals with psoriasis are available in many communities. Urge patients and families to consider participating in these groups.

The use of touch takes on an added significance for patients with psoriasis. For example, shake the patient's hand during an introduction or place a hand on the patient's shoulder when explaining a procedure. *Do not wear gloves during these social interactions. Touch, more than any other gesture,*

*communicates acceptance of the person and the skin problem.*

## **NCLEX Examination Challenge 25-1**

### **Health Promotion and Maintenance**

A 45-year-old client is receiving subcutaneous injections of a biologic therapy for plaque psoriasis. Which condition will the nurse **immediately** report to the health care provider?

- A. Missed injection
- B. Increased pruritus
- C. Cough with fever
- D. New plaques on leg

# Skin Infections

## ❖ Pathophysiology

Skin infection can be bacterial, viral, or fungal. [Chart 25-9](#) lists key features and common locations of each type.

### Chart 25-9

#### ▶ Key Features

#### Common Skin Infections

SIGNS AND SYMPTOMS	DISTRIBUTION
<b>Bacterial Infections</b>	
<i>Folliculitis</i>	
Isolated erythematous pustules occur singly or in groups; hairs grow from centers of many of the lesions. Occasional papules are present. There is little or no associated discomfort. There is no residual scarring.	Areas of hair-bearing skin, especially buttocks, thighs, beard area, and scalp
<i>Furuncle</i>	
Small, tender, erythematous nodules become pus filled and more tender over time. Lesions may be single or multiple and also recurrent. Regional lymphadenopathy is sometimes present; fever is rare. Occasional scarring results.	Areas of hair-bearing skin, especially buttocks, thighs, abdomen, posterior neck regions, and axillae
<i>Cellulitis</i>	
Localized area of inflammation may enlarge rapidly if not treated. Redness, warmth, edema, tenderness, and pain are present. On rare occasions, blisters are present. Cellulitis is often accompanied by lymphadenopathy and fever.	Lower legs, areas of persistent lymphedema, and areas of skin trauma (e.g., leg ulcer, puncture wound)
<b>Viral Infections</b>	
<i>Herpes Simplex</i>	
Grouped vesicles are present on an erythematous base. Vesicles evolve to pustules, which rupture, weep, and crust. Older lesions may appear as punched-out, shallow erosions with well-defined borders. Lesions are associated with itching, stinging, or pain. Secondary bacterial infection with necrosis is possible in immunocompromised patients.	Type 1 classically on the face and type 2 on the genitalia, but either may develop in any area where inoculation has occurred; recurrent infections occur repeatedly in the same skin area
<i>Herpes Zoster (Varicella Zoster)</i>	
Lesions are similar in appearance to herpes simplex and also progress with weeping and crusting. Grouped lesions present unilaterally along a segment of skin following the pathway of a spinal or cranial nerve (dermatomal distribution). Eruption is preceded by deep pain and itching. Postherpetic neuralgia is common in older adults. Secondary infection with necrosis is possible in immunocompromised patients.	Anterior or posterior trunk following involved dermatome; face, sometimes involving trigeminal nerve and eye
<b>Fungal Infections</b>	
<i>Dermatophytosis</i>	
Annular or serpiginous patches are present with elevated borders, scaling, and central clearing. Itching is common. Lesions may be single or multiple.	Anywhere on the body
<i>Candidiasis</i>	
Erythematous macular eruption occurs with isolated pustules or papules at the border (satellite lesions). Candidiasis is associated with burning and itching. Oral lesions (thrush) appear as creamy white plaques on an inflamed mucous membrane. Cracks or fissures at the corners of the mouth may be present.	Skinfold areas: perineal and perianal region, axillae, beneath breasts, and between the fingers; under wet or occlusive dressings Lesions possibly present on the oral or vaginal mucous membranes

## Bacterial Infections

Bacterial skin lesions usually start at the hair follicle, where bacteria easily collect and grow in the warm, moist environment. **Folliculitis** is a superficial infection involving only the upper part of the follicle and is often caused by *Staphylococcus*. The rash is raised and red and usually shows small pustules. **Furuncles** (boils) are also caused by *Staphylococcus*, but the infection is much deeper in the follicle ([Fig. 25-5](#)). This larger, inflamed, raised bump may or may not have a pustular “head” at its point. Cellulitis often occurs as a generalized infection with either *Staphylococcus* or *Streptococcus* and involves the deeper connective tissue.

**FIG. 25-5** A furuncle.

Minor skin trauma usually occurs before the appearance of folliculitis and furuncles and may contribute to the development of cellulitis. Patients may spread the infection to other parts of their bodies by scratching or rubbing the skin. Furuncles most often occur in areas of heat and moisture, such as in the hair-bearing skinfold areas. Cellulitis can occur as a result of secondary bacterial infection of an open wound, or it may be unrelated to skin trauma.

A common skin problem is infection with methicillin-resistance *Staphylococcus aureus* (MRSA). This infection can range from mild folliculitis to extensive furuncles. It is easily spread to other body areas and to other people by direct contact with infected skin and by contact with clothing, linens, athletic equipment, and other objects used by a person with MRSA. The infection does not respond to cleansing with antibacterial soaps or most types of topical and many oral antibiotic therapies. If MRSA infects a wound or enters the bloodstream, deep wound infection, sepsis, organ damage, and death can occur. The incidence is highest among adults living in communal environments, such as dormitories or prisons, and among patients in hospitals or other health care settings. (See [Chapter 23](#) for a more detailed MRSA discussion.)

Cutaneous anthrax is an infection caused by the spores of the bacterium *Bacillus anthracis*. In the United States the most common risk factor is contact with an infected animal. Those most at risk for cutaneous anthrax include farm workers, veterinarians, and tannery and wool workers. This organism has now become a tool for terrorism.

## Nursing Safety Priority QSEN

### Action Alert

Consider the possibility of bioterrorism whenever lesions consistent with cutaneous anthrax appear in patients who do not have a history of exposure to infected animals.

The infection can be confined to the skin, or it may be systemic. At first a raised vesicle appears on an exposed body area such as the head or arms ([Fig. 25-6](#)). The lesion may itch and often resembles an insect bite. Within a few days, the center of the vesicle becomes hemorrhagic and sinks inward, starting an area of necrosis and ulceration. The tissue around the wound swells and can become very edematous. With necrosis, an eschar forms (see [Fig. 25-6](#)). The two features that distinguish anthrax lesions from insect bites or other skin lesions are that it is painless and that eschar forms, regardless of treatment. Patients may have only one lesion, or there may be multiple lesions, usually in the same body area.

**FIG. 25-6** Cutaneous anthrax. Note ulcer with vesicular ring, induration, and erythema (**A**). As eschar forms, induration lessens, surrounding desquamation occurs, but erythema persists (**B**). (From The Centers for Disease Control and Prevention, Atlanta, GA [<https://www.cdc.gov/anthrax>].)

Some patients develop systemic symptoms with cutaneous anthrax. The area becomes edematous and tender. Fever, chills, and enlarged lymph nodes may be present. Diagnosis is made based on lesion features, a positive culture, or the presence of anthrax antibodies in the patient's blood. Cultures are obtained from patients who have a fever.

Oral antibiotics for 60 days are indicated for patients who have no edema or systemic symptoms and whose lesions are not located on the head or neck. The antibiotics of choice are ciprofloxacin (Cipro) or doxycycline (Doryx, Vibramycin). For patients who have a fever, have lesions on the head or neck, are pregnant, or have extensive edema, antibiotics are given IV and then followed by an oral course of 60 days (Weant et al., 2014).

### Viral Infections

*Herpes simplex virus (HSV)* infection is the most common viral infection of adult skin and has two types. Type 1 (HSV-1) infections cause the classic recurring cold sore. The severity of the disease increases with age and is worse when the patient is immunosuppressed. Genital herpes, caused by type 2 infection (HSV-2), is also recurrent (see Chapter 74).

After the first infection the virus remains in a dormant state in the nerve ganglia, and the patient has no symptoms. Reactivation stimulates the virus to travel down sensory nerves to the skin, where lesions reappear. Recurrence of HSV infection in healthy people is triggered by stressors, such as dry lips, sunburn, trauma, fever, menses, and fatigue. The virus can also be spread by contact between an actively infected person and a susceptible host. *Autoinoculation*, or transfer of either viral type from one part of the body to another, is also possible.

The time span between episodes and the severity of each attack vary. Outbreaks of oral herpes simplex usually last 3 to 10 days. The patient may have tingling or burning of the lip before any lesion is evident. The patient sheds virus and is contagious for the first 3 to 5 days.

The clinical picture of HSV-1 infection is isolated or grouped painful vesicles on a red base. The infection can occur anywhere on the skin and may be spread by respiratory droplets or direct contact with an active lesion or virus-containing fluid (e.g., saliva).

Herpetic whitlow is a form of herpes simplex that occurs on the fingertips of health care personnel who come into contact with viral secretions. It can be spread easily to patients and can become severe in immunosuppressed patients.

*Herpes zoster* (shingles) is infection caused by reactivation of the varicella-zoster virus (VZV) in patients who have previously had chickenpox. The dormant virus resides in the dorsal root ganglia of sensory nerves. Multiple lesions occur in a segmental distribution on the skin area innervated by the infected nerve (Fig. 25-7). Herpes zoster eruptions usually occur after several days of discomfort, which may vary from minor irritation and itching to severe, deep pain. The eruption usually lasts several weeks. **Postherpetic neuralgia** (severe pain persisting after the lesions have resolved) is common in older patients. Early diagnosis of shingles and prompt treatment with antiviral drugs help decrease the duration and severity of postherpetic neuralgia.

**FIG. 25-7** Herpes zoster (shingles).

Herpes zoster occurs most often in older adults or in anyone who is immunosuppressed. The disorder can be accompanied by fever and malaise. *It is contagious to people who have not previously had chickenpox and have not been vaccinated against the disease.* Reduce the risk of viral transmission by isolating patients with fluid-filled blisters and vesicles until the lesions have crusted over and are dry. Complications include full-thickness skin necrosis, Bell's palsy, or eye infection, and scarring if the virus is introduced into the eye.

### Fungal Infections

*Dermatophyte* infections, especially superficial infections, differ in lesion appearance, body location, and species of the organism. The term *tinea* is used to describe dermatophytoses; this term is then followed by the location description. For example, *tinea pedis* involves the foot (athlete's foot), *tinea manus* involves the hands, *tinea cruris* involves the groin (jock itch), *tinea capitis* involves the head, and *tinea corporis* involves the rest of the body (ringworm).

Depending on the species, dermatophytes live mainly in the soil, on animals, and on humans. Superficial infection can start only when the infecting organism comes in contact with impaired skin in a susceptible host. Infections are spread by direct contact with infected humans or animals. Some infections, such as *tinea capitis* and *tinea corporis*, can be transmitted by inanimate objects. For example, *tinea capitis* can be spread by sharing contaminated combs, hats, pillowcases, and other objects with individuals with poor personal hygiene.

*Candida albicans*, also known as *yeast infection*, is a common fungal infection of skin and mucous membranes. The organism is present almost everywhere and easily grows in a warm, moist environment. Risk factors for this infection include immunosuppression, long-term antibiotic therapy, diabetes mellitus, and obesity.

Infected skin has a moist, red, irritated appearance with itching and burning. Common areas for infection are the perineum, vagina, axillae, under the breasts, and in the mouth (where it is known as *thrush* or *oral candidiasis*).

Prevention is aimed at keeping skinfold areas clean and dry. Turning patients and positioning to enhance airflow also aid in prevention. When the infection is present, meticulous cleanliness and the use of topical antifungal agents are needed.

### Health Promotion and Maintenance

Preventing skin infection, especially bacterial and fungal infections, involves avoiding the offending organism and practicing good hygiene to remove the organism before infection can occur.

*Handwashing and not sharing personal items with others are the best ways to avoid contact with these organisms, including MRSA.* [Chart 25-10](#) lists strategies to teach patients and family members to prevent infection spread to other body areas and to others.

#### Chart 25-10

### 🏠 Patient and Family Education: Preparing for Self-Management

## Preventing the Spread of MRSA

- Avoid close contact with others, including participation in contact sports, until the infection has cleared.
- Take all prescribed antibiotics exactly as prescribed for the entire time prescribed.
- Keep the infected skin area covered with clean, dry bandages.
- Change the bandage whenever drainage seeps through it.
- Place soiled bandages in a plastic bag and seal it closed before placing it in the regular trash.
- Wash your hands with soap and warm water before and after touching the infected area or handling the bandages.
- Shower (rather than bathe) daily, using an antibacterial soap.
- Wash all uninfected skin areas before washing the infected area or use a fresh washcloth to wash the uninfected areas.
- Use each washcloth only once before laundering and avoid using bath sponges or puffs.
- Sleep in a separate bed from others until the infection is cleared.
- Avoid sitting on or using upholstered furniture.
- Do not share clothing, washcloths, towels, athletic equipment, shavers or razors, or any other personal items.
- Clean surfaces that may have come into contact with your infected skin, drainage, or used bandages (e.g., bathroom counters, shower/bath stalls, toilet seats) with household disinfectant or bleach water mixed daily (1 tablespoon of liquid bleach to 1 quart of water).
- Wash all soiled clothing and linens with hot water and laundry detergent. Dry clothing either in a hot dryer or outside on a clothesline in the sun.
- Urge family members and close friends to shower daily with an antibacterial soap.
- If another person helps you change the bandages, make certain that he or she uses disposable gloves, pulls them off inside out when finished, places them with the soiled bandages in a sealed bag, and washes his or her hands thoroughly.

MRSA, Methicillin-resistant *Staphylococcus aureus*.

For older adults who have had chickenpox and therefore are at risk for shingles (herpes zoster), the vaccine Zostavax is available to prevent VZV reactivation and shingles. The Centers for Disease Control and Prevention (CDC) recommends the vaccine for anyone older than 50 years who has a healthy immune system. This one-time subcutaneous injection significantly reduces the incidence of shingles. Cost remains a factor in vaccination, and few insurance carriers currently include this coverage.

## Nursing Safety Priority QSEN

### Drug Alert

Zostavax is a live viral vaccine and should not be used in patients with severe immunosuppression because of the risk for viral dissemination. Always check with the prescriber before giving any live vaccines to severely immune compromised patients or those receiving biologic agents for

autoimmune disease.

### ❖ **Interprofessional Collaborative Care**

Depending on the type of infection and associated health issues, patients with skin infections may be treated in a hospital setting, long-term care facility, or home environment. Members of the interprofessional team who collaborate most closely to care for this patient include the primary health care provider, who will assess the infection and prescribe treatment, and the nurse.

### ◆ **Assessment: Noticing**

#### **History.**

Concentrate on risk factors for each type of infection. If the location and appearance of lesions suggest a bacterial infection, ask about a recent history of skin trauma or recent staphylococcal or streptococcal infections. Assess living conditions, home sanitation, personal hygiene habits, and leisure or sport activities. Ask whether fever and malaise are also present.

Lesions appearing on the lips, in the mouth, or in the genital region are more likely to be a possible viral infection. Ask about:

- A history of similar lesions in the same location
- Presence of burning, tingling, or pain
- Recent stress factors that preceded the outbreak
- Recent contact with an infected person

Information that the same type of lesions has occurred before is important in helping differentiate viral from bacterial lesions. Ask whether the patient has had chickenpox in the past and about a history of shingles. Also ask whether he or she has received the shingles vaccination Zostavax.

Obtain information about a probable dermatophyte infection based on lesion location. If tinea corporis or tinea capitis is present, assess the social and home factors that may contribute to infection, such as direct contact with an infected person, poor personal hygiene, or frequent contact with animals. If tinea cruris and tinea pedis are suspected, ask about the type and frequency of athletic activities.

#### **Physical Assessment/Signs and Symptoms.**

*Because most skin infections are contagious, take precautions to prevent the spread of infection when performing a physical assessment.* [Chart 25-9](#) lists the signs and symptoms of common skin infections.

#### **Laboratory Assessment.**

When pustules are present in bacterial infections, the infecting organism is confirmed by swab culture of the purulent material ([Cross, 2014](#)). Blood cultures may be helpful if fever and malaise are present. Various cultures and other techniques are used to identify viral and fungal infections (see [Chapter 24](#)).

### ◆ **Planning and Implementation: Responding**

Most skin infections heal well with nonsurgical management. Surgery may be required when an infectious agent is present in deep-tissue layers. *Priority nursing interventions focus on patient and family education to prevent infection spread to other body areas or to other people* (see [Chart 25-10](#)). Meticulous skin care is needed for prevention of infection spread. In some instances drug therapy is needed.

*Skin care with proper cleansing is the most effective intervention to prevent infection spread.* Teach patients with bacterial infections to bathe daily with an antibacterial soap and to not squeeze any pustules or crusts. Teach patients to gently remove crusts before applying topical drugs so the drugs can be more easily absorbed. Teach the patient to apply warm compresses to furuncles or areas of cellulitis to increase comfort. Most superficial skin infections resolve more quickly if the involved skin dries between treatments. Excessive moisture, especially if occluded by dressings, clothing, or bedding, promotes organism growth. Position bedridden patients for optimal air circulation to the area and avoid occlusive dressings or garments.

*Transmission-Based Precautions* may be needed to reduce the infection spread to other people. For

most superficial bacterial infections, proper handwashing prevents cross-contamination. However, when hospitalized patients are colonized with antibiotic-resistant *Staphylococcus*, strict adherence to isolation procedures is necessary.

Of the dermatophyte infections, tinea capitis, tinea corporis, and tinea pedis are most easily transmitted to others. Teach patients to avoid sharing personal items, such as hairbrushes, articles of clothing, or footwear. Repeated infections transmitted by dogs or cats indicate that the pet also needs to be treated.

*Drug therapy* for superficial infection involves topical agents. Mild bacterial infections of the skin usually resolve with topical antibacterial treatment. Patients with extensive infections, especially if fever or lymphadenopathy is present, require systemic antibiotic therapy. The most common systemic drugs used for bacterial skin infections are the penicillins and cephalosporins. For those who are allergic to drugs from these classes, tetracyclines, macrolides, or aminoglycoside antibiotics may be used. For patients infected with MRSA or other drug-resistant organisms, drug therapy may involve IV vancomycin or oral linezolid or clindamycin.

Acyclovir (Zovirax, Xerese ) , valacyclovir (Valtrex), or famciclovir (Famvir) is used for the treatment of viral infections. Topical treatment decreases the numbers of active viruses on the skin surface and reduces pain in herpetic infections and localized lesions in immunocompromised patients during an initial outbreak. Topical treatment is of little benefit in recurrent infection. IV administration is limited to severe primary infections, immunosuppressed patients with symptoms of systemic infection, and recurrent outbreaks.

Topical antifungal agents are used for patients with dermatophyte or yeast infections at least twice a day until the lesions have cleared. To prevent recurrence, therapy is usually continued for 1 to 2 weeks after clearing. In some instances antifungal powders may also help suppress fungal growth. For widespread or resistant fungal infections, systemic antifungal agents, such as ketoconazole (Nizoral), are given.

## NCLEX Examination Challenge 25-2

### Health Promotion and Maintenance

Which statement, made by the student nurse, requires further teaching by the nurse preceptor?

- A. "I will always remove crusts from bacterial lesions before applying topical antimicrobials."
- B. "I will avoid using adult briefs for my bedridden incontinent client who has a perineal yeast infection."
- C. "If signs and symptoms of a systemic infection are present, I will contact the health care provider to discuss ordering blood cultures."
- D. "I will tell my client that transmission-based precautions are not necessary after the first dose of oral antiviral therapy for herpes zoster is taken."

## Parasitic Disorders

Parasitic skin disorders occur most often in patients with poor hygiene and in those who are homeless. Examine any patient who shows obvious signs of a self-care deficit for contagious parasitic infections.

### Pediculosis

**Pediculosis** is a lice infestation: *pediculosis capitis* (head lice), *pediculosis corporis* (body lice), and *pediculosis pubis* (pubic, or crab, lice). Human lice are oval and 2 to 4 mm long. The female louse lays many eggs (*nits*) at the hair shaft base in hair-bearing areas.

The most common manifestation of pediculosis is itching (pruritus). Excoriation from scratching also may be present. Some parasites may carry disease (e.g., typhus).

*Pediculosis capitis* occurs more often in people with longer hair. Scalp itching from parasite bites is intense. A secondary infection may also be present from scratching (Simmons, 2015).

Because the louse is difficult to see, examine the scalp for visible white flecks of the nits attached to the hair shaft near the scalp. Matting and crusting of the scalp and a foul odor indicate a probable secondary infection.

*Pediculosis corporis* is caused by lice that live and lay eggs in the seams of clothing. The parasites also cause itching. The only visible sign of infestation may be excoriations on the trunk, abdomen, or extremities.

*Pediculosis pubis* causes intense itching of the vulvar or perirectal region. Pubic lice are more compact and crablike in appearance than body lice and can be contracted from infested bed linens or during sexual intercourse with an infected individual. Although these lice are usually found in the genital region, they can also infest the axillae, the eyelashes, and the chest.

The treatment of pediculosis is chemical killing of the parasites with topical sprays, creams, and shampoos. Agents used include permethrin (Elimite), lindane (Bio-Well, Kwell, Kwellada), or topical malathion (Ovide, Prioderm). Oral agents such as ivermectin (Stromectol) may also be used. In the case of pediculosis capitis, spinosad (Natroba, ParaPro) is a topical agent used as part of an overall lice-management program. Areas where the patient's head has rested (e.g., on pillows of chair backs) will also need to be treated. Clothing and bed linens should be washed in hot water with detergent or dry cleaned. The use of a fine-tooth comb helps remove nits but does not cure the infection. For any louse infestation, social contacts are treated when possible.

## NCLEX Examination Challenge 25-3

### Physiological Integrity

The nurse is teaching a client how to treat pediculosis (lice). Which teaching will the nurse include? **Select all that apply.**

- A. Use a fine-tooth comb to remove nits.
- B. Chemical killing of these parasites is required.
- C. Wash bed linens in cold water to remove lice and eggs.
- D. Lice do not affect clothing items because they jump off of fabric.
- E. Eggs of lice must be killed to reduce the risk for development of skin cancer.
- F. Lice can infest hair on the head, in the genital region, in the axillae, on eyelashes, and on other body hair (e.g., arms, chest, legs).

### Scabies

**Scabies** is a contagious skin infection caused by mite infestations. It is transmitted by close contact with an infested person or infested bedding. Infestation is common among patients with poor

hygiene or crowded living conditions. The scabies mite is carried by pets and is found among homeless individuals and institutionalized older patients. Health care personnel are at risk for contracting scabies from contact with an infected patient or his or her bed linen (McGoldrick, 2015).

Curved or linear ridges in the skin are a feature of scabies (Fig. 25-8). The itching is very intense, and patients often report that it becomes unbearable at night.

**FIG. 25-8** Scabies. Note the lines indicating burrowing of the organism under the skin.

The visible, horizontal white skin ridges are formed by burrowing of the mite into the outer skin layers. Examine the skin between the fingers and on the palms and inner aspects of the wrists, where these ridges are most common. A hypersensitivity reaction to the mite results in excoriated erythematous papules; pustules; and crusted lesions on the elbows, nipples, lower abdomen, buttocks, and thighs and in the axillary folds. Males can have lesions on the penis.

Infestation is confirmed by taking a scraping of a lesion and examining it under the microscope for mites and eggs. Close contacts also should be examined for possible infestation.

Treatment involves the use of scabicides, such as permethrin (Acticin), lindane (Kwell, Kildane, Scabene, Thionex), crotamitron (Eurax) or benzyl benzoate (Ascabiol). Laundering clothes and personal items with hot water and detergent is sufficient to eliminate the mites.

## Bedbugs

A common parasite is the bedbug, *Cimex lectularius*. Infestations are increasingly common as a result of travel and resistance to pesticides. This pest does not live on humans; however, it feeds on human blood. The bite causes an itchy discomfort. The most common mode of infestation is carrying the “hitch-hiking” bug home from an infested environment such as a hotel room. This problem is not related to socioeconomic level or to a lack of cleanliness.

The adult bedbug is about the size, shape, and color of an apple seed. After feeding, it may double in size and have a red or black color. The insect bites a human host at night and sucks blood for 3 to 10 minutes. The bite area resembles a mosquito or flea bite with a raised bite mark surrounded by a wheal. The degree of itching and redness is related to how allergic the individual is to the insect's saliva. All body areas are susceptible; and one insect can bite multiple times, resulting in clusters of bite marks (Barnes & Murray, 2013).

Management of the patient with bedbug bites is symptomatic for discomfort from itching, usually with topical antihistamines. When the discomfort is more widespread or the allergic reaction is severe, systemic antihistamines or corticosteroids may be used. Because humans do not harbor the insect, the usual topical insecticides are not needed.

Bedbugs can live anywhere, hiding in cracks and crevices. They can live and lay their eggs in soft upholstery or in wooden crevices. Eradicating the infestation and preventing re-infestations require

considerable effort and can be frustrating. Often the home environment needs the extensive eradication efforts of a licensed professional pest-control company with experience in the management of bedbugs ([Barnes & Murray, 2013](#); [Fulton, 2015](#)).

# Trauma

## ❖ Pathophysiology

Skin trauma can vary from an aseptic surgical incision to a grossly infected, draining pressure injury with deep-tissue destruction. Injury to the skin starts a series of actions to repair the skin and restore TISSUE INTEGRITY to a protective barrier.

## Phases of Wound Healing

Wound healing occurs in three phases: inflammatory phase, proliferative phase, and maturation phase. Table 25-3 lists the key events for each stage of normal wound healing. The length of each phase depends on the type of injury and degree of loss of TISSUE INTEGRITY, the patient's overall health, and whether the wound is healing by first, second, or third intention (Fig. 25-9).

**TABLE 25-3**  
**Normal Wound Healing**

<b>Inflammatory Phase</b> <ul style="list-style-type: none"><li>• Begins at the time of injury or cell death and lasts 3 to 5 days.</li><li>• Immediate responses are vasoconstriction and clot formation.</li><li>• After 10 minutes, vasodilation occurs with increased capillary permeability and leakage of plasma (and plasma proteins) into the surrounding tissue.</li><li>• White blood cells (especially macrophages) migrate into the wound.</li><li>• Signs and symptoms of local edema, pain, erythema, and warmth are present.</li></ul>
<b>Proliferative Phase</b> <ul style="list-style-type: none"><li>• Begins about the fourth day after injury and lasts 2 to 4 weeks.</li><li>• Fibrin strands form a scaffold or framework.</li><li>• Mitotic fibroblast cells migrate into the wound, attach to the framework, divide, and stimulate the secretion of collagen.</li><li>• Collagen, together with ground substance, builds tough and inflexible scar tissue.</li><li>• Capillaries in areas surrounding the wound form “buds” that grow into new blood vessels.</li><li>• Capillary buds and collagen deposits form the “granulation” tissue in the wound, and the wound contracts.</li><li>• Epithelial cells grow over the granulation tissue bed.</li></ul>
<b>Maturation Phase</b> <ul style="list-style-type: none"><li>• Begins as early as 3 weeks after injury and may continue for a year or longer.</li><li>• Collagen is reorganized to provide greater tensile strength.</li><li>• Scar tissue gradually becomes thinner and paler in color.</li><li>• The mature scar is firm and inelastic when palpated.</li></ul>

**The process of wound healing**

▶ Healing by first intention

Clean incision

Early suture

"Hairline" scar

An aseptically made wound with minimal tissue destruction and minimal tissue reaction begins to heal as the edges are approximated by close sutures or staples. No open areas or dead spaces are left to serve as potential sites of infection.

▶ Healing by second intention (granulation) and contraction

Gaping, irregular wound

Granulation and contraction

Growth of epithelium over scar

An infected or chronic wound or one with tissue damage so extensive that the edges cannot be smoothly approximated is usually left open and allowed to heal from the inside out. The nurse periodically cleans and assesses the wound for healthy tissue production. Scar tissue is extensive, and healing is prolonged.

▶ Healing by third intention (delayed closure)

Infected wound

Granulation

Closure with wide scar

A potentially infected surgical wound may be left open for several days. If no clinical signs of infection occur, the wound is then closed surgically.

**FIG. 25-9** The process of wound healing.

A wound without tissue loss, such as a clean laceration or a surgical incision, can be closed with sutures, staples, or adhesives. The wound edges are brought together with the skin layers lined up in correct anatomic position (**approximated**) and held in place until healing is complete. This type of wound represents healing by **first intention**, in which the closed wound eliminates dead space and shortens the phases of tissue repair. Inflammation resolves quickly, and connective tissue repair is minimal, resulting in less remodeling and a thin scar. Fig. 25-10 shows the appearance of a normally healing surgical wound over time.

**FIG. 25-10** Appearance of a normally healing surgical wound over time.

Deeper-tissue injuries with greater loss of TISSUE INTEGRITY, such as a chronic pressure injury or venous stasis ulcer, result in a cavity that requires gradual filling in of the dead space with connective tissue. This represents healing by **second intention** and prolongs the repair process.

Wounds at high risk for infection, such as surgical incisions into a nonsterile body cavity or contaminated traumatic wounds, may be intentionally left open for several days. After **debris** (dead tissues) and exudate have been removed (débrided) and inflammation has subsided, the wound is closed by first intention. This type of healing represents delayed primary closure (**third intention**) and results in a scar similar to that found in wounds that heal by first intention. Healing can be impaired by many factors (Table 25-4).

**TABLE 25-4**  
**Causes of Impaired Wound Healing**

CAUSE	MECHANISM
<b>Altered Inflammatory Response</b>	
<i>Local</i>	
Arteriosclerosis Diabetes Vasculitis Thrombosis Venous insufficiency Lymphedema Pharmacologic vasoconstriction Irradiated tissue Crush injuries Primary closure under tension	Reduced local tissue circulation, resulting in ischemia, impaired leukocytic response to wounding, and increased probability of wound infection
<i>Systemic</i>	
Leukemia Prolonged administration of high-dose anti-inflammatory drugs: • Corticosteroids • Aspirin	Systemic inhibition of leukocytic response, resulting in impaired host resistance to infection
<b>Impaired Cellular Proliferation</b>	
<i>Local</i>	
Biofilm formation Wound infection Foreign body Necrotic tissue Repeated injury or irritation Movement of wound (e.g., across a joint) Wound desiccation or maceration	Prolonged inflammatory response, which can result in low tissue oxygen tension and further tissue destruction
<i>Systemic</i>	
Aging Chronic stress Nutritional deficiencies: • Calories • Protein • Vitamins • Minerals • Water Impaired oxygenation: • Pulmonary insufficiency • Heart failure • Hypovolemia Cirrhosis Uremia Prolonged hypothermia Coagulation disorders Cytotoxic drugs	Impaired cellular proliferation and collagen synthesis Decreased wound contraction

### Mechanisms of Wound Healing

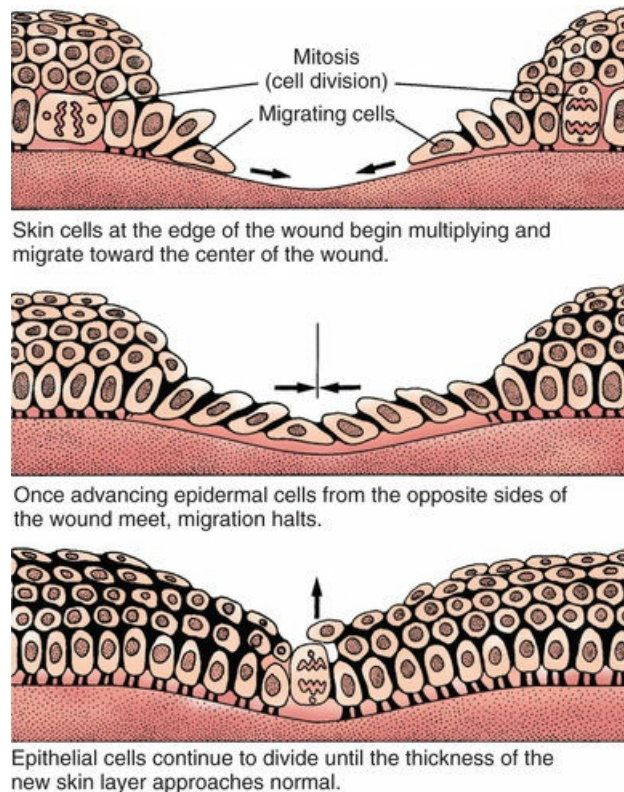

When skin injury occurs, the body restores TISSUE INTEGRITY through three processes: re-epithelialization, granulation, and wound contraction. The depth of injury and extent of tissue integrity loss determine to what degree each process contributes to wound healing.

#### Partial-Thickness Wounds.

Partial-thickness wounds are superficial with minimal loss of TISSUE INTEGRITY from damage to the

epidermis and upper dermal layers. These wounds heal by **re-epithelialization**, the production of new skin cells by undamaged epidermal cells in the basal layer of the dermis, which also lines the hair follicles and sweat glands (Fig. 25-11). Injury is followed immediately by local inflammation that causes the formation of a fibrin clot and releases growth factors that stimulate epidermal cell division (mitosis). New skin cells move into open spaces on the wound surface where the fibrin clot acts as a frame to guide cell movement. Regrowth across the open area (**resurfacing**) is only one cell layer thick at first. As healing continues, the cell layer thickens, stratifies (forms layers), and produces keratin to resemble normal skin.

**FIG. 25-11** Re-epithelialization and wound contraction. (Modified from Swaim, S. F. [1980]. *Surgery of traumatized skin*. Philadelphia: Saunders.)

In a healthy adult, healing of a partial-thickness wound takes about 5 to 7 days. This process is more rapid in skin that is hydrated, well oxygenated, and has few microorganisms.

### Full-Thickness Wounds.

In deep partial-thickness wounds and full-thickness wounds, loss of tissue integrity and damage extend into the lower layers of the dermis and subcutaneous tissue. As a result, most of the epithelial cells at the base of the wound are destroyed, and the wound cannot heal by re-epithelialization alone. Removal of the damaged tissue results in a defect that must be filled with scar tissue (**granulation**) for healing to occur. During the second phase of healing, new blood vessels form at the base of the wound, and fibroblast cells begin moving into the wound space. These cells deposit new collagen to replace the lost tissue.

Fibroblasts also begin to pull the wound edges inward along the path of least resistance (**contraction**) (see Fig. 25-11). This causes the wound to decrease in size at a uniform rate. Complete wound closure by contraction depends on the mobility of the surrounding skin as tension is applied to it. If tension in the surrounding skin exceeds the force of wound contraction, healing will be delayed until undamaged epidermal cells at the wound edges can bridge the defect. The bridging of epithelial cells across a large area of granulation tissue results in an unstable barrier rather than near-normal skin. A venous leg ulcer is one example of a skin defect that heals poorly by contraction. Re-epithelialization of these chronic wounds often results in a thin epidermal barrier that is easily re-injured.

The natural healing processes of re-epithelialization, granulation, and contraction can slow and even stop in the presence of chronic infection, unrelieved pressure, or mechanical obstacles. For example, dead tissue not only supports bacterial growth but also obstructs collagen deposition and wound contraction. Once dead tissue is removed, 60% of chronic wounds remained colonized with communities of bacteria that grow together in an extracellular matrix on the wound surface in the form of a biofilm. Stress-response mediators and other factors alter the cutaneous microbiome, leading to chronic inflammation and allowing biofilm bacteria to become more virulent and resistant to antimicrobials (Holmes et al., 2015). Thus thorough wound cleansing and débridement are essential for healing. In the case of chronic wounds, healing may stop spontaneously without an obvious cause. In addition, infection in chronic wounds may not show the expected signs or symptoms. Often the only manifestation is an increase in wound size or failure of the wound to decrease in size. Nonhealing chronic wounds that remain open for extended periods are of particular concern. Although rare, these wounds are at higher risk for evolving into an aggressive malignancy (Marjolin ulcer) (Tobin & Sanger, 2014; Yu et al., 2013).

## Considerations for Older Adults

### Patient-Centered Care QSEN

As skin ages, the process of wound healing is less efficient. Re-epithelialization and wound contraction slow, and replacement of connective tissue is reduced. Thus the strength of a healed wound in an older adult is reduced with poor TISSUE INTEGRITY, and the area is at greater risk for re-injury. When inadequate nutrition, incontinence, or immobility is present, any wound in an older adult has a high risk for becoming a chronic wound. Although prevention strategies provide the best outcome, aggressive treatment of any degree of loss of skin tissue integrity, no matter how small, should be started as soon as it is discovered in an older adult (Touhy & Jett, 2015).

### ❖ Interprofessional Collaborative Care

Collaborative management of skin trauma and the setting for care vary with the depth and type of injury. Interventions always focus on supporting a healing environment, enhancing wound healing, preventing infection, and restoring function to the area. Members of the interprofessional team who collaborate most closely to care for the patient with skin trauma include the surgeon (if indicated), who performs any necessary surgical repair of an affected area; the primary health care provider, who assesses healing and prescribes treatment; and the nurse.

# Skin Cancer

## ❖ Pathophysiology

Any skin cancer occurs as a result of failure of CELLULAR REGULATION over cell division. (See Chapter 21 for a discussion of the general mechanisms leading to changes in CELLULAR REGULATION and cancer development.) *Overexposure to sunlight is the major cause of skin cancer, although other factors also are associated.* Because sun damage is an age-related skin finding, screening for suspicious lesions is an important part of physical assessment of the older adult. The most common precancerous lesions are actinic (solar) keratosis, and the most common skin cancers are squamous cell carcinoma, basal cell carcinoma, and melanoma, as described in Table 25-5. A biopsy of suspicious lesions is necessary to determine whether a skin lesion is malignant.

**TABLE 25-5**  
**Common Premalignant Lesions and Skin Cancers**

SIGNS AND SYMPTOMS	DISTRIBUTION	COURSE
<b>Actinic (Solar) Keratosis (Premalignant)</b>		
Small (1-10 mm) macule or papule with dry, rough, adherent yellow or brown scale Base may be erythematous Associated with yellow, wrinkled, weather-beaten skin Thick, indurated keratoses more likely to be malignant	Cheeks, temples, forehead, ears, neck, backs of hands, and forearms	May disappear spontaneously or reappear after treatment Slow progression to squamous cell carcinoma possible
<b>Squamous Cell Carcinoma</b>		
Firm, nodular lesion topped with a crust or a central area of ulceration Indurated margins Fixation to underlying tissue with deep invasion	Sun-exposed areas, especially head, neck, and lower lip Sites of chronic irritation or injury (e.g., scars, irradiated skin, burns, leg ulcers)	Rapid invasion with metastasis via the lymphatics in 10% of cases Larger tumors more prone to metastasis
<b>Basal Cell Carcinoma</b>		
Pearly papule with a central crater and rolled, waxy borders Telangiectasias and pigment flecks visible on close inspection	Sun-exposed areas, especially head, neck, and central portion of face	Metastasis rare May cause local tissue destruction; 50% recurrence rate related to inadequate treatment
<b>Melanoma</b>		
Irregularly shaped, pigmented papule or plaque Variegated colors, with red, white, and blue tones	Can occur anywhere on the body, especially where nevi (moles) or birthmarks are evident Commonly found on upper back and lower legs Soles of feet and palms in dark-skinned people	Horizontal growth phase followed by vertical growth phase Rapid invasion and metastasis with high morbidity and mortality

## Etiology and Genetic Risk

*Actinic (solar) keratoses* are premalignant lesions of the cells of the epidermis. These lesions are common in adults with chronically sun-damaged skin. Progression to squamous cell carcinoma may occur if lesions are untreated.

*Squamous cell carcinomas* are cancers of the epidermis. They can invade locally and are potentially metastatic (Fig. 25-12). Chronic skin damage from repeated injury or irritation also predisposes to this malignancy. Chronic wounds that remain open for long periods are also at increased risk for malignant transformation to cancer.

**FIG. 25-12** **A** and **B**, Varying presentations of squamous cell carcinoma. (**A** and **B** from Bologna, J. L., Jorizzo, J. L., & Schaffer, J. V. [2012]. *Dermatology* (3rd ed.). St. Louis: Saunders.)

*Basal cell carcinomas* arise from the basal cell layer of the epidermis (Fig. 25-13). Early lesions often go unnoticed; and, although metastasis is rare, underlying tissue destruction can occur. Genetic predisposition and chronic irritation are risk factors; however, UV exposure is the most common cause.

**FIG. 25-13** Basal cell carcinoma.

*Melanomas* are pigmented cancers arising in the melanin-producing epidermal cells (Fig. 25-14). Most often they start as the benign growth of a **nevus** (mole) (Skin Cancer Foundation, 2016). Normal nevi have regular, well-defined borders and are uniform in color, ranging from light colors to dark brown. The lesion's surface may be rough or smooth. Nevi with irregular or spreading borders and those with multiple colors are abnormal. Other suspicious features include sudden changes in lesion size and reports of itching or bleeding.

**FIG. 25-14** Melanoma.

Risk factors include genetic predisposition, excessive exposure to UV light, and the presence of one or more precursor lesions that resemble unusual moles. *This skin cancer is highly metastatic, and a person's survival depends on early diagnosis and treatment.*

## Genetic/Genomic Considerations

### Patient-Centered Care QSEN

Genetic mutations in the CDKN2A and CDK4 have been identified for some cases of familial melanoma. These mutations in a suppressor gene result in loss of CELLULAR REGULATION for cell growth. Other genetic considerations for melanoma are that some specific mutations in the genes of the actual tumor cells increase the response of these cells to targeted therapy. All melanomas should be tested for mutations of the BRAF and KIT genes (OMIM, 2016). Always ask patients who have a diagnosed melanoma whether any other family members have ever had this disease.

### Incidence/Prevalence

The incidence of skin cancer is highest among light-skinned races and adults older than 55 years (ACS, 2015). Skin cancer occurs more often among those who work outdoors, live at higher altitudes or lower latitudes, or spend much time sunbathing. Occupational exposure to arsenic or other chemical carcinogens also increases risk. Melanoma reflects only 1% of total skin care cases but has one of the highest associated mortality rates (ACS, 2017).

### Health Promotion and Maintenance

The most effective prevention strategy for skin cancer is avoiding or reducing skin exposure to sunlight. However, even when adults understand the cause of skin cancer and the seriousness of the disease, preventive behaviors are not always practiced. Common prevention practices are listed in [Chart 25-11](#). *Teach all individuals to avoid tanning beds and salons.*

## Chart 25-11

### Patient and Family Education: Preparing for Self-Management

#### Prevention of Skin Cancer

- Avoid sun exposure between 11 AM and 3 PM.
- Use sunscreens with the appropriate skin protection factor for your skin type.
- Wear a hat, opaque clothing, and sunglasses when you are in the sun.
- Keep a “body map” of your skin spots, scars, and lesions to detect when changes have occurred.

- Examine your body monthly for possibly cancerous or precancerous lesions.
- Seek medical advice if you note any of these:
  - A change in the color of a lesion, especially if it darkens or shows evidence of spreading
  - A change in the size of a lesion, especially rapid growth
  - A change in the shape of a lesion, such as a sharp border becoming irregular or a flat lesion becoming raised
  - Redness or swelling of the skin around a lesion
  - A change in sensation, especially itching or increased tenderness of a lesion
  - A change in the character of a lesion, such as oozing, crusting, bleeding, or scaling

Secondary prevention (early detection) is critical to survival with melanoma. Teach adults to be aware of their skin markings. Keeping a total body spot and lesion map can provide baseline information about suspicious new lesions and help identify changes in existing lesions. Once a map is made, the person should systematically inspect his or her body monthly for new lesions and for changes in any existing lesions by performing thorough *skin self-examination (SSE)*. Some people find taking pictures of their skin on a regular basis makes identifying changes easier. Teach everyone to evaluate all skin lesions using the ABCDE guide for melanoma (see [Chapter 24](#)) and to consult his or her health care provider to examine any lesion having unusual features. When lesions such as moles are present, they should be monitored annually by a dermatologist or other health care professional.

### ❖ **Interprofessional Collaborative Care**

Care of the patient with skin cancer, depending on the degree of cancer and associated health concerns, may be treated in the hospital, ambulatory surgical, or outpatient setting. Members of the interprofessional team who most often care for patients with skin cancer include the surgeon to remove cancerous lesions, the oncologist to manage radiation and/or chemotherapy, the pharmacist to dispense medication, the social worker to assist with care coordination and payer sources, the spiritual leader of the patient's choice to provide comfort, and the nurse.

### ◆ **Assessment: Noticing**

In addition to age and race, ask the patient about any family history of skin cancer and any past surgery for removal of skin growths. Recent changes in the size, color, or sensation of any mole, birthmark, wart, or scar are also significant. Ask in which geographic regions the patient has lived and where he or she currently resides. Obtain information about occupational and recreational activities in relation to sun exposure and any occupational history of exposure to chemical carcinogens (e.g., arsenic, coal tar, pitch, radioactive waste, radium). Ask whether any skin lesions are repeatedly irritated by the rubbing of clothing.

Skin that has been injured previously is at greater risk for cancer development, an effect known as *Koebner's phenomenon*. Ask the patient if he or she has ever experienced a severe skin injury that resulted in a scar. Examine all scarred skin areas for the presence of potentially cancerous lesions. A biopsy may be required to rule out cancer in a chronic open wound that fails to close with proper treatment.

Skin cancers vary in their appearance and distribution. Although most skin cancers appear in sun-exposed areas of the body, inspect the entire skin surface and any unusual lesions, particularly moles, warts, birthmarks, and scars. Also examine hair-bearing areas of the body, such as the scalp and genitalia. Palpate lesions to determine surface texture. Document the location, size, color, and features of all lesions and any reports of tenderness or itching. Use the ABCDE method of evaluating all lesions for possible melanoma (see [Chapter 24](#)).

### ◆ **Planning and Implementation: Responding**

Surgical and nonsurgical interventions are combined for the effective management of skin cancer. Treatment is determined by the size and severity of the malignancy, the location of the lesion, and the age and general health of the patient.

#### **Surgical Management.**

Surgical intervention is needed to manage any type of skin cancer. It can range from local removal of small lesions to massive excision of large areas of the skin and underlying tissue for treatment of melanoma. Surgical types for skin cancer include:

- Cryosurgery—Cell destruction by the local application of liquid nitrogen ( $-200^{\circ}\text{C}$ ) to isolated lesions, causing cell death and tissue destruction.
- Curettage and electrodesiccation—Removal of cancerous cells with the use of a dermal curette to scrape away cancerous tissue, followed by the application of an electric probe to destroy remaining tumor tissue.
- Excisional biopsy—Total surgical removal of small lesions for pathologic examination.
- Mohs' surgery—A specialized form of excision usually for basal and squamous cell carcinomas. Tissue is sectioned horizontally in layers, and each layer is examined histologically to determine the presence of residual tumor cells.
- Wide excision—Deep skin resection often involving removal of full-thickness skin in the area of the lesion. Depending on tumor depth, subcutaneous tissues and lymph nodes may also be removed.

#### **Nonsurgical Management.**

*Drug therapy* may involve topical or systemic chemotherapy, biotherapy, or targeted therapy.

Topical chemotherapy with 5-fluorouracil cream is used for treatment of multiple actinic keratoses or for widespread superficial basal cell carcinoma that would require several surgical procedures to eradicate. Therapy is continued for several weeks; and the treated areas become increasingly tender and inflamed as the lesions crust, ooze, and erode. Prepare the patient for an unsightly appearance during therapy and reassure him or her that the cosmetic result will be positive. Imiquimod (Aldara) is a newer topical treatment option for superficial basal cell carcinoma. This type of therapy stimulates the immune system to produce interferon, a chemical that attacks cancer cells.

Several systemic agents are indicated for treatment of locally advanced or metastatic squamous cell skin cancer. These include a platinum based-agent (Cisplatin or Carboplatin), 5-fluorouracil, and cetuximab (Erbix) for advanced squamous cell carcinoma. Oral drugs approved for advanced basal cell carcinoma include vismodegib (Erivedge) and sonidigib (Odomzo).

*Biotherapy* with interferon, monoclonal antibodies, and targeted therapy are now accepted treatment for melanoma after surgical removal. Interferon is used for melanomas that are at stage 3 or higher. The patient is first started on high-dose IV interferon infusions daily for 5 days per week for 4 weeks. Maintenance doses, given subcutaneously, are then continued three times per week for 1 year. The patient must learn to self-inject the drug.

Monoclonal antibody therapy with ipilimumab (Yervoy), a drug that targets the CTLA4 (cytotoxic T-lymphocyte associated antigen 4) receptor and blocks it, leads to greater T-cell lymphocyte activity. (T-cells are a type of lymphocyte that can stimulate antitumor immune responses.) The side effects of this drug include significant inflammation in many tissues, including the pituitary gland, liver, skin, GI tract, and nervous system. Some of the side effects can be life threatening ([Bryce & Passoni, 2013](#)).

Targeted therapy is available for melanomas with specific mutations in the *BRAF* gene. Normally the *BRAF* gene is involved in CELLULAR REGULATION of growth. Mutations in this gene allow melanoma to grow and metastasize. When melanoma cells are positive for a specific *BRAF* mutation

(V600E), the cells respond to the drug vemurafenib (Zelboraf). The drug inhibits an enzyme important in signaling cell division and prevents melanoma cell division. This oral drug interacts with a variety of other drugs, and allergic reactions are common.

*Radiation therapy* for skin cancer is limited to older patients with large, deeply invasive basal cell tumors and to those who are poor risks for surgery. Melanoma is relatively resistant to radiation therapy. Immune check inhibitors stimulate the immune system to recognize and destroy cancer cells more effectively. Pembrolizumab (Keytruda) and nivolumab (Opdivo) target a protein on the surface of T-cells (PD-1). Blocking PD-1 increases T-cell activation, which helps the body attack melanoma cells but can also stimulate the immune system to attack noncancerous tissue. To avoid serious side effects, teach patients to report any new symptoms to the health care team immediately (ACS, 2015).

## NCLEX Examination Challenge 25-4

### Physiological Integrity

The nurse is performing an assessment on a female client and notices a large, irregularly shaped mole on her upper back. The client expresses concern about the cosmetic appearance of the lesion. What is the **priority** nursing intervention?

- A. Refer to a dermatological health care provider.
- B. Ask if there are any other lesions that bother her.
- C. Perform a head-to-toe skin assessment and document the findings.
- D. Teach about the importance of avoiding excessive sun exposure and tanning beds.

## Other Skin Disorders

### Toxic Epidermal Necrolysis and Stevens-Johnson Syndrome

Toxic epidermal necrolysis (TEN) and Stevens-Johnson Syndrome (SJS) (Fig. 25-15) are life-threatening cutaneous reactions to medications. Thought to be variations in severity of the same immune process, TEN/SJN is characterized by diffuse erythema and blister formation, often involving the mucous membranes. The most common causative drugs are allopurinol, antiepileptics, NSAIDs, chemotherapy agents, sulfonamides, pyrazolones, barbiturates, and antibiotics. Discontinuation of the drug is usually followed by gradual healing in 2 to 3 weeks, with widespread peeling of the epidermis (Dodiuk-Gad et al., 2015).

**FIG. 25-15** Stevens-Johnson syndrome. (Courtesy Stevens Johnson Syndrome Foundation, Littleton, CO.)

This problem can occur at any age and as a result of almost any drug therapy. However, older patients with cancer who are receiving chemotherapy, some targeted therapies, and immunotherapy are at greatest risk. Other precipitating factors include stem cell transplantation and neutropenia-induced infections.

The drug thought to be causing a toxic reaction is discontinued, and management focuses on systemic support and prevention of secondary infection. Patients are often admitted to burn units, where fluid and electrolyte balance, caloric intake, and hypothermia can be closely monitored. Topical antibacterial drugs are used to suppress bacterial growth until healing occurs.

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Wash your hands before and after touching any skin lesions. **QSEN: Safety**
- Use Standard Precautions when providing care to a patient who has any areas of nonintact skin. **QSEN: Safety**
- Ensure that the skin of incontinent patients is kept clean and dry. **QSEN: Evidence-Based Practice**
- Assist patients with limited mobility to change positions while awake. Base frequency of repositioning on individual patient assessment criteria. **QSEN: Evidence-Based Practice**
- Use a structured approach (e.g., Braden scale or other validated tool) to evaluate the pressure injury risk for all patients on admission and regularly thereafter. **QSEN: Evidence-Based Practice**
- Use pressure-distribution devices for any patient who is identified to be at risk for pressure injury formation (i.e., requires prolonged bedrest, is an older adult, has some degree of immobility, is incontinent, has some degree of malnutrition, is dehydrated, has decreased sensory perception, or has an altered mental state). **QSEN: Safety**
- Use a lift sheet or mechanical lift to move immobilized older patients rather than pulling or dragging them across bed linens. **QSEN: Safety**

### Health Promotion and Maintenance

- Teach the patient with mobility problems and caregivers how to redistribute skin pressure in the home environment. **QSEN: Patient-Centered Care**
- Encourage adults to reduce sun exposure and exposure to ultraviolet (UV) light. **QSEN: Patient-Centered Care**
- Teach adults how to examine all skin areas on a monthly basis for new lesions and changes to existing lesions and to keep a record or “body map” of skin lesions. **QSEN: Patient-Centered Care**
- Teach patients with skin scarring from a previous skin injury to examine this area at least monthly for changes. **QSEN: Patient-Centered Care**
- Urge patients to regularly bathe, shampoo the hair, and keep fingernails clean. **QSEN: Patient-Centered Care**
- Teach patients with infected skin lesions or infestations how to limit transmission. **QSEN: Safety**
- Teach patients the ABCDE method of evaluating a lesion for melanoma. **QSEN: Patient-Centered Care**
- Assess the patient's ability to see and reach the affected skin area and care for the problem. **QSEN: Patient-Centered Care**

### Psychosocial Integrity

- Assess the patient's and family's feelings about how a skin, hair, or nails condition has affected body image. **QSEN: Patient-Centered Care**
- Support the patient and family in coping with changes in skin integrity and body image. **QSEN: Patient-Centered Care**
- Encourage the patient with a visible wound or other skin problem to participate in the care of the wound. **QSEN: Patient-Centered Care**
- Professionally demonstrate acceptance of the patient with skin changes. **Ethics**

- Encourage patients with chronic skin problems, especially those that alter appearance, to become involved in a community support group. **QSEN: Patient-Centered Care**

### **Physiological Integrity**

- Keep skin well hydrated to promote TISSUE INTEGRITY. **QSEN: Evidence-Based Practice**
- Use appropriate risk assessment tools to perform a focused skin assessment and re-assessment to determine risk for pressure injury development and adequacy of the skin's protective functions.  
**Clinical Judgment**
- Keep skinfold areas clean and dry. **QSEN: Evidence-Based Practice**
- Ask the patient who has started taking a newly prescribed drug if skin changes have occurred since starting the drug. **QSEN: Patient-Centered Care**
- Evaluate any open skin area on a patient daily for size, depth, exudate, presence of infection, and indicators of healing. **Clinical Judgment**
- Differentiate the signs and symptoms for all pressure injury categories. **Clinical Judgment**
- Evaluate wounds for size, depth, presence of infection, and indications of healing. **Clinical Judgment**

## CHAPTER 26

# Care of Patients With Burns

---

Tammy Coffee

## PRIORITY AND INTERRELATED CONCEPTS

---

***The priority concepts for this chapter are:***

- TISSUE INTEGRITY
- FLUID AND ELECTROLYTE BALANCE
- PERFUSION
- GAS EXCHANGE

***The interrelated concepts for this chapter are:***

- NUTRITION
- COMFORT
- MOBILITY

## LEARNING OUTCOMES

---

### **Safe and Effective Care Environment**

1. Collaborate with the interprofessional team to coordinate high-quality care for patients with burn injury.
2. Protect patients with burns from infection.

### **Health Promotion and Maintenance**

3. Teach adults fire- and burn-prevention strategies.

### **Psychosocial Integrity**

4. Implement nursing interventions to help patients and families cope with the psychosocial impact of burn injury.

### **Physiological Integrity**

5. Ensure optimal pain control and increase COMFORT for the patient with a burn injury.
6. Prioritize nursing care for the patient with burns during the resuscitation, acute, and rehabilitation phases of burn injury to preserve TISSUE INTEGRITY, FLUID AND ELECTROLYTE BALANCE, and GAS EXCHANGE.

Physiologic, metabolic, and psychological changes take place with loss of TISSUE INTEGRITY associated with burns. These complex injuries can range from “sunburn” to major injuries involving all layers of the skin. The function of many body systems is changed when the skin is injured. The patient with burns needs comprehensive care for weeks to months to survive the injury, reduce complications, and return to the best functional status. Nurses coordinate the activities of an interprofessional team comprised of health care providers, nurses with burn specialty, registered dietitians, therapists, and religious and spiritual leaders (as requested by the patient) to provide the best care and patient outcomes.

# Introduction to Burn Injury

## ❖ Pathophysiology

Tissue destruction caused by a burn injury leads to local and systemic problems that affect FLUID AND ELECTROLYTE BALANCE and lead to protein losses; sepsis; and changes in metabolic, endocrine, respiratory, cardiac, hematologic, and immune functioning. The extent of problems is related to age, general health, extent of injury, depth of injury, and the specific body area injured. Even after healing, the burn injury may cause late complications such as contracture formation and scarring. Priorities of care are the prevention of infection and closure of the burn wound. A lack of or delay in wound healing is a key factor for all systemic problems and a major cause of disability and death among patients who are burned.

## Skin Changes

### Anatomic Changes.

The skin is the largest organ of the body (see [Chapter 24](#)). Each of its two major layers, the epidermis and the dermis, has several sublayers. The epidermis is the outer layer of skin. It can grow back after a burn injury because the epidermal cells surrounding sweat and oil glands and hair follicles extend into dermal tissue and regrow to heal partial-thickness wounds. Together the sweat and oil glands and the hair follicles are the *dermal appendages*, which vary in depth in different body areas. For example, the sweat and oil glands in the palm of the hand and the sole of the foot extend deep into the dermis. This allows for healing of deep burns in these areas. The epidermis has no blood vessels, and nutrients must diffuse from the second layer of skin, the dermis.

The dermis is thicker than the epidermis and is made up of collagen, fibrous connective tissue, and elastic fibers. Within the dermis are the blood vessels, sensory nerves, hair follicles, lymph vessels, sebaceous glands, and sweat glands.

When burn injury occurs, skin can regrow as long as parts of the dermis are present. When the entire dermal layer is burned, all cells and dermal appendages are destroyed, and the skin can no longer restore itself. The subcutaneous tissue lies below the dermis and is separated from the dermis by the basement membrane, a thin, noncellular protein surface. With deep burns, the subcutaneous tissues may be damaged, leaving bones, tendons, and muscles exposed.

### Functional Changes.

The skin has many functions when TISSUE INTEGRITY is intact (see [Table 24-1](#)). It is a protective barrier against injury and microbial invasion. Burns break this barrier, greatly increasing the risk for infection.

The skin helps maintain the delicate FLUID AND ELECTROLYTE BALANCE essential for life. After a burn injury, massive fluid loss occurs through excessive evaporation. The rate of evaporation is in proportion to the total body surface area (TBSA) burned and the depth of injury.

The skin is an excretory organ through sweating. Full-thickness burns destroy the sweat glands, reducing excretory ability.

The sensations of pain, pressure, temperature, and touch are triggered on the skin in normal daily activities, which allows a person to react to changes in the environment. *All burn injuries are painful.* With partial-thickness burns, nerve endings are exposed, increasing sensitivity and pain. With full-thickness burns, nerve endings are completely destroyed. At first these wounds may not transmit sensation except at wound edges. Despite this destruction, patients often have dull or pressure-type pain in these areas.

Skin exposed to sunlight activates vitamin D. Partial-thickness burns reduce the activation of vitamin D, and this function is lost completely in areas of full-thickness burns.

The internal body temperature remains within a narrow range (about 84.2° to 109.4° F [29° to 43° C]) compared with the temperatures of the external environment. Skin TISSUE INTEGRITY is important in maintaining normal body temperature. Circulating blood in the skin both provides and dissipates heat efficiently. When heat is applied to the skin, the temperature under the dermis rises rapidly. As soon as the heat source is removed, compensatory processes quickly return the area to a normal temperature. If the heat source is not removed or if it is applied at a rate that exceeds the

skin's capacity to dissipate it, cells are destroyed.

Physical identity is partly determined by the skin's cosmetic quality, which contributes to each individual's unique appearance. A patient who sustains a major burn often develops reduced self-image and other psychosocial problems as a result of appearance changes.

### Depth of Burn Injury.

The severity of a burn is determined by how much of the body surface area is involved and the depth of the burn. The degree of TISSUE INTEGRITY loss is related to the agent causing the burn, the temperature of the heat source, and how long the skin is exposed to it.

Differences in skin thickness in various parts of the body also affect burn depth. In areas where the skin is thin (e.g., eyelids, ears, nose, genitalia, tops of the hands and feet, fingers, and toes), a short exposure to high temperatures causes a deep burn injury. The skin is thinner in older adults (Touhy & Jett, 2015), which increases their risk for greater burn severity, even at lower temperatures of shorter duration.

Burn wounds are classified as superficial-thickness wounds, partial-thickness wounds, full-thickness wounds, and deep full-thickness wounds. The partial-thickness wounds are further divided into superficial and deep subgroups. Table 26-1 lists the differences of these burns.

**TABLE 26-1**  
**Classification of Burn Depth**

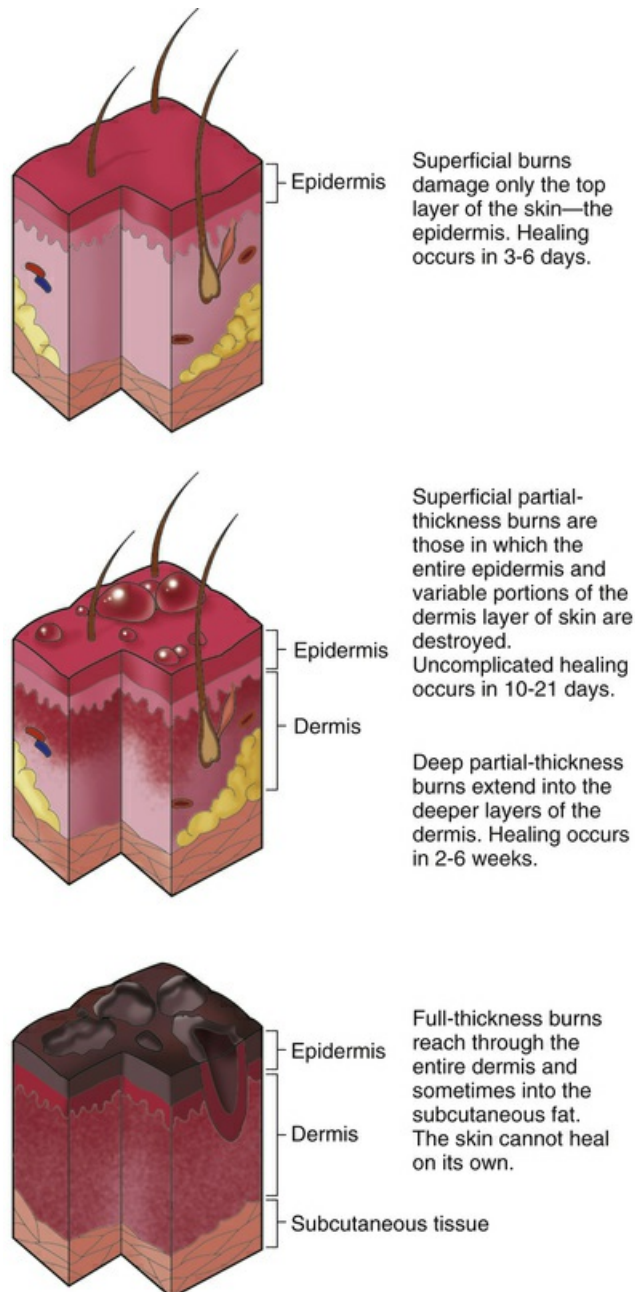

CHARACTERISTIC	SUPERFICIAL	SUPERFICIAL PARTIAL-THICKNESS	DEEP PARTIAL-THICKNESS	FULL-THICKNESS	DEEP FULL-THICKNESS
Color	Pink to red	Pink to red	Red to white	Black, brown, yellow, white, red	Black
Edema	Mild	Mild to moderate	Moderate	Severe	Absent
Pain	Yes	Yes	Yes	Yes and no	Absent
Blisters	No	Yes	Rare	No	No
Eschar	No	No	Yes, soft and dry	Yes, hard and inelastic	Yes, hard and inelastic
Healing time	3-6 days	About 2 wk	2-6 wk	Weeks to months	Weeks to months
Grafts required	No	No	Can be used if healing is prolonged	Yes	Yes
Example	Sunburn, flash burns	Scalds, flames, brief contact with hot objects	Scalds; flames; prolonged contact with hot objects, tar, grease, chemicals	Scalds; flames; prolonged contact with hot objects, tar, grease, chemicals, electricity	Flames; electricity, grease, tar, chemicals

Burns are classified as minor, moderate, or major, depending on the depth, extent, and location of injury (Table 26-2). Fig. 26-1 shows the tissue layers involved with different depths of injury.

**TABLE 26-2**  
**Classification of Burn Injury and Burn Center Referral Criteria**

CHARACTERISTICS	COMMENTS
<b>Minor Burns</b> Partial-thickness burns less than 10% TBSA Full-thickness burns less than 2% TBSA No burns of eyes, ears, face, hands, feet, or perineum No electrical burns No inhalation injury No complicated additional injury Patient is younger than 60 years and has no chronic cardiac, pulmonary, or endocrine disorder	Patients in this category should receive emergency care at the scene and be taken to a hospital emergency department. A special expertise hospital or designated burn center is usually not necessary.
<b>Moderate Burns</b> Partial-thickness burns 15%-25% TBSA Full-thickness burns 2%-10% TBSA No burns of eyes, ears, face, hands, feet, or perineum No electrical burns No inhalation injury No complicated additional injury Patient is younger than 60 years and has no chronic cardiac, pulmonary, or endocrine disorder	Patients in this category should receive emergency care at the scene and be transferred to either a special-expertise hospital or a designated burn center.
<b>Major Burns</b> Partial-thickness burns greater than 25% TBSA Full-thickness burns greater than 10% TBSA Any burn involving the eyes, ears, face, hands, feet, perineum Electrical injury Inhalation injury Patient is older than 60 years Burn complicated with other injuries (e.g., fractures) Patient has cardiac, pulmonary, or other chronic metabolic disorders	Patients who meet <i>any one</i> of the criteria for a major burn should receive emergency care at the nearest emergency department and then be transferred to a designated burn center as soon as possible.

TBSA, Total body surface area.

**FIG. 26-1** Tissues involved in burns of various depths.

### Superficial-Thickness Wounds.

Superficial-thickness wounds have the least damage because the epidermis is the only part of the skin that is injured. The epithelial cells and basement membrane, needed for total regrowth, remain present.

These wounds are caused by prolonged exposure to low-intensity heat (e.g., sunburn) or short (flash) exposure to high-intensity heat. Redness with mild edema, alterations in COMFORT, and increased sensitivity to heat occurs as a result. **Desquamation** (peeling of dead skin) occurs 2 to 3 days after the burn. The area heals rapidly in 3 to 6 days without a scar or other complication.

### Partial-Thickness Wounds.

A partial-thickness wound involves TISSUE INTEGRITY loss of the entire epidermis and varying depths of the dermis. Depending on the amount of dermal tissue damaged, partial-thickness wounds are further subdivided into superficial partial-thickness and deep partial-thickness injuries.

*Superficial partial-thickness wounds* are caused by injury to the upper third of the dermis, leaving a

good blood supply. These wounds are pink and moist and **blanch** (lighten) when pressure is applied (Fig. 26-2). The small vessels bringing blood to this area are injured, resulting in the leakage of large amounts of plasma, which in turn lifts the heat-destroyed epidermis, causing blister formation. The blisters continue to increase in size after the burn as cell and protein breakdown occur. Small blisters are often left intact if they are not located over a joint. Large blisters usually are opened and débrided to promote healing.

**FIG. 26-2** Typical appearance of a superficial partial-thickness burn injury.

Superficial partial-thickness wounds increase pain sensation. Nerve endings are exposed, and any stimulation (touch or temperature change) causes intense pain. With standard care, these burns heal in 10 to 21 days with no scar; but some minor pigment changes may occur.

*Deep partial-thickness wounds* extend deeper into the skin dermis, and fewer healthy cells remain. Blisters usually do not form because the dead tissue layer is thick, sticks to the underlying dermis, and does not readily lift off the surface. The wound surface is red and dry with white areas in deeper parts (dry because fewer blood vessels are patent). When pressure is applied to the burn, it blanches slowly or not at all (Fig. 26-3). Edema is moderate, and pain is less than with superficial burns because more of the nerve endings have been destroyed.

**FIG. 26-3** Typical appearance of a deep partial-thickness burn injury.

Blood flow to these areas is reduced, and progression to deeper injury can occur from hypoxia and ischemia. Adequate hydration, nutrients, and oxygen are needed for regrowth of skin cells and prevention of conversion to deeper burns. These wounds can convert to full-thickness wounds when tissue damage increases with infection, hypoxia, or ischemia. Deep partial-thickness wounds generally heal in 2 to 6 weeks, but scar formation results. Surgical intervention with skin grafting can reduce healing time.

#### **Full-Thickness Wounds.**

A full-thickness wound occurs with destruction of the entire epidermis and dermis, leaving no skin cells to repopulate (Fig. 26-4). This wound does not regrow, and areas not closed by wound contraction (see Chapter 25) require grafting.

**FIG. 26-4** Typical appearance of a full-thickness burn injury.

The full-thickness burn has a hard, dry, leathery *eschar* that forms from coagulated particles of destroyed skin. *The eschar is dead tissue; it must slough off or be removed from the wound before healing can occur.* These thick particles often stick to the lower tissue layers, making eschar removal difficult. Edema is severe under the eschar in a full-thickness wound. When the injury is **circumferential** (completely surrounds an extremity or the chest), blood flow and chest movement for breathing may be reduced by tight eschar. **Escharotomies** (incisions through the eschar) or **fasciotomies** (incisions through eschar and fascia) may be needed to relieve pressure and allow normal blood flow and breathing. (See the **Surgical Management** discussion in the **Preventing Hypovolemic Shock and Inadequate Gas Exchange** section.)

A full-thickness burn may be waxy white, deep red, yellow, brown, or black. Thrombosed and heat-coagulated blood vessels may be seen beneath the surface of the burn and leave the burned tissue without a blood supply. Sensation is reduced or absent because of nerve-ending destruction. Healing time depends on establishing a good blood supply in the injured areas. This process can range from weeks to months.

#### **Deep Full-Thickness Wounds.**

Deep full-thickness wounds extend beyond the skin and damage muscle, bone, and tendons. These burns occur with flame, electrical, or chemical injuries. The wound is blackened and depressed, and sensation is completely absent (Fig. 26-5). All full-thickness burns need early excision and grafting. Grafting decreases pain and length of stay and hastens recovery. Amputation may be needed when an extremity is involved.

**FIG. 26-5** Typical appearance of a deep full-thickness burn injury.

## **Vascular Changes**

Circulation to the burned skin is disrupted immediately after injury by blood vessel occlusion. Macrophages in damaged tissues release chemicals that at first cause blood vessel constriction. Blood vessel thrombosis may occur, causing necrosis, which can lead to deeper injuries in these areas.

*Fluid shift* occurs after initial vasoconstriction as a result of blood vessels near the burn dilating and leaking fluids into the interstitial space (Fig. 26-6). This fluid shift, also known as *third spacing* or *capillary leak syndrome*, is a continuous leak of plasma from the vascular space into the interstitial space. The impaired FLUID AND ELECTROLYTE BALANCE leads to loss of plasma fluids and proteins, which decreases blood volume and blood pressure (McCance et al., 2014). Leakage of fluid and electrolytes from the vascular space continues, causing extensive edema, even in areas that were not burned. Fluid shift, with excessive weight gain, occurs in the first 12 hours after the burn and can continue for 24 to 36 hours.

The amount of fluid shifted depends on the extent and severity of injury. Capillary leak occurs in both burned and unburned areas when tissue damage is extensive (i.e., more than 25% total body surface area [TBSA]). Edema develops as plasma and electrolytes escape into the interstitial space. The proteins now in the interstitial space increase the movement of fluids out from the vascular space.

Profound disruptions of FLUID AND ELECTROLYTE BALANCE and acid-base balance occur as a result of the fluid shift and cell damage. These imbalances often include hypovolemia, metabolic acidosis, **hyperkalemia** (high blood potassium level), and **hyponatremia** (low blood sodium level). Hyperkalemia occurs as a result of direct cell injury that releases large amounts of cellular potassium. Sodium is retained by the body as a result of the endocrine response to stress. Aldosterone secretion increases, leading to increased sodium reabsorption by the kidney. However, this sodium quickly passes into the interstitial spaces of the burned area with the fluid shift. Thus, despite the increased amount of sodium in the body, most of the sodium is trapped in the interstitial space, and a sodium deficit occurs in the blood. **Hemoconcentration** (elevated blood osmolarity, hematocrit, and hemoglobin) develops from vascular dehydration. This problem increases blood viscosity, reducing blood flow and increasing tissue hypoxia.

*Fluid remobilization* starts at about 24 hours after injury, when the capillary leak stops. The diuretic stage begins at about 48 to 72 hours after the burn injury as capillary membrane integrity returns and edema fluid shifts from the interstitial spaces into the intravascular space. Blood volume increases, leading to increased kidney blood flow and diuresis unless kidney damage has occurred. Body weight returns to normal over the next few days as edema subsides.

During this phase, hyponatremia develops because of increased kidney sodium excretion and the loss of sodium from wounds. **Hypokalemia** (low blood potassium level) results from potassium moving back into the cells and also being excreted in urine. Anemia often develops as a result of hemodilution, but it is generally not severe enough to require blood transfusions. Transfusions are needed only if the patient's hematocrit is less than 20% to 25% and the patient has signs and symptoms of hypoxia. Protein continues to be lost from the wounds. Metabolic acidosis is possible because of the loss of bicarbonate in the urine and the increased rate of metabolism.

## Cardiac Changes

Heart rate increases, and cardiac output decreases because of the initial fluid shifts and

hypovolemia that occur after a burn injury. Cardiac output may remain low until 18 to 36 hours after the burn injury. It improves with fluid resuscitation and reaches normal levels before plasma volume is restored completely. Proper fluid resuscitation and support with oxygen prevent further complications.

### **Pulmonary Changes**

Direct injury to the lungs from contact with flames rarely occurs. Rather, respiratory problems are caused by superheated air, steam, toxic fumes, or smoke. *Such problems are a major cause of death in patients with burns and are most likely to occur when the burn takes place indoors.* Respiratory failure with burn injuries can result from airway edema during fluid resuscitation, pulmonary capillary leak, chest burns that restrict chest movement, and carbon monoxide poisoning.

Respiratory damage from an inhalation injury can occur in the upper and major airways and the lung tissue. The upper airway is affected when inhaled smoke or irritants cause edema and obstruct the trachea. Heat can reach the upper airway, causing an inflammatory response that leads to edema of the mouth and throat with the potential of airway obstruction.

Chemicals and toxic gases produced during combustion can cause airway injury. The ciliated membranes lining the trachea normally trap foreign materials. Smoke and gases slow this activity, allowing particles to enter the bronchi. The lining of the trachea and bronchi may slough 48 to 72 hours after injury and obstruct the lower airways.

Lung tissue injuries result from toxic irritant damage to the alveoli and capillaries. Leaking capillaries cause alveolar edema, which can occur immediately or up to a week after the injury. The fluid that diffuses into the lung tissue spaces contains proteins that form fibrinous membranes and lead to respiratory distress. Progressive pulmonary failure develops, leading to acute pulmonary insufficiency and infection.

### **Gastrointestinal Changes**

The fluid shifts and decreased cardiac output that occur after injury decrease blood flow to the GI tract. Gastric mucosal TISSUE INTEGRITY and motility are impaired. The sympathetic nervous system stress response increases secretion of epinephrine and norepinephrine, which inhibit GI motility and further reduce blood flow to the area. Peristalsis decreases, and a paralytic ileus may develop. Secretions and gases collect in the GI tract, causing abdominal distention.

**Curling's ulcer** (acute gastroduodenal ulcer that occurs with the stress of severe injury) may develop within 24 hours after a severe burn injury because of reduced GI blood flow and mucosal damage (McCance et al., 2014). The mucus lining the stomach normally protects the tissue from the hydrogen ions secreted into the stomach. With decreased gastric mucus production and increased hydrogen ion production, ulcers may develop. This complication is now less common because of the use of H<sub>2</sub> histamine blockers, proton pump inhibitors, drugs that protect GI tissues, and early enteral feeding.

### **Metabolic Changes**

A serious burn injury greatly increases metabolism by increasing secretion of catecholamines, antidiuretic hormone, aldosterone, and cortisol. With this hypermetabolism, the patient's oxygen use and calorie needs are high.

The catecholamines activate the stress response. The increased production (and loss) of heat break down protein and fat (*catabolism*), rapidly use glucose and calories, and increase urine nitrogen loss. The heat and water lost from the burn also increase metabolic rate and calorie needs. Depending on the extent of injury, the patient's calorie needs double or triple normal energy needs. These increased rates peak 4 to 12 days after the burn and can remain elevated for months until all wounds are closed.

The hypermetabolic condition also increases core body temperature. The patient loses heat through the burned areas. Core body temperature increases as a response to the adjustment in temperature regulation by the hypothalamus, resulting in a low-grade fever.

### **Immunologic Changes**

Burn injury disrupts or destroys the protective skin tissue integrity, increasing the risk for infection. The injury activates the inflammatory response and often suppresses all types of immune functions.

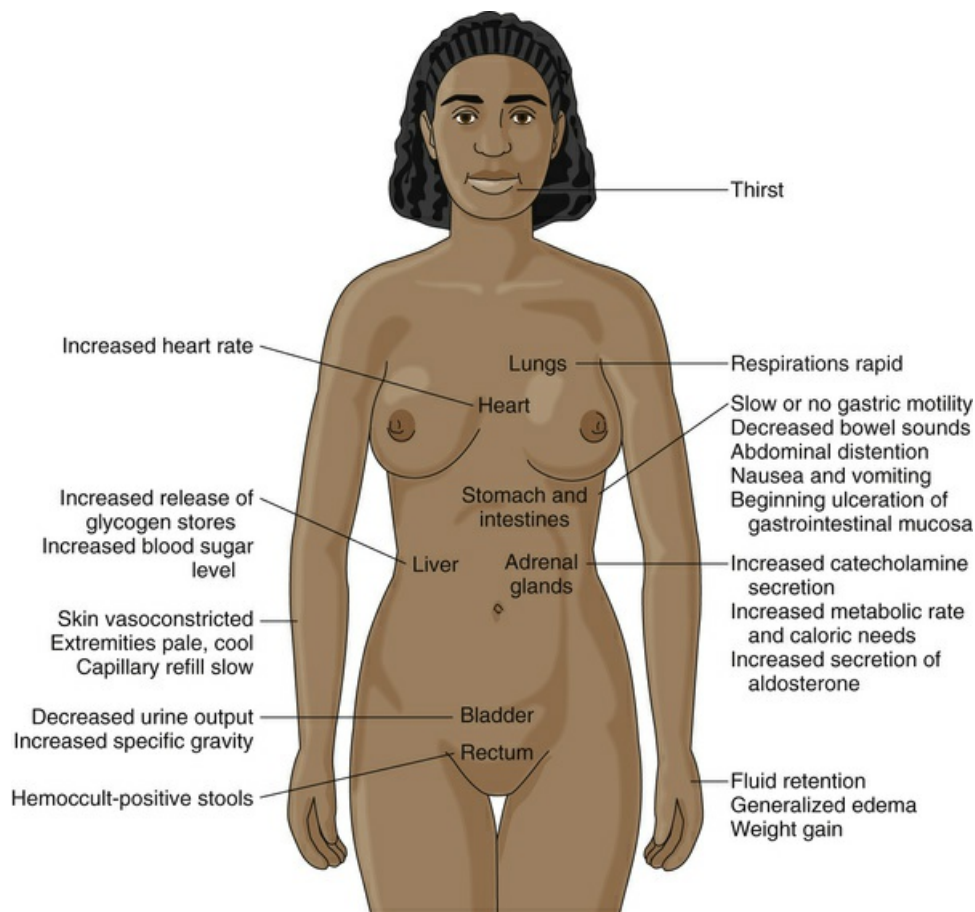

Antibiotic therapy and other interventions for burns further reduce immune function.

## Compensatory Responses

Any injury is a stressor and can disrupt homeostasis. Two compensatory (adaptive) responses have immediate benefit: the inflammatory response and the sympathetic nervous system stress response. Together these responses cause changes that result in many of the signs and symptoms seen in the first 2 to 3 days after a burn injury.

*Inflammatory compensation* is helpful by triggering healing in the injured tissues and also is responsible for the serious problems that occur with the fluid shift. This compensation causes blood vessels to leak fluid into the interstitial space and white blood cells to release chemicals that trigger local tissue reactions. These responses cause the massive fluid shift, edema, and hypovolemia that are seen in the **resuscitation phase** (first 24 to 48 hours) after a burn injury. The extent of the inflammatory response depends on the burn severity. **Chapter 17** explains inflammation and the inflammatory responses in detail.

*Sympathetic nervous system compensation* is the stress response that occurs when any physical stressors are present. Changes caused by sympathetic compensation are most evident in the cardiovascular, respiratory, and GI systems. **Fig. 26-7** shows the results of sympathetic nervous system stimulation.

**FIG. 26-7** Physiologic actions of the sympathetic nervous system compensatory responses to burn injury (early phase).

## Etiology

Burn injuries are caused by dry heat (flame), moist heat (scald), contact with hot or rough surfaces, chemicals, electricity, and ionizing radiation. The cause of the injury affects both the prognosis and the treatment.

*Dry heat injuries* are caused by open flame in house fires and explosions. Explosions usually result in flash burns because they produce a brief exposure to very high temperatures.

*Moist heat (scald) injuries* are caused by contact with hot liquids or steam. Scald injuries are more common among older adults than younger adults. Hot liquid spills usually burn the upper, front areas of the body. Immersion scald injuries usually involve the lower body.

*Contact burns* occur when hot metal, tar, or grease contacts the skin, often leading to a full-thickness injury. Hot metal injuries occur when a body part contacts a hot surface, such as a space heater or iron. They also can occur in industrial settings from molten metals. Tar and asphalt temperatures usually are greater than 400° F (204.4° C), and deep injuries occur within seconds when the skin is immersed in or splashed with them. Hot grease injuries from cooking are usually deep because of the high temperature of the grease.

*Chemical burns* occur in home or industrial accidents or as the result of assault. Injury occurs when chemicals directly contact the skin and epithelial tissues or are ingested. The severity of the injury depends on the duration of contact, the concentration of the chemical, the amount of tissue exposed, and the action of the chemical.

Alkalis found in oven cleaners, fertilizers, drain cleaners, and heavy industrial cleaners damage the tissues by causing the skin and its proteins to liquefy. This allows for deeper spread of the chemical and more severe burns. Acids found in bathroom cleaners, rust removers, pool chemicals, and industrial drain cleaners damage TISSUE INTEGRITY by coagulating cells and skin proteins, which can limit the depth of tissue damage. Chemical disinfectants and gasoline are easily absorbed through the skin and have toxic effects on the kidneys and liver.

*Electrical injuries* are burns occurring when an electrical current enters the body (Fig. 26-8). These injuries have been called the “grand masquerader” of burns because the surface injuries may look small but the associated internal injuries can be huge. Tissue injury from electrical trauma results from electrical energy being converted to heat energy. The extent of injury depends on the type of current, the pathway of flow, the local tissue resistance, and the duration of contact. Once the current penetrates the skin, it flows throughout the involved body part, generating heat and damaging tissues. Deep muscle injury may be present even when superficial muscles appear normal or uninjured.

**FIG. 26-8** Mechanism of electrical injury: currents passing through the body follow the path of least resistance to the ground.

The longer the electricity is in contact with the body, the greater the damage. The duration of

contact is increased by tetanic contractions of the strong flexor muscles in the forearm, which can prevent the person from releasing the electrical source.

It is difficult to know the exact path a current takes in the body. The course of flow is defined by the locations of the “contact sites,” which are the entrance and exit wounds (Fig. 26-9). At first the wounds may not be obvious. The path of the injury may involve many internal organs between the two contact sites.

**FIG. 26-9** Electrical entrance and exit wounds. **A**, Possible entrance site. **B**, Possible exit site.

Burn injuries from electricity can occur as *thermal burns*, *flash burns*, or *true electrical injury*. Thermal burns occur when clothes ignite from heat or flames produced by electrical sparks. External burn injuries can occur when the electrical current jumps, or “arcs,” between two body surfaces. These injuries usually are severe and deep. True electrical injury occurs when direct contact is made with an electrical source. Internal damage results and can be devastating. Damage starts on the inside and goes out; deep-tissue destruction may not be apparent immediately after injury. Organs in the path of the current may become ischemic and necrotic.

*Radiation injuries* occur when people are exposed to large doses of radioactive material. The most common type of tissue injury from radiation exposure occurs with therapeutic radiation. This injury is usually minor and rarely causes extensive skin damage.

Radiation exposure is more serious in industrial settings where radioactive energy is produced or used. Injury severity depends on the type of radiation, distance from the source, duration of exposure, absorbed dose, and depth of penetration into the body. [Chapter 22](#) discusses potential tissue damage from alpha, beta, and gamma radiation.

### **Incidence/Prevalence**

Fires and burns are associated with unintentional injury deaths and fatal home injuries. Fire is the third leading cause of death in children between 2 and 14 years ([National Safety Council, 2017](#)).

Although the number of fatalities and injuries caused by residential fires has declined gradually over the past several decades, many residential fire-related deaths remain preventable and continue to pose a significant public health problem.

An estimated 3280 fire and burn deaths occur each year from all sources of burn injury ([Haynes, 2016](#)). Most deaths occur at the scene of the incident or during transport.

The number of deaths from burn injuries decreases with appropriate intervention. Factors that increase the risk for death include age older than 60 years, a burn greater than 40% TBSA, and the presence of an inhalation injury. When a patient has all three of these factors, the risk for death is very high. Better outcomes from burn injuries occur because of vigorous fluid resuscitation, early burn wound excision, improved critical care monitoring, early enteral NUTRITION, antibiotics, and the use of specialized burn centers.

## Health Promotion and Maintenance

Minor burns are common, and prevention involves planning and awareness. Teach all people to assess how hot the water is before bathing, showering, or immersing a body part in it. Hot water tanks should be set below 140° F (60° C). Reinforce the use of potholders when taking food from ovens. Stress the importance of never adding a flammable substance (e.g., gasoline, kerosene, alcohol, lighter fluid, charcoal starter) to an open flame. Suggest the use of sunscreen agents and protective clothing to avoid sunburn.

Teach people to reduce the risk for house fires by never smoking in bed, avoiding smoking when drinking alcohol or taking drugs that induce sleep, and keeping matches and lighters out of the reach of children or people who are cognitively impaired. When space heaters are used, stress the importance of keeping clothing, bedding, and other flammable objects away from them. Remind people to keep the screens and doors closed on the fronts of fireplaces and to have chimneys swept each year. Also remind patients using home oxygen not to smoke or have open flames in a room where oxygen is in use.

Leaving a burning building is critical to prevent injury or death. Teach all people to use home smoke detectors and carbon monoxide detectors and to ensure that these are in good working order. The number of detectors needed depends on the size of the home. Recommendations are that each bedroom has a separate smoke detector; there should be at least one detector in the hallway of each story and at least one detector is needed for the kitchen, each stairwell, and each home entrance. Teach everyone to develop a planned escape route with alternatives for when a main route is blocked by fire. Reinforce that no one should ever re-enter a burning building to retrieve belongings.

# Resuscitation Phase of Burn Injury

## Overview

Events within the first hour after injury can make the difference between life and death for the patient with a burn injury. Immediate care focuses on maintaining an open airway, ensuring adequate breathing and circulation, limiting the extent of injury, and maintaining the function of vital organs. [Chart 26-1](#) outlines the emergency management of a burn injury.

### Chart 26-1

## Best Practice for Patient Safety & Quality Care QSEN

### Emergency Management of Burns

#### General Management for All Types of Burns

- Assess for airway patency.
- Administer oxygen as needed.
- Cover the patient with a blanket.
- Keep the patient on NPO status.
- Elevate the extremities if no fractures are obvious.
- Obtain vital signs.
- Initiate an IV line and begin fluid replacement.
- Administer tetanus toxoid for prophylaxis.
- Perform a head-to-toe assessment.

#### Specific Management

##### Flame Burns

- Smother the flames.
- Remove smoldering clothing and all metal objects.

##### Chemical Burns

- If dry chemicals are present on skin or clothing, DO NOT WET THEM.
- Brush off any dry chemicals present on the skin or clothing.
- Remove the patient's clothing.
- Ascertain the type of chemical causing the burn.
- Do not attempt to neutralize the chemical unless it has been positively identified and the appropriate neutralizing agent is available.

##### Electrical Burns

- At the scene, separate the patient from the electrical current.

- Smother any flames that are present.
- Initiate cardiopulmonary resuscitation.
- Obtain an electrocardiogram (ECG).

### Radiation Burns

- Remove the patient from the radiation source.
- If the patient has been exposed to radiation from an unsealed source, remove his or her clothing (using tongs or lead protective gloves).
- If the patient has radioactive particles on the skin, send him or her to the nearest designated radiation decontamination center.
- Help the patient bathe or shower.

The **resuscitation phase** is the first phase of a burn injury. It begins at the onset of injury and continues for about 24 to 48 hours. During this phase, the injury is evaluated and the immediate problems of fluid imbalance (loss), edema, and reduced blood flow are assessed. The priorities for management during this period are to (1) secure the airway, (2) support circulation and organ PERFUSION by fluid replacement, (3) keep the patient comfortable with analgesics, (4) prevent infection through careful wound care, (5) maintain body temperature, and (6) provide emotional support.

### ❖ Interprofessional Collaborative Care

Care of the patient with burns may take place in various locations depending on the severity of burn. Patients with very minor burns may be treated in an outpatient setting, whereas patients with more serious burns are likely to be treated initially in an emergency department (ED) and then hospitalized.

### ◆ Assessment: Noticing

#### History.

Knowledge of circumstances surrounding the burn injury is valuable in planning the management of a burn patient. If possible, obtain information directly from the patient. If this is not possible, ask family members or witnesses to the event. Ask about the circumstances of the injury, the time and place of injury, and the source and cause of injury. Ask detailed questions about how the burn occurred and the events occurring from the time of injury until help arrived. Also obtain demographic data, health history (including pre-existing illness), drug use, any additional injuries, and pain information.

Demographic data include age, weight, and height. The rate of serious complications and death from burn injuries is increased among adults older than 50 years. [Chart 26-2](#) lists the age-related differences in older adults' responses to a burn injury. The patient's preburn weight is used to calculate fluid rates, energy requirements, and drug doses. This weight is the *dry weight*, because it is the patient's weight before edema forms. Calculations based on a weight obtained after fluid replacement is started are not accurate. Height is important in determining total body surface area (TBSA), which is used to calculate NUTRITION needs.

### ■ Chart 26-2

## Nursing Focus on the Older Adult

### Age-Related Changes Increasing Complications from Burn Injury

AGE-RELATED CHANGES	COMPLICATIONS AND NURSING CONSIDERATIONS
Thinner skin, sensory impairment, decreased mobility	Sensory impairment and decreased mobility increase the risk for burn injury.

	Thinner skin increases the depth of injury even when the exposure to the cause of injury is of shorter duration.
Slower healing time	Longer time with open areas results in a greater risk for infection, metabolic derangements, and loss of function from contracture formation and scar tissue.
More likely to have cardiac impairments	Limits the aggressiveness of fluid resuscitation. Increases the risk for shock and acute kidney injury (AKI).
Reduced inflammatory and immune responses	Increases the risk for infection and sepsis. Patient may not have a fever when infection is present.
Reduced thoracic and pulmonary compliance	Increased risk for atelectasis, hypoxia, and other pulmonary complications.
More likely to have pre-existing medical conditions such as diabetes mellitus, kidney impairment, or pulmonary impairment	Any of these disorders compromise vital organ function and can interfere with fluid resuscitation efforts or other treatments.

A health history, including any pre-existing illnesses, must be known for appropriate management. Obtain specific information about the patient's history of cardiac or kidney problems, chronic alcoholism, substance abuse, and diabetes mellitus; any of these problems influence fluid resuscitation. The stress of a burn can make a mild disease process worsen. Obtain a drug history that includes allergies, current drugs, and immunization status from the patient or family. Determine the dose and time the last drug was taken. Ask whether the patient smokes or drinks alcohol daily; these factors influence treatment plans and responses.

Other injuries may occur at the time of the burn. Such injuries increase the risk for complications or death. Determine whether additional injuries such as fractures, chest injuries, and abdominal trauma are causing alterations in COMFORT.

### Physical Assessment/Signs and Symptoms.

Physical assessment findings in the resuscitation phase differ greatly from findings later in the course of the injury. Use a systematic approach to ensure that no problem is missed. Assessment of the respiratory system is most critical to prevent life-threatening complications.

#### Respiratory Assessment.

Patients with major burn injuries and those with inhalation injury, as listed in [Table 26-3](#), are at risk for respiratory problems. *Thus continuous airway assessment is a nursing priority.*

**TABLE 26-3**

#### Factors Determining Inhalation Injury or Airway Obstruction

- Patients who were injured in a closed space
- Intra-oral charcoal, especially on teeth and gums
- Patients who were unconscious at the time of injury
- Patients with singed scalp hair, nasal hairs, eyelids, or eyelashes
- Patients who are coughing up carbonaceous sputum
- Changes in voice such as hoarseness or brassy cough
- Use of accessory muscles or stridor
- Poor oxygenation or ventilation
- Edema, erythema, and ulceration of airway mucosa
- Wheezing, bronchospasm
- Patients with extensive burns or burns of the face

#### Direct Airway Injury.

The degree of inhalation damage depends on the fire source, temperature, environment, and types of toxic gases generated. Ask about the source of the fire, duration of exposure, and whether the fire was in an enclosed space. Inspect the mouth, nose, and pharynx. Burns of the lips, face, ears, neck, eyelids, eyebrows, and eyelashes are strong indicators that an inhalation injury may be present. Burns inside the mouth and singed nasal hairs also indicate possible inhalation injury. Black particles of carbon in the nose, mouth, and sputum and edema of the nasal septum indicate smoke inhalation, as does a "smoky" smell to the patient's breath.

A change in respiratory pattern may indicate a pulmonary injury. The patient may:

- Become progressively hoarse
  - Develop a brassy cough
  - Drool or have difficulty swallowing
  - Produce sounds on exhalation that include audible wheezes, crowing, and stridor
- Any of these changes may mean the patient is about to lose his or her airway.

## Nursing Safety Priority QSEN

### Critical Rescue

Monitor patient's respiratory efforts closely to recognize possible airway involvement. For a burn patient in the resuscitation phase who is hoarse, has a brassy cough, drools or has difficulty swallowing, or produces an audible breath sound on exhalation, respond by immediately applying oxygen and notifying the Rapid Response Team.

Upper-airway edema and inhalation injury are most common in the trachea and mainstem bronchi. Auscultation of these areas may reveal wheezes, which indicate partial obstruction. *Patients with severe inhalation injuries may have such rapid obstruction that, within a short time, they cannot force air through the narrowed airways. As a result, the wheezing sounds disappear. This finding indicates impending airway obstruction and demands immediate intubation.* Many patients are intubated when an inhalation injury is first suspected rather than waiting until obstruction makes intubation difficult or impossible.

### Carbon Monoxide Poisoning.

Carbon monoxide (CO) is one of the leading causes of death from a fire. It is a colorless, odorless, tasteless gas released in the process of combustion. Inhalation injury is a risk for carbon monoxide poisoning (Lafferty et al., 2017).

CO is rapidly transported across the lung membrane and binds tightly to hemoglobin in place of oxygen to form carboxyhemoglobin (COHb), which impairs oxygen unloading at the tissue level. Even though the oxygen-carrying capacity of the hemoglobin is reduced, the blood gas value of partial pressure of arterial oxygen (PaO<sub>2</sub>) is normal (Laing, 2013). The vasodilating action of carbon monoxide causes the “cherry red” color (or at least the absence of cyanosis) in these patients. Symptoms vary with the concentration of COHb (Table 26-4).

**TABLE 26-4**  
**Physiologic Effects of Carbon Monoxide Poisoning**

CARBON MONOXIDE LEVEL	PHYSIOLOGIC EFFECTS
1%-10% (normal)	Increased threshold to visual stimuli Increased blood flow to vital organs
11%-20% (mild poisoning)	Headache Decreased cerebral function Decreased visual acuity Slight breathlessness
21%-40% (moderate poisoning)	Headache Tinnitus Nausea Drowsiness Vertigo Altered mental state Confusion Stupor Irritability Decreased blood pressure, increased and irregular heart rate Depressed ST segment on ECG and dysrhythmias Pale to reddish-purple skin
41%-60% (severe poisoning)	Coma Convulsions Cardiopulmonary instability
61%-80% (fatal poisoning)	Death

ECG, Electrocardiogram.

## NCLEX Examination Challenge 26-1

### Health Promotion and Maintenance

The client asks about ways to prevent carbon monoxide poisoning. Which teaching will the nurse provide?

- A. "You can see black smoke when carbon monoxide is in the air."
- B. "If you are experiencing carbon monoxide poisoning, your skin will begin to turn blue."
- C. "The only way to get poisoned from carbon monoxide gas is if you are in the presence of a fire."
- D. "It is important to have carbon monoxide detectors in your home because this is an odorless gas."

### Thermal (Heat) Injury.

Except for steam inhalation, aspiration of scalding liquid, or explosion of flammable gases under pressure, thermal burns to the respiratory tract are usually limited to the upper airway above the glottis (nasopharynx, oropharynx, and larynx).

## Nursing Safety Priority QSEN

### Action Alert

Heat damage of the pharynx is often severe enough to produce edema and upper airway obstruction, especially epiglottitis. The problem can occur any time during resuscitation. In the unresuscitated patient, supraglottic edema may be delayed because of the dehydration that occurs with hypovolemia. However, during fluid resuscitation, the tissues rehydrate and then swell. When it is known that the upper airways were exposed to heat, intubation may be performed as an early intervention before obstruction occurs. When intubation has not been performed in a patient whose upper airways were exposed to heat or toxic gases, continually assess the upper airway for recognition of edema and obstruction.

Inhaled steam can injure the lower respiratory tract down to the major bronchioles. Ulcerations, redness, and edema of the mouth and epiglottis occur first, with rapid swelling leading to upper airway obstruction. Stridor, hoarseness, and shortness of breath result.

### Smoke Poisoning.

Smoke poisoning, or chemical injury from the inhalation of combustion by-products, is a common type of inhalation injury. Toxic by-products are produced when plastics or home furnishings are burned. The products impair respiratory cell function.

### Pulmonary Fluid Overload.

Pulmonary edema can occur even when the lung tissues have not been damaged directly. Other damaged tissues release such large amounts of inflammatory mediators, causing capillary leak, that even lung capillaries leak fluid into the pulmonary tissue spaces.

Circulatory overload from fluid resuscitation may cause congestive heart failure. This problem creates high pressure within pulmonary blood vessels that pushes fluid into the lung tissue spaces. Excess lung tissue fluid makes GAS EXCHANGE difficult. *The patient is short of breath and has dyspnea in the supine position. Crackles are heard on auscultation.*

## Nursing Safety Priority QSEN

### Critical Rescue

Monitor patients' respiratory efforts closely to recognize possible development of pulmonary edema. When signs and symptoms of pulmonary edema are present, respond by elevating the head of the bed to at least 45 degrees, applying oxygen, and notifying the burn team or the Rapid Response Team.

## External Factors.

Patients with burn injuries also may have breathing problems from external factors, such as tight eschar from deep circumferential chest burns. The eschar either restricts chest movement or compresses structures in the neck and throat so airflow is impaired. Inspect the patient's chest hourly for ease of respiration, amount of chest movement, rate of breathing, and effort. If the patient is being mechanically ventilated, increased airway pressures may indicate the need for an escharotomy. Use continuous pulse oximetry to assess breathing effectiveness in maintaining blood oxygen levels.

## Cardiovascular Assessment.

Changes in the cardiovascular system begin immediately after the burn injury and include shock as a result of disrupted FLUID AND ELECTROLYTE BALANCE. *Hypovolemic shock is a common cause of death in the resuscitation phase in patients with serious injuries.* See [Chapter 37](#) for discussion of shock.

At first, cardiac signs and symptoms are caused by hypovolemia and decreased cardiac output. Monitor the degree of edema and assess cardiac status by measuring central and peripheral pulses, blood pressure, capillary refill, and pulse oximetry. Noninvasive blood pressure readings are inaccurate in patients with large burns of the upper extremities, and invasive blood pressure monitoring may be needed. At first, the patient has tachycardia, decreased blood pressure, and decreased peripheral pulses. Peripheral capillary refill is slow or absent as blood flow decreases. With fluid resuscitation, peripheral edema increases, as does the patient's weight.

Electrocardiographic (ECG) changes can indicate damage to the heart as a result of electrical burn injuries or stress that induces a myocardial infarction. Obtain baseline ECG tracings at the time of admission and continue the ECG monitoring throughout the resuscitation phase. Compare current ECG tracings with the initial tracings to assess whether the patient is experiencing new-onset conduction abnormalities from the burn injury or the fluid resuscitation.

## Kidney/Urinary Assessment.

Changes in kidney function with burn injury are related to decreased blood flow and cellular debris. During the fluid shift, blood flow to the kidney may not be adequate for filtration. As a result, urine output is greatly decreased compared with IV fluid intake. The urine is very concentrated and has a high specific gravity.

Other substances may be present in the blood that flows through the kidney. Destroyed red blood cells release hemoglobin and potassium. When muscle damage occurs from a major burn or electrical injury, *myoglobin* is released from damaged muscle and circulates to the kidney. Most damaged cells release proteins that form uric acid. All of these large molecules in the blood may precipitate in the kidney tubular system. A "sludge" then forms that blocks kidney blood and urine flow and may cause kidney failure.

Assess kidney function by accurately measuring urine output hourly and comparing this value with fluid intake. Urine output is decreased during the first 24 hours of the resuscitation phase. Fluid resuscitation is provided at the rate needed to maintain urine output at 30 to 50 mL per hour or 0.5 mL/kg/hr. Assess response to fluid resuscitation by measuring urine specific gravity, blood urea nitrogen (BUN), serum creatinine, and serum sodium levels in addition to hourly urine output. Examine the urine for color, odor, and the presence of particles or foam.

## Skin Assessment.

Assess the skin to determine the size and depth of burn injury. The size of the injury is first estimated in comparison with the *total body surface area (TBSA)*. For example, a burn that involves 40% of the TBSA is a 40% burn. The size of the injury is important not only for diagnosis and prognosis but also for calculating drug doses, fluid replacement volumes, and caloric needs.

Inspect the skin TISSUE INTEGRITY to identify injured areas and changes in color and appearance. Except with electrical burns, this initial size assessment usually can be made accurately with specific assessment tools and charts.

The most rapid method for calculating the size of a burn injury in adult patients whose weights are in normal proportion to their heights is the *rule of nines* ([Fig. 26-10](#)). With this method, the body is divided into areas that are multiples of 9%. It is useful at the site of injury, but more accurate evaluations using other methods are made in the burn unit.

**FIG. 26-10** Rule of nines for estimating burn percentage.

Because specific treatments are related to the depth of the burn injury, initial assessment of the skin includes estimations of burn depth. Criteria for depth of injury are based on appearance and associated characteristics (see the [Depth of Burn Injury](#) section).

Accurate evaluation of burn depth is performed using thermography, vital dyes, indocyanine green (ICG) video angiography, and laser Doppler imaging (LDI), which provide precise measurement of the amount of PERFUSION of the injured tissue. ICG and LDI are the most accurate of the three methods. LDI is used more frequently because it is relatively accurate, less invasive, and faster than the other methods ([Park et al., 2013](#)).

### **Gastrointestinal Assessment.**

Although the GI tract usually is not injured directly, changes in function occur in all burn patients. The decreased blood flow and sympathetic stimulation reduce GI motility and promote development of a paralytic ileus. Bowel sounds are usually reduced or absent in a patient with severe burns. Other indications of a paralytic ileus include nausea, vomiting, and abdominal distention. Patients with burns of 25% TBSA or who are intubated generally require a nasogastric (NG) tube inserted to prevent aspiration and remove gastric secretions. Assess the tube for placement and patency after insertion. Examine each stool and vomitus for gross blood or other material that indicates partially digested blood (“coffee ground”-appearing crumbs). Test for the presence of occult blood on any vomit or stool.

### **Laboratory Assessment.**

Certain changes in laboratory test values are found in different phases of postburn recovery and reflect tissue damage or compensatory responses. However, other changes in specific laboratory findings may suggest complications.

During the resuscitation phase and before the start of fluid resuscitation, blood analysis reflects the fluid shift and direct tissue damage. Baseline laboratory test values and early postburn expected changes are listed in [Chart 26-3](#).

### **Chart 26-3**

## **Laboratory Profile**

## Burn Assessment During the Resuscitation Phase

TEST	NORMAL RANGE FOR ADULTS	NORMAL RANGE FOR ADULTS (♣)	SIGNIFICANCE OF ABNORMAL FINDINGS
<b>Serum Studies</b>			
Hemoglobin	12-16 g/dL (women) 14-18 g/dL (men)	120-160 g/L (women) 140-180 g/L (men)	Elevated as a result of fluid volume loss
Hematocrit	37%-47% (women) 42%-52% (men)	0.37-0.47 volume fraction (women) 0.42-0.52 volume fraction (men)	Elevated as a result of fluid volume loss
Urea nitrogen	10-20 mg/dL	3.6-7.1 mmol/L (older adult may be slightly higher)	Elevated as a result of fluid volume loss
Glucose	74-106 mg/dL	4.1-5.9 mmol/L	Elevated as a result of the stress response and altered uptake across injured tissues
<b>Electrolytes</b>			
Sodium	136-145 mEq/L (mmol/L)	136-145 mEq/L (mmol/L)	Decreased; sodium is trapped in edema fluid and lost through plasma leakage
Potassium	3.5-5.0 mEq/L (mmol/L)	3.5-5.0 mEq/L (mmol/L)	Elevated as a result of disruption of the sodium-potassium pump, tissue destruction, and red blood cell hemolysis
Chloride	98-106 mEq/L (mmol/L)	98-106 mEq/L (mmol/L)	Elevated as a result of fluid volume loss and reabsorption of chloride in urine
<b>Arterial Blood Gas Studies</b>			
PaO <sub>2</sub>	80-100 mm Hg	80-100 mm Hg	Slightly decreased
PaCO <sub>2</sub>	35-45 mm Hg	35-45 mm Hg	Slightly increased from respiratory injury
pH	7.35-7.45	7.35-7.45	Low as a result of metabolic acidosis
Carboxyhemoglobin (COHb)	0%-10%	No greater than 10%; over 20% is considered critical	Elevated as a result of inhalation of smoke and carbon monoxide
<b>Other</b>			
Total protein	6.4-8.3 g/dL	64-83 g/L	Low; protein exudate is lost through the wound
Albumin	3.5-5.0 g/dL	35-50 g/L	Low; protein is lost through the wound and through vascular membranes because of increased permeability

Data from Pike-MacDonald, S. (Ed.). (2013). *Mosby's Canadian manual of diagnostic and laboratory tests* (1st Canadian ed.). Toronto: Elsevier Canada; and Pagana, K., Pagana, T. J., & Pagana, T. N. (2017). *Mosby's diagnostic and laboratory test reference* (13th ed.). St. Louis: Mosby.

Changes in the total white blood cell (WBC) count and differential reflect immune function and inflammatory responses to the burn injury. The burn patient's total WBC count, especially the neutrophil percentage, first rises and then drops rapidly, with a "left shift" (see [Chapter 17](#)) as the immune system becomes unable to sustain its defenses. If sepsis occurs, the total WBC count may be as low as 2000 cells/mm<sup>3</sup> ( $2 \times 10^9/L$ ).

Other laboratory tests that provide useful information about the burn patient's status include urine electrolyte assays, urine cultures, liver enzyme studies, and clotting studies. Drug and alcohol screens are obtained if drug or alcohol intoxication is suspected.

## Cultural/Spiritual Considerations

### Patient-Centered Care OSEN

For African-American patients, a sickle cell preparation is performed if sickle status is unknown. The trauma of a burn injury can trigger a sickle cell crisis in patients who have the disease and those who carry the trait.

### Imaging Assessment.

Standard x-rays and scans do not provide direct assessment data about the burn wound. These assessments are not performed unless other trauma is suspected.

### Other Diagnostic Assessment.

Specific diagnostic studies are performed when deep organ trauma is suspected. Such studies include renal scans, computed tomography (CT), ultrasonography, bronchoscopy, and magnetic resonance imaging (MRI). When burn injuries involve the eye, an ophthalmic evaluation is performed to detect corneal damage (see [Chapters 46](#) and [47](#) for specific eye and vision evaluation procedures).

### ◆ Analysis: Interpreting

The priority collaborative problems for patients with burn injuries in the resuscitation phase who have sustained a burn injury greater than 25% of the TBSA include:

1. Potential for decreased oxygenation due to upper airway edema, pulmonary edema, airway obstruction, or pneumonia
2. Potential for shock due to increase in capillary permeability, active fluid volume loss, electrolyte

imbalance, and inadequate fluid resuscitation

3. Pain (acute and chronic) due to tissue injury, damaged or exposed nerve endings, débridement, dressing changes, invasive procedures, and donor sites

4. Potential for acute respiratory distress syndrome (ARDS) due to inhalation injury

### ◆ **Planning and Implementation: Responding**

#### **Supporting Oxygenation**

##### **Planning: Expected Outcomes.**

With proper intervention, the patient is expected to maintain a patent airway and have adequate oxygenation. Indicators include that the patient should have either normal or nearly normal oxygen saturation, PaO<sub>2</sub>, PaCO<sub>2</sub>, and arterial pH.

##### **Interventions.**

Nursing and medical interventions are used to support normal pulmonary function and prevent the pulmonary problems that can result from lung injury or fluid overload and heart failure. (Even young healthy people can develop fluid overload and heart failure.) Specific management plans depend on the cause of the problem and the status of the respiratory tract. *Thus monitoring the patient's respiratory status is a priority nursing intervention.*

##### **Nonsurgical Management.**

Interventions include airway maintenance, promotion of ventilation, monitoring GAS EXCHANGE, oxygen therapy, drug therapy, positioning, and deep breathing.

*Airway maintenance* begins at the burn scene in an unconscious patient and may involve only a chin-lift or a head-tilt maneuver. *Remember that upper airway edema becomes pronounced 8 to 12 hours after the beginning of fluid resuscitation. Then patients often require nasal or oral intubation if crowing, stridor, or dyspnea is present.*

A bronchoscopy is performed to examine the vocal cords and airways of patients at risk for obstruction. Patients with severe smoke inhalation or poisoning may require a bronchoscopy on admission and routinely thereafter for examination of the respiratory tract, deep suctioning of the lungs, and removal of sloughing necrotic tissue. Assess the endotracheal tube hourly to ensure patency and location in intubated patients.

Other causes of airway obstruction are excessive secretions and sloughed tissue from damaged lungs. Suction as indicated based on clinical assessment. Vigorous endotracheal or nasotracheal tube suctioning is performed after chest physiotherapy and aerosol treatments. Patients report that deep endotracheal suctioning is extremely painful. Therefore suctioning the endotracheal tube often requires increased analgesia or sedation.

*Promoting ventilation* includes ensuring that skeletal muscle movement of the chest is adequate for ventilation. Chest movement can be restricted by eschar and tight dressings that cover the neck, chest, and abdomen. Observe the patient for ease of respiratory movements and loosen tight dressings as needed to assist with ventilation.

*Monitor* for GAS EXCHANGE by using laboratory tests (e.g., arterial blood gas, carboxyhemoglobin levels) and assessing for cyanosis, disorientation, and increased pulse rate. Additional monitoring may include chest x-ray findings, pulmonary artery catheter pressures, and central venous pressure measurement.

Cyanide poisoning may occur in patients burned in house fires. An elevated plasma lactate level is one indicator of cyanide toxicity even in patients who do not have severe burns.

*Oxygen therapy* with humidified oxygen by facemask, cannula, or hood is used to manage any breathing impairment in the burn patient. Arterial oxygenation less than 60 mm Hg is an indication for intubation and mechanical ventilation. Keep emergency airway equipment near the bedside. This equipment includes oxygen, masks, cannulas, manual resuscitation bags, laryngoscope, endotracheal tubes, and equipment for tracheostomy. [Chapter 32](#) addresses specific nursing actions for patients during mechanical ventilation.

*Drug therapy* with antibiotics is used when pneumonia or other pulmonary infections impair

breathing. Drug selection is based on known culture and sensitivity reports or on the specific organisms common to that burn unit.

Patients with pulmonary edema and any degree of heart failure may receive beta blockers to improve left ventricular function and prevent or treat pulmonary edema. Diuretics, a mainstay of therapy for pulmonary edema from other causes, may or may not be used in the resuscitation phase, depending on the patient's blood volume and kidney function.

When a patient's activity during mechanical ventilation severely compromises respiratory mechanics, it may be necessary to use a paralytic drug, such as atracurium or vecuronium. Paralytic drugs remove all breathing control from the patient, making mechanical ventilation easier. *These drugs do not prevent the patient from seeing and hearing or from experiencing fear, pain, and loss of control. Any patient receiving neuromuscular blockade drugs must also receive drugs for sedation, analgesia, and antianxiety unless clinically contraindicated.*

## Nursing Safety Priority QSEN

### Action Alert

As required by The Joint Commission's National Patient Safety Goals, ensure that all alarms are operative on ventilators. Check patients who are receiving neuromuscular blockage frequently, because they cannot call for help if they become extubated accidentally.

*Positioning and deep breathing* can improve breathing and GAS EXCHANGE. Turn the patient frequently and assist him or her out of bed to a chair as much as possible. Teach the patient to use coughing and deep-breathing exercises. Urge him or her to use incentive spirometry hourly while awake. Chest physiotherapy may be helpful to mobilize lung secretions.

### Surgical Management.

A tracheotomy may be needed when long-term intubation is expected. This procedure increases the risk for infection in burn patients even more than in nonburned patients. Emergency tracheotomies are performed when an airway becomes occluded and oral or nasal intubation cannot be achieved.

Other surgical procedures for improving the burn patient's GAS EXCHANGE include inserting chest tubes and performing an escharotomy. Chest tubes are used to re-expand the lung when a pneumothorax or hemothorax has occurred (see [Chapter 32](#)). Tight eschar on the neck, chest, or abdomen can restrict respiratory movement. Escharotomies (described in the following [Surgical Management](#) section) can relieve this restriction and permit greater respiratory movement.

## Preventing Hypovolemic Shock and Inadequate Gas Exchange

### Planning: Expected Outcomes.

With appropriate intervention, the patient is expected to have blood pressure and tissue oxygenation restored to normal. Indicators include these vital signs and assessment parameters:

- Blood pressure at or near the patient's normal range
- Palpable peripheral pulses (or heard with Doppler) in all extremities
- Oxygen saturation, partial pressure of arterial oxygen (PaO<sub>2</sub>), partial pressure of arterial carbon dioxide (PaCO<sub>2</sub>), and arterial pH at or near the normal ranges

### Interventions.

Interventions focus on increasing blood fluid volume, supporting compensation, and preventing complications. Nonsurgical management is often sufficient for achieving these aims. Surgical management may be needed for full-thickness burns.

### Nonsurgical Management.

Fluid volume and tissue blood flow (PERFUSION) are restored through IV fluid therapy and drug therapy. Priority nursing interventions are carrying out fluid resuscitation and monitoring for indications of effectiveness or complications.

*Rapid infusion of IV fluids, known as fluid resuscitation, is needed to maintain sufficient blood*

volume for normal cardiac output, mean arterial pressure, and tissue oxygenation. [Chart 26-4](#) lists best practices for fluid resuscitation. There are many formulas for calculating IV fluid needs, but the most commonly used one for adult patients is the Parkland Formula (4 mL/kg/%TBSA burn of crystalloid solution). For example, the calculated fluid needs for a 154-lb man with a 50% TBSA burn would be  $4 \text{ mL} \times 70 \text{ kg} \times 50\% \text{ TBSA} = 14,000 \text{ mL}$  over the first 24 hours. Although the types and amounts of electrolytes, crystalloids, and colloids vary, the purpose of any formula is to prevent shock by maintaining blood fluid volume.

#### **Chart 26-4**

### **Best Practice for Patient Safety & Quality Care** QSEN

#### **Fluid Resuscitation of the Burn Patient**

- Initiate and maintain at least one large-bore IV line in an area of intact skin (if possible).
- Coordinate with physicians to determine the appropriate fluid type and total volume to be infused during the first 24 hours postburn.
- Administer one half of the total 24-hour prescribed volume within the first 8 hours postburn and the remaining volume over the next 16 hours.
- Assess IV access site, infusion rate, and infused volume at least hourly.
- Monitor these vital signs at least hourly:
  - Blood pressure
  - Pulse rate
  - Respiratory rate
  - Breath sounds
  - Voice quality (if not intubated)
  - Oxygen saturation
  - End-tidal carbon dioxide levels
- Assess urine output at least hourly:
  - Volume
  - Color
  - Specific gravity
  - Character

- Presence of protein
- Assess for fluid overload:
- Formation of dependent edema
- Engorged neck veins
- Rapid, thready pulse
- Presence of lung crackles or wheezes on auscultation
- Measure additional body fluid output hourly.

Resuscitation for a severe burn requires large fluid loads in a short time to maintain blood flow to vital organs. All common formulas recommend that half of the calculated fluid volume for 24 hours be given in the first 8 hours after injury. The other half is given over the next 16 hours for a total of 24 hours (Culleiton & Simko, 2013a). Fluid boluses are avoided because they increase capillary pressure and worsen edema. In the second 24-hour period after a burn injury, the volume and content of the IV fluids are based on the patient's specific FLUID AND ELECTROLYTE BALANCE needs and his or her response to treatment. This resuscitation involves hourly infusion volumes that are greatly in excess of the 125 mL to 150 mL per hour common infusion rates.

*Fluid replacement formulas are calculated from the time of injury and not from the time of arrival at the hospital. For example, if a burn injury occurred at 8 AM but the patient was not admitted to the hospital until 10 AM, the first 8-hour period would be completed at 4 PM (8 hours after the injury). Thus if resuscitation was delayed by 2 hours until admission to the hospital, calculated fluids would need to be given over the next 6-hour period rather than an 8-hour period. Burn resuscitation formulas are guides. The patient's response to therapy determines exact fluid requirements.*

The management of extensive burns requires a large-bore central venous catheter so massive fluid loads can be given. Peripheral lines are less useful.

Monitoring patient responses is critical to determine the adequacy of resuscitation for hydration and blood PERFUSION of the brain, heart, and kidneys. Urine output is the most common and most sensitive noninvasive assessment parameter for cardiac output and tissue PERFUSION. *Regardless of the total amount of fluid calculated as needed for the patient, the amount of fluid given depends on how much IV fluid per hour is needed to maintain the hourly urine output at 0.5 mL/kg (about 30 mL/hr).* Adjustment of the IV fluid rate on the basis of urine output plus serum electrolyte values is known as the *titration* of fluid. In burns larger than 35% TBSA, the use of invasive cardiac and pulmonary function monitoring may be needed in addition to urine output and vital signs to guide resuscitation.

Burn patients can develop severe hypovolemic shock and need invasive cardiac monitoring. Vital parameters such as central venous pressure, pulmonary artery pressures, and cardiac output are obtained on an hourly to continuous basis.

Monitor the ECG activity of patients who have sustained large burns. Compare current ECG findings with those obtained on admission.

## NCLEX Examination Challenge 26-2

### Safe and Effective Care Environment

Which assessment finding does the nurse interpret as demonstrating a client's fluid resuscitation adequacy?

A. Decreased skin turgor

- B. Decreased pulse pressure
- C. Decreased core body temperature
- D. Decreased urine specific gravity

*Drug therapy* for shock prevention in burn patients is different from that for the heart failure patient. A common mistake in management is giving diuretics to increase urine output rather than changing the amount and rate of fluid infused. *Diuretics do not increase cardiac output; they actually decrease circulating volume and cardiac output by pulling fluid from the circulating blood volume to enhance diuresis.* This effect reduces blood flow to other vital organs (especially the heart, lungs, and brain) and greatly increases the risk for severe hypovolemic shock. Therefore diuretics are not generally used to improve urine output for burn patients. An exception is the patient with an electrical burn injury. In electrical burns, muscle and deep-tissue damage release the large protein myoglobin, which precipitates in and obstructs the renal tubules. Although the diuretic mannitol (Osmitrol) is often used in this situation, it should always be given after adequate urine output has been established. Hourly urine output should be maintained at 0.5 mL/kg in adults (Rice et al., 2017).

## Considerations for Older Adults

### Patient-Centered Care OSEN

In older patients, especially those with cardiac disease, a complicating factor in fluid resuscitation may be heart failure or myocardial infarction. Drugs that increase cardiac output (e.g., dopamine [Intropin]) or that strengthen the force of myocardial contraction may be used along with fluid therapy. Assess the cardiac status of older adults at least every hour during fluid resuscitation.

### Surgical Management.

The surgical procedure for the treatment of inadequate tissue PERFUSION is *escharotomy*. An incision through the burn eschar relieves pressure caused by the constricting force of fluid buildup under circumferential burns on the extremity or chest and improves circulation. If the pressure is not relieved, arterial compression can occur with a loss of blood flow to the extremity, leading to ischemia and possible necrosis. Incisions are made along the length of the extremity and extend into the subcutaneous tissue, relieving the tourniquet effect of the eschar (see Fig. 26-5 and Fig. 26-11). If tissue pressure remains elevated after escharotomy, a *fasciotomy* (a deeper incision extending through the fascia) may be needed.

**FIG. 26-11** Escharotomy to release circumferential burn eschar and improve circulation to a distal extremity. **A**, Tight circumferential eschar restricting swelling as edema forms in the tissue beneath the eschar. Edema compresses blood vessels, which inhibits blood flow to the distal extremity. **B**, An escharotomy incision allows outward swelling of edematous tissues. The restricted blood flow to the distal extremity is relieved. **C**, An anterior axillary incision is made bilaterally to relieve respiratory distress.

### Managing Pain and Alterations in Comfort.

The pain associated with burn injuries is both chronic and acute, with the causes being

multifactorial. Accurate assessment of the patient's pain and COMFORT level before and during procedures is an essential part of pain management.

### Planning: Expected Outcomes.

The patient's pain level is expected to be alleviated or reduced. Indicators that a patient has pain or an alteration in COMFORT include reports of pain, moaning and/or crying, demonstrating facial grimace, and/or loss of appetite. Indicators that the patient's pain level or alteration in comfort has decreased include verbalization of lessened pain, relaxed facial expressions, and interest in activities that are within the patient's current capabilities (e.g., eating, therapy).

### Interventions.

Pain management is tailored to the patient's tolerance for pain, expectation for COMFORT level, coping mechanisms, and physical status. *The priority nursing actions include continually assessing the patient's pain level, using appropriate pain-reducing strategies, and preventing complications.*

### Nonsurgical Management.

Interventions for the patient having pain or COMFORT alterations include drug therapy, complementary therapy measures, and environmental manipulation.

*Drug therapy* for pain usually requires opioid analgesics (e.g., morphine sulfate, hydromorphone [Dilaudid], fentanyl) and nonopioid analgesics. Although these drugs may provide adequate pain relief when no procedures are being performed, they rarely offer more than moderate relief during painful procedures. They may depress respiratory function and reduce intestinal motility. Thus nonpharmacologic interventions also are needed for the burn patient.

During the resuscitation phase, the IV route is used for giving opioid drugs because of problems with absorption from the muscle and stomach (Culleiton & Simko, 2013b). When given IM or subcutaneously, these drugs remain in the tissue spaces and do not relieve pain. When edema is present, all the doses are rapidly absorbed at once when the fluid shift is resolving. This delayed but rapid absorption can result in lethal blood levels of opioids.

## Nursing Safety Priority QSEN

### Drug Alert

Give opioid drugs for pain only by the IV route during the resuscitation phase to prevent delayed rapid absorption leading to lethal blood levels.

Anesthetic agents, such as ketamine (Ketalar) and nitrous oxide, also reduce pain. Use strict protocols when giving these agents to prevent serious complications.

*Complementary and integrative therapy* measures for pain reduction include relaxation techniques, meditative breathing, guided imagery, music therapy, massage, and healing or therapeutic touch. Hypnosis and autohypnosis can be used by lucid, cooperative patients under the direction of trained therapists. Therapeutic touch, acupuncture, and acupressure are used to a limited extent for burn patients; the results are variable. Active music interventions for distraction have been useful in reducing patients' perceptions of pain and anxiety.

*Environmental changes*, such as providing a quiet environment, using nonpainful tactile stimulation, and increasing the patient's control, can increase COMFORT. Sleep deprivation increases patients' discomfort. Increasing sleep or rest time in a quiet environment helps reduce the adverse effects of sleep deprivation, replenishes hormone stores, helps prevent critical care unit psychosis, and restores the diurnal effects of endorphins. Coordinate with the interprofessional health care team to ensure that procedures are performed during the patient's waking hours.

Tactile stimulation can reduce pain. Help the patient change positions every 2 hours to reduce pressure on any specific area, improve circulation to painful areas, and ease pain. Massage nonburn areas to reduce pain transmission and stimulate endorphin release. Apply heat and maintain warm room temperatures to prevent shivering.

To reduce anxiety and increase feelings of confidence and independence, encourage the patient to participate in pain control measures. For example, make a contract with the patient that specifies how long a painful procedure will last. This helps patients deal with the pain for that particular

period. Patient-controlled analgesia (PCA) also reduces pain. Important issues and techniques for the best use of PCA include giving an initial bolus of 5 to 10 mg of morphine (or equivalent drug), increasing the PCA dose as needed to achieve pain relief, and planning for a change in dosing regimens at night (e.g., giving a bolus dose at bedtime). See [Chapter 4](#) for a detailed discussion of combination drug therapy for pain management.

### **Surgical Management.**

Early surgical excision of the burn wound is used in many burn centers (see the [Surgical Excision](#) section). Early excision under anesthesia reduces the pain from daily débridement at the bedside or during hydrotherapy.

## **Preventing Acute Respiratory Distress Syndrome (ARDS)**

### **Planning: Expected Outcomes.**

The patient with a burn injury is expected to:

- Not experience acute respiratory distress
- Have arterial blood gases (ABGs) within normal limits
- Maintain normal lung compliance

### **Interventions.**

Patients who develop acute respiratory distress syndrome (ARDS) from burn injuries require thorough assessments and interventions. Interventions focus on increasing lung compliance and improving partial pressure of arterial oxygen (PaO<sub>2</sub>) levels. The priority nursing care actions are coordinating respiratory therapy strategies and monitoring the patient's response to these interventions.

In collaboration with the health care provider and respiratory therapist, give positive end-expiratory pressure (PEEP) to provide a continuous positive pressure in the airways and alveoli. This procedure enhances the diffusion of oxygen across the alveolar-capillary membrane. PEEP can be combined with intermittent mandatory volume (IMV) to enhance its effectiveness.

Assess and document the patient's response so needed ventilator changes can be made. Monitor pulse oximetry and ABG levels to assess changes in respiratory status.

## **Nursing Safety Priority** QSEN

### **Critical Rescue**

Recognize indications of respiratory distress or change in respiratory patterns and respond by immediately reporting assessment findings to the burn team and the respiratory therapist.

Neuromuscular blocking drugs (atracurium) can be used in patients receiving mechanical ventilation to reduce oxygen consumption (see the discussion of specific nursing care in the Supporting Gas Exchange section).

### **◆Evaluation: Reflecting**

Evaluate the care of the patient in the resuscitation phase of burn injury based on the identified priority patient problem. The primary expected outcomes are that the patient will be properly oxygenated without GAS EXCHANGE complications, not experience hypovolemic shock, experience absence of or manageable levels of pain, and avoid Acute Respiratory Distress Syndrome (ARDS).

## **Clinical Judgment Challenge 26-1**

### **Patient-Centered Care; Teamwork and Collaboration; Evidence-Based Practice** QSEN

You are caring for a patient who sustained burns that are pink, moist, sensate, and blanching. Vital signs show a heart rate of 150 beats/min and blood pressure of 90/30. The patient's urine output is

15 mL/hr.

1. Based on the information provided, is the patient experiencing signs of shock?
2. Which degree burn does this patient have? Provide rationale.
3. How do you anticipate administering pain medication during the acute phase of burn injury?
4. With whom will you collaborate to provide the highest quality interprofessional care for this patient?

# Acute Phase of Burn Injury

## Overview

The acute phase of burn injury begins about 36 to 48 hours after injury, when the fluid shift resolves, and lasts until wound closure is complete. During this phase, the nurse coordinates interprofessional care that is directed toward continued assessment and maintenance of the cardiovascular and respiratory systems and toward GI and NUTRITION status, burn wound care, pain control, and psychosocial interventions.

## ❖ Interprofessional Collaborative Care

Patients in the acute phase of a more serious burn injury are most likely to be treated in an emergency department (ED).

### ◆ Assessment: Noticing

#### Physical Assessment/Signs and Symptoms

##### Cardiopulmonary Assessment.

*In the acute phase of burn injury, the priority nursing interventions are to assess the cardiovascular and respiratory systems to maintain these systems and to identify or prevent complications. At this time, the patient may develop pneumonia that can result in respiratory failure requiring mechanical ventilation. Although cardiovascular problems related to the fluid shift should be resolved, the patient is at risk for infection and sepsis, which affect cardiovascular function.*

##### Neuroendocrine Assessment.

The increased metabolic demands placed on the body after a severe burn injury can severely deplete NUTRITION stores. Weigh the patient daily without dressings or splints and compare the weight with his or her preburn weight. A 2% loss of body weight indicates a mild deficit. A 10% or more weight loss requires the evaluation and modification of calorie intake. For very accurate calorie requirements, indirect calorimetry may be used. This method assesses energy expenditure by measuring oxygen consumption and carbon dioxide production. Measurements are taken while the patient is at rest—usually at least 30 minutes after the most recent dressing changes or other stressful procedures. Indirect calorimetry may be performed on admission to a burn center and then weekly until the wounds are closed.

##### Immune Assessment.

The patient with a burn injury is at risk for infection because of open wounds and reduced immune function. *Burn wound sepsis is a serious complication of burn injury, and infection is the leading cause of death during the acute phase of recovery.* Continually assess the patient for signs and symptoms of local and systemic infections (Table 26-5), including changes in wound appearance, changes in neurologic and GI function, and subtle changes in vital signs. Monitor for signs and symptoms of gram-positive, gram-negative, and fungal infections (Table 26-6). Enforce meticulous handwashing by all care personnel.

**TABLE 26-5**

**Local and Systemic Indicators of Infection**

Local Indicators	Systemic Indicators
<ul style="list-style-type: none"> <li>• Conversion of a partial-thickness injury to a full-thickness injury</li> <li>• Ulceration of healthy skin at the burn site</li> <li>• Erythematous, nodular lesions in uninvolved skin and vesicular lesions in healed skin</li> <li>• Edema of healthy skin surrounding the burn wound</li> <li>• Excessive burn wound drainage</li> <li>• Pale, boggy, dry, or crusted granulation tissue</li> <li>• Sloughing of grafts</li> <li>• Wound breakdown after closure</li> <li>• Odor</li> </ul>	<ul style="list-style-type: none"> <li>• Altered level of consciousness</li> <li>• Changes in vital signs (tachycardia, tachypnea, temperature instability, hypotension)</li> <li>• Increased fluid requirements for maintenance of a normal urine output</li> <li>• Hemodynamic instability</li> <li>• Oliguria</li> <li>• GI dysfunction (diarrhea, vomiting, abdominal distention, paralytic ileus)</li> <li>• Hyperglycemia</li> <li>• Thrombocytopenia</li> <li>• Change in total white blood cell count (above or below normal)</li> <li>• Metabolic acidosis</li> <li>• Hypoxemia</li> </ul>

**TABLE 26-6**  
**Indications of Sepsis Caused by Different Organisms**

SIGNS AND SYMPTOMS	GRAM-POSITIVE	GRAM-NEGATIVE	FUNGAL
Onset	Insidious, 2-6 days	Rapid, 12-36 hr	Delayed
Cognition	Severe disorientation and lethargy	Mild disorientation	Mild disorientation
Ileus	Severe	Severe	Mild
Diarrhea	Rare	Severe	Occasional
Temperature	Fever	Hypothermia	Fever
Hypotension	Late	Early	Late
White blood cell count	Neutrophilia	Neutropenia	Neutrophilia
Platelets	Normal	Low	Low

## Nursing Safety Priority QSEN

### Action Alert

Use aseptic technique in caring for wounds and during invasive monitoring to prevent infection.

#### Musculoskeletal Assessment.

Patients with a burn injury are at risk for musculoskeletal and MOBILITY problems as a result of other injuries, immobility, healing processes, and treatment. The musculoskeletal status is evaluated on admission and throughout the postburn period. Assess active and passive range of motion for all joints, including the neck. Give special attention to joints in the burn area. Ranges and limitations are documented for future reference.

#### ◆ Analysis: Interpreting

During the acute phase of the burn injury, the patient may have initial problems that extend into the acute phase and may develop new problems. The priority collaborative problems for patients with burn injuries greater than 25% TBSA in the acute phase of recovery include:

1. Wound care management due to impaired TISSUE INTEGRITY associated with burn injury and skin grafting procedures
2. Potential for infection of open burn wounds due to the presence of multiple invasive catheters, reduced immune function, and poor NUTRITION
3. Weight loss due to increased metabolic rate, reduced calorie intake, and increased urinary nitrogen losses
4. Decreased MOBILITY due to open burn wounds, pain, scars, and contractures
5. Decreased self-esteem due to trauma, changes in physical appearance and lifestyle, and alterations in sensory and motor function

#### ◆ Planning and Implementation: Responding

##### Managing Wound Care

##### Planning: Expected Outcomes.

With appropriate intervention, the burn patient is expected to have no wound extension and have wounds healed. Indicators include that the patient:

- Has presence of granulation, re-epithelialization, and scar tissue formation
- Has decreased wound size
- Has no new wounds

##### Interventions.

Interventions focus on preserving skin TISSUE INTEGRITY, enhancing burn wound healing, and preventing complications.

## Nonsurgical Management.

Nonsurgical burn wound management involves removing exudates and necrotic tissue, cleaning the area, stimulating granulation and revascularization, and applying dressings. Restoring skin TISSUE INTEGRITY, whether by natural healing or grafting, starts with the removal of eschar and other cellular debris from the burn wound. This removal is called **débridement** and can be performed nonsurgically through mechanical or enzymatic actions that separate eschar over time. The purpose is to prepare the wound for grafting and wound closure by a natural process. *Priority nursing interventions include assessing the wound, providing wound care, and preventing infection and other complications.*

### Mechanical Débridement.

Burn wounds are débrided and cleaned one or two times each day during **hydrotherapy** (the application of water for treatment). Nurses, unlicensed assistive personnel (UAP), and physical therapists perform hydrotherapy daily to débride and examine the wounds. Hydrotherapy is performed by showering the patient on a special shower table or washing only small areas of the wound at the bedside. Showering enhances wound inspection and allows water temperature to be kept constant. Immersion of the patient in a tub or whirlpool is no longer performed because it increases the risk for infection.

Nurses and skilled technicians use forceps and scissors to remove loose, dead tissue during hydrotherapy. At most burn units, small blisters are left intact because they are a protective barrier that promotes wound healing. Larger blisters are opened. Washcloths or gauze sponges are used to débride soft, “cheesy” eschar. Wash burn areas thoroughly and gently with mild soap or detergent and water. Then rinse these areas with room-temperature water.

### Enzymatic Débridement.

Enzymatic débridement can occur naturally by autolysis or artificially by the application of exogenous agents. **Autolysis** is the disintegration of tissue by the action of the patient's own cellular enzymes. This process is seldom used alone in North America for larger burns because it is slow and prolongs the hospital stay, increasing the risk for infection.

Topical enzyme agents, such as collagenase (Santyl), are used for rapid wound débridement. When these agents are applied to the burn wound in a once-a-day dressing change, the enzymes digest collagen in necrotic tissues.

### Dressing the Burn Wound.

After burn wounds are cleaned and débrided, topical antibiotics are reapplied to prevent infection (see the Minimizing Infection section). Some type of dressing is then applied to the burn wound. Burn dressings include standard wound dressings, biologic dressings, synthetic dressings, and artificial skin.

#### Standard Wound Dressings.

Standard dressings are multiple layers of gauze applied over the topical agents on the wound. The number of gauze layers depends on:

- Depth of the injury
- Amount of drainage expected
- Area injured
- Patient's MOBILITY
- Frequency of dressing changes

The gauze layers are held in place with roller-type gauze bandages applied in a distal to proximal direction or with circular net fabrics. Cover gauze dressings on the patient's extremities with elastic wraps, especially if the patient is ambulatory. Dressings are generally changed and reapplied every 12 to 24 hours after thoroughly cleaning the areas.

#### Biologic Dressings.

Biologic dressings are often used for temporary wound coverage and closure. These dressings are skin or membranes obtained from human tissue donors (homograft or allograft) or animals (heterograft or xenograft). When applied over open wounds, a biologic dressing adheres and

promotes healing or prepares the wound for permanent skin graft coverage.

Various biologic materials are used in healing partial-thickness and granulating full-thickness wounds that are clean and free of eschar. The type of biologic dressing selected depends on the type of wound to be covered and the availability of the material.

*Homografts*, also called *allografts*, are human skin obtained from a cadaver and provided through a skin bank. Disadvantages to the use of homografts are the high costs and the risk for transmitting a bloodborne infection.

*Heterografts*, also called *xenografts*, are skin obtained from another species. Pigskin (porcine) is the most common heterograft and is compatible with human skin. Pigskin is assessed daily for adherence and need for replacement. Fig. 26-12 shows a small burn covered with a porcine dressing.

**FIG. 26-12** Burn wound covered with a porcine dressing.

*Cultured skin* can be grown from a small specimen of epidermal cells from an unburned area of the patient's body. The cells are grown in a laboratory to produce cell sheets that can be grafted on the patient to generate a permanent skin surface. The length of time for culturing and growing the skin is long, and the cell sheets are fragile. This process is very costly.

*Artificial skin* is a substance with two layers—a Silastic epidermis and a porous dermis made from beef collagen and shark cartilage. After the artificial skin is applied to a clean, excised wound surface, fibroblasts move into the collagen part and create a structure similar to normal dermis. The artificial dermis slowly dissolves and is replaced with blood vessels and connective tissue (*neodermis*). The neodermis supports a standard autograft placed over it when the Silastic layer is removed.

### **Biosynthetic Wound Dressings.**

Biosynthetic wound dressings are a combination of biosynthetic and synthetic materials. Biobrane is commonly used and effective in the treatment of clean superficial partial-thickness burns such as scalds, as a covering for meshed autografts, and as a donor site dressing. It is made of a nylon fabric that is partially embedded into a silicone film. Collagen is incorporated into both the silicone and the nylon components. The nylon fabric comes into contact with the wound surface and adheres to it until epithelialization has occurred. The porous silicone film allows exudates to pass through.

### **Synthetic Dressings.**

Synthetic dressings are made of solid silicone and plastic membranes. They are applied directly to the surface of a prepared wound and remain in place until they fall off or are removed. Many of these dressings are transparent or translucent, and the wound can be inspected without removing the dressing. Pain is reduced at the site because these agents also prevent contact of the wound's nerve endings with air. These dressings also are used to cover donor sites where skin was obtained for autografting.

Transparent film is the dressing commonly used for the care of donor site wounds (Fig. 26-13). This dressing type promotes faster healing with low infection rates, minimal pain, and reduced cost.

**FIG. 26-13** A, Donor site covered with a transparent dressing. B, Donor site covered with Xeroform dressing.

### Surgical Management.

Grafting is used for wound closure when full-thickness injuries cannot close and when natural healing would result in loss of joint function, an unacceptable cosmetic appearance, or a high potential for wound recurrence. Successful skin grafting requires a clean and granulating or freshly excised wound bed. Partial-thickness (split-thickness) or full-thickness strips of skin are removed from the donor area, transferred to the wound, and sutured or stapled in place. Full-thickness free grafts and myocutaneous flaps are used to cover deep, massive ulcers or ulcers in which vital structures, such as bone or tendon, are exposed.

Surgical management of burn wounds involves excision and wound covering. Surgical excision is performed early in the postburn period. Autografting by taking an area of the patient's healthy skin with intact TISSUE INTEGRITY and transplanting it to an excised burn wound may be performed throughout the acute phase when wounds are ready and donor sites are available. Early grafting reduces the time patients are at risk for infection and sepsis.

### Surgical Excision.

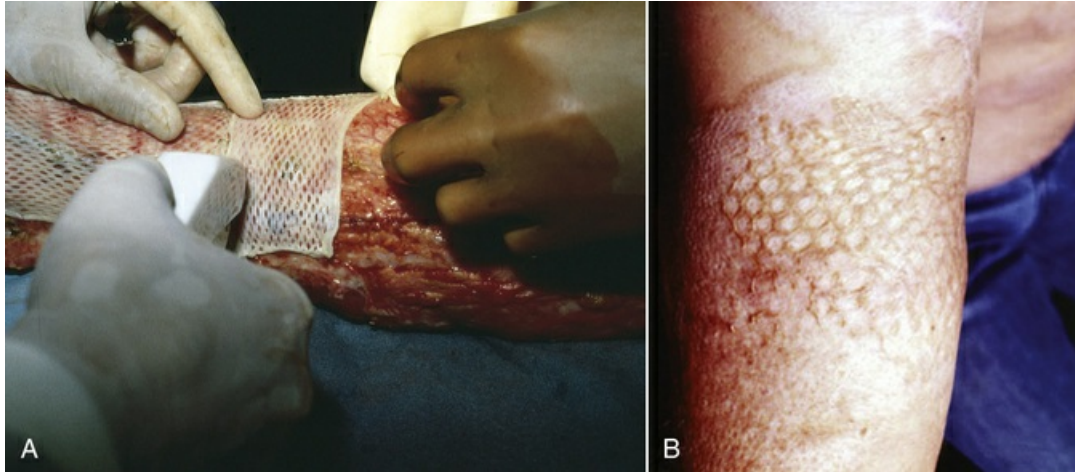

Surgical excision is a common treatment for full-thickness and deep partial-thickness wounds. The patient is taken to the operating room within the first 5 days after injury and again as needed until all wounds are closed permanently.

The surgeon excises the burn wound usually by removing very thin layers of the necrotic burn surface until bleeding tissue is encountered. (Bleeding indicates that a bed of healthy dermis or subcutaneous fat has been reached.) For very deep burns, the surgeon cuts away the wound to the level of superficial fascia. Blood loss is minimal, and grafting is usually successful.

### Wound Covering.

Permanent skin coverage for large full-thickness injuries occurs by applying an autograft. Skin for an autograft is taken from the patient's body. The surgeon removes a piece of skin from a remote unburned area of the body and transplants it to cover the burn wound. Skin grafts are generally of split thickness, and a partial-thickness injury is formed at the site of surgical removal (the *donor site*). Grafts are placed either on a clean granulated bed or over an area from which dead tissue has just been removed.

Patients with larger burns may have only 5% to 20% of the skin surface available to use for covering the 80% to 95% burned area. Coverage for these wounds may require either repeated skin removal from the same donor site (with time allowed between harvests for healing) or meshing of the split-thickness skin grafts (Fig. 26-14). This technique allows a small graft to be stretched to cover a larger area. Healing time is slower for a meshed graft because the skin must fill in open meshed areas (and attach to the granulation bed).

**FIG. 26-14** Typical appearance of meshed autografts. **A**, Appearance of meshed autograft at application. **B**, Appearance of meshed autograft after healing.

After surgery, graft sites are immobilized with bulky cotton pressure dressings for 3 to 5 days to allow vascularization, or “take,” of the newly grafted skin. Do not disturb the dressing and encourage elevation and complete rest of the grafted area to allow blood vessels to connect the graft with the wound bed. Any activity that might cause movement of the dressing against the body and separation of the graft from the wound is prohibited.

After dressings are removed, monitor the graft for indications of failure to vascularize, nonadherence to the wound, or graft necrosis. A dusky color or sharp line of color change suggests inadequate venous or lymphatic drainage. Other techniques to monitor trends of blood flow in the graft, depending on the graft's location, include pulse oximetry, laser Doppler imaging, ultrasonography, and transcutaneous oxygen determination.

Grafts and donor sites on posterior body surfaces present special problems. For the graft to become fully vascularized or for the donor sites to dry, the patient must be immobilized in a side-lying or prone position for 7 to 10 days.

An alternative to this positioning is the use of special low-pressure or air-fluidized beds, such as the Clinitron bed or KinAir bed, which not only reduces ischemia of the graft while the patient is supine but also helps prevent breakdown of intact skin.

### Minimizing Potential for Infection.

Burn wound infection occurs through **auto-contamination**, in which the patient's own normal flora overgrows and invades other body areas; and **cross-contamination**, in which organisms from other people or environments are transferred to the patient. Signs of infection include foul-smelling discharge, fever, blood culture and/or wound site colonization, and white blood count elevation.

### Planning: Expected Outcomes.

The patient is expected to remain free from infection and not develop sepsis.

### Interventions.

Interventions focus on preventing infection and removing infected tissue.

### Nonsurgical Management.

*Priority nursing interventions include using principles of infection control to prevent transmission,*

providing a safe environment, and monitoring for early detection of infection. Drug therapy, isolation therapy, and environmental management are strategies for preventing and managing infection.

### Drug Therapy for Infection Prevention.

Burn wound conditions promote the growth of *Clostridium tetani*, and all burn patients are at risk for this deadly infection. Tetanus toxoid administration enhances immunity to *C. tetani* and is routinely given on admission. Administration of tetanus immune globulin (human) (Hyper Tet) is recommended when the patient's tetanus immunization status is not known.

Topical antimicrobial drugs are used for infection prevention in burn wounds. Chart 26-5 lists commonly used topical agents. The expected outcome of this therapy is to reduce bacterial growth in the wound and prevent sepsis. A variety of agents can be used. Some topicals come in a form of ointments and creams (e.g., silver sulfadiazine, Sulfamylon, bacitracin) and need to be applied once or twice daily. Other products such as Acticoat, Mepilex Ag, and Aquacel Ag contain antimicrobials, which release over a period of several days and can be left on the wound for up to 7 days, thus eliminating the need for daily dressing changes.

#### Chart 26-5

### Common Examples of Drug Therapy

#### Burn Wounds

TOPICAL DRUG	NURSING IMPLICATIONS
Silver sulfadiazine (Silvadene, Thermazene)	Watch for allergic reaction causing a drop in white blood cell count. Do not use if reaction to sulfonamide has occurred. Use on deep partial-thickness or full-thickness wounds. Monitor wounds for infection.
Collagenase (Santyl) with Polysporin powder	Apply once a day. Use on partial-thickness wounds with eschar. Monitor wounds for infection. May be used with barrier dressing such as Xeroform.
Mafenide acetate (Sulfamylon)	Premedicate for pain before application. Monitor blood gas and serum electrolyte levels. Monitor wounds for infection.
Nitrofurazone (Furacin)	Observe closely for signs of allergic reaction and evidence of superinfection.
Gentamicin sulfate (Garamycin, Gentamar)	Nephrotoxic; monitor kidney function closely, especially changes in serum creatinine and blood urea nitrogen. Otoxic; monitor hearing weekly.
Polymyxin B-bacitracin (Poly-Bac, Polysporin)	Apply every 2-8 hours to keep area moist.
Acticoat	Do not use with oil-based products or other antimicrobials. Do not use for any patient with a known sensitivity to any of the components of this drug. May dry out and adhere to wound surface; soak off to remove.
PolyMem	Normally leave in place for 7 days. Remove earlier if exudate is visible through outer membrane. Use on partial-thickness wounds and donor sites. Cover with a secondary dressing. Monitor wounds for infection.
Aquacel Ag	Use on partial-thickness wounds and donor sites. Cover with a secondary dressing. Do not use for patients who have allergic reactions to the dressing or any of its components. Moisten with sterile water or normal saline to ease removal. Do not use with oil-based products.
Mepilex Ag	Do not use along with oxidizing agents such as hydrogen peroxide. Cover with secondary dressing. May be used with partial-thickness burns, full-thickness burns, skin grafts, and donor sites.

### Drug Therapy for Treatment of Infection.

Systemic antibiotics are used when burn patients have symptoms of an actual infection, including septicemia. Broad-spectrum antibiotics are given until the results of blood cultures and sensitivity status are available. At that time, antibiotics that are effective against the specific organism(s) causing the infection are used. Often burn patients require a higher dose of these drugs to maintain effective blood levels. Peak and trough blood levels may be used to determine treatment effectiveness and risk for toxicity.

### Providing a Safe Environment.

Providing a safe environment can include isolation therapy, which is used in some burn centers in the belief that it reduces cross-contamination. More often it involves coordinating all members of the health care team in the use of asepsis and monitoring for early recognition of actual infection. Proper and consistent handwashing is the most effective technique for preventing infection transmission.

*Use of asepsis* requires all health care personnel to wear gloves during all contact with open wounds. The use of sterile versus clean gloves for routine wound care varies by agency and is a matter of debate. Regardless of sterility, change gloves when handling wounds on different areas of

the body and between handling old and new dressings.

The equipment on burn units is not shared among patients. Disposable items (e.g., pillows, dishes) are used as much as possible. Assign any equipment used in daily routine care (e.g., blood pressure cuffs, stethoscopes) to each patient for the duration of his or her stay. Daily cleaning of the equipment and general housekeeping are essential for infection control. All other equipment must be cleaned after use on one patient and before use on another. Because *Pseudomonas* has been found in plants, the presence of plants and flowers is prohibited. Some burn units do not permit patients to eat raw foods (e.g., salads, fruit, pepper) to reduce exposure to organisms. Rugs and upholstered articles harbor organisms, and their use is restricted.

Visitors are restricted when the patient is immunosuppressed. Ill people, small children, and other patients should not come into direct contact with the burn patient. Some burn units recommend that all visitors wear protective clothing (gowns, gloves, masks, and shoe and hair covers) in the burn patient's room, but no data support the effectiveness of this approach.

*Early detection* involves careful monitoring of the burn wounds at each dressing change. Examine all wounds for signs of infection, which include pervasive odor, texture or color changes (especially focal, dark red, or brown discoloration in the eschar), purulent drainage, exudate, sloughing grafts, and/or redness of wound edges extending to the nonburned skin.

Laboratory cultures and biopsies are recommended. Quantitative biopsies of the eschar and granulation tissue are performed routinely to monitor the growth of organisms.

### **Surgical Management.**

Infected burn wounds with colony counts at or near  $10^5$  colonies per gram of tissue may be life threatening, even with antibiotic therapy. Surgical excision of the wound may be needed to control these infections.

## **NCLEX Examination Challenge 26-3**

### **Safe and Effective Care Environment**

Which nursing intervention(s) decrease(s) the risk for cross-contamination in the client with a severe burn injury? **Select all that apply.**

- A. Place client in isolation.
- B. Encourage multiple visitors to support client.
- C. Ensure that no plants or flowers are in the client's room.
- D. Teach family members not to bring fresh fruit and vegetables to the client.
- E. Change gloves after cleaning and dressing of one wound area, before cleaning and dressing another.

### **Minimizing Weight Loss**

#### **Planning: Expected Outcomes.**

The patient is expected to maintain adequate nutrient intake for meeting the body's calorie needs. Indicators include that the patient should have mild or no deviations from the normal ranges for:

- Weight/height ratio
- Food intake
- Hematocrit and hemoglobin
- Serum albumin and prealbumin
- Blood glucose

#### **Interventions.**

Interventions include calculating the patient's calorie needs and providing an adequate daily source

of calories and nutrients that the patient can ingest. Coordinate with a registered dietitian to meet the expected outcomes regarding the patient's NUTRITION status. Therapy begins with calculating the patient's current daily calorie needs. Several formulas and charts are used for this calculation. Nutrition requirements for a patient with a large burn area can exceed 5000 kcal/day. Not meeting this need leads to very rapid weight loss. In addition to a high-calorie intake, a diet high in protein is needed for wound healing. Work with the dietitian and the patient to plan additions to standard nutrition patterns.

Oral diet therapy may be delayed for several days after the injury until the GI tract is motile. Nasoduodenal tube feedings are often started soon after admission. Beginning enteral feedings early helps decrease weight loss, gut atrophy, bacterial translocation, and sepsis. This type of supplement prevents NUTRITION deficits in severely burned patients.

Encourage patients who can eat solid foods to ingest as many calories as possible. Consider the patient's preferences with diet planning and food selection. Encourage patients to request food whenever they feel they can eat, not just according to the hospital's standard meal schedule. Offer frequent high-calorie, high-protein supplemental feedings. Keep an accurate calorie count for foods and beverages that are actually ingested by the patient.

Patients who cannot swallow but who have adequate gastric motility may meet calorie and NUTRITION needs through enteral tube feedings (see Chapter 60). Parenteral nutrition may be used when the GI tract is not functional or when the patient's nutrition needs cannot be met by oral and enteral feeding. This method is used as a last resort because it is invasive and can lead to infectious and metabolic complications.

## Maintaining Mobility

### Planning: Expected Outcomes.

The patient with a burn injury is expected to maintain or regain an optimal MOBILITY. Indicators include that the patient has minimal limitations in these actions:

- Muscle movement
- Joint MOBILITY
- Walking
- Self-positioning

### Interventions.

Interventions focus on maintaining or achieving the patient's preburn range of joint motion and MOBILITY and preventing contracture formation.

### Nonsurgical Management.

Nonsurgical management includes the nursing interventions of positioning, range-of-motion exercises, ambulation, and pressure dressings.

*Positioning* is critical for patients with burn injuries because the position of COMFORT for the patient is often one of joint flexion, which leads to contracture development. Maintain the patient in a neutral body position with minimal flexion. Best practices for preventing contractures are listed in Chart 26-6. Splints and other devices may be used to maintain good positioning of the hands, elbows, knees, neck, and axillae.

## Chart 26-6

### Best Practice for Patient Safety & Quality Care QSEN

#### Positioning to Prevent Contractures

AFFECTED BODY PART	POSITION OF FUNCTION	INTERVENTION
Head and neck	Hyperextension	No pillow. Place a towel roll under the patient's neck or shoulder. Neck splint.
Posterior neck	Flexion	Have patient turn the head from side to side.
Upper chest and chest	Shoulder retraction	Place patient in supine position. Place a folded towel under the spine, between the scapulae.
Lateral trunk	Flexion to uninvolved side	Place patient supine with the arm on the affected side up over the head.
Anterior shoulder	Abduction and external rotation	Maintain the upper arm at 90 degrees of abduction from the lateral aspect of the trunk.
Posterior shoulder	Slight flexion and interior rotation	Keep the arm slightly behind the midline.

Axilla	Abduction with 10- to 15-degree forward flexion and external rotation	Support the abducted arm with suspension from IV pole or bedside table. Axilla splint.
Elbow	Extension and supination	Keep the joint in the extended position.
Wrist	30 to 45 degrees of extension	Use a splint.
Fingers		
MP joints	70 to 90 degrees of flexion	Use a splint.
PIP and DIP joints	Extension	Use a splint.
Ankle	90 degrees of dorsiflexion	Use a padded footboard or splint with heels free of pressure.
Legs	15 to 20 degrees of abduction	Place small pillow between legs.
Hip	Extension and neutral rotation	Place patient supine with lower extremity extended. Use trochanter roll. Use foam wedge along lateral aspect of thigh.

DIP, Distal interphalangeal; MP, metatarsophalangeal; PIP, proximal interphalangeal.

*Range-of-motion exercises* to maintain MOBILITY are performed actively at least three times a day. If the patient cannot move a joint actively, perform passive range-of-motion exercises. Give burned hands special attention. Urge the patient to perform active range-of-motion exercises for the hand, thumb, and fingers every hour while he or she is awake.

## NCLEX Examination Challenge 26-4

### Health Promotion and Maintenance

The nurse is encouraging range-of-motion exercises for the client, who states, "This hurts terribly; I don't want to do this." Identify the appropriate nursing response(s). **Select all that apply.**

- A. "You have to do the exercises to get well."
- B. "Range of motion helps promote mobility."
- C. "Just visualize a beach to get your mind off of the pain."
- D. "Let me check when you were last given pain medication."
- E. "Which techniques for pain management have you used in the past that were helpful?"
- F. "The health care provider has ordered these exercises, and it is important that you do them as instructed."

*Ambulation* is started as soon as possible after the fluid shifts have resolved because it maintains MOBILITY, inhibits bone density loss, strengthens muscles, stimulates immune function, promotes ventilation, and prevents many complications. Patients with attached equipment (IV catheters, nasogastric tubes, ECG leads, extensive dressings) can ambulate with preparation and assistance. This activity is performed two or three times a day and progresses in length each time.

*Compression dressings* are applied after grafts heal to help prevent contractures and tight hypertrophic scars, which can inhibit MOBILITY. They also inhibit venous stasis and edema in areas with decreased lymph flow. Compression dressings may be elastic wraps or specially designed, custom-fitted, elasticized clothing that provides continuous pressure. Fig. 26-15 shows such a garment. For best effectiveness, pressure garments must be worn at least 23 hours a day, every day, until the scar tissue is mature (12 to 24 months). They can be uncomfortable with itchiness and increased warmth. Reinforce to the patient and family that wearing pressure garments is beneficial in saving mobility and reducing scarring.

**FIG. 26-15** Patient wearing full-body compression garments. (From Herndon, D. N. [2012]. *Total burn care* (4th ed.). Philadelphia: Saunders.)

### Surgical Management.

Surgical management restores MOBILITY rather than prevents immobility. Surgical release of contractures is commonly performed in the neck, axilla, elbow flexion areas, and hand. Specific surgical procedures vary for each patient.

Nursing responsibilities include interventions to prevent contractures from re-forming and the care of new grafts and suture lines. Constantly reinforce the need for the patient to adhere to exercise and splinting regimens to prevent the recurrence of joint immobility.

### Supporting Positive Self-Esteem

#### Planning: Expected Outcomes.

After intervention, the patient with a burn injury is expected to have a positive perception of his or her own appearance, body functions, and self-worth. Indicators include that the patient should consistently demonstrate these behaviors:

- Willingness to touch the affected body part
- Adjustment to changes in body function
- Willingness to use strategies to enhance appearance and function
- Successful progression through the grieving process
- Use of support systems

#### Interventions.

Nonsurgical and surgical interventions can assist patients who have self-image problems as a result of burn injury.

### Nonsurgical Management.

Understanding the stages of grief is helpful in managing care for the patient with burns. Assess which stage of grief the patient is currently experiencing and help interpret his or her behaviors. The patient often is unaware of or is confused by his or her feelings. Reassure the patient that feelings of grief, loss, anxiety, anger, fear, and guilt are normal. The patient may be grieving the loss of body parts, appearance, role identity, social identity, and family members. Coordinate with other health care team members (e.g., psychologist, psychiatrist, social worker, case manager, spiritual leader of the patient's choosing) to address these issues.

Accept the physical and psychological features of the patient. Present patients and families with realistic expected outcomes for the patient's functional capacity and physical appearance. Provide

information sessions and counseling for the family to identify patterns of support. Facilitate the patient's use of these systems and the development of new support systems. Make referrals to support groups. Evaluate the effectiveness and use of support resources throughout the course of recovery.

Engaging in decision making and independent activities fosters feelings of self-worth. Plan and encourage the patient's active participation in care activities. Assist family members to understand that it is more beneficial for the patient to perform these activities than to have them performed by someone else. Urge families to include the patient in family decision making to the same degree that he or she participated in this process before the injury.

### **Surgical Management.**

Reconstructive and cosmetic surgery can be performed many years after the burn injury. Restoring function and improving appearance through surgical techniques often promote the patient's positive self-image and self-worth. Many patients have unrealistic expectations of reconstructive surgery and envision an appearance identical to or equal in quality to the preburn state. Teach the patient and family about expected cosmetic outcomes.

### **◆Evaluation: Reflecting**

Evaluate the care of the patient in the acute phase of burn injury on the basis of the identified priority patient problems. The expected outcomes include that the patient will have appropriately managed wound care, remain free from infection, experience minimal weight loss, maintain MOBILITY, and have positive self-esteem.

# Rehabilitative Phase of Burn Injury

## Overview

Although rehabilitation efforts are started at the time of admission, the technical rehabilitative phase begins with wound closure and ends when the patient achieves his or her highest level of functioning. The emphasis is on the psychosocial adjustment of the patient; the prevention of scars and contractures; and the resumption of preburn activity, including resuming work, family, and social roles. This phase may take years or even last a lifetime as patients adjust to life after a burn (Cukor et al., 2015).

## ❖ Interprofessional Collaborative Care

Although attention is placed first on the physical interventions for the burn injury, psychological care is equally important. Continue to provide psychosocial support to the patient and family throughout hospitalization and in the rehabilitative phase.

Obtaining information from the patient and family aids in the assessment and diagnosis of psychological problems and directs management. Explore the patient's feelings about the burn injury. It is extremely difficult for patients to concentrate on the many tasks before them when obstacles such as guilt and grief are in the forefront.

Ask whether there is a history of psychological problems. To assist with a future plan of care, assess and document the type of coping mechanisms the patient has used successfully during times of stress. Also assess the patient's family unit and the history of interaction. Consider cultural, spiritual, and ethnic factors when planning psychosocial interventions.

Throughout the hospitalization, the patient progresses through a variety of stages and exhibits many feelings, including denial, regression, and anger. Assess the patient's feelings at each stage so appropriate plans of care can be implemented.

## Care Coordination and Transition Management

Discharge planning for the patient with a burn injury begins at admission to the hospital or burn center. The interdisciplinary team meets regularly to evaluate the progress of each discipline and help the patient reach mutually established discharge outcomes. Table 26-7 lists common discharge needs of the patient with burns.

---

**TABLE 26-7**

### Needs to Address Before Discharge of the Patient With Burns

---

- Early patient assessment
- Financial assessment
- Evaluation of family resources
- Weekly discharge planning meeting
- Psychological referral
- Patient and family teaching (home care)
- Designation of principal learners (specific family members or significant others who will help with care)
- Development of teaching plan
- Training for wound care
- Rehabilitation referral
- Home assessment (on-site visit)
- Medical equipment
- Public health nursing referral
- Evaluation of community resources
- Visit to referral agency
- Re-entry programs for school or work environment
- Long-term care placement
- Environmental interventions
- Auditory testing
- Speech therapy
- Prosthetic rehabilitation

## Psychosocial Preparation.

During the recovery period and for some time after discharge, patients with severe burn injuries often have psychological problems that require intervention. Such problems include post-traumatic stress disorder, sexual dysfunction, and severe depression. Assistance is coordinated with the patient, family, and health care team. Psychosocial assistance is best provided by a professional counselor with experience in helping burn patients.

One specific area to address with the patient is the reaction of others to the sight of healing wounds and disfiguring scars. Patients with facial burns are especially subjected to stares and other negative reactions from the public. Visits from friends and short public appearances before discharge may help the patient begin adjusting to this problem. Community reintegration programs can assist the psychosocial and physical recovery of the patient with serious burns.

### **Home Care Management.**

The patient with severe burns is discharged from the acute care setting when serious complications are resolved and minimal wound areas remain open. During the first weeks at home, the patient usually needs at least daily wound care, physical therapy, NUTRITION support, symptom management, and drug therapy.

Although the patient usually views going home positively, the problems of physical care and the psychological stresses from changes in appearance, role, function, and lifestyle may overwhelm the patient and family. Successful discharge depends on extensive planning and preparation of the patient, family, and home environment through education and the involvement of appropriate support agencies and services.

Preparation for discharge includes assessment of the family and home care situation from physical and social perspectives. Consider the needs of the patient when evaluating the home for cleanliness; access to bathing facilities, electricity, and running water; stairways; number of occupants; temperature control; and safety. If the burn injuries occurred in a house fire, a new residence may need to be established.

### **Self-Management Education.**

Education about burn care and living with the consequences of burn injuries begins when the patient is admitted to the hospital or burn center. A weekly plan for patient education is outlined; a positive outcome is progression toward independence for the patient and family. Critical for this outcome is teaching patients and family members to perform such care tasks as dressing changes. Allow patients and family members to first observe dressing changes, then to assist in performing the changes, and then to change the dressings independently under your supervision.

Before discharge, all people who will be involved in the patient's home care participate in discharge planning and teaching sessions. In addition to details about dressing changes, explain signs and symptoms of infection, drug regimens, proper use of prosthetic and positioning devices, correct application and care of pressure garments, COMFORT measures to reduce pruritus, and dates for follow-up appointments.

### **Health Care Resources.**

The interprofessional health care team evaluates the family's capacity and willingness to assist in caring for the patient after discharge. A visiting nurse or case manager with extensive experience in providing burn care can help the family with care problems arising at home. This nurse can help the family determine which special equipment, supplies, or services will be needed. The frequency of home visits depends on the patient's condition and the ability of family members to function as care providers. The home care nurse may need a brief visit to the patient while in the hospital and may need to observe burn wound care.

The home care of a patient after a serious burn often involves daily physical therapy and rehabilitation sessions at special centers. Address and resolve transportation problems before the patient is discharged.

When rehabilitation is prolonged, the patient may be discharged to a rehabilitation facility. Consult with the rehabilitation team and provide copies of the care and teaching plans used with the patient.

## **Clinical Judgment Challenge 26-2**

### **Patient-Centered Care; Teamwork and Collaboration; Evidence-Based Practice QSEN**

You are caring for a veteran who was involved in combat where he experienced an explosion near a burn pit that left him with multiple burns. The patient tells you that he has trouble sleeping and

is having frequent flashbacks. He can't look at his burns during dressing changes, is asking his family to feed him, and is not participating in occupational and physical therapy.

1. Which interventions would be appropriate for this patient?
2. Which other member of the interprofessional team may you need to contact?
3. What teaching can you provide to the patient's family?
4. Which specific veteran-focused resources may be helpful to your patient?

### ◆ **Evaluation: Reflecting**

Evaluate the care of the patient in the rehabilitative phase of burn injury on the basis of the identified priority patient problems. The expected outcomes include that the patient will:

- Maintain adequate GAS EXCHANGE and PERFUSION to all vital organs
- Maintain a patent airway
- Have cardiac output restored to normal
- Have pain alleviated or reduced
- Experience no further loss of skin TISSUE INTEGRITY
- Have wounds healed without complications
- Remain free from infection
- Not experience sepsis
- Maintain an adequate NUTRITION for meeting the body's calorie needs
- Regain and maintain an optimal ability to move purposefully
- Have a positive perception of his or her own appearance and body functions

# Get Ready for NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Use strict aseptic technique when caring for patients who have open burn wounds to prevent infection. **QSEN: Safety**
- Monitor vital signs at least every 8 hours and assess wounds at least daily for signs of wound infection or sepsis. (For patients with greater than 25% TBSA burn, monitor vital signs more frequently.) **QSEN: Safety**
- Administer prescribed opioid analgesics intravenously during the resuscitation phase of burn recovery. **QSEN: Evidence-Based Practice**

### Health Promotion and Maintenance

- Encourage adults to have and maintain home smoke and carbon monoxide detectors. **QSEN: Safety**
- Teach patients to not smoke in bed or in rooms where home oxygen is in use and to not smoke when taking substances that induce sedation (drugs or alcohol). **QSEN: Safety**
- Teach patients who have reduced sensation in hands or feet to use a bath thermometer to check water temperature before bathing. **QSEN: Safety**
- Teach patients to avoid exposing burned skin to the sun or to temperature extremes. **QSEN: Safety**
- Instruct adults to set hot water tank temperatures to manufacturer recommendations. **QSEN: Safety**

### Psychosocial Integrity

- Allow patients time to grieve over a change in body image and other fire-related loss. **QSEN: Patient-Centered Care**
- Reassure patients that pain will be managed effectively and COMFORT will be promoted. **QSEN: Patient-Centered Care**
- Explain procedures to the patient and family. **Ethics**
- Assess the patient's and family's use of coping strategies related to burn injury, treatment, possible role changes, and possible outcomes. **QSEN: Patient-Centered Care**
- Support the patient and family in coping with permanent changes in appearance and function. **QSEN: Patient-Centered Care**
- Encourage the patient with wounds and scars related to burn injury to participate in self-care. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Always prioritize the airway and adequacy of breathing. **QSEN: Safety**
- Keep an endotracheal or tracheostomy kit at the bedside of any patient with facial burns, burns inside the mouth, singed nasal hairs, or a “smoky” smell to the breath. **QSEN: Safety**
- Notify the Rapid Response Team immediately if the patient with an inhalation injury becomes more breathless or audible wheezes disappear. **QSEN: Safety**
- Administer analgesics, sedatives, and antianxiety drugs to patients receiving paralytic drugs during mechanical ventilation. **QSEN: Evidence-Based Practice**

- Administer half of the fluid volume calculated for the first 24 hours after burn injury in the first 8 hours postburn. **QSEN: Evidence-Based Practice**
- Use laboratory and assessment data to determine the effectiveness of fluid resuscitation during the resuscitation phase of burn injury. **QSEN: Evidence-Based Practice**
- Encourage the patient to actively participate in pain control measures. **QSEN: Patient-Centered Care**
- Position patients to promote COMFORT, prevent contractures, and promote joint function. **QSEN: Evidence-Based Practice**
- Assist patients to ambulate several times each day as soon as the fluid shifts have resolved. **QSEN: Evidence-Based Practice**
- Coordinate with the registered dietitian to meet the NUTRITION needs for the patient during the acute phase of burn injury. **QSEN: Teamwork and Collaboration**
- Evaluate wound healing during the acute phase of burn injury. **Clinical Judgment**
- Use appropriate positioning and range-of-motion interventions for prevention of MOBILITY problems. **QSEN: Safety**

## UNIT VII

# Interprofessional Collaboration for Patients With Problems of the Respiratory System

### OUTLINE

---

Chapter 27 Assessment of the Respiratory System

Chapter 28 Care of Patients Requiring Oxygen Therapy or Tracheostomy

Chapter 29 Care of Patients With Noninfectious Upper Respiratory Problems

Chapter 30 Care of Patients With Noninfectious Lower Respiratory Problems

Chapter 31 Care of Patients With Infectious Respiratory Problems

Chapter 32 Care of Critically Ill Patients With Respiratory Problems

## CHAPTER 27

# Assessment of the Respiratory System

Harry Rees

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is GAS EXCHANGE.**  
**The interrelated concept for this chapter is PERFUSION.**

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to perform a complete respiratory assessment, including GAS EXCHANGE and PERFUSION.

### Health Promotion and Maintenance

2. Explain how physiologic aging changes of the respiratory system affect GAS EXCHANGE, PERFUSION, and the associated care of older adults.
3. Teach all adults measures to take to protect the respiratory system, including the avoidance of tobacco use.

### Psychosocial Integrity

4. Implement patient-centered nursing interventions to help patients and families cope with the psychosocial impact caused by a respiratory system problem.

### Physiological Integrity

5. Apply knowledge of anatomy and physiology to perform an evidence-based assessment for the patient with a respiratory health problem.
6. Interpret assessment findings for the patient with a respiratory health problem.
7. Teach the patient and caregivers about diagnostic procedures associated with respiratory health problems.

The respiratory system uses ventilation to provide the body with atmospheric oxygen (O<sub>2</sub>), which is an essential nutrient for all cells. GAS EXCHANGE is the oxygen transport to the cells and carbon dioxide transport away from cells through ventilation and diffusion. Once ventilation and diffusion exchange these gases in the lungs, blood oxygen is then available to cells by perfusion and diffusion. PERFUSION is the arterial blood flow through the tissues (peripheral perfusion) and blood that is pumped by the heart (central perfusion). See [Chapter 2](#) for overviews of the concepts of gas exchange and perfusion.

The respiratory system includes the upper airways, lungs, lower airways, and alveolar air sacs. Air with oxygen enters the nose and mouth and moves through the airways (trachea, bronchi, bronchioles) and into the air sacs (alveoli) of the lungs. Once in the air sacs, the oxygen from the air diffuses into the blood so it can be transported to all tissues and organs. Carbon dioxide (CO<sub>2</sub>), the waste gas created in the tissues, diffuses from the blood into the lungs so it can be exhaled. All systems depend on adequate GAS EXCHANGE for tissue PERFUSION. Any respiratory problem affects total body health and well-being.

## Anatomy and Physiology Review

The purpose of breathing is to ensure GAS EXCHANGE. This process has two parts: (1) oxygenation for tissue PERFUSION so cells have enough oxygen to metabolize and generate energy; and (2) removal of carbon dioxide, the waste product of metabolism. The respiratory system also influences acid-base balance, speech, smell, fluid balance, and temperature control.

### Upper Respiratory Tract

The upper airways include the nose, the sinuses, the pharynx, and the larynx (Fig. 27-1).

FIG. 27-1 Structures of the upper respiratory tract.

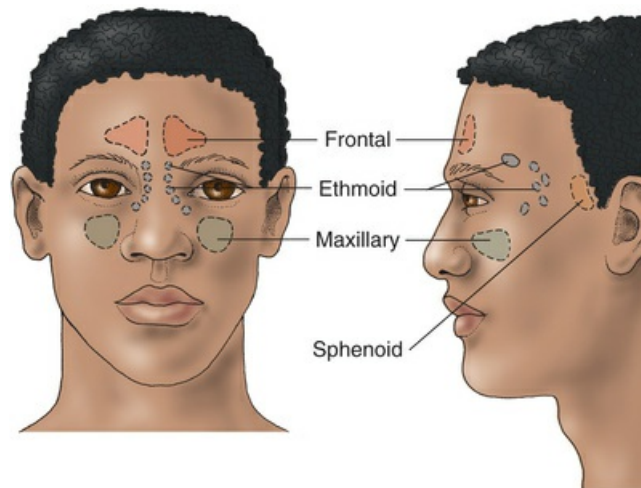

### Nose and Sinuses

The nose is the organ of smell, with receptors from cranial nerve I (*olfactory*) located in the upper areas. The nose is rigid with a bony upper portion and a cartilaginous moveable lower portion. The septum divides the nose into two cavities that are lined with mucous membranes and have a rich blood supply. The **anterior nares** are the external openings into the nasal cavities. The posterior nares are openings from the nasal cavity into the throat.

The **turbinates** are three bones that protrude into the nasal cavities from the internal portion of the nose (see Fig. 27-1). Turbinates increase the total surface area for filtering, warming, and humidifying inspired air before it passes into the nasopharynx.

The **paranasal sinuses** are air-filled cavities within the bones that surround the nasal passages (Fig. 27-2). Lined with ciliated membrane, the sinuses provide resonance to speech, decrease the weight of the skull, and act as shock absorbers in the event of facial trauma.

**FIG. 27-2** Paranasal sinuses.

## Pharynx

The pharynx (throat) is a passageway for both the respiratory and digestive tracts. It is located behind the oral and nasal cavities. The throat is divided into the nasopharynx, the oropharynx, and the laryngopharynx (see Fig. 27-1).

The nasopharynx is located behind the nose, above the soft palate. It contains the adenoids and the opening of the eustachian tube. The adenoids trap organisms that enter the nose or mouth. The **eustachian tubes** connect the nasopharynx with the middle ears and open during swallowing to equalize pressure within the middle ear.

The oropharynx is located behind the mouth, below the nasopharynx. It extends from the soft palate to the base of the tongue and is used for breathing and swallowing. The *palatine tonsils*, which are part of the immune system, are located on the sides of the oropharynx and protect against invading organisms.

The **laryngopharynx** is the area located behind the larynx from the base of the tongue to the esophagus. It is the dividing point between the larynx and the esophagus.

## Larynx

The **larynx** ("voice box") is located above the trachea, just below the throat at the base of the tongue. It is composed of several cartilages (Fig. 27-3). The *thyroid cartilage* is the largest and is commonly called the *Adam's apple*. The *cricoid cartilage*, which contains the vocal cords, lies below the thyroid cartilage. The *cricothyroid membrane* is located below the level of the vocal cords and joins the thyroid and cricoid cartilages. This site is used in an emergency for access to the lower airways through a *cricothyroidotomy*, which is an opening made between the thyroid and cricoid cartilage and results in a tracheostomy.

**FIG. 27-3** Structures of the larynx.

Inside the larynx are two pairs of vocal cords: the false vocal cords and the true vocal cords. The **glottis** is the opening between the true vocal cords (Fig. 27-4). The **epiglottis** is a small, elastic flap attached to the top of the larynx. It opens during breathing and prevents food from entering the trachea (aspiration) by closing over the glottis during swallowing.

**FIG. 27-4** Detail of the glottis (two vocal folds and the intervening space, the rima glottidis).

## Lower Respiratory Tract

### Airways

The lower airways are the trachea; two mainstem bronchi; lobar, segmental, and subsegmental bronchi; bronchioles; alveolar ducts; and alveoli (Fig. 27-5). The lower respiratory tract (*tracheobronchial tree*) consists of muscle, cartilage, and elastic tissues forming branching tubes. These tubes decrease in size from the trachea to the respiratory bronchioles and allow gases to move to and from the lungs. **GAS EXCHANGE** takes place in the lung tissue between the alveoli and the lung capillaries, not in the airways.

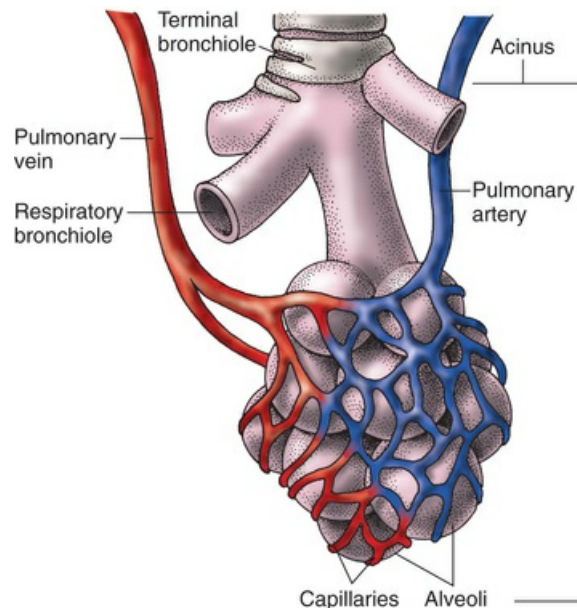

**FIG. 27-5** Structures of the lower respiratory tract.

The *trachea* is in front of the esophagus. It branches into the right and left mainstem bronchi at the *carina* junction. The trachea contains 6 to 10 C-shaped rings of cartilage. The open portion of the C is the back portion of the trachea and shares a wall with the esophagus.

The *mainstem bronchi*, or primary bronchi, begin at the carina and contain the same tissues as the trachea. The right bronchus is slightly wider, shorter, and more vertical than the left bronchus and can more easily be accidentally intubated when an endotracheal tube is passed. In addition, when a foreign object is aspirated from the throat, it usually enters the right bronchus.

The mainstem bronchi branch into the secondary (lobar) bronchi that enter each of the five lobes of the two lungs. Each lobar bronchus branches into progressively smaller divisions. The cartilage rings of these lobar bronchi are complete and resist collapse. The bronchi are lined with a ciliated, mucus-secreting membrane that moves particles away from the lower airways.

The *bronchioles* branch from the secondary bronchi and divide into smaller and smaller tubes, which are the terminal and respiratory bronchioles (Fig. 27-6). These tubes have a small diameter, have no cartilage, and depend entirely on the elastic recoil of the lung to remain open.

**FIG. 27-6** The terminal bronchioles and the acinus.

*Alveolar ducts* branch from the respiratory bronchioles and resemble a bunch of grapes. Alveolar sacs arise from these ducts and contain groups of alveoli, which are the basic units of **GAS EXCHANGE** (see [Fig. 27-6](#)). A pair of healthy adult lungs has about 290 million alveoli, which are surrounded by lung capillaries. These numerous small alveoli normally make a large surface area for **GAS EXCHANGE** (about the size of a tennis court). **Acinus** is a term for the structural unit consisting of a respiratory bronchiole, an alveolar duct, and an alveolar sac.

The alveolar walls have cells called *type II pneumocytes* that secrete **surfactant**, a fatty protein that reduces surface tension in the alveoli. Without surfactant, **atelectasis** (alveolar collapse) occurs, reducing **GAS EXCHANGE** because the alveolar surface area is reduced.

## Lungs

The lungs are elastic, cone-shaped organs located in the pleural cavity in the chest. The apex (top) of each lung extends above the clavicle; the base (bottom) of each lung lies just above the diaphragm. The lungs are composed of millions of alveoli and their related ducts, bronchioles, and bronchi. The right lung, which is larger and wider than the left, is divided into three lobes: upper, middle, and lower. The left lung is divided into only two lobes. About 60% to 65% of lung function occurs in the right lung. Any problem with the right lung interferes with **GAS EXCHANGE** and **PERFUSION** to a greater degree than a problem in the left lung.

The **pleura** is a continuous smooth membrane with two surfaces that totally enclose the lungs. The parietal pleura lines the inside of the chest cavity and the upper surface of the diaphragm. The visceral pleura covers the lung surfaces. These surfaces are lubricated by a thin fluid that allows the surfaces to glide across each other smoothly during breathing.

Blood flow in the lungs occurs through two separate systems: bronchial and pulmonary. The bronchial system carries the blood needed to oxygenate lung tissues. These arteries are part of systemic circulation and do not participate in gas exchange.

The pulmonary circulation is a highly vascular capillary network. Oxygen-poor blood travels from the right ventricle of the heart into the pulmonary artery. This artery eventually branches into arterioles to form capillary networks that are meshed around and through the alveoli—the site of **GAS EXCHANGE** (see [Fig. 27-6](#)). Freshly oxygenated blood travels from the capillaries to the pulmonary veins and then to the left atrium. From the left atrium, oxygenated blood flows into the left ventricle, where it is pumped throughout the systemic circulation.

## Accessory Muscles of Respiration

Breathing occurs through changes in the size of and pressure within the chest cavity. Contraction and relaxation of chest muscles (and the diaphragm) cause changes in the size and pressure of the chest cavity. At times, back and abdominal muscles are used in addition to chest muscles when the

work of breathing is increased.

## NCLEX Examination Challenge 27-1

### Physiological Integrity

Which description of respiratory physiologic features is correct?

- A. The elastic tissues of the tracheobronchial tree are the major structures responsible for gas exchange.
- B. The epiglottis closes during speech to divert air movement into and through the vocal cords to produce sound.
- C. Any problem with the right lung interferes with gas exchange and perfusion to a greater degree than a problem in the left lung.
- D. The left lung is responsible for approximately 60% of gas exchange, and the right lung is responsible for 60% of pulmonary perfusion.

## Oxygen Delivery and the Oxygen-Hemoglobin Dissociation Curve

Oxygen delivery to the tissues requires the binding of oxygen to hemoglobin in red blood cells. Each molecule of hemoglobin can bind four oxygen molecules, which fills (*saturates*) all of its binding sites. Each red blood cell normally has hundreds of thousands of hemoglobin molecules. When blood passes through the lung alveoli, where oxygen concentration is the greatest, oxygen diffuses from the alveoli into red blood cells and binds to all those hemoglobin molecules. This oxygen-rich blood then goes to the left side of the heart and is pumped out into systemic circulation. In tissues away from the source of oxygen, hemoglobin unloads (*dissociates*) the oxygen molecules and delivers them to the tissues. A by-product of glucose metabolism, diphosphoglycerate (DPG) reduces the attraction of hemoglobin for oxygen and can help shift the direction of the oxyhemoglobin dissociation curve. Fig. 27-7 shows the oxygen-hemoglobin dissociation curve.

**FIG. 27-7** The oxygen-hemoglobin dissociation curve.  $P_{50}$ , The partial pressure of  $O_2$  at which hemoglobin is 50% saturated;  $PO_2$ , oxygen partial pressure.

Tissue oxygen delivery through dissociation or “unloading” from hemoglobin is based on tissues’ need for oxygen. The curve in Fig. 27-7 shows that the rate of this unloading changes, depending on how much oxygen is already in the tissues. When blood perfuses tissues in which the oxygen levels are high, as indicated in the upper right-hand corner of the figure, hemoglobin binds oxygen very

tightly, and little oxygen is unloaded or dissociated from the hemoglobin into the tissues. This prevents oxygen delivery from being wasted by unloading it where it is not needed. When blood perfuses tissues in which oxygen levels are very low, as indicated in the lower left-hand corner of Fig. 27-7, hemoglobin binds oxygen less tightly and will rapidly and easily unload its remaining oxygen to provide these tissues with needed oxygen. So how rapidly and easily hemoglobin dissociates oxygen to the tissues changes depending on oxygen need. The S-shaped curve indicates that it is harder for oxygen to dissociate from hemoglobin in tissues that are well oxygenated and much easier in tissues that are “starving” for oxygen.

The curve in Fig. 27-7 indicates that, on average, 50% of hemoglobin molecules have completely dissociated their oxygen molecules when blood perfuses tissues that have an oxygen tension (concentration) of 26 mm Hg. This is considered a “normal” point at which 50% of hemoglobin molecules are no longer saturated with oxygen.

When the need for oxygen is greater in tissues, this curve shifts to the *right*, which means that the hemoglobin will dissociate oxygen faster even when the tissue oxygen tension levels are greater than 26 mm Hg. Conditions that shift the curve to the right include increased tissue temperature, increased tissue carbon dioxide concentration, decreased tissue pH (acidosis), chronic hypoxia, and increased levels of DPG. This means that it is easier for hemoglobin to unload oxygen to these tissues because they need it to support the higher metabolism, and the right shift is a tissue protection that increases oxygen delivery to the tissues that need it the most.

When tissues need less oxygen because they are metabolizing more slowly than usual, the oxygen-hemoglobin dissociation curve shifts to the *left*, which means that the tissue oxygen tension level has to be even *lower* for hemoglobin to unload oxygen. Tissue conditions that cause a shift to the left include decreased tissue temperature, decreased carbon dioxide levels, decreased glucose breakdown products (including DPG), and a higher tissue pH (alkalosis). This action prevents wasting oxygen delivery to tissues that are not using the oxygen they already have. Aging blood cells, including banked blood, have lower levels of DPG. Thus massive blood transfusions may shift the curve to the left, even when tissues could use more oxygen.

A clinical example of how these actions are helpful is one in which a person is having a myocardial infarction (heart attack). Blood flow to the area is reduced; and the heart muscle is metabolizing under hypoxic conditions, which creates more carbon dioxide in the tissue and acidosis. As a result, the hemoglobin that reaches this hypoxic tissue unloads more oxygen at a faster rate to prevent ischemia and cardiac muscle cell death. What if this person believes that he or she is having indigestion, which can have similar symptoms, and tries to correct the problem by taking in large amounts of bicarbonate-based antacids? The antacids increase the pH in the blood and all tissues, shifting the oxygen-hemoglobin dissociation curve to the left. As a result, the hypoxic cardiac muscle cells receive even less oxygen, and more of them die.

## Respiratory Changes Associated With Aging

The respiratory changes that occur with aging are described in Chart 27-1. Many additional respiratory changes in older adults result from heredity and a lifetime of exposure to environmental pollutants (e.g., cigarette smoke, bacteria, industrial fumes and irritants).

### Chart 27-1

## Nursing Focus on the Older-Adult

### Changes in the Respiratory System Related to Aging

PHYSIOLOGIC CHANGE	NURSING INTERVENTIONS	RATIONALES
<b>Alveoli</b>		
Alveolar surface area decreases.	Encourage vigorous pulmonary hygiene (i.e., encourage patient to turn, cough, and deep breathe) and use of incentive spirometry, especially if he or she is confined to bed or has had surgery.	Potential for mechanical or infectious respiratory complications is increased in these situations.
Diffusion capacity decreases.		
Elastic recoil decreases.	Encourage upright position.	The upright position minimizes ventilation-perfusion mismatching.
Bronchioles and alveolar ducts dilate.		
Ability to cough decreases.		
Airways close early.		
<b>Lungs</b>		
Residual volume increases.	Include inspection, palpation, percussion, and auscultation in lung assessments.	Inspection, palpation, percussion, and auscultation are needed to detect normal age-related changes.
Vital capacity decreases.	Help patient actively maintain health and fitness.	Health and fitness help keep losses in respiratory functioning to a minimum.
Efficiency of oxygen and carbon dioxide exchange decreases.	Assess patient's respirations for abnormal breathing patterns.	Periodic breathing patterns (e.g., Cheyne-Stokes) can occur.
Elasticity decreases.	Encourage frequent oral hygiene.	Oral hygiene aids in the removal of secretions.

<b>Pharynx and Larynx</b>		
Muscles atrophy. Vocal cords become slack. Laryngeal muscles lose elasticity, and airways lose cartilage.	Have face-to-face conversations with patient when possible.	Patient's voice may be soft and difficult to understand.
<b>Pulmonary Vasculature</b>		
Vascular resistance to blood flow through pulmonary vascular system increases. Pulmonary capillary blood volume decreases. Risk for hypoxia increases.	Assess patient's level of consciousness and cognition.	Patient can become confused during acute respiratory conditions because of reduced oxygen levels in the brain.
<b>Exercise Tolerance</b>		
Body's response to hypoxia and hypercarbia decreases.	Assess for subtle manifestations of hypoxia.	Early assessment helps prevent complications.
<b>Muscle Strength</b>		
Respiratory muscle strength, especially the diaphragm and the intercostals, decreases.	Encourage pulmonary hygiene and help patient actively maintain health and fitness.	Regular pulmonary hygiene and overall fitness help maintain maximal functioning of the respiratory system and prevent illness.
<b>Susceptibility to Infection</b>		
Effectiveness of the cilia decreases. Immunoglobulin A decreases. Alveolar macrophages are altered.	Encourage pulmonary hygiene and help patient actively maintain health and fitness.	Regular pulmonary hygiene and overall fitness help maintain maximal functioning of the respiratory system and prevent illness.
<b>Chest Wall</b>		
Anteroposterior diameter increases. Thorax becomes shorter. Progressive kyphoscoliosis occurs. Chest wall compliance (elasticity) decreases. Mobility of chest wall may decrease. Osteoporosis is possible, leading to chest wall abnormalities.	Discuss the normal changes of aging.	Patients may be anxious because they must work harder to breathe.
	Discuss the need for increased rest periods during exercise.	Older patients have less tolerance for exercise.
	Encourage adequate calcium intake (especially during a woman's premenopause phase).	Calcium intake helps prevent osteoporosis by building bone in younger patients.

Respiratory disease is a major cause of illness and chronic disability in older patients. Although respiratory function normally declines with age, there is usually no problem keeping pace with the demands of ordinary activity. However, the sedentary older adult often feels breathless during exercise (Touhy & Jett, 2016).

It is difficult to determine which respiratory changes in older adults are related to normal aging and which changes are caused by respiratory disease or exposure to pollutants. Age-related changes in the muscles and the cardiac and vascular system also may cause abnormal breathing, even if the lungs are normal.

## NCLEX Examination Challenge 27-2

### Physiological Integrity

Which conditions are **most** likely to cause a “left shift” of the oxyhemoglobin dissociation curve?  
**Select all that apply.**

- A. Reduced blood and tissue levels of diphosphoglycerate (DPG)
- B. Reduced blood and tissue pH
- C. Increased metabolic demands
- D. Alkalosis
- E. Increased body temperature
- F. Reduced blood and tissue levels of oxygen

### Health Promotion and Maintenance

Lung and breathing problems are common causes of death in North America (McCance et al., 2014). Some respiratory problems are chronic, and the patient has physical and lifestyle limitations. Many acute health problems, medical therapies, and surgeries adversely affect respiratory function temporarily or permanently. Exposure to inhalation irritants, especially to cigarette smoke, is the most common cause of chronic respiratory problems and physical limitations. In addition, smoking is a modifiable factor that greatly increases the risk for cardiovascular disease, stroke, and many types of cancer. Three compounds in cigarette smoke that have been implicated in the development of these serious diseases are tar, nicotine, and carbon monoxide. In the years after a patient has stopped smoking, his or her risk for respiratory-related disorders decreases significantly. Therefore assessing smoking habits, actively promoting smoking cessation, determining exposure to other

inhalation irritants, and teaching adults to protect the respiratory system are important nursing functions. Although cigarette smoking has declined in both countries, about 21% of the United States population continues to smoke cigarettes (Nguyen et al., 2015), and slightly less than 20% of the Canadian population continues to smoke cigarettes (Statistics Canada, 2016).

*Assessing smoking habits* begins by determining whether the patient is a current smoker or has ever smoked. The smoking history includes the number of cigarettes smoked daily, the duration of the smoking habit, and the age of the patient when smoking started even for patients who are not current smokers. Record the smoking history in **pack-years**, which is the number of packs per day multiplied by the number of years the patient has smoked.

Ask those who do not currently smoke whether and to what extent they are exposed to the smoke of others. Passive smoking has two origins: direct exposure to smoke by being in the same environment with an adult(s) who is actively smoking (*secondhand smoke [SHS]*); and indirect exposure from smoke that clings to hair and clothing (*thirdhand smoke*). Passive smoking contributes to health problems, especially when chronic exposure occurs in small, confined spaces.

*Social smokers* are adults who smoke cigarettes only in the presence of others, borrow rather than purchase cigarettes, prefer the company of nonsmokers, and do not smoke for stress relief. Often the social smoker does not consider himself or herself to be a smoker and must be asked specifically, “Do you ever smoke in social situations?” Even intermittent smoking has adverse effects on respiratory and cardiovascular health and may lead to nicotine addiction.

Hookah or water-pipe smoking is increasing in North America, especially among young adults. Many smokers have the false belief that hookah smoking is safer than cigarette smoking. The exposure to inhaled toxins during hookah smoking is as great or greater than with cigarette smoking.

Electronic nicotine delivery systems (ENDS) with either battery-powered electronic cigarettes or a vape pen, also known as *vaping*, are an alternative to traditional cigarettes and sometimes are used as a method of quitting smoking. A vape pen is a larger device with a greater volume of liquid often worn as a pendant or necklace around the neck. An advantage of ENDS is that they do not contain combustion products that affect either the user or bystanders (Antolin & Barkley, 2015). The liquids and the vapors produced contain nicotine; and new evidence indicates that other lung toxins are present in the flavorings, especially diacetyl (Hua & Talbot, 2016). These toxins appear responsible for new-onset bronchiolitis obliterans (“popcorn lung”) and for worsening of other existing lung injury conditions. This issue is especially problematic for adults using vape pens because these devices allow almost continuous use and exposure to the liquids. Although previously unregulated, the Food and Drug Administration now has responsibility for assessing health effects of ENDS and setting safety standards (American Lung Association [ALA], 2016).

## Gender Health Considerations

### Patient-Centered Care QSEN

Lesbian women, gay men, bisexual men and women, and transgender (LGBT) adults report higher rates of smoking compared with their heterosexual counterparts (ALA, 2015). Therefore screening for smoking and tobacco-related health conditions is especially important when working with LGBT patients.

## Cultural/Spiritual Considerations

### Patient-Centered Care QSEN

The prevalence of smoking is higher among African Americans, blue-collar workers, and less-educated adults than in the overall North American population. It is highest among Native American and Native Canadian Indians. Development of culturally appropriate smoking-cessation programs and research examining barriers to cessation in these populations may help reduce this disparity.

*Promoting smoking cessation* is a sensitive and sometimes uncomfortable issue for nurses and other

health care professionals to approach with patients who smoke. However, this opportunity for a “teachable moment” may be the beginning support a patient needs to be successful in this healthful pursuit, especially if the patient is hospitalized for a smoking-related illness (Keating, 2016). Acute care settings have automatic smoking-cessation protocols that attach to the patient's electronic medical record when an active smoking history is recorded. **The Joint Commission requires documentation of screening for tobacco use and that a tobacco treatment program be offered or provided as part of their quality measures.**

Ask about the patient's desire to quit, past attempts to quit, and the methods used. A “yes” response to any of the following questions indicates nicotine dependence. The more “yes” responses, the greater the nicotine dependence. Ask the smoker these questions:

- How soon after you wake up in the morning do you smoke?
- Do you wake up in the middle of your sleep time to smoke?
- Do you find it difficult not to smoke in places where smoking is prohibited?
- Do you smoke when you are ill?

Drug therapies are available over the counter and by prescription to help those addicted to nicotine to modify their behavior and stop smoking. Over-the-counter nicotine replacement therapies (NRTs) include nicotine-releasing transdermal patches, gums, and lozenges. Prescribed NRT products include nasal sprays and inhalers. NRT products have a success rate of smoking cessation of at least 50% (Barnett et al., 2015). They have the highest success rates when used along with a smoking-cessation program. Chart 27-2 lists suggestions for you to use in providing support to the person interested in stopping cigarette smoking.

### Chart 27-2

## Patient and Family Education: Preparing for Self-Management

### Smoking Cessation

- Make a list of the reasons you want to stop smoking (e.g., your health and the health of those around you, saving money, social reasons).
- Set a date to stop smoking and keep it. Decide whether you are going to begin to cut down on the amount you smoke or are going to stop “cold turkey.” Whichever way you decide to do it, keep this important date!
- Ask for help from those around you. Find someone who wants to quit smoking and “buddy up” for support. Look for assistance in your community, such as formal smoking-cessation programs, counselors, and certified acupuncture specialists or hypnotists.
- Consult your health care provider about nicotine replacement therapy (e.g., patch, gum) or other pharmacologic therapy to assist in smoking cessation.
- Remove ashtrays and lighters from your view.
- Talk to yourself! Remind yourself of all the reasons you want to quit.
- Think of a way to reward yourself with the money you save from not smoking for a year.
- Avoid places that might tempt you to smoke. If you are used to having a cigarette after meals, get up from the table as soon as you are finished eating. Think of new things to do at times when you used to smoke (e.g., taking a walk, exercising, calling a friend).
- Find activities that keep your hands busy: needlework, painting, gardening, even holding a pencil.
- Take five deep breaths of clean, fresh air through your nose and out your mouth if you feel the

urge to smoke.

- Keep plenty of healthy, low-calorie snacks, such as fruits and vegetables, on hand to nibble on. Try sugarless gum or mints as a substitute for tobacco.
- Drink at least eight glasses of water each day.
- Begin an exercise program with the approval of your primary health care provider. Be aware of the positive, healthy changes in your body since you stopped smoking.
- List the many reasons why you are glad that you quit. Keep the list handy as a reminder of the positive things you are doing for yourself.
- If you have a cigarette, think about the conditions that caused you to light it. Try and think of a strategy to avoid that (or those) conditions.
- Don't beat yourself up for backsliding; just face the next day as a new day.
- Think of each day without tobacco as a major accomplishment. It is!

## Nursing Safety Priority QSEN

### Drug Alert

Teach adults using drugs for nicotine replacement therapy that smoking while taking these drugs greatly increases circulating nicotine levels and the risk for stroke or heart attack.

Additional drug therapy for smoking cessation includes the oral drugs bupropion (Zyban) and varenicline (Chantix). Bupropion decreases cravings and withdrawal symptoms, as well as reduces the depression associated with nicotine-withdrawal symptoms. Varenicline interferes with the nicotine receptors. This promotes smoking cessation by reducing the pleasure derived from nicotine and the symptoms of nicotine withdrawal.

## Nursing Safety Priority QSEN

### Drug Alert

Both bupropion and varenicline carry a black box warning that use of these drugs can cause manic behavior and hallucinations. These drugs also may unmask serious mental health issues. Teach patients prescribed either of these drugs and their families to report any change in behavior or thought processes to the prescriber immediately.

## Veterans' Health Considerations

### Patient-Centered Care QSEN

Cigarette smoking among military veterans is declining more slowly than among the general population, with a 27% smoking rate among veterans compared with a 21% smoking rate among the nonveteran population. Health care costs from cigarette smoking in military veterans is about 7.8% of the total budget for the Veterans' Health Administration (VHA), with costs related to inpatient care as high as 11.4% (Barnett et al., 2015). The slower decline appears to be related to a remaining high smoking prevalence among veterans who have psychiatric and substance use disorders and among female veterans. The VHA has implemented several strategies to promote smoking cessation among veterans, including extending the use of NRT to veterans who are not part of a formal smoking cessation program and eliminating copayments for NRT. Be sure to assess the smoking status of all veterans and inform them of VHA smoking-cessation assistance.

*Assessing exposure to inhalation irritants* should be part of any health assessment within the demographic history. Include the patient's current and past geographic living area, home conditions, occupation, and hobbies. Areas with high levels of air pollution contribute to respiratory problems. Exposure to dust, particles, chemicals, gases, or toxic fumes can occur in the workplace, making work history information important. Ask about dates of employment and a brief job description. Exposure to industrial dusts of any type or to chemical fumes may cause breathing disorders. Bakers, coalminers, stone masons, cotton handlers, woodworkers, welders, potters, plastic and rubber manufacturers, printers, farm workers, those working in grain elevators or flour mills, and steel foundry workers are at risk for work-related breathing problems.

Ask about the type of heat used at home (e.g., gas heater, wood-burning stove, fireplace, kerosene heater). Determine exposure to irritants (e.g., fumes, chemicals, animals, birds, air pollutants). Ask about hobbies such as painting, ceramics, model airplanes, refinishing furniture, or woodworking, which may expose the patient to harmful chemicals.

*Protecting the respiratory system* starts with making adults aware of the sources of inhalation irritants. Teach adults who live in areas with high levels of air pollution to remain indoors with windows closed on days when air quality is poor and not to engage in heavy physical activity. Teach adults who have workplace or home exposure to inhalation irritants to wear masks during these exposures and ensure that the area is well ventilated.

# Assessment: Noticing and Interpreting

## Patient History

Accurate patient information is important for identifying the type and severity of breathing problems that may interfere with GAS EXCHANGE. Age, gender, and race can affect the physical and diagnostic findings related to breathing (Jarvis, 2016). Many diagnostic studies for respiratory disorders (e.g., pulmonary function tests) use these data for determining predicted normal values. As described in the Health Promotion and Maintenance section, explore the home, community, and workplace for environmental factors that could cause or worsen lung disease. Use this opportunity to teach patients about measures to protect the respiratory system.

### Gender Health Considerations

#### Patient-Centered Care QSEN

Women, especially smokers, have greater bronchial responsiveness (i.e., bronchial hyperreactivity) and larger airways than men. This factor increases the risk for a more rapid decline in lung function as a woman ages, especially in women who were or are smokers. Be sure to measure gas exchange adequacy with pulse oximetry when assessing women.

### Cultural/Spiritual Considerations

#### Patient-Centered Care QSEN

Compared with white adults, black adults and others with dark skin usually show a lower oxygen saturation (3% to 5% lower) as measured by pulse oximetry; this results from deeper coloration of the nail bed and does not reflect true oxygen status. Use additional respiratory assessment techniques to assess gas exchange adequacy in adults with dark skin.

Ask patients about their respiratory history (Table 27-1), including smoking history, drug use, travel, and area of residence. Document the smoking history in pack-years.

**TABLE 27-1**

#### Important Aspects to Assess in a Respiratory System History

<ul style="list-style-type: none"><li>• Smoking history</li><li>• Childhood illnesses:</li><li>• Asthma</li><li>• Pneumonia</li><li>• Communicable diseases</li><li>• Hay fever</li><li>• Allergies</li><li>• Eczema</li><li>• Frequent colds</li><li>• Croup</li><li>• Cystic fibrosis</li><li>• Adult illnesses:</li><li>• Pneumonia</li><li>• Sinusitis</li><li>• Tuberculosis</li><li>• HIV and AIDS</li><li>• Lung disease such as emphysema and sarcoidosis</li><li>• Diabetes</li><li>• Hypertension</li><li>• Heart disease</li><li>• Influenza, pneumococcal (Pneumovax), and BCG vaccinations</li></ul>	<ul style="list-style-type: none"><li>• Surgeries of the upper or lower respiratory system</li><li>• Injuries to the upper or lower respiratory system</li><li>• Hospitalizations</li><li>• Date of last chest x-ray, pulmonary function test, tuberculin test, or other diagnostic tests and results</li><li>• Recent weight loss</li><li>• Night sweats</li><li>• Sleep disturbances</li><li>• Lung disease and condition of family members</li><li>• Geographic areas of recent travel</li><li>• Occupation and leisure activities</li></ul>
---	---

AIDS, Acquired immune deficiency syndrome; BCG, bacille Calmette-Guérin; HIV, human immune deficiency virus.

*Drug use*, both prescribed drugs and illicit drugs, can affect lung function, even when taken systemically. Ask about drugs taken for breathing problems and those taken for other conditions. For example, a cough can be a side effect of some antihypertensive drugs (angiotensin-converting enzyme inhibitors [ACEIs] and angiotensin receptor blockers [ARBs]). Determine which over-the-counter drugs (e.g., cough syrups, antihistamines, decongestants, inhalants) the patient uses. Assess use of complementary and integrative therapies. Ask about past drug use. Some drugs for other conditions can cause permanent changes in lung function. For example, patients may have

pulmonary fibrosis if they received bleomycin (Blenoxane) as chemotherapy for cancer or amiodarone (Cordarone) for cardiac problems. Marijuana and illicit drugs, such as cocaine, are often inhaled and can affect lung function.

*Allergies* to foods, dust, molds, pollen, bee stings, trees, grass, animal dander and saliva, or drugs can affect breathing. Ask the patient to describe specific allergic responses. For example, does he or she wheeze, have trouble breathing, cough, sneeze, or have rhinitis after exposure to the allergen? Has he or she ever been treated for an allergic response? If the patient has allergies, ask about the specific cause, treatment, and response to treatment.

## Nursing Safety Priority QSEN

### Action Alert

Document any known allergies, especially to drugs, and the specific type of allergic response in a prominent place in the patient's medical record.

*Travel and geographic area of residence* may reveal exposure to certain diseases. For example, *histoplasmosis*, a fungal disease caused by inhalation of contaminated dust, is found in the central parts of the United States and Canada. *Coccidioidomycosis* is found in the western and southwestern parts of the United States, in Mexico, and in parts of Central America, as is *Hantavirus*. With veterans, ask about location of deployments within the past year.

### Family History and Genetic Risk

Obtain a family history to assess for respiratory disorders that have a genetic component, such as cystic fibrosis, some lung cancers, and emphysema. Patients with asthma often have a family history of allergy. Ask about a history of infectious disease, such as tuberculosis, because family members may have similar environmental exposures.

### Current Health Problems

Whether the breathing problem is acute or chronic, the current health problem usually includes cough, sputum production, chest pain, and shortness of breath at rest or on exertion. Explore the current illness in chronologic order. Ask about the onset of the problem, how long it lasts, the location of the problem, how often it occurs, whether the problem has become worse over time, which symptoms occur with it, which actions or interventions provide relief and which ones make it worse, and which treatments have been used.

*Cough* is a sign of lung disease. Ask the patient how long the cough has been present and whether it occurs at a specific time of day (e.g., on awakening in the morning) or in relation to any physical activity. Ask whether the cough produces sputum or is dry, tickling, or hacking.

*Sputum production* is an important symptom associated with coughing. Check the color, consistency, odor, and amount of sputum.

Describe the consistency of sputum as thin, thick, watery, or frothy. Smokers with chronic bronchitis have mucoid sputum. Excessive pink, frothy sputum is common with pulmonary edema. Bacterial pneumonia often produces rust-colored sputum, and a lung abscess may cause foul-smelling sputum. **Hemoptysis** (blood in the sputum) may be seen in patients with chronic bronchitis or lung cancer. Grossly bloody sputum may occur with tuberculosis, pulmonary infarction, lung cancer, or lung abscess.

Ask the patient to quantify sputum by describing its volume in terms such as teaspoon, tablespoon, and cup. Normally the lungs can produce up to 90 mL of sputum per day.

*Chest pain* can occur with other health problems in addition to with lung problems. A detailed description of chest pain helps distinguish its cause. Ask whether the pain is continuous or made worse by coughing, deep breathing, or swallowing. Cardiac pain is usually intense and “crushing” and may radiate to the arm, shoulder, or neck. Pulmonary pain varies, depending on the cause, and most often feels like something is “rubbing” inside. Pain may appear only on deep inhalation or be present at the end of inhalation and the end of exhalation. Pulmonary pain is not made worse by touching or pressing over the area.

*Dyspnea* (difficulty in breathing or breathlessness) is a subjective perception and varies among

patients (Baker et al., 2013). A patient's feeling of dyspnea may not be consistent with the severity of the problem. However, patients with chronic lung disease can reliably report dyspnea levels that accurately correspond to the severity of their disease (Croucher, 2014). Determine the type of onset (slow or abrupt), the duration, relieving factors (position changes, drug use, activity cessation), and whether wheezing or stridor occurs with dyspnea.

Try to quantify dyspnea by asking whether this symptom interferes with ADLs and, if so, how severely. For example, does dyspnea occur after walking one block or climbing one flight of stairs? Table 27-2 classifies dyspnea with changes in ADL performance. Because dyspnea can be an independent predictor of life-threatening illness, early assessment provides an opportunity to optimize care, improve symptom management, ensure the appropriate level of intervention and care, and determine best use of resources (Baker et al., 2013).

**TABLE 27-2**  
**Correlation of Dyspnea Classification With Performance of ADLs**

CLASSIFICATION	ADLs KEY
<i>Class I:</i> No significant restrictions in normal activity. Employable. Dyspnea occurs only on more-than-normal or strenuous exertion.	4: No breathlessness, normal.
<i>Class II:</i> Independent in essential ADLs but restricted in some other activities. Dyspneic on climbing stairs or on walking on an incline but not on level walking. Employable only for sedentary job or under special circumstances.	3: Satisfactory, mild breathlessness. Complete performance is possible without pause or assistance but not entirely normal.
<i>Class III:</i> Dyspnea commonly occurs during usual activities such as showering or dressing, but the patient can manage without assistance from others. Not dyspneic at rest; can walk for more than a city block at own pace but cannot keep up with others of own age. May stop to catch breath partway up a flight of stairs. Is not likely to be employed.	2: Fair, moderate breathlessness. Must stop during activity. Complete performance is possible without assistance, but performance may be too debilitating or time consuming.
<i>Class IV:</i> Dyspnea produces dependence on help in some essential ADLs such as dressing and bathing. Not usually dyspneic at rest. Dyspneic on minimal exertion; must pause on climbing one flight, walking more than 100 yards, or dressing. Often restricted to home if lives alone. Has minimal or no activities outside of home.	1: Poor, marked breathlessness. Incomplete performance; assistance is necessary.
<i>Class V:</i> Entirely restricted to home and often limited to bed or chair. Dyspneic at rest. Dependent on help for most needs.	0: Performance not indicated or recommended; too difficult.

ADLs, Activities of daily living.

Ask about **orthopnea**, which is shortness of breath occurring when lying down and is relieved by sitting up. Assess for paroxysmal nocturnal dyspnea (PND), which awakens the patient from sleep with the feeling of an inability to breathe. PND also occurs while lying flat and is relieved by sitting up. It often occurs with chronic lung disease and left-sided heart failure.

## NCLEX Examination Challenge 27-3

### Safe and Effective Care Environment

Which assessment findings are **most important** for the nurse to determine when assessing a client with dyspnea? **Select all that apply.**

- A. Onset of or when the client first noticed dyspnea
- B. Results of most recent pulmonary function test
- C. Conditions that relieve the dyspnea sensation
- D. Whether or not dyspnea interferes with ADLs
- E. Inspection of the external nose and its symmetry
- F. Whether stridor is present with dyspnea

## Physical Assessment

### Assessment of the Nose and Sinuses

Inspect the patient's external nose for deformities or polyps and the nares for symmetry of size and shape. To observe the interior nose, ask the patient to tilt the head back for a penlight examination. The experienced nurse may use a nasal speculum and nasopharyngeal mirror for a more thorough inspection of the nasal cavity.

Inspect for color, swelling, drainage, and bleeding. Nasal mucous membranes normally appear redder than the oral mucosa but are pale, engorged, and bluish-gray in patients with allergic rhinitis. Check the nasal septum for bleeding, perforation, or deviation. Septal deviation is common

and appears as an S shape, tilting toward one side or the other. A perforated septum is present if the light shines through the perforation into the opposite side; this condition is often found in cocaine users. Nasal polyps are pale, shiny, gelatinous lumps or “bags” attached to the turbinates. Block one naris at a time to check how well air moves through the unblocked side.

### Assessment of the Pharynx, Trachea, and Larynx

Assessment of the pharynx begins with inspection of the mouth. To examine the posterior pharynx, use a tongue depressor to press down one side of the tongue at a time (to avoid stimulating the gag reflex). As the patient says “ah,” observe the rise and fall of the soft palate and inspect for color and symmetry, drainage, edema or ulceration, and enlarged tonsils.

Inspect the neck for symmetry, alignment, masses, swelling, bruises, and the use of accessory neck muscles in breathing. Palpate lymph nodes for size, shape, mobility with palpation, consistency, and tenderness.

Gently palpate the trachea for position, mobility, tenderness, and masses. The trachea should be in the midline. Many lung disorders cause the trachea to deviate from the midline. Tension pneumothorax, large pleural effusion, mediastinal mass, and neck tumors push the trachea *away* from the affected area. Pneumonectomy, fibrosis, and atelectasis pull it *toward* the affected area.

The larynx is usually examined by a specialist with a laryngoscope. An abnormal voice, especially hoarseness, may be heard when there are problems of the larynx.

### Assessment of the Lungs and Thorax

#### Inspection.

Inspect the front and back of the thorax with the patient sitting up. Normal landmarks of the chest front (anterior) and back (posterior) are shown in Fig. 27-8. The patient should be undressed to the waist. Observe the chest and compare one side with the other. Work from the top (apex) and move downward toward the base, going from side to side, while inspecting for discoloration, scars, lesions, masses, and spinal curvatures. Assessing from side to side allows you to compare the findings for each lung at the same level (Jarvis, 2016).

FIG. 27-8 Anterior and posterior chest landmarks.

Observe the rate, rhythm, and depth of inspirations and the symmetry of chest movement. Impaired movement or unequal expansion may indicate disease. Observe the type of breathing (e.g., pursed-lip or diaphragmatic breathing) and the use of accessory muscles.

Examine the shape of the patient's chest, and compare the anteroposterior (AP or front-to-back) diameter with the lateral (side-to-side) diameter. This ratio normally is about 1 : 1.5, depending on

body build. It increases to 1 : 1 in patients with emphysema, which results in the typical barrel-chest appearance.

Normally the ribs slope downward. Patients with air trapping in the lungs caused by emphysema have ribs that are more horizontal. Observe or palpate the distance between the ribs (*intercostal space*). This distance is usually one finger-breadth (2 cm). It increases in disorders that cause air trapping, such as emphysema. Observe for retraction of muscle between the ribs and at the sternal notch. Retractions are areas that get sucked inward when the patient inhales. This does not occur during normal respiratory effort. Retractions may occur when the patient is working hard to inhale around an obstruction.

### Palpation.

Palpate the chest after inspection to assess respiratory movement symmetry and observable abnormalities. Palpation also can help identify areas of tenderness and check vocal or tactile **fremitus** (vibration).

Assess chest expansion by placing your thumbs on the patient's spine at the level of the ninth ribs and extending the fingers sideways around the rib cage. As the patient inhales, both sides of the chest should move upward and outward together in one symmetric movement, moving your thumbs apart. On exhalation, the thumbs should come back together as they return to the midline. Unequal expansion may be a result of pain, trauma, or air in the pleural cavity. Respiratory lag or slowed movement on one side indicates a pulmonary problem (Jarvis, 2016).

Palpate any abnormalities found on inspection (e.g., masses, lesions, swelling). Also palpate for tenderness, especially if the patient reports pain. **Crepitus** (air trapped in and under the skin, also known as *subcutaneous emphysema*) is felt as a crackling sensation beneath the fingertips. Document this finding and report it to the primary health care provider when it occurs around a wound site or a tracheostomy site or if a pneumothorax is suspected.

**Tactile (vocal) fremitus** is felt as a vibration of the chest wall produced when the patient speaks. Fremitus is decreased if sound wave transmission from the larynx to the chest wall is slowed, such as when the pleural space is filled with air (pneumothorax) or fluid (**pleural effusion**) or when the bronchus is obstructed. Fremitus is increased with pneumonia and lung abscesses because the increased density of the chest enhances vibration transmission.

### Percussion.

Use percussion to assess for pulmonary resonance, the boundaries of organs, and diaphragmatic excursion. Percussion involves tapping the chest wall, which sets the underlying tissues into motion and produces audible sounds (Fig. 27-9). This action produces five different sounds that help determine whether the lung tissue contains air or fluid or is solid (Table 27-3).

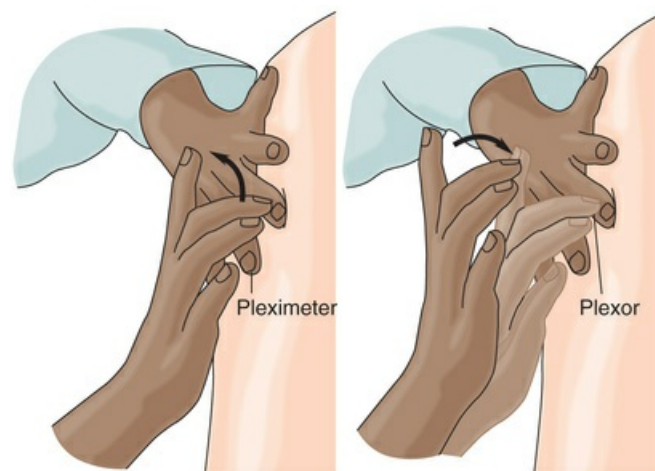

FIG. 27-9 Percussion technique.

---

### TABLE 27-3

## Characteristics of the Five Percussion Notes

NOTE	PITCH	INTENSITY	QUALITY	DURATION	FINDINGS
Resonance	Low	Moderate to loud	Hollow	Long	Resonance is characteristic of normal lung tissue.
Hyperresonance	Higher than resonance	Very loud	Booming	Longer than resonance	Hyperresonance indicates the presence of trapped air, so it is commonly heard over an emphysematous or asthmatic lung and occasionally over a pneumothorax.
Flatness	High	Soft	Extreme dullness	Short	An example location is the sternum. Flatness percussed over the lung fields may indicate a massive pleural effusion.
Dullness	Medium	Medium	Thudlike	Medium	Example locations are over the liver and the kidneys. Dullness can be percussed over an atelectatic lung or a consolidated lung.
Tympany	High	Loud	Musical, drumlike	Short	Examples are the cheek filled with air and the abdomen distended with air. Over the lung, a tympanic note usually indicates a large pneumothorax.

## Auscultation.

Lung auscultation is listening with a stethoscope for normal breath sounds, abnormal (*adventitious*) sounds, and voice sounds. It provides information about the flow of air through the trachea and lungs and helps identify fluid, mucus, or obstruction in the respiratory system.

Begin auscultation with the patient sitting in an upright position. With the stethoscope pressed firmly against the chest wall (clothing can muffle sounds), instruct the patient to breathe slowly and deeply through an open mouth. (Breathing through the nose sets up turbulent sounds that are transmitted to the lungs.) Use a systematic approach, beginning at the lung apices and moving from side to side down through the intercostal spaces to the lung bases (Fig. 27-10). Avoid listening over bony structures. Listen to a full respiratory cycle, noting the quality and intensity of the breath sounds.

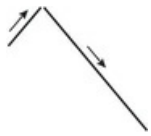

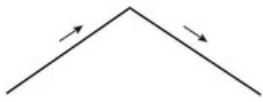

**FIG. 27-10** Sequence for percussion and auscultation.

*Normal breath sounds* are produced as air vibrates while moving through the passages from the larynx to the alveoli. Breath sounds are identified by their location, intensity, pitch, and duration within the respiratory cycle (e.g., early or late inspiration and expiration). Normal breath sounds are known as “bronchial” or “tubular” (harsh hollow sounds heard over the trachea and mainstem bronchi), “bronchovesicular” (heard over the branching bronchi), and “vesicular” (soft rustling sounds heard in lung tissue over small bronchioles) (Table 27-4). Describe these sounds as *normal*, *increased*, *diminished*, or *absent*.

**TABLE 27-4**

## Characteristics of Normal Breath Sounds

	PITCH	AMPLITUDE	DURATION	QUALITY	NORMAL LOCATION
Bronchial (tubular, tracheal) 	High	Loud	Inspiration < expiration	Harsh, hollow, tubular, blowing	Trachea and larynx
Bronchovesicular 	Moderate	Moderate	Inspiration = expiration	Mixed	Over major bronchi where fewer alveoli are located; posterior, between scapulae (especially on right); anterior, around upper sternum in first and second intercostal spaces
Vesicular 	Low	Soft	Inspiration > expiration	Rustling, like the sound of the wind in the trees	Over peripheral lung fields where air flows through smaller bronchioles and alveoli

From Jarvis, C. (2016). *Physical examination and health assessment* (7th ed.). St. Louis: Saunders.

Bronchial breath sounds heard at the lung edges are abnormal and occur when the bronchial sounds are transmitted to an area of increased density, such as with atelectasis, tumor, or pneumonia. When heard in an abnormal location, bronchovesicular breath sounds may indicate normal aging or an abnormality such as consolidation and chronic airway disease.

*Adventitious sounds* are additional breath sounds along with normal sounds, and they indicate pathologic changes in the lung. Table 27-5 describes adventitious sounds: crackle, wheeze, rhonchus, and pleural friction rub. These sounds vary in pitch, intensity, and duration and can occur in any phase of the respiratory cycle. Document exactly what you hear on auscultation.

**TABLE 27-5**

## Characteristics of Adventitious Breath Sounds

ADVENTITIOUS SOUND	CHARACTER	ASSOCIATION
Fine crackles Fine rales High-pitched rales	Popping, discontinuous sounds caused by air moving into previously deflated airways; sounds like hair being rolled between fingers near the ear “Velcro” sounds late in inspiration usually associated with restrictive disorders	Asbestosis Atelectasis Interstitial fibrosis Bronchitis Pneumonia Chronic pulmonary diseases
Coarse crackles Low-pitched crackles	Lower-pitched, coarse, rattling sounds caused by fluid or secretions in large airways; likely to change with coughing or suctioning	Bronchitis Pneumonia Tumors Pulmonary edema
Wheeze	Squeaky, musical, continuous sounds associated with air rushing through narrowed airways; may be heard without a stethoscope Arise from the small airways Usually do not clear with coughing	Inflammation Bronchospasm (bronchial asthma) Edema Secretions Pulmonary vessel engorgement (as in cardiac “asthma”)
Rhonchus (rhonchi)	Lower-pitched, coarse, continuous snoring sounds Arise from the large airways	Thick, tenacious secretions Sputum production Obstruction by foreign body Tumors
Pleural friction rub	Loud, rough, grating, scratching sounds caused by the inflamed surfaces of the pleura rubbing together; often associated with pain on deep inspirations Heard in lateral lung fields	Pleurisy Tuberculosis Pulmonary infarction Pneumonia Lung cancer

*Voice sounds* (vocal resonance) through the normally air-filled lung are muffled and unclear because sound vibrations travel poorly through air. These sounds become louder and more distinct when the sound travels through a solid tissue or liquid. The presence of pneumonia, atelectasis, pleural effusion, tumor, or abscess causes increased vocal resonance.

## NCLEX Examination Challenge 27-4

### Safe and Effective Care Environment

The nurse assessing the respiratory status of a client discovers that tactile fremitus has increased

from the assessment performed yesterday. For which possible respiratory problem should the nurse assess further?

- A. Pneumothorax
- B. Pneumonia
- C. Pleural effusion
- D. Emphysema

### Other Indicators of Respiratory Adequacy

Assess other indicators of respiratory adequacy, because GAS EXCHANGE affects all body systems. Some indicators (e.g., cyanosis) reflect immediate gas exchange and PERFUSION problems. Other changes (e.g., clubbing, weight loss) reflect long-term oxygenation problems.

*Skin and mucous membrane* changes (e.g., pallor, cyanosis) may indicate inadequate GAS EXCHANGE and PERFUSION. Assess the nail beds and the mucous membranes of the oral cavity. Examine the fingers for clubbing (see Fig. 30-10), which indicates long-term hypoxia.

*General appearance* includes muscle development and general body build. Long-term respiratory problems lead to weight loss and a loss of general muscle mass. Arms and legs may appear thin or poorly muscled. Neck and chest muscles may be hypertrophied, especially in the patient with chronic obstructive pulmonary disease (COPD) (McCance et al., 2014).

*Endurance* decreases when breathing is inadequate for GAS EXCHANGE. Observe how easily the patient moves and whether he or she is short of breath while resting or becomes short of breath when walking 10 to 20 steps. Note how often the patient stops for breath between words while speaking.

## Psychosocial Assessment

Breathing difficulty often induces anxiety. The patient may be anxious because of reduced oxygen to the brain or because the sensation of not getting enough air is frightening. The thought of having a serious problem, such as lung cancer, can also induce anxiety. Encourage the patient to express his or her feelings and fears about symptoms and their possible meaning.

Assess those aspects of the patient's lifestyle that either can affect respiratory function or are affected by it. Some respiratory problems may become worse with stress. Ask about current life stresses and usual coping mechanisms.

Chronic respiratory disease may cause changes in family roles or relationships, social isolation, financial problems, and unemployment or disability. Discuss coping mechanisms to assess the patient's reaction to these stressors and identify strengths. For example, the patient may react to stress with dependence on family members, withdrawal, or failure to adhere to interventions. Help the patient identify available support systems.

## Diagnostic Assessment

### Laboratory Assessment

Several laboratory tests (Chart 27-3) are useful in assessing respiratory problems. A red blood cell (RBC) count provides data about oxygen transport. Hemoglobin, found in RBCs, transports oxygen to the tissues. A deficiency of hemoglobin could cause hypoxemia.

**Chart 27-3**

## Laboratory Profile

### Respiratory Assessment

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Blood Studies		
Complete Blood Count		
Red blood cells		Elevated levels (polycythemia) are often related to the excessive production of erythropoietin in response to a chronic hypoxic

	Females: 4.2-5.4 million/mm <sup>3</sup> , or 4.2-5.4 × 10 <sup>12</sup> /L Males: 4.7-6.1 million/mm <sup>3</sup> , or 4.7-6.1 × 10 <sup>12</sup> /L	state, as in COPD, and from living at a high altitude. Decreased levels indicate possible anemia, hemorrhage, or hemolysis.
Hemoglobin, total	Females: 12-16 g/dL, or 120-160 g/L Males: 14-18 g/dL, or 140-180 g/L	Same as for red blood cells.
Hematocrit	Females: 37%-47%, or 0.37-0.47 volume fraction Males: 42%-52%, or 0.42-0.52 volume fraction	Same as for red blood cells.
WBC count (leukocyte count, WBC count)	Total: 5000-10,000/mm <sup>3</sup> , or 5-10 × 10 <sup>9</sup> /L	Elevations indicate possible acute infections or inflammations. Decreased levels may indicate an overwhelming infection, an autoimmune disorder, or immunosuppressant therapy.
<b>Differential White Blood Cell (Leukocyte) Count</b>		
Neutrophils	2500-8000/mm <sup>3</sup> , or 50%-62% of total, or 5-6.2 × 10 <sup>9</sup> /L	Elevations indicate possible acute bacterial infection (pneumonia), COPD, or inflammatory conditions (smoking). Decreased levels indicate possible viral disease (influenza).
Eosinophils	50-500/mm <sup>3</sup> , or 1%-4% of total, or 0.0-0.3 × 10 <sup>9</sup> /L	Elevations indicate possible COPD, asthma, or allergies. Decreased levels indicate pyogenic infections.
Basophils	15-50/mm <sup>3</sup> , or 0.5%-1% of total, or 0.02-0.05 × 10 <sup>9</sup> /L	Elevations indicate possible inflammation; seen in chronic sinusitis, hypersensitivity reactions. Decreased levels may be seen in an acute infection.
Lymphocytes	1000-4000/mm <sup>3</sup> , or 20%-40% of total, or 1.0-4.0 × 10 <sup>9</sup> /L	Elevations indicate possible viral infection, pertussis, and infectious mononucleosis. Decreased levels may be seen during corticosteroid therapy.
Monocytes	100-700/mm <sup>3</sup> , or 2%-8% of total, or 0.1-0.7 × 10 <sup>9</sup> /L	Elevations: see Lymphocytes; also may indicate active tuberculosis. Decreased levels: see Lymphocytes.
<b>Arterial Blood Gases</b>		
PaO <sub>2</sub>	80-100 mm Hg Older adults: values may be lower	Elevations indicate possible excessive oxygen administration. Decreased levels indicate possible COPD, asthma, chronic bronchitis, cancer of the bronchi and lungs, cystic fibrosis, respiratory distress syndrome, anemias, atelectasis, or any other cause of hypoxia.
PaCO <sub>2</sub>	35-45 mm Hg	Elevations indicate possible COPD, asthma, pneumonia, anesthesia effects, or use of opioids (respiratory acidosis). Decreased levels indicate hyperventilation/respiratory alkalosis.
pH	Up to 60 yr: 7.35-7.45 60-90 yr: 7.31-7.42 >90 yr: 7.26-7.43	Elevations indicate metabolic or respiratory alkalosis. Decreased levels indicate metabolic or respiratory acidosis.
HCO <sub>3</sub> <sup>-</sup>	21-28 mEq/L (21-28 mmol/L)	Elevations indicate possible respiratory acidosis as compensation for a primary metabolic alkalosis. Decreased levels indicate possible respiratory alkalosis as compensation for a primary metabolic acidosis.
SpO <sub>2</sub>	95%-100% Older adults: values may be slightly lower	Decreased levels indicate possible impaired ability of hemoglobin to release oxygen to tissues.

COPD, Chronic obstructive pulmonary disease; HCO<sub>3</sub><sup>-</sup>, bicarbonate ion; PaCO<sub>2</sub>, partial pressure of arterial carbon dioxide; PaO<sub>2</sub>, partial pressure of arterial oxygen; SpO<sub>2</sub>, peripheral oxygen saturation; WBC, white blood cell.

Data from Pagana, K., Pagana, T. J., & Pagana, T. N. (2017). *Mosby's diagnostic and laboratory test reference* (13th ed.). St. Louis: Mosby; and Pagana, K., Pagana, T., & Pike-MacDonald, S. (2013). *Mosby's Canadian manual of diagnostic and laboratory tests*. St. Louis: Mosby.

Arterial blood gas (ABG) analysis assesses GAS EXCHANGE and PERFUSION as oxygenation (partial pressure of arterial oxygen [PaO<sub>2</sub>]), alveolar ventilation (partial pressure of arterial carbon dioxide [PaCO<sub>2</sub>]), and acid-base balance. Blood gas studies provide information for monitoring treatment results, adjusting oxygen therapy, and evaluating the patient's responses. See [Chapter 12](#) for more details on blood gas analysis.

Sputum specimens can help identify organisms or abnormal cells. Sputum culture and sensitivity analyses identify bacterial infection and determine which specific antibiotics will be most effective. Cytologic examination can identify cancer cells. Allergic conditions may be identified by cytologic testing.

## Imaging Assessment

Chest x-rays with digital images are used for patients with pulmonary problems to evaluate chest status and provide a baseline for comparison with future changes. These chest x-rays are performed from **posteroanterior** (PA; back to front) and left lateral (LL) positions.

Chest x-rays are used to assess lung pathology such as with pneumonia, atelectasis, pneumothorax, and tumor. They also can detect pleural fluid and the placement of an endotracheal tube or other invasive catheters. A computer-enhanced image can be adjusted to emphasize a specific area. However, these images have limitations and may appear normal, even when severe chronic bronchitis, asthma, or emphysema is present.

Sinus and facial x-rays are used to assess fluid levels in the sinus cavities to assist in the diagnosis of acute or chronic sinusitis.

*Computed tomography* (CT) assesses soft tissues with consecutive cross-sectional views of the entire chest. This type of imaging can verify the identity of a suspicious lesion or clot. CT scans may require a contrast agent injected IV to enhance the visibility of tumors, blood vessels, and heart chambers. Your role is to provide information to the patient and determine whether he or she has any sensitivity to the contrast material. Ask the patient whether he or she has a known allergy to iodine or shellfish. In addition, IV contrast medium can be nephrotoxic. Ask about his or her kidney

function and whether he or she takes drugs for type 2 diabetes. If the patient usually takes metformin, the drug is stopped at least 24 hours before contrast medium is used and is not restarted until adequate kidney function is confirmed (see [Chapter 65](#)).

## Other Noninvasive Diagnostic Assessment

### Pulse Oximetry.

Pulse oximetry identifies hemoglobin saturation with oxygen. Usually hemoglobin is almost 100% saturated with oxygen in superficial tissues. The pulse oximeter uses a wave of infrared light and a sensor placed on the patient's finger, toe, nose, earlobe, or forehead ([Fig. 27-11](#)). Ideal normal pulse oximetry values are 95% to 100%. Normal values are a little lower in older patients and in those with dark skin. To avoid confusion with the PaO<sub>2</sub> values from arterial blood gases, pulse oximetry readings are recorded as the SpO<sub>2</sub> (peripheral arterial oxygen saturation) or SaO<sub>2</sub>.

**FIG. 27-11** **A**, A typical pulse oximeter. **B**, Typical capnography equipment without the use of an endotracheal tube. (A From Young, A. P., & Proctor, D. [2008]. *Kinn's the medical assistant: An applied learning approach* (10th ed.). St. Louis: Saunders. B Copyright ©2016 Medtronic. All rights reserved. Used with the permission of Medtronic.)

Pulse oximetry can detect desaturation before symptoms (e.g., dusky skin, pale mucosa, pale or blue nail beds) occur. Causes for low readings include patient movement, hypothermia, decreased peripheral blood flow, ambient light (sunlight, infrared lamps), decreased hemoglobin, edema, and fingernail polish. When patients have any degree of impaired peripheral blood flow, the most accurate place to test oxygen saturation is on the forehead. Some brands of inexpensive portable oximeters have been shown to produce unreliable results in acutely ill patients compared with arterial blood sampling for SaO<sub>2</sub> and should not be used in patients who have known abnormal oxygen saturation values ([Jones et al., 2015](#)).

Results lower than 91% in an adult who does not have a chronic respiratory problem (and certainly below 86%) are an emergency and require immediate assessment and treatment. When the SpO<sub>2</sub> is below 85%, body tissues have a difficult time becoming oxygenated. An SpO<sub>2</sub> lower than 70% is usually life threatening, but in some cases values below 80% may be life threatening. Pulse oximetry is less accurate at lower values.

### Capnometry and Capnography.

Capnometry and capnography are methods that measure the amount of carbon dioxide present in exhaled air, which is an indirect measurement of arterial carbon dioxide levels. These noninvasive tests measure the partial pressure of end-tidal carbon dioxide (PEtCO<sub>2</sub>, also known as EtCO<sub>2</sub>) levels in both intubated patients and those breathing spontaneously. With capnometry, the exhaled air sample is tested with a sensor that changes the CO<sub>2</sub> level into a color or number for analysis. With capnography, the CO<sub>2</sub> level is graphed as a specific waveform along with a number. These methods provide information about CO<sub>2</sub> production, pulmonary perfusion, alveolar ventilation, respiratory patterns, ventilator effectiveness, and possible rebreathing of exhaled air. Because capnography is a more sensitive indicator of gas exchange adequacy than pulse oximetry, it can be especially useful in early detection of respiratory depression (Carlisle, 2015). See the [Quality Improvement box](#) for an example of its use.

## Quality Improvement QSEN

### Reducing Cases of Opioid-Induced Respiratory Depression With Increased Use of Capnography

Carlisle, H. (2015). Promoting the use of capnography in acute care settings. An evidence-based practice project. *Journal of PeriAnesthesia Nursing*, 30(3), 201-208.

Opioid-induced respiratory depression (OIRD) is a common yet preventable complication of opioid analgesia. The incidence of this life-threatening problem is on the rise as better pain management with opioid analgesics has increased. **The Joint Commission, the American Society for Pain Management Nursing, the Institute for Safe Medication Practices, and many other groups recommend using capnography to monitor patients at risk for OIRD for the need for early intervention.** Capnography has been proven to be superior for early detection of respiratory changes over the more commonly used pulse oximetry.

This quality improvement project was developed at a large university medical center hospital after two deaths from OIRD had occurred. Because OIRD can be prevented, the hospital examined the number of patients considered to be at risk for OIRD (determined by meeting one or more of the established risk criteria) who actually were being monitored with capnography. Of the patients who qualified as being at risk, only 4.4% were being monitored with capnography. The goal of the project was to increase the number of at-risk patients being monitored using capnography and reducing the overall incidence of OIRD.

The team charged with the improvement project first assessed the barriers to the use of capnography. The major barriers included (1) confusion about whether capnography monitoring required a physician order; (2) inadequate numbers of monitors; and (3) lack of familiarity of this proper use and interpretation of capnography monitoring.

Implementation of the project involved acting on all three barriers. The hospital increased the number of monitors by nearly 50% to a total of 93. A variety of information sessions, videos, and other in-service type education methods were used to increase the registered nurse's understanding of, comfort with, and correct use of capnography monitoring. Over time, an inactive computer-generated standing conditional order for capnography monitoring was developed and designed to open whenever a patient met one or more of the at-risk criteria for OIRD. This order served as a reminder to physicians and nurses and could be activated by either professional. This move empowered nurses to use their clinical judgment in deciding which patients would be best served with capnography monitoring.

A re-evaluation of the use of capnography monitoring in patients at-risk for OIRD a year after the implementation of the project demonstrated an increase in its use from 4.4% to 15%. Although this increase is positive, it is not yet at recommended levels.

## Commentary: Implications for Practice and Research

This quality improvement project demonstrated that empowering nurses results in better patient care and earlier intervention for serious complications associated with the widespread use of opioid analgesics, especially in the early postoperative period. Although the use of capnography monitoring increased, so did the quantity and quality of nursing assessments for at-risk patients. The authors of the project warn that, as the use of capnography monitoring increases, it should not ever substitute for close clinical monitoring by knowledgeable registered nurses.

The normal value of the partial pressure of end-tidal carbon dioxide (PEtCO<sub>2</sub>) ranges between 20 and 40 mm Hg. Changes in PEtCO<sub>2</sub> reflect changes in breathing effectiveness and GAS EXCHANGE. These changes occur before hypoxia can be detected using pulse oximetry because, even in the presence of diseased lungs, carbon dioxide moves out of the body more easily than oxygen moves into it. The use of both pulse oximetry and PEtCO<sub>2</sub> for patients at risk for respiratory problems can provide information to direct early intervention (Carlisle, 2014).

Conditions that increase PEtCO<sub>2</sub> above normal levels are those that reflect inadequate GAS EXCHANGE or an increase in cellular metabolism, both of which increase production of carbon dioxide (CO<sub>2</sub>). Conditions of inadequate gas exchange include hypoventilation, partial airway obstruction, and rebreathing exhaled air. Conditions that increase cellular metabolism include fever, acidosis, and heavy exercise.

Conditions that decrease PEtCO<sub>2</sub> below normal levels are those that reflect poor pulmonary ventilation, such as pulmonary embolism, apnea, total airway obstruction, and malposition of an endotracheal tube. Other causes of low PEtCO<sub>2</sub> include hyperventilation not based on oxygen need in which CO<sub>2</sub> is blown off faster than it is generated in the tissues. Cardiopulmonary arrest decreases PEtCO<sub>2</sub>, and PEtCO<sub>2</sub> may be used to determine the effectiveness of CPR and whether there is a spontaneous return of circulation.

## Clinical Judgment Challenge 27-1

### Patient-Centered-Care; Teamwork and Collaboration QSEN

The patient is an 82-year-old woman who was admitted from home with pneumonia. Your assessment findings reveal coarse crackles in her right lower lobe and oxygen saturation (SpO<sub>2</sub>) of 88% without supplemental oxygen. Her temperature is 100.4° F (38° C).

1. Which additional assessment information is it most important for you to obtain now?
2. Which interprofessional team members should be contacted and why?
3. What are some additional diagnostic assessments you should anticipate for this patient?
4. Which additional referrals might be appropriate for this patient?

### Pulmonary Function Tests.

Pulmonary function tests (PFTs) assess lung function and breathing problems. These tests measure lung volumes and capacities, flow rates, diffusion capacity, GAS EXCHANGE, airway resistance, and distribution of ventilation. The results are interpreted by comparing the patient's data with expected findings for age, gender, race, height, weight, and smoking status.

PFTs are useful in screening patients for lung disease even before the onset of symptoms (Parker, 2014). Repeated testing over time provides data that may be used to guide management (e.g., changes in lung function can support a decision to continue, change, or discontinue a specific therapy). Testing before surgery may identify patients at risk for lung complications after surgery. The most common reason for performing PFTs is to determine the cause of dyspnea. When performed while the patient exercises, PFTs help determine whether dyspnea is caused by lung problems or cardiac problems or by muscle weakness.

### Patient Preparation.

Explain the purpose of the tests and advise the patient not to smoke for 6 to 8 hours before testing. Depending on the reasons for testing, bronchodilator drugs may be withheld for 4 to 6 hours before the test. The patient with breathing problems often fears further breathlessness and is anxious before these “breathing” tests. Help reduce anxiety by describing what will happen during and after the testing.

### Procedure.

PFTs can be performed at the bedside or in the respiratory laboratory by a respiratory therapist or respiratory technician. The patient is asked to breathe through the mouth only. A nose clip may be used to prevent air from escaping. The patient performs different breathing maneuvers while measurements are obtained. Table 27-6 describes the most commonly used PFTs and their uses.

**TABLE 27-6**  
**Characteristics and Purposes of Pulmonary Function Tests**

TEST	PURPOSE
<i>FVC (forced vital capacity)</i> records the maximum amount of air that can be exhaled as quickly as possible after maximum inspiration.	Indicates respiratory muscle strength and ventilatory reserve. Reduced in obstructive and restrictive diseases.
<i>FEV<sub>1</sub> (forced expiratory volume in 1 sec)</i> records the maximum amount of air that can be exhaled in the first second of expiration.	Is effort dependent and declines normally with age. It is reduced in certain obstructive and restrictive disorders.
<i>FEV<sub>1</sub>/FVC</i> is the ratio of expiratory volume in 1 sec to FVC.	Indicates obstruction to airflow. This ratio is the hallmark of obstructive pulmonary disease. It is normal or increased in restrictive disease.
<i>FEF<sub>25%-75%</sub></i> records the forced expiratory flow over the 25%-75% volume (middle half) of the FVC.	This measure provides a more sensitive index of obstruction in the smaller airways.
<i>FRC (functional residual capacity)</i> is the amount of air remaining in the lungs after normal expiration. FRC test requires use of the helium dilution, nitrogen washout, or body plethysmography technique.	Increased FRC indicates hyperinflation or air trapping, often from obstructive pulmonary disease. FRC is normal or decreased in restrictive pulmonary diseases.
<i>TLC (total lung capacity)</i> is the amount of air in the lungs at the end of maximum inhalation.	Increased TLC indicates air trapping from obstructive pulmonary disease. Decreased TLC indicates restrictive disease.
<i>RV (residual volume)</i> is the amount of air remaining in the lungs at the end of a full, forced exhalation.	RV is increased in obstructive pulmonary disease such as emphysema.
<i>DLCO (diffusion capacity of the lung for carbon monoxide)</i> reflects the surface area of the alveolocapillary membrane. The patient inhales a small amount of CO, holds for 10 sec, and then exhales. The amount inhaled is compared with the amount exhaled.	Is reduced whenever the alveolocapillary membrane is diminished (emphysema, pulmonary hypertension, and pulmonary fibrosis). It is increased with exercise and in conditions such as polycythemia and congestive heart disease.

### Follow-Up Care.

Because many breathing maneuvers are performed during PFTs, assess the patient for increased dyspnea or bronchospasm after these studies. Document any drugs given during testing.

### Exercise Testing.

Exercise increases metabolism and increases gas transport because energy is used. Exercise testing assesses the patient's ability to work and perform ADLs, differentiates reasons for exercise limitation, evaluates disease influence on exercise capacity, and determines whether supplemental oxygen is needed during exercise. These tests are performed on a treadmill or bicycle or by a self-paced 12-minute walking test. Exercise in the patient with normal pulmonary function is limited by circulatory factors, whereas exercise in the pulmonary patient is limited by breathing capacity, GAS EXCHANGE compromise, or both. Explain exercise testing, and assure the patient that he or she will be closely monitored by trained professionals throughout the test.

## Other Invasive Diagnostic Assessment

### Endoscopic Examinations.

Endoscopic studies to assess breathing problems include bronchoscopy, laryngoscopy, and mediastinoscopy. With *laryngoscopy*, a tube for visualization is inserted into the larynx to assess the function of the vocal cords, remove foreign bodies caught in the larynx, or obtain tissue samples for biopsy or culture. A *mediastinoscopy* is the insertion of a flexible tube through the chest wall just above the sternum into the area between the lungs. It is performed in the operating room with the patient under general anesthesia to examine for the presence of tumors and obtain tissue samples for biopsy or culture. Most complications are related to the anesthetic agents and bleeding. The most common procedure is the bronchoscopy.

A **bronchoscopy** is the insertion of a tube in the airways as far as the secondary bronchi to view airway structures and obtain tissue samples. It is used to diagnose and manage pulmonary diseases. Rigid bronchoscopy usually requires general anesthesia in the operating room. Flexible bronchoscopy can be performed in the ICU or a special endoscopy suite with low-dose sedation. It is used to evaluate the airway and to help with placing or changing an endotracheal tube, collecting

specimens, and diagnosing infections. It is often used for lung cancer staging and removal of secretions that are not cleared with normal suctioning. Stents can be placed during bronchoscopy to open up strictures in the trachea and bronchus.

#### Patient Preparation.

Explain the procedure to the patient and verify that consent for the procedure was obtained. Expected outcomes, risks, and benefits of the procedure must be discussed with the patient by the primary health care provider performing the procedure. Document patient allergies. Other tests before the procedure may include a complete blood count, platelet count, prothrombin time, electrolytes, and chest x-ray. The patient should be NPO for 4 to 8 hours before the procedure to reduce the risk for aspiration. Premedication with one of the benzodiazepines may be used to provide both sedation and amnesia. Opioids may also be used.

### Nursing Safety Priority QSEN

#### Action Alert

**In accordance with The Joint Commission's National Patient Safety Goals, verify the patient's identity with *two* types of identifiers (name and at least one person-specific number such as birth date, medical record number, or social security number) before a bronchoscopy.**

Benzocaine spray as a topical anesthetic to numb the oropharynx is used cautiously, if at all. This agent may induce a condition called **methemoglobinemia**, which is the conversion of normal hemoglobin to methemoglobin (Wesley, 2014). Methemoglobin is an altered iron state that does not carry oxygen, resulting in tissue hypoxia. Other topical anesthetic sprays, such as lidocaine, are less likely to induce this problem.

The normal blood level of methemoglobin is less than 1%. When this level increases, tissue GAS EXCHANGE is reduced. Cyanosis occurs with methemoglobin levels between 10% and 20%, and death can occur when levels reach 50% to 70%. Suspect methemoglobinemia if a patient becomes cyanotic after receiving a topical anesthetic, if he or she does not respond to supplemental oxygen, and if blood is a characteristic chocolate-brown in color. It can be reversed with oxygen and IV injection of 1% methylene blue (1 to 2 mg/kg).

### Nursing Safety Priority QSEN

#### Critical Rescue

Assess patients who receive a benzocaine topical anesthetic to the oropharynx to recognize indications of methemoglobinemia. These include cyanosis that is unresponsive to oxygen therapy and chocolate-brown-colored blood. If either of these symptoms is present, respond by notifying the Rapid Response Team.

#### Procedure.

The procedure can be done in a bronchoscopy suite or at the ICU bedside. The bronchoscope is inserted through either the naris or the oropharynx. Maintain IV access and continuously monitor the patient's pulse, blood pressure, respiratory rate, and oxygen saturation. Apply supplemental oxygen.

#### Follow-Up Care.

Monitor the patient until the effects of the sedation have resolved and a gag reflex has returned. Continue to monitor vital signs, including oxygen saturation, and assess breath sounds every 15 minutes for the first 2 hours. Also assess for potential complications, including bleeding, infection, or hypoxemia.

#### Thoracentesis.

**Thoracentesis** is the needle aspiration of pleural fluid or air from the pleural space for diagnostic or management purposes. Microscopic examination of the pleural fluid helps in making a diagnosis. Pleural fluid may be drained to relieve blood vessel or lung compression and the respiratory distress caused by cancer, empyema, pleurisy, or tuberculosis. Drugs can also be instilled into the pleural space during thoracentesis.

### Patient Preparation.

Patient preparation is essential before thoracentesis to ensure cooperation during the procedure and prevent complications. Tell the patient to expect a stinging sensation from the local anesthetic agent and a feeling of pressure when the needle is pushed through the posterior chest. Stress the importance of not moving, coughing, or deep breathing during the procedure to avoid puncture of the pleura or lung.

Ask the patient about any allergy to local anesthetic agents. Verify that he or she has signed an informed consent. The entire chest or back is exposed, and the hair on the skin over the aspiration site is clipped if necessary. The site depends on the volume and location of the fluid.

Fig. 27-12 shows the best position for thoracentesis, which widens the spaces between the ribs and permits easy access to the pleural fluid. Properly position and physically support the patient during the procedure. Use pillows to make the patient comfortable and to provide physical support. When the sitting position is used for the procedure, stand in front of the patient to prevent the table from moving and the patient from falling

**FIG. 27-12** Position for thoracentesis. (From Harkreader, H., Hogan, M. A., & Thobaben, M. [2007]. *Fundamentals of nursing: Caring and clinical judgment* [3rd ed.]. Philadelphia: Saunders.)

### Procedure.

Thoracentesis is often performed at the bedside by a nurse practitioner or a physician, although CT or ultrasound may be used to guide it. The person performing the procedure and any assistants wear goggles and masks to prevent accidental eye or oral splash exposure to the pleural fluid. After the skin is prepped, a local anesthetic is injected into the selected site. Keep the patient informed of the procedure while observing for shock, pain, nausea, pallor, diaphoresis, cyanosis, tachypnea, and dyspnea.

The short 18- to 25-gauge thoracentesis needle (with an attached syringe) is advanced into the pleural space. Fluid in the pleural space is slowly aspirated with gentle suction. A vacuum collection bottle may be needed to remove larger volumes of fluid. To prevent re-expansion pulmonary edema, usually no more than 1000 mL of fluid is removed at one time. If a biopsy is performed, a second, larger needle with a cutting edge and collection chamber is used. After the needle is withdrawn, pressure is applied to the puncture site, and a sterile dressing is applied. In some cases, pigtail drain catheters may be left in place to a water-seal drainage system, rather than doing a thoracentesis aspiration on a recurring basis.

### Follow-Up Care.

After thoracentesis, a chest x-ray is performed to rule out possible pneumothorax and **mediastinal**

**shift** (shift of central thoracic structures toward one side). Monitor vital signs, and listen to the lungs for absent or reduced sounds on the affected side. Check the puncture site and dressing for leakage or bleeding. Assess for complications, such as reaccumulation of fluid in the pleural space, subcutaneous emphysema, infection, and tension pneumothorax. Urge the patient to breathe deeply to promote lung expansion. Document the procedure, including the patient's response; the volume and character of the fluid removed; any specimens sent to the laboratory; the location of the puncture site; and respiratory assessment findings before, during, and after the procedure.

Teach the patient about the symptoms of a **pneumothorax** (partial or complete collapse of the lung), which can occur within the first 24 hours after a thoracentesis. Symptoms include:

- Pain on the affected side that is worse at the end of inhalation and the end of exhalation
- Rapid heart rate
- Rapid, shallow respirations
- A feeling of air hunger
- Prominence of the affected side that does not move in and out with respiratory effort
- Trachea slanted more to the unaffected side instead of being in the center of the neck
- New onset of “nagging” cough
- Cyanosis

Instruct the patient to go to the nearest emergency department immediately if these symptoms occur.

### Lung Biopsy.

A lung biopsy is performed to obtain tissue for histologic analysis, culture, or cytologic examination. The samples are used to make a definite diagnosis of inflammation, cancer, infection, or lung disease. There are several types of lung biopsies. The site and extent of the lesion determine which one is used. Transbronchial biopsy (TBB) and transbronchial needle aspiration (TBNA) are performed during bronchoscopy. Transthoracic needle aspiration is performed through the skin (percutaneous) for areas that cannot be reached by bronchoscopy.

#### Patient Preparation.

The patient may worry about the outcome of the biopsy and may associate the term *biopsy* with *cancer*. Explain what to expect before and after the procedure and explore the patient's feelings. An analgesic or sedative may be prescribed before the procedure. Inform the patient undergoing percutaneous biopsy that discomfort is reduced with a local anesthetic agent but that pressure may be felt during needle insertion and tissue aspiration. Open lung biopsy is performed in the operating room with the patient under general anesthesia, and the usual preparations before surgery apply (see [Chapter 14](#)).

#### Procedure.

Percutaneous lung biopsy is usually performed in the radiology department after an informed consent has been obtained. Fluoroscopy or CT is used to visualize the area and guide the procedure. The patient is usually placed in the side-lying position, depending on the location of the lesion. The skin is cleansed with an antiseptic agent, and a local anesthetic is given. Under sterile conditions, a spinal-type needle is inserted through the skin into the desired area, and tissue is obtained for microscopic examination. A dressing is applied after the procedure. A CT scan or chest x-ray must follow the biopsy to confirm that there is no pneumothorax.

An open-lung biopsy is performed in the operating room. The patient undergoes a thoracotomy in which lung tissue is exposed and appropriate tissue specimens are taken. A chest tube is placed to remove air and fluid so the lung can re-inflate, and then the chest is closed.

#### Follow-Up Care.

Monitor the patient's vital signs and breath sounds at least every 4 hours for 24 hours and assess for signs of respiratory distress (e.g., dyspnea, pallor, diaphoresis, tachypnea). Pneumothorax is a serious complication of needle biopsy and open-lung biopsy. Report reduced or absent breath sounds immediately. Monitor for hemoptysis (which may be scant and transient) or, in rare cases, for frank bleeding from vascular or lung trauma.

## Clinical Judgment Challenge 27-2

### Safety; Patient-Centered Care; Teamwork and Collaboration QSEN

Your patient is a 56-year-old man who had an extensive open abdominal surgery yesterday. He has thick secretions and developed a mucus plug. He has just returned from a bronchoscopy.

1. What are your priorities for postprocedure care? Provide a rationale for your choices.
2. The patient is also receiving frequent opioids for pain control after his recent surgery. What, if any, concerns do you have about this therapy?
3. Would you consider using capnography to monitor this patient? Why or why not?
4. Which interprofessional team members would be most important to consider involving in the care of this patient?

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Assess any patient's geographic, home, occupational, and recreational exposure to inhalation irritants. **QSEN: Safety**
- Document any known specific allergies that have respiratory symptoms. **QSEN: Safety**
- Assess the patient's respiratory status every 15 minutes for at least the first 2 hours after undergoing an endoscopic test for respiratory disorders. **QSEN: Safety**

### Health Promotion and Maintenance

- Teach the older adult about the effects of aging on the respiratory system. **QSEN: Patient-Centered Care**
- Encourage all adults to use masks and adequate ventilation when exposed to inhalation irritants. **QSEN: Evidence-Based Practice**
- Promote smoking cessation for adults who smoke. **QSEN: Patient-Centered Care**
- Support the adult who chooses to stop smoking by helping him or her decide about drug therapy for smoking cessation and finding an appropriate smoking-cessation program. **QSEN: Patient-Centered Care**

### Psychosocial Integrity

- Allow the patient the opportunity to express fear or anxiety about tests of respiratory function or about a potential change in respiratory function. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Ask the patient about respiratory problems in any other members of the family because some problems have a genetic component. **QSEN: Patient-Centered Care**
- Ask the patient about current and past drug use (prescribed, over-the-counter, and illicit), and evaluate drug use for potential lung damage. **QSEN: Patient-Centered Care**
- Calculate the pack-year smoking history for the patient who smokes or who has ever smoked cigarettes. **QSEN: Patient-Centered Care**
- Distinguish between normal and abnormal (adventitious) breath sounds. **QSEN: Patient-Centered Care**
- Interpret arterial blood gas values to assess the patient's respiratory status. **QSEN: Patient-Centered Care**
- Assess the degree to which breathing problems interfere with the patient's ability to perform ADLs. **QSEN: Patient-Centered Care**
- Assess the airway and breathing effectiveness for any patient who has shortness of breath or any change in mental status. **QSEN: Evidence-Based Practice**
- Teach patients and caregivers about what to expect during tests and procedures to assess respiratory function and respiratory disease. **QSEN: Patient-Centered Care**
- Explain nursing care needs for the patient after bronchoscopy or open lung biopsy. **QSEN: Patient-Centered Care**

## CHAPTER 28

# Care of Patients Requiring Oxygen Therapy or Tracheostomy

---

Harry Rees

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is GAS EXCHANGE.**

✚ The GAS EXCHANGE concept exemplar for this chapter is Tracheostomy, p. 537.

**The interrelated concept for this chapter is TISSUE INTEGRITY.**

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to coordinate high-quality care and promote GAS EXCHANGE in patients requiring oxygen therapy or tracheostomy.
2. Teach the patient receiving oxygen or who has a tracheostomy and caregiver(s) about home safety affected by oxygen therapy or tracheostomy.
3. Prioritize evidence-based care for patients requiring oxygen therapy or tracheostomy for problems affecting GAS EXCHANGE.

### Health Promotion and Maintenance

4. Identify community resources for patients requiring oxygen therapy or tracheostomy.

### Psychosocial Integrity

5. Implement nursing interventions to decrease the psychosocial impact caused by requiring oxygen therapy or tracheostomy.

### Physiological Integrity

6. Apply knowledge of anatomy and physiology to assess patients with respiratory problems affecting GAS EXCHANGE who require oxygen therapy or tracheostomy.
7. Explain appropriate techniques to administer prescribed oxygen therapy and provide tracheostomy care.

GAS EXCHANGE with oxygenation and tissue perfusion are impaired as a result of many problems with the respiratory system. Oxygen therapy through various delivery systems, including tracheostomy, can help improve gas exchange and tissue perfusion.

# Oxygen Therapy

## Overview

In addition to being an essential body nutrient, oxygen ( $O_2$ ) is a gas used as a drug for relief of **hypoxemia** (low levels of oxygen in the blood) and **hypoxia** (decreased tissue oxygenation). The oxygen content of atmospheric air is about 21%. Oxygen therapy is prescribed for both acute and chronic breathing problems when the patient's oxygen needs cannot be met by atmospheric ("room") air alone. Indications for use include decreased partial pressure of arterial oxygen ( $PaO_2$ ) levels or decreased arterial oxygen saturation ( $SaO_2$ ). Nonrespiratory conditions, such as heart failure, sepsis, fever, and decreased hemoglobin levels or poor hemoglobin quality, can affect GAS EXCHANGE and also are indications for oxygen therapy. These conditions increase oxygen demand, decrease the oxygen-carrying capability of the blood, or decrease cardiac output.

The purpose of oxygen therapy is to use the lowest *fraction of inspired oxygen* ( $FiO_2$ ) to have an acceptable blood oxygen level without causing harmful side effects. *Although oxygen improves the  $PaO_2$  level, it does not cure the problem or stop the disease process.* Most patients with hypoxia require an oxygen flow of 2 to 4 L/min via nasal cannula or up to 40% via Venturi mask to achieve an oxygen saturation of at least 95%. For a patient who is hypoxemic and has chronic **hypercarbia** (increased partial pressure of arterial carbon dioxide [ $PaCO_2$ ] levels), the  $FiO_2$  delivered should be titrated to correct the hypoxemia and achieve generally acceptable oxygen saturations in the range of 88% to 92%.

## ❖ Interprofessional Collaborative Care

Oxygen therapy may be used in any setting. Most patients are prescribed oxygen therapy through their primary health care provider without first having been hospitalized.

### ◆ Assessment: Noticing

Arterial blood gas (ABG) analysis is the best measure to determine the need for oxygen therapy and evaluate its effects. Oxygen need is also determined by noninvasive monitoring such as pulse oximetry and capnography (Carlisle, 2014).

### ◆ Interventions: Responding

Before starting oxygen therapy and while caring for a patient receiving oxygen therapy, you must be knowledgeable about oxygen hazards and complications. Know the rationale and the expected outcome related to oxygen therapy for each patient receiving oxygen. Chart 28-1 lists best practices for patients using oxygen therapy.

## 📄 Chart 28-1

### Best Practice for Patient Safety & Quality Care QSEN

#### Oxygen Therapy

- Check the health care provider's prescription with the type of delivery system and liter flow or percentage of oxygen actually in use.
- Obtain a prescription for humidification if oxygen is being delivered at 4 L/min or more.
- Be sure that the oxygen and humidification equipment are functioning properly.
- Check the skin around the patient's ears, back of the neck, and face every 4 to 8 hours for pressure points, signs of irritation, and loss of TISSUE INTEGRITY.
- Ensure that mouth care is provided every 8 hours and as needed; assess nasal and oral mucous

membranes for cracks or other signs of dryness or impaired tissue integrity.

- Pad the elastic band and change its position frequently to prevent skin breakdown.
- Pad tubing in areas that put pressure on the skin.
- Cleanse the cannula or mask by rinsing with clear, warm water every 4 to 8 hours or as needed.
- Cleanse skin under the tubing, straps, and mask every 4 to 8 hours or as needed.
- Lubricate the patient's nostrils, face, and lips with nonpetroleum cream to relieve the drying effects of oxygen.
- Position the tubing so it does not pull on the patient's face, nose, or artificial airway.
- Ensure that there is no smoking and that no candles or matches are lit in the immediate area.
- Assess and document the patient's response to oxygen therapy.
- Ensure that the patient has an adequate oxygen source during any periods of transport.
- Provide the patient with ongoing teaching and reassurance to enhance his or her adherence to oxygen therapy.

## Hazards and Complications of Oxygen Therapy

### Combustion.

Oxygen does not burn, but it enhances combustion so fire burns better in its presence. For example, when the oxygen content of the air around a lighted cigarette is nearly 50%, the entire cigarette flames up and can catch items nearby on fire. Open fires, even small ones such as candles or cigarettes, should not be in the same room during oxygen therapy. Take precautions during oxygen delivery, including posting a sign on the door of the patient's room. Smoking is prohibited in the patient's room, including at home, when oxygen is in use.

All electrical equipment in rooms where oxygen is in use must have grounded plugs and be plugged into grounded outlets to prevent fires from electrical arcing sparks. Frayed cords are not used because they can spark and ignite a flame. Flammable solutions (containing high concentrations of alcohol or oil) are not used in rooms in which oxygen is in use. (This does not include alcohol-based hand rubs.)

### Oxygen-Induced Hypoventilation.

For many years oxygen was thought to induce hypoventilation in the patient with chronic lung disease who also had carbon dioxide retention (**hypercarbia**). As a result, nurses and physicians were reluctant to administer oxygen to these hypoxic patients, leading to serious problems and even deaths related to inadequate GAS EXCHANGE. Research disproves the hypoxic drive theory and has found that patients with chronic lung disease are at risk for oxygen-induced hypercapnia but not for severely reduced respiratory effort (Makic et al., 2013). Therefore oxygen therapy is prescribed at the lowest liter flow needed to manage hypoxemia. A system that delivers more precise oxygen levels (e.g., a Venturi mask) is preferred. Monitor the patient's response to therapy closely to ensure adequate gas exchange and correction of hypoxemia. Responses to monitor include the level of consciousness, respiratory pattern and rate, and pulse oximetry. *Untreated or inadequately treated hypoxemia is a threat to life for any person with a breathing problem.*

### Oxygen Toxicity.

Oxygen toxicity is related to the concentration of oxygen delivered, duration of oxygen therapy, and degree of lung disease present. A continuous oxygen level greater than 50% for more than 24 to 48 hours may injure the TISSUE INTEGRITY of the lungs.

The causes and indications of lung injury from oxygen toxicity are the same as those for acute respiratory distress syndrome (ARDS) (see Chapter 32). Initial problems include dyspnea, nonproductive cough, chest pain beneath the sternum, GI upset, and crackles on auscultation. As

exposure to high levels of oxygen continues, the problems become more severe, with decreased vital capacity, decreased compliance, and hypoxemia. With prolonged exposure to high oxygen levels, atelectasis, pulmonary edema, hemorrhage, and hyaline membrane formation may result. Surviving this critical condition depends on correcting the underlying disease process and decreasing the oxygen amount delivered.

The toxic effects of oxygen are difficult to manage, making prevention a priority. The lowest level of oxygen needed to maintain GAS EXCHANGE and prevent oxygen toxicity is prescribed. Monitor arterial blood gases (ABGs) during oxygen therapy and notify the primary health care provider when PaO<sub>2</sub> levels become greater than 90 mm Hg. Also monitor the prescribed oxygen level and length of therapy to identify patients at risk. High oxygen levels are avoided unless absolutely necessary. The use of noninvasive positive airway pressure techniques with oxygen or the use of mechanical ventilation (see Chapter 32) may reduce the amount of oxygen needed. As soon as the patient's condition allows, the prescribed amount of oxygen is decreased.

### Absorptive Atelectasis.

Normally nitrogen in the air maintains patent airways and alveoli. Making up 79% of room air, nitrogen prevents alveolar collapse. When high oxygen levels are delivered, nitrogen is diluted, oxygen diffuses from the alveoli into the blood, and the alveoli collapse. Collapsed alveoli cause atelectasis (called *absorptive atelectasis*), which is detected as crackles and decreased breath sounds on auscultation.

## Nursing Safety Priority QSEN

### Action Alert

Monitor the patient receiving high levels of oxygen closely to recognize indications of absorptive atelectasis (new onset of crackles and decreased breath sounds) every 1 to 2 hours when oxygen therapy is started and as often as needed thereafter.

### Drying of the Mucous Membranes.

When the prescribed oxygen flow rate is higher than 4 L/min, humidify the delivery system to prevent damage to TISSUE INTEGRITY (Fig. 28-1). Ensure that oxygen bubbles through the water in the humidifier.

FIG. 28-1 Bubble humidifier bottle used with oxygen therapy

Oxygen can also be humidified via a large-volume jet nebulizer in mist form (aerosol). A heated nebulizer raises the humidity even more and is used for oxygen delivery through an artificial airway. Usually the upper airway passages warm the air during breathing, but these passages are bypassed with an artificial airway, such as an endotracheal tube.

For the patient to receive humidified oxygen, the humidifier or nebulizer must have a sufficient amount of sterile water, and the flow rate must be adequate. Condensation often forms in the tubing. Remove this condensation as it collects by disconnecting the tubing and emptying the water. Minimize the time the tubing is disconnected because the patient does not receive oxygen during this period. Some humidifiers and nebulizers have a water trap that hangs from the tubing so the condensation can be drained without disconnecting. Check the water level and change the humidifier as needed.

## Nursing Safety Priority QSEN

### Action Alert

Assess the tubing system used for oxygen delivery to recognize buildup of condensation. Respond by draining condensation. To prevent bacterial contamination of the oxygen delivery system, never drain the fluid from the water trap back into the humidifier or nebulizer.

### Infection.

The humidifier or nebulizer may be a source of bacteria, especially if it is heated. Oxygen delivery equipment such as cannulas and masks can also harbor organisms. Change equipment per agency policy, which ranges from every 24 hours for humidification systems to every 7 days or whenever necessary for cannulas and masks.

## NCLEX Examination Challenge 28-1

### Safe and Effective Care Environment

The nurse notes that a client with a history of chronic obstructive pulmonary disease (COPD) who is receiving oxygen therapy at 2 L/min and had an oxygen saturation of 88% 1 hour ago now has dyspnea and an oxygen saturation of 80%. Should the nurse increase the  $FiO_2$ ?

- A. No; increasing the  $FiO_2$  will severely depress the respiratory rate by blunting the hypoxic drive.
- B. No; an oxygen saturation of 80% is acceptable for a client with COPD.
- C. Yes; hypoxia must be treated despite the risk for oxygen-induced hypercapnia.
- D. Yes; the expected outcome for any client with hypoxia is to achieve a saturation of at least 97%.

### Oxygen Delivery Systems.

Oxygen can be delivered by many systems. Regardless of the type of delivery system used, it is important to understand its indications, advantages, and disadvantages. Use the equipment properly and ensure appropriate equipment maintenance. Provide interprofessional collaboration by consulting a respiratory therapist whenever there is a question or concern about an oxygen delivery system.

The type of delivery system used depends on:

- Oxygen concentration required by the patient
- Oxygen concentration achieved by a delivery system
- Importance of accuracy and control of the oxygen concentration
- Patient comfort
- Importance of humidity
- Patient mobility

Oxygen delivery systems are classified by the rate of oxygen delivery as either low-flow or high-flow systems. Low-flow systems have a low fraction of inspired oxygen ( $FiO_2$ ) and do not provide enough oxygen to meet the patient's total oxygen and air volume needs. Thus part of the tidal

volume is supplied by the patient as he or she breathes room air. The total level of oxygen inspired depends on the respiratory rate and tidal volume. High-flow systems have a flow rate that meets the entire oxygen need and tidal volume, regardless of the patient's breathing pattern. These systems are used for critically ill patients and when delivery of precise levels of oxygen is needed.

If the patient needs a mask but is able to eat, request a prescription for a nasal cannula to be used at mealtimes only. Reapply the mask after the meal is completed. To increase mobility, up to 50 feet of connecting tubing can be used with connecting pieces, although the longer tubing can be a safety issue for patients who are unsteady while ambulating.

### Low-Flow Oxygen Delivery Systems.

Low-flow systems include the nasal cannula, simple facemask, partial rebreather mask, and nonrebreather mask (Table 28-1). These systems are easy to use and fairly comfortable, but the amount of oxygen delivered varies and depends on the patient's breathing pattern. The oxygen is diluted with room air (21% oxygen), which lowers the amount actually inspired.

**TABLE 28-1**  
**Comparison of Low-Flow Oxygen Delivery Systems**

FiO <sub>2</sub> DELIVERED	NURSING INTERVENTIONS	RATIONALES
<b>Nasal Cannula</b>		
24%-40% FiO <sub>2</sub> at 1-6 L/min ≈ 24% at 1 L/min ≈ 28% at 2 L/min ≈ 32% at 3 L/min ≈ 36% at 4 L/min ≈ 40% at 5 L/min ≈ 44% at 6 L/min	Ensure that prongs are in the nares properly. Apply water-soluble jelly to nares PRN. Assess the patency of the nostrils. Assess the patient for changes in respiratory rate and depth.	A poorly fitting nasal cannula leads to hypoxemia and skin breakdown with loss of TISSUE INTEGRITY. This substance prevents mucosal irritation related to the drying effect of oxygen; promotes comfort. Congestion or a deviated septum prevents effective delivery of oxygen through the nares. The respiratory pattern affects the amount of oxygen delivered. A different delivery system may be needed.
<b>Simple Facemask</b>		
40%-60% FiO <sub>2</sub> at 5-8 L/min; flow rate must be set at least at 5 L/min to flush mask of carbon dioxide ≈ 40% at 5 L/min ≈ 45%-50% at 6 L/min ≈ 55%-60% at 8 L/min	Be sure that mask fits securely over nose and mouth. Assess skin and provide skin care to the area covered by the mask. Monitor the patient closely for risk for aspiration. Provide emotional support to the patient who feels claustrophobic. Suggest to the primary health care provider to switch the patient from a mask to the nasal cannula during eating.	A poorly fitting mask reduces the FiO <sub>2</sub> delivered. Pressure and moisture under the mask may cause loss of TISSUE INTEGRITY. The mask limits the patient's ability to clear the mouth, especially if vomiting occurs. Emotional support decreases anxiety, which contributes to a claustrophobic feeling. Use of the cannula promotes GAS EXCHANGE during eating.
<b>Partial Rebreather Mask</b>		
60%-75% at 6-11 L/min, a liter flow rate high enough to maintain reservoir bag two-thirds full during inspiration and expiration	Make sure that the reservoir does not twist or kink, which results in a deflated bag. Adjust the flow rate to keep the reservoir bag inflated.	Deflation results in decreased oxygen delivered and increases the rebreathing of exhaled air. The flow rate is adjusted to meet the pattern of the patient.
<b>Nonrebreather Mask</b>		
80%-95% FiO <sub>2</sub> at a liter flow high enough to maintain reservoir bag two-thirds full	Interventions as for partial rebreather mask; this patient requires close monitoring. Make sure that valves and rubber flaps are patent, functional, and not stuck. Remove mucus or saliva. Closely assess the patient on increased FiO <sub>2</sub> via nonrebreather mask. Intubation is the only way to provide more precise FiO <sub>2</sub> .	Rationales as for partial rebreather mask. Monitoring ensures proper functioning and prevents harm. Valves should open during expiration and close during inhalation to prevent dramatic decrease in FiO <sub>2</sub> . Suffocation can occur if the reservoir bag kinks or if the oxygen source disconnects. The patient may require intubation.

FiO<sub>2</sub>, Fraction of inspired oxygen.

### Nasal Cannula.

The nasal cannula (prongs) (Fig. 28-2) is used at flow rates of 1 to 6 L/min. Oxygen concentrations of 24% (at 1 L/min) to 44% (at 6 L/min) can be achieved. Flow rates greater than 6 L/min do not increase GAS EXCHANGE because the **anatomic dead space** (places where air flows but the structures are too thick for gas exchange) is full. High flow rates also increase mucosal irritation and damage to TISSUE INTEGRITY.

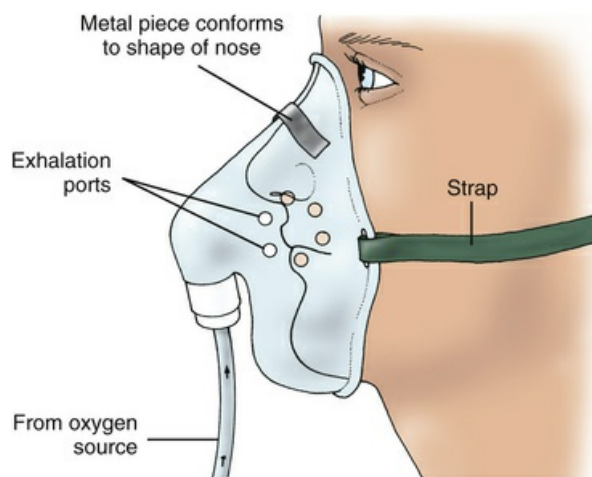

**FIG. 28-2** Nasal cannula (prongs). (From Perry, A. G., Potter, P. A., & Ostendorf, W. R. [2017]. *Clinical nursing skills and techniques* [9th ed.]. St. Louis: Mosby.)

The nasal cannula is often used for chronic lung disease and for any patient needing long-term oxygen therapy. Place the nasal prongs in the nostrils, with the openings facing the patient, following the natural anatomic curve of the nares.

### Facemasks.

Facemasks can deliver a wide range of oxygen flow rates and concentrations.

*Simple facemasks* are used to deliver oxygen concentrations of 40% to 60% for short-term oxygen therapy or in an emergency (Fig. 28-3). A minimum flow rate of 5 L/min is needed to prevent rebreathing of exhaled air. Ensure that the mask fits well to maintain inspired oxygen levels. Care for the skin under the mask and strap to prevent breakdown (Ambutas et al., 2014).

**FIG. 28-3** Simple facemask used to deliver oxygen.

*Partial rebreather masks* provide oxygen concentrations of 60% to 75% with flow rates of 6 to 11 L/min. These masks have a reservoir bag but no flaps (Fig. 28-4). With each breath, the patient rebreathes one third of the exhaled tidal volume, which is high in oxygen and increases the fraction of inspired oxygen ( $FiO_2$ ). For best oxygen delivery, be sure that the bag remains slightly inflated at the end of inspiration. If needed, call the respiratory therapist for assistance.

**FIG. 28-4** Partial rebreather mask.

*Nonrebreather masks* provide the highest oxygen level of the low-flow systems and can deliver an  $\text{FiO}_2$  greater than 90%, depending on the patient's breathing pattern. This mask is often used with patients whose respiratory status is unstable and who may require intubation.

The nonrebreather mask has a one-way valve between the mask and the reservoir and usually has two flaps over the exhalation ports (Fig. 28-5). The valve allows the patient to draw all needed oxygen from the reservoir bag, and the flaps prevent room air from entering through the exhalation ports (which would dilute the oxygen concentration). During exhalation, air leaves through these exhalation ports while the one-way valve prevents exhaled air from re-entering the reservoir bag. The flow rate is kept high (10 to 15 L/min) to keep the bag inflated during inhalation. Assess for this safety feature at least hourly.

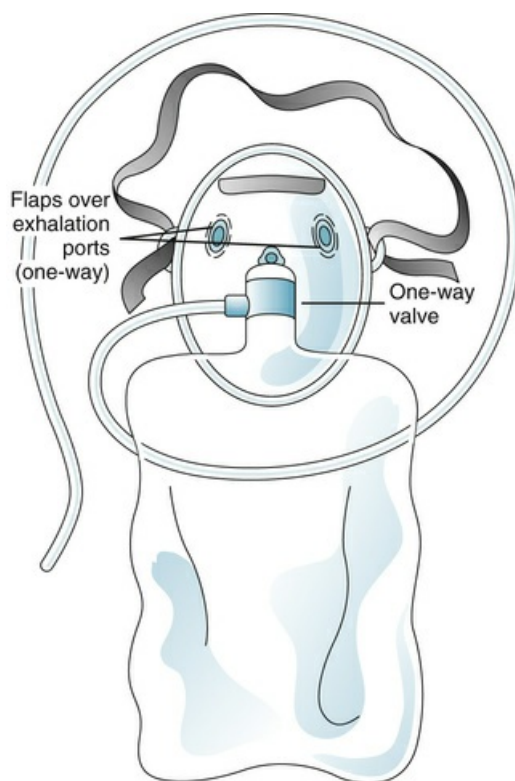

FIG. 28-5 Nonrebreather mask.

## Nursing Safety Priority QSEN

### Critical Rescue

Ensure that the valve and flaps on a nonrebreather mask are intact and functional during each breath. If the oxygen source should fail or be depleted when both flaps are in place, the patient would not be able to inhale room air.

### High-Flow Oxygen Delivery Systems.

High-flow systems (Table 28-2) include the Venturi mask, aerosol mask, face tent, Vapotherm high-flow nasal cannula, tracheostomy collar, and T-piece. These devices deliver an accurate oxygen level when properly fitted, with oxygen concentrations from 24% to 100% at 8 to 15 L/min. More recently, high-flow nasal cannulas (HFNCs) such as Vapotherm are more widely used for precise temperature and oxygen control along with humidification. With use of these devices at liter flows of 40 to 60 L/min, an  $FiO_2$  approaching that of a nonrebreather system can be achieved.

**TABLE 28-2**  
Comparison of High-Flow Oxygen Delivery Systems

FiO <sub>2</sub> DELIVERED	NURSING INTERVENTIONS	RATIONALES
<b>Venturi Mask (Venti Mask)</b>		
24%-50% FiO <sub>2</sub> with flow rates as recommended by the manufacturer, usually 4-10 L/min; provides high humidity	Perform constant surveillance to ensure an accurate flow rate for the specific FiO <sub>2</sub> .	An accurate flow rate ensures FiO <sub>2</sub> delivery.
	Keep the orifice for the Venturi adaptor open and uncovered.	If the Venturi orifice is covered, the adaptor does not function, and oxygen delivery varies.
	Provide a mask that fits snugly and tubing that is free of kinks.	FiO <sub>2</sub> is altered if kinking occurs or if the mask fits poorly.
	Assess the patient for dry mucous membranes.	Comfort measures may be indicated.
	Change to a nasal cannula during mealtime.	Oxygen is a drug that needs to be given continuously.
<b>Aerosol Mask, Face Tent, Tracheostomy Collar</b>		
24%-100% FiO <sub>2</sub> with flow rates of at least 10 L/min; provides high humidity	Assess that aerosol mist escapes from the vents of the delivery system during inspiration and expiration.	Humidification should be delivered to the patient.
	Empty condensation from the tubing.	Emptying prevents the patient from being lavaged with water, promotes an adequate flow rate, and ensures a continued prescribed FiO <sub>2</sub> .
	Change the aerosol water container as needed.	Adequate humidification is ensured only when there is sufficient water in the canister.

T-Piece		
24%-100% FiO <sub>2</sub> with flow rates of at least 10 L/min; provides high humidity	Empty condensation from the tubing.	Condensation interferes with flow rate delivery of FiO <sub>2</sub> and may drain into the tracheostomy if not emptied.
	Keep the exhalation port open and uncovered.	If the port is occluded, the patient can suffocate.
	Position the T-piece so it does not pull on the tracheostomy or endotracheal tube.	The weight of the T-piece pulls on the tracheostomy and causes pain or erosion of skin at the insertion site.
	Make sure the humidifier creates enough mist. A mist should be seen during inspiration and expiration.	An adequate flow rate is needed to meet the inspiration effort of the patient. If not, the patient will be "air-hungry."

FiO<sub>2</sub>, Fraction of inspired oxygen.

*Venturi masks* (Venti masks) deliver the most accurate oxygen concentration without intubation. They work by pulling in a proportional amount of room air for each liter flow of oxygen. An adaptor is located between the bottom of the mask and the oxygen source (Fig. 28-6). Adaptors with holes of different sizes allow specific amounts of air to mix with the oxygen, resulting in more precise delivery of oxygen. Each adaptor requires a different flow rate. For example, to deliver 24% of oxygen, the flow rate must be 4 L/min. Another type of Venturi mask has one adaptor with a dial that is used to select the amount of oxygen desired.

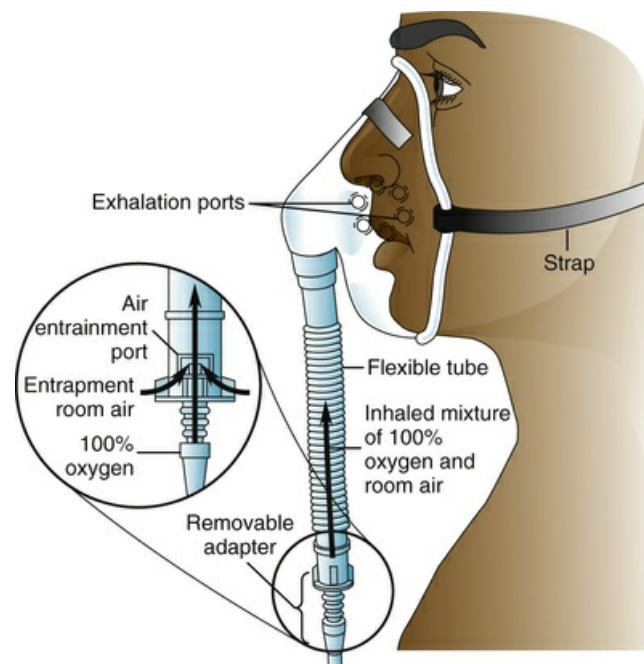

FIG. 28-6 Venturi mask for precise oxygen delivery.

*Other high-flow systems* include the face tent, aerosol mask, tracheostomy collar, and T-piece. They are often used to provide high humidity with oxygen delivery. A dial on the humidity source regulates the delivered oxygen level. A face tent fits over the chin, with the top extending halfway across the face. Although the oxygen level delivered varies, the face tent is useful for patients who have facial trauma or burns. An aerosol mask is used when high humidity is needed. The tracheostomy collar is used to deliver high humidity and the desired oxygen to the patient with a tracheostomy. A special adaptor, called the *T-piece*, is used to deliver any desired FiO<sub>2</sub> to the patient with a tracheostomy, laryngectomy, or endotracheal tube (Fig. 28-7). Adjust the flow rate so the aerosol appears on the exhalation side of the T-piece. The high-flow nasal cannula (HFNC) is increasing in use for adults. Some systems require heated humidification, and some use blenders to more accurately adjust FiO<sub>2</sub>. The FiO<sub>2</sub> and flow rates can be adjusted independently and may achieve an actual FiO<sub>2</sub> close to the predicted FiO<sub>2</sub>. The use of pulse oximetry is recommended to titrate the HFNC to patient response.

**FIG. 28-7** T-piece apparatus for attachment to an endotracheal or tracheostomy tube.

### Noninvasive Positive-Pressure Ventilation.

Noninvasive positive-pressure ventilation (NPPV) is a type of noninvasive ventilation (NIV). This technique uses positive pressure to keep alveoli open and improve GAS EXCHANGE without the need for and dangers of intubation (Bajaj et al., 2015). It is used to manage dyspnea, hypercarbia and acute exacerbations of chronic obstructive pulmonary disease (COPD), cardiogenic pulmonary edema, and acute asthma attacks (see the Evidence-Based Practice box). Although NPPV prevents the complications associated with intubation, including ventilator-associated pneumonia (VAP), risks and complications are associated with it. Masks must fit tightly to form a proper seal, which can lead to loss of TISSUE INTEGRITY with skin breakdown over the nose or face. Full facemasks cause fewer skin problems than do nasal-oral masks (Schallom et al., 2015). Leaks can cause uncomfortable pressure around the eyes, and gastric insufflation can lead to vomiting and the potential for aspiration. Thus NPPV should be used only on alert patients who have the ability to protect their airway, although a nasogastric (NG) tube may still be required for safety.

## Evidence-Based Practice QSEN

### When Is Noninvasive Ventilation (NIV) Most Effective?

Bajaj, A., Rathor, P., Sehgal, V., & Shetty, A. (2015). Efficacy of noninvasive ventilation after planned extubation: A systematic review and meta-analysis of randomized controlled trials. *Heart & Lung, 44*(2), 150-157.

Extubation failure with subsequent reintubation places patients at continuing risk for complications and the possibility of permanent intubation. Therefore the use of methods that reduce intubation failure have great clinical importance. The objective of this meta-analysis was to update the evidence on the efficacy of noninvasive ventilation (NIV) compared with conventional oxygen therapy after planned extubation. The method used was a systematic literature review of PubMed, EMBASE, and Cochrane for randomized controlled trials (RCTs) comparing NIV with conventional oxygen therapy after planned extubation. The results of this large analysis showed that NIV decreased reintubation rate significantly compared to conventional oxygen therapy in chronic obstructive pulmonary disease (COPD) and patients at high risk for extubation failure. However, in a mixed medical ICU population, there was no statistical difference of reintubation rate between the two groups. These results indicate that use of NIV after planned extubation significantly decreases the reintubation rate in COPD patients and patients at high risk for extubation failure.

### Level of Evidence: 1

The study was a meta-analysis of nine large, multi-site RCTs. In addition, the study added a separate analysis of three different subgroups to determine if NIV was more effective with a particular group of patients.

### Commentary: Implications for Practice and Research

The use of NIV immediately after planned extubation among patients with COPD or other identified high risk for extubation failure decreased the rate of reintubation, ICU mortality, hospital

mortality, and ICU length of stay when compared with conventional oxygen therapy. This therapy is relatively low cost for actual expenses and those caused by increased lengths of stay or more invasive interventions. Reduction of patient risks and increased comfort are also benefits. Nurses should consider requesting this type of respiratory support after planned extubation for patients with COPD and those at high risk for extubation failure. Nursing research assessing patient and family tolerance and perceptions of NIV may provide results that further promote its use.

NPPV can deliver oxygen or may use just room air. A nasal mask, nasal pillows, or full-facemask delivery system allows mechanical delivery. The three most common modes of delivery for NPPV are (1) continuous positive airway pressure (CPAP), which delivers a set positive airway pressure throughout each cycle of inhalation and exhalation; (2) volume-limited or flow-limited, which delivers a set tidal volume with the patient's inspiratory effort; and (3) pressure-limited, which includes pressure support, pressure control, and bi-level positive airway pressure (BiPAP), which cycles different pressures at inspiration and expiration.

For BiPAP, a cycling machine delivers a set inspiratory positive airway pressure each time the patient begins to inspire. As he or she begins to exhale, the machine delivers a lower set end-expiratory pressure. Together, these two pressures improve tidal volume, can reduce respiratory rate, and may relieve dyspnea.

For CPAP the effect is to open collapsed alveoli. Patients who may benefit from this form of oxygen or air delivery include those with atelectasis after surgery or cardiac-induced pulmonary edema or those with COPD. It is not helpful for patients with respiratory failure following extubation. However, both CPAP and BiPAP are used after extubation to prevent respiratory failure and the need for re-intubation. NPPV is used in palliative care to relieve dyspnea, including for those patients with "do-not-intubate" orders. However, this practice is controversial. The Society of Critical Care Medicine recommends discussing goals and expected outcomes with the patient and family before initiating therapy.

NPPV is used for sleep apnea. The effect is to hold open the upper airways (Fig. 28-8). Patients using CPAP or BiPAP at home for sleep apnea often bring their home equipment to the hospital. They feel more comfortable using their own equipment. The reasons for using NPPV remain when the patient enters the hospital, and the need continues while hospitalized.

**FIG. 28-8** Nasal continuous positive airway pressure (CPAP). (From Perry, A. G., Potter, P. A., & Ostendorf, W. R. [2017]. *Clinical nursing skills and techniques* [9th ed.]. St. Louis: Mosby.)

The number of patients using NPPV therapy is increasing in every setting. Nurses caring for the patient with NPPV must be knowledgeable about the equipment, technique, and potential complications. Respiratory therapy support can help safely manage a patient receiving NPPV.

### Transtracheal Oxygen Therapy.

Transtracheal oxygen (TTO) is a long-term method of delivering oxygen directly into the lungs. A small, flexible catheter is passed into the trachea through a small incision with the patient under local anesthesia. TTO avoids damage to TISSUE INTEGRITY from nasal prongs and is less visible. A TTO team provides patient education, including the purpose of TTO and care of the catheter. Different flow rates are prescribed for rest and activity. A flow rate also is prescribed for the nasal cannula, which is used when the TTO catheter is being cleaned.

## Clinical Judgment Challenge 28-1

### Patient-Centered Care; Teamwork and Collaboration; Evidence-Based Practice QSEN

Your patient is a 56-year-old woman who just had laparoscopic surgery. She is morbidly obese, has COPD, and is a current smoker. She does not use oxygen at home. During this early postoperative period, she is prescribed oxygen.

1. Which type of oxygen delivery device do you believe will deliver the most precise  $FiO_2$  for this patient?
2. For which potential complication of a higher  $FiO_2$  would this patient be at risk, and how could this be avoided?
3. The PACU report indicates that the patient had frequent episodes of snoring with decreased oxygen saturation while sleeping. Should you request a referral and to whom?
4. Your patient continues to require oxygen to maintain a saturation of 88%. It appears that she will need home oxygen. With whom should you consult for this possibility?

## Care Coordination and Transition Management

### Home Care Management.

The patient must be stable before home oxygen is considered. For Medicare to cover the cost of home oxygen therapy, the patient must have severe hypoxemia defined as a partial pressure of arterial oxygen ( $PaO_2$ ) level of less than 55 mm Hg or arterial oxygen saturation ( $SpO_2$ ) of less than 88% on room air and at rest. The criteria vary when hypoxemia is caused by nonpulmonary problems or when oxygen is needed only at night or with exercise.

### Self-Management Education.

When home oxygen therapy is prescribed, begin a teaching plan about it. The nurse or respiratory therapist teaches the patient about the equipment needed for home oxygen therapy and the safety aspects of using and maintaining the equipment. Equipment may include oxygen source, delivery devices, and humidity sources. Work with the discharge planner to help the patient select a durable medical equipment (DME) company to deliver oxygen equipment and select a community health nursing agency for follow-up care in the home. Re-evaluation of the need for oxygen therapy occurs on a periodic basis.

While providing discharge planning and teaching, be sensitive to the patient's emotional adjustment to oxygen therapy. Encourage the patient to share feelings and concerns. He or she may be concerned about social acceptance. Help him or her realize that adherence to oxygen therapy is important for being able to participate in ADLs and other events that bring enjoyment.

### Home Care Preparation.

Home oxygen therapy is provided in one of three ways: compressed gas in a tank or a cylinder, liquid oxygen in a reservoir, or an oxygen concentrator. Compressed gas in an oxygen tank (green) is the most often used oxygen source. The large H cylinder may be used as a stationary source, and the smaller E tank is available for transporting the patient (Fig. 28-9). Even smaller cylinders are available for the patient to carry. Teach the patient and family to check the gauge daily to assess the

amount of oxygen left in the tank. As a safety precaution, the tanks must always be in a stand or rack. A tank that is accidentally knocked over could suddenly decompress and move around in an uncontrolled manner.

**FIG. 28-9** Small E-size oxygen tank (cylinder) for portability. (From Perry, A. G., Potter, P. A., & Ostendorf, W. R. [2017]. *Clinical nursing skills and techniques* [9th ed.]. St. Louis: Mosby.)

Liquid oxygen for home use is oxygen gas that has been liquefied. A concentrated amount of oxygen is available in a lightweight and easy-to-carry container similar to a Thermos bottle (Fig. 28-10). This portable tank is filled from a large stationary liquid vessel. Liquid oxygen lasts longer than gaseous oxygen but is more expensive.

**FIG. 28-10** Portable liquid oxygen. (Courtesy Chad Therapeutics, Chatsworth, CA.)

The **oxygen concentrator** or *oxygen extractor* is a machine that removes nitrogen from room air, increasing oxygen levels to more than 90%. This device is the least expensive system and does not need to be filled. It is often used in the home as a stationary system. A smaller version that can plug into DC electrical outlets can be rented for longer car or boat trips.

*Regardless of the type of oxygen delivery system used, review safety issues with the patient and all family members.*

## Nursing Safety Priority QSEN

### Action Alert

Assess the patient's and caregivers' knowledge of oxygen therapy to recognize any deficiencies. Respond by providing safety information and stressing the importance of not smoking when he or she is using oxygen. Teach the patient and all family members that smoking materials, candles, gas burners, and fireplaces (and other open flames) are not to be used in the same room that oxygen is being used.

## NCLEX Examination Challenge 28-2

### Health Promotion and Maintenance

What must the nurse include for discharge education for a client who is newly prescribed to use oxygen therapy at home? **Select all that apply.**

- A. The consequences of smoking while using oxygen
- B. The need to limit potted plants in the home
- C. The types of oxygen delivery devices available for home use
- D. The use of oxygen when performing ADLs
- E. The need to travel only in specially designated cars
- F. Performing proper skin care under the device and its straps

# Gas Exchange Concept Exemplar Tracheostomy

## Overview

**Tracheotomy** is the surgical incision into the trachea to create an airway to help maintain GAS EXCHANGE. **Tracheostomy** is the tracheal *stoma* (opening) that results from the tracheotomy. A tracheotomy can be an emergency procedure or a scheduled surgery. Tracheostomies can be temporary or permanent. Indications for tracheostomy include acute airway obstruction, the need for airway protection, laryngeal or facial trauma or burns, and airway involvement during head or neck surgery. They also are used for prolonged unconsciousness, paralysis, or the inability to be weaned from mechanical ventilation. With temporary tracheostomies, the nurse is key in evaluating patient readiness for progression toward decannulation (removal of the tracheostomy tube) (Morris et al., 2014).

## Interprofessional Collaborative Care

Although the initial tracheotomy to form a tracheostomy is usually performed in an acute care setting, care of the patient who has a tracheostomy often occurs in the community. Care for the patient requiring long-term tracheostomy is best when a team approach is used. In addition to the nurse, interprofessional team members often include the primary health care provider, respiratory therapist, registered dietitian, discharge planner, and social worker.

### Analysis: Interpreting

The priority collaborative problems for patients requiring tracheostomy include:

1. Decreased GAS EXCHANGE due to weak chest muscles, obstruction, or other physical problems that interfere with ventilation and diffusion of gases
2. Inadequate communication due to tracheostomy or intubation
3. Potential for weight loss due to inadequate nutrition from presence of endotracheal tube
4. Potential for infection due to invasive procedures or problems with the normal protective mechanisms of the respiratory tract
5. Potential for loss of tracheal TISSUE INTEGRITY due to pressure and trauma from tracheostomy tubes

### Interventions: Responding

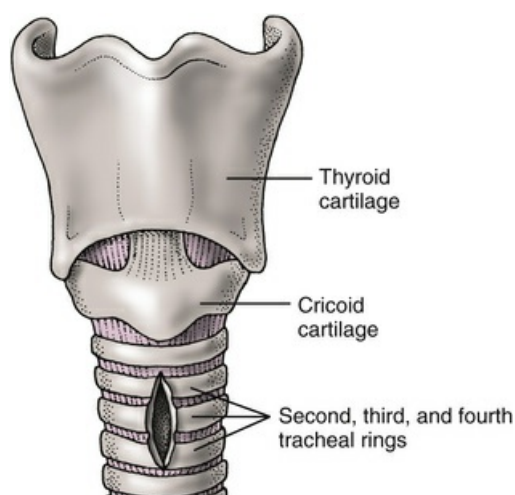

#### Preoperative Care.

The care for the patient having a tracheotomy is similar to that for a laryngectomy (see Chapter 29). Focus on his or her knowledge deficits through teaching and discuss tracheostomy care, communication, and speech.

#### Operative Procedures.

Initially the neck is extended, and an endotracheal (ET) tube is placed by the anesthesia provider to maintain the airway. Incisions are made through the neck and the tracheal rings to enter the trachea (Fig. 28-11).

**FIG. 28-11** Vertical tracheal incision for a tracheostomy.

After the trachea is entered, the ET tube is removed while the tracheostomy tube is inserted. The tracheostomy tube is secured in place with sutures and tracheostomy ties or Velcro tube holders. A chest x-ray determines proper placement of the tube.

### Postoperative Care.

Immediately after surgery, focus care on ensuring a patent airway. Confirm the presence of bilateral breath sounds. Perform a respiratory assessment at least hourly. Assess the patient for complications from the procedure.

### Complications.

Major complications can arise after surgery. [Table 28-3](#) lists symptoms, management, and prevention of complications of tracheostomy.

**TABLE 28-3**  
**Complications of Tracheostomy**

COMPLICATIONS AND DESCRIPTION	MANIFESTATIONS	MANAGEMENT	PREVENTION
Tracheomalacia: Constant pressure exerted by the cuff causes tracheal dilation and erosion of cartilage, leading to loss of tissue integrity.	An increased amount of air is required in the cuff to maintain the seal. A larger tracheostomy tube is required to prevent an air leak at the stoma. Food particles are seen in tracheal secretions. The patient does not receive the set tidal volume on the ventilator.	No special management is needed unless bleeding occurs.	Use an uncuffed tube as soon as possible. Monitor cuff pressure and air volumes closely and detect changes.
Tracheal stenosis: Narrowed tracheal lumen is caused by scar formation from irritation of tracheal mucosa and impaired tissue integrity by the cuff.	Stenosis is usually seen after the cuff is deflated or the tracheostomy tube is removed. The patient has increased coughing, inability to expectorate secretions, or difficulty breathing or talking.	Tracheal dilation or surgical intervention is used.	Prevent pulling of and traction on the tracheostomy tube. Properly secure the tube in the midline position. Maintain proper cuff pressure. Minimize oronasal intubation time.
Tracheoesophageal fistula (TEF): Excessive cuff pressure causes erosion of the posterior wall of the trachea and loss of TISSUE INTEGRITY. A hole is created between the trachea and the anterior esophagus. The patient at highest risk also has a nasogastric tube present.	Similar to tracheomalacia: Food particles are seen in tracheal secretions. Increased air in cuff is needed to achieve a seal. The patient has increased coughing and choking while eating. The patient does not receive the set tidal volume on the ventilator.	Manually administer oxygen by mask to prevent hypoxemia. Use a small, soft feeding tube instead of a nasogastric tube for tube feedings. A gastrostomy or jejunostomy may be performed by the physician. Monitor the patient with a nasogastric tube closely; assess for TEF and aspiration.	Maintain cuff pressure. Monitor the amount of air needed for inflation and detect changes. Progress to a deflated cuff or cuffless tube as soon as possible.
Trachea—innominate artery fistula: A malpositioned tube causes its distal tip to push against the lateral wall of the tracheostomy. Continued pressure causes necrosis and erosion of the innominate artery. <i>This is a medical emergency.</i>	The tracheostomy tube pulsates in synchrony with the heartbeat. There is heavy bleeding from the stoma. This is a life-threatening complication.	Remove the tracheostomy tube immediately. Apply direct pressure to the innominate artery at the stoma site. Prepare the patient for immediate surgical repair.	Correct the tube size, length, and midline position. Prevent pulling or tugging on the tracheostomy tube. Immediately notify the physician of the pulsating tube.

*Tube obstruction* can occur as a result of secretions or by cuff displacement. Indicators are

difficulty breathing; noisy respirations; difficulty inserting a suction catheter; thick, dry secretions; and high peak pressures (if a mechanical ventilator is used). Assess the patient at least hourly for tube patency. Prevent obstruction by helping the patient cough and deep breathe, providing inner cannula care, humidifying oxygen, and suctioning. If tube obstruction results from cuff prolapse over the end of the tube, the primary health care provider repositions or replaces the tube.

*Tube dislodgment and accidental decannulation* can occur when the tube is not secure. Prevent this problem by securing the tube in place to reduce movement and traction or accidental pulling by the patient. *Tube dislodgment in the first 72 hours after surgery is an emergency because the tracheostomy tract has not matured and replacement is difficult. The tube may end up in the subcutaneous tissue instead of in the trachea (also referred to as “false passage”). The patient will not be able to be ventilated.* Obese patients or those with short, large necks may be particularly difficult to recannulate if the tracheostomy tube is dislodged.

## Nursing Safety Priority QSEN

### Critical Rescue

Monitor the patient for tube placement. When you recognize that the tube is dislodged on an immature tracheostomy, respond by ventilating the patient using a manual resuscitation bag and facemask while another nurse calls the Rapid Response Team.

*For safety, ensure that a tracheostomy tube of the same type (including an obturator) and size (or one size smaller) is at the bedside at all times, along with a tracheostomy insertion tray.* If decannulation occurs after 72 hours, extend the patient's neck and open the tissues of the stoma with a curved Kelly clamp to secure the airway. With the obturator inserted into the tracheostomy tube, quickly and gently replace the tube and remove the obturator. Check for airflow through the tube and for bilateral breath sounds. *If you cannot secure the airway, notify a more experienced nurse, respiratory therapist, or physician for assistance. Ventilate with a bag-valve-mask. If the patient is in distress, call the Rapid Response Team for help.* To reduce tube dislodgment problems, many institutions have a “difficult airway” cart for high-risk patients.

*Pneumothorax* (air in the chest cavity) can develop during the tracheotomy procedure if the chest cavity is entered. Chest x-rays after placement are used to assess for pneumothorax.

*Subcutaneous emphysema* occurs when there is an opening or tear in the trachea and air escapes into the fresh tissue planes of the neck. Air can progress throughout the chest and other tissues into the face. Inspect and palpate for air under the skin around the new tracheostomy.

## Nursing Safety Priority QSEN

### Critical Rescue

Assess the skin around a new tracheostomy to recognize subcutaneous emphysema. If it is puffy and you can feel a crackling sensation when pressing on this skin, respond by notifying the physician immediately.

*Bleeding* in small amounts from the tracheotomy incision is expected for the first few days, but constant oozing is abnormal. Wrap gauze around the tube and pack gauze gently into the wound to apply pressure to the bleeding sites. Bleeding can occur in the trachea itself or in the tissues surrounding the incision. If hemorrhage occurs, the site may need surgical exploration or ligation of blood vessels.

*Infection* can occur at any time. In the hospital, use sterile technique to prevent infection during suctioning and tracheostomy care. Assess the stoma site at least once every 8 hours for purulent drainage, redness, pain, swelling, or loss of TISSUE INTEGRITY. Tracheostomy dressings may be used to keep the stoma clean and dry. These dressings resemble a 4 × 4 gauze pad with an area removed to fit around the tube. If tracheostomy dressings are not available, fold standard sterile 4 × 4s to fit around the tube. *Do not cut the dressing because small bits of gauze could then be aspirated through the tube.* Change these dressings often because moist dressings provide a medium for bacterial growth.

Careful wound care prevents most local infections.

### Tracheostomy Tubes.

Many types of tracheostomy tubes are available (Fig. 28-12). The one chosen depends on patient needs. Tubes are available in many sizes and are made of plastic or metal. Most tubes are disposable. A tracheostomy tube may have a cuff and an inner cannula. A cuffed tube is used for patients receiving mechanical ventilation. The cuff is a small balloon surrounding the outside of the tracheostomy tube (see Figure 28-12). When inflated to the proper size and pressure, the cuff comes into contact with the trachea and seals it off so that all air movement occurs within the tracheostomy tube, not around it. Usually the cuff is inflated through the use of a pilot balloon, which remains on the outside of the body where it can be accessed. As shown in Figure 28-12, the pilot balloon is a small balloon with a valve on one end and a thin long tube on the other end. The thin tube is connected to the cuff. To inflate the cuff, an air-filled syringe is attached to the pilot balloon valve. As the syringe is pressed, air first enters the pilot balloon and then moves through the thin tube to inflate the cuff. In addition to the function of inflating the cuff, the pilot balloon can determine whether any air is in the cuff because the pilot remains inflated when the cuff is inflated. It does not indicate air volume or pressure in the cuff.

**FIG. 28-12** Tracheostomy tubes. **A**, Dual-lumen cuffed tracheostomy tube with disposable inner cannula. **B**, Single-lumen cannula cuffed tracheostomy tube. **C**, Dual-lumen cuffed fenestrated tracheostomy tube. (Courtesy Mallinckrodt, Inc., Shiley Tracheostomy Products, St. Louis, MO.)

For tubes with a reusable inner cannula, inspect, suction, and clean the inner cannula. During the

first 24 hours after surgery, perform cannula care as often as needed, perhaps hourly. Thereafter care is determined by the patient's needs and agency policy. In planning for self-care, teach the patient to remove the inner cannula and check for cleanliness. Instruct him or her about suctioning and tracheostomy cleaning.

Because breathing and swallowing move the tube, even a cuffed tube does not protect against aspiration. Having a cuffed tube inflated may give a false sense of security that aspiration cannot occur during feeding or mouth care. In addition, the pilot balloon does not reflect whether the correct amount of air is present in the cuff.

A fenestrated tube functions in many different ways. When the inner cannula is in place, the fenestration is closed, and this tube works like a double-lumen tube. With the inner cannula removed and the plug or stopper locked in place, air can pass through the fenestration, around the tube, and up through the natural airway so the patient can cough and speak. If the patient has trouble with these actions, he or she should be evaluated for proper tube placement, patency, size, and fenestration. *Do not cap the tube until the problem is identified and corrected.*

A fenestrated tube may or may not have a cuff. With a cuff, some air flows through the natural airway when the patient is not being mechanically ventilated.

## Nursing Safety Priority QSEN

### Action Alert

Always deflate the cuff before capping the tube with the decannulation cap; otherwise the patient has no airway.

Patients with metal tracheostomy tubes scheduled for MRI need to change to a plastic tube. Metal tubes could be dislodged or heat up with exposure to the magnetic field during the scan.

## Care Issues for the Patient With a Tracheostomy

### Preventing Tissue Damage.

Loss of TISSUE INTEGRITY can occur at the point where the inflated cuff presses against the tracheal mucosa. Mucosal ischemia occurs when the pressure exerted by the cuff on the mucosa exceeds the capillary perfusion pressure. To reduce the risk for tracheal damage, keep the cuff pressure between 14 and 20 mm Hg or 20 and 30 cm H<sub>2</sub>O (ideally, 25 cm H<sub>2</sub>O or less).

Most cuffs use a high volume of air while keeping low pressure on the tracheal mucosa. Inflate the cuff to form a seal between the trachea and the cuff with the least amount of pressure. If the cuff cannot be inflated to seal well enough, a larger-diameter tube may be needed. A pressure cuff inflator can be used to inflate the cuff to a specified pressure or to check the cuff pressure (Fig. 28-13).

**FIG. 28-13** Aneroid pressure manometer for cuff inflation and measuring cuff pressures. (Courtesy J. T. Posey Company, Arcadia, CA.)

Check the cuff pressure at least once during each shift using either a pressure cuff inflator or the minimal leak technique. When using an inflator, keep the pressure at 14 to 20 mm Hg or 20 to 30 cm H<sub>2</sub>O. In rare situations, the cuff pressure is increased to maintain ventilator volumes when peak pressures are greater than 50 mm Hg (65 cm H<sub>2</sub>O) and positive end-expiratory pressure (PEEP) is greater than 10 mm Hg (14 cm H<sub>2</sub>O). High PEEP values can deflate the cuff over time, and more air may need to be added to maintain a proper seal. Manufacturers have guidelines for the specific volumes for each cuff size. Most cuffs are adequately inflated with less than 10 mL of air.

When using the minimal leak technique to ensure adequate cuff pressure and reduce the risk for pressure injury, a pressure cuff inflator is not used. Instead, after completing tracheostomy care and suctioning the airway above the cuff, attach a 10-mL Luer-Lok syringe to the valve in the pilot balloon. Place a stethoscope on the side of the patient's neck near the tracheostomy tube and slowly deflate the cuff with the syringe while listening for a loud, gurgling air rush as the seal is broken and air bypasses the tracheostomy tube on inhalation. Then while re-injecting the air in the syringe, continue to listen for air passing the cuff. When air is no longer heard passing the cuff, the airway is sealed. At this point, remove 1 mL of air from the cuff. This ensures that the airway is sealed sufficiently to allow adequate ventilation and keep the tube fitting just loose enough to prevent tracheal injury.

Although a high cuff pressure alone can injure tracheal TISSUE INTEGRITY, other factors contribute to the risk for damage (Makic et al., 2013). The patient who is malnourished, dehydrated, hypoxic, older, or receiving corticosteroids is at risk for greater tissue damage. Tube friction and movement damage the mucosa and lead to tracheal stenosis. Reduce local airway damage by maintaining proper cuff pressures, stabilizing the tube, suctioning only when needed, and preventing malnutrition, dehydration, and hypoxia.

### Ensuring Air Warming and Humidification.

The tracheostomy tube bypasses the nose and mouth, which normally humidify and warm the inspired air. If humidification and warming are not adequate, tracheal damage can occur. Inadequate humidity promotes thick, dried secretions that can occlude the airways.

To prevent these complications, humidify the air as prescribed. Continually assess for a fine mist emerging from the tracheostomy collar or T-piece during ventilation. To increase the amount of humidity delivered, a warming device can be attached to the water source with a temperature probe in the tubing circuit. Monitor the circuit temperature hourly by feeling the tubing and by checking the probe. Ensure adequate hydration, which also helps liquefy secretions. Increasing the flow rate at the flow meter increases the amount of delivered humidity.

## Action Alert

Keep the temperature of the air entering a tracheostomy between 98.6° and 100.4° F (37° and 38° C) and never exceed 104° F (40° C).

## Suctioning.

Suctioning maintains a patent airway and promotes GAS EXCHANGE by removing secretions when the patient cannot cough adequately. Chart 28-2 lists best practices for suctioning. Assess the patient's need for suctioning (e.g., audible or noisy secretions; crackles or wheezes heard on auscultation; restlessness, increased pulse or respiratory rates, or mucus present in the artificial airway) (Morris et al., 2013). Other indications include patient requests for suctioning or an increase in the peak airway pressure on the ventilator.

## Chart 28-2

### Best Practice for Patient Safety & Quality Care QSEN

#### Suctioning the Artificial Airway

- Assess the need for suctioning (routine unnecessary suctioning causes mucosal damage, bleeding, and bronchospasm).
- Wash hands. Don protective eyewear. Maintain Standard Precautions.
- Explain to the patient that sensations such as shortness of breath and coughing are to be expected but that any discomfort will be very brief.
- Check the suction source. Occlude the suction source and adjust the pressure dial to between 80 and 120 mm Hg to prevent hypoxemia and trauma to the mucosa.
- Set up a sterile field.
- Preoxygenate the patient with 100% oxygen for 30 seconds to 3 minutes (at least three hyperinflations) to prevent hypoxemia. Keep hyperinflations synchronized with inhalation.
- Quickly insert the suction catheter until resistance is met. *Do not apply suction during insertion.*
- Withdraw the catheter 0.4 to 0.8 inch (1 to 2 cm) and begin to apply suction. Apply continuous suction and use a twirling motion of the catheter during withdrawal to avoid injury to TISSUE INTEGRITY. *Never suction longer than 10 to 15 seconds.*
- Hyperoxygenate for 1 to 5 minutes or until the patient's baseline heart rate and oxygen saturation are within normal limits.
- Repeat as needed for up to three total suction passes.
- Suction mouth as needed and provide mouth care.
- Remove gloves and wash hands.
- Describe secretions and document patient's responses.

Deep endotracheal suctioning is painful. Unconscious patients may still feel pain, and this should be kept in mind during the suctioning procedure. At the very least, provide verbal acknowledgment of the discomfort and reassurance of when the procedure will end.

Suctioning is often performed through an artificial airway, but the nose or mouth also can be used. Suctioning of both routes is routine for the patient with retained secretions.

Suctioning through the nose has complications and can be painful. Selecting a small suction

catheter and coating it with a water-soluble lubricant helps minimize trauma and increase comfort. Slow, careful placement of the catheter following the nasopharyngeal anatomy reduces pain and prevents injuring TISSUE INTEGRITY. Placing a nasopharyngeal airway and suctioning through it can prevent trauma to the nasal mucosa. Advance the catheter through the nasopharynx and into the laryngopharynx while the patient receives oxygen by mask or nasal cannula. Once the catheter enters the larynx, the patient may cough. On inhalation, insert the catheter into the trachea. If needed, disconnect the catheter from suction and attach it to an oxygen source so the patient receives oxygen via the catheter.

Suctioning can cause hypoxia, injury to mucosal TISSUE INTEGRITY, trauma, infection, vagal stimulation, bronchospasm, and cardiac dysrhythmias.

*Hypoxia* can be caused by these factors in the patient with a tracheostomy:

- Ineffective oxygenation before, during, and after suctioning
- Use of a catheter that is too large for the artificial airway
- Prolonged suctioning time
- Excessive suction pressure
- Too frequent suctioning

Prevent hypoxia by hyperoxygenating the patient with 100% oxygen using a manual resuscitation bag attached to an oxygen source. Instruct the patient to take deep breaths 3 or 4 times with the existing oxygen delivery system before suctioning. Monitor the heart rate or use a pulse oximeter while suctioning to assess tolerance of the procedure. Assess for hypoxia (e.g., increased heart rate and blood pressure, oxygen desaturation, cyanosis, restlessness, anxiety, dysrhythmias). Oxygen saturation below 90% by pulse oximetry indicates hypoxemia. If hypoxia occurs, stop the suctioning procedure. Using the 100% oxygen delivery system, reoxygenate the patient until baseline parameters return.

Use a correct-size catheter to reduce the risk for hypoxia and still remove secretions effectively. The size should not exceed half of the size of the tracheal lumen. The standard catheter size for an adult is 12 Fr or 14 Fr.

*Loss of TISSUE INTEGRITY* by trauma results from frequent suctioning, prolonged suctioning, excessive suction pressure, and nonrotation of the catheter. Prevent trauma to the mucosa by suctioning only when needed and lubricating the catheter with sterile water or saline before insertion. *Apply continuous suction only during catheter withdrawal because intermittent suction does not protect the mucosa and can lead to “dropping” of secretions in the airway.* Use a twirling motion during withdrawal to prevent grabbing of the mucosa.

Apply suction for only 10 to 15 seconds. Estimate this time frame by holding your own breath and counting to 10 or 15 while suctioning. Longer suctioning can cause alveolar collapse.

*Infection* is possible because each catheter pass introduces bacteria into the trachea. In the hospital, use sterile technique for suctioning and for all suctioning equipment (e.g., suction catheters, gloves, saline or water). Suction the mouth or nose *after* suctioning the artificial airway. Clean technique is used at home because the number of virulent organisms in the home environment is lower than in the hospital.

## Nursing Safety Priority QSEN

### Action Alert

Never use oral suction equipment for suctioning an artificial airway because this can introduce oral bacteria into the lungs.

*Vagal stimulation and bronchospasm* are possible during suctioning. Vagal stimulation results in bradycardia, hypotension, heart block, ventricular tachycardia, or other dysrhythmias. *If vagal stimulation occurs, stop suctioning immediately and oxygenate the patient manually with 100% oxygen.* Bronchospasm may occur when the catheter passes into the airway. The patient may need a bronchodilator to relieve bronchospasm and respiratory distress. The hypoxia caused by suctioning can stimulate a variety of cardiac dysrhythmias. If the patient has cardiac monitoring in place, check the monitor during suctioning.

## NCLEX Examination Challenge 28-3

### Safe and Effective Care Environment

For which possible complication of tracheostomy tube dislodgment does the nurse remain alert in a client during the first 72 hours after placement?

- A. Oxygen toxicity
- B. Increased secretions
- C. Movement of the tube into a “false passage”
- D. Increased risk for aspiration during swallowing

### Providing Tracheostomy Care.

Tracheostomy care keeps the tube free of secretions, maintains a patent airway, and provides wound care (Schreiber, 2015). It is performed whether or not the patient can clear secretions. Perform tracheostomy care according to agency policy, usually every 8 hours and as needed. Chart 28-3 outlines best practices for tracheostomy care.

### Chart 28-3

## Best Practice for Patient Safety & Quality Care QSEN

### Tracheostomy Care

- Assemble the necessary equipment.
- Wash hands. Maintain Standard Precautions.
- Suction the tracheostomy tube if necessary.
- Remove old dressings and excess secretions.
- Set up a sterile field.
- Remove and clean the inner cannula. Use half-strength hydrogen peroxide to clean the cannula and sterile saline to rinse it. If the inner cannula is disposable, remove the cannula and replace it with a new one.
- Clean the stoma site and then the tracheostomy plate with half-strength hydrogen peroxide followed by sterile saline. Ensure that none of the solutions enters the tracheostomy.
- Change tracheostomy ties if they are soiled. Secure new ties in place before removing soiled ones to prevent accidental decannulation. If a knot is needed, tie a square knot that is visible on the side of the neck. Only one finger should be able to be placed between the tie tape and the neck.
- Wash hands.
- Document the type and amount of secretions and the general condition of the stoma and surrounding skin tissue integrity. Document the patient's response to the procedure and any teaching or learning that occurred.

Before tracheostomy care, assess the patient as described in Chart 28-4. The need for suctioning and tracheostomy care is determined by the secretions, the specific disorder, the ability of the patient to cough, the need for mechanical ventilation, and wound care. Using a penlight, inspect the inner lumen of a single-lumen tube to assess for secretions.

## Chart 28-4

### Focused Assessment

#### The Patient With a Tracheostomy

- Note the quality, pattern, and rate of breathing:
- Within patient's baseline?
- Tachypnea can indicate hypoxia.
- Dyspnea can indicate secretions in the airway.
- Assess for any cyanosis, especially around the lips, which could indicate hypoxia.
- Check the patient's pulse oximetry reading.
- If oxygen is prescribed, is the patient receiving the correct amount, with the correct equipment and humidification?
- Assess the tracheostomy site:
- Note the color, consistency, and amount of secretions in the tube or externally.
- If the tracheostomy is sutured in place, is there any redness, swelling, or drainage from suture sites?
- If the tracheostomy is secured with ties, what is the condition of the ties? Are they moist with secretions or perspiration? Are the secretions dried on the ties? Is the tie secure?
- Assess the condition of the skin around the tracheostomy and neck for tissue integrity. Be sure to check underneath the neck for secretions that may have drained to the back. Check for any skin breakdown related to pressure from the ties or related to excess secretions.
- Assess behind the faceplate for the size of the space between the outer cannula and the patient's tissue. Are any secretions collected in this area?
- If the tube is cuffed, check cuff pressure.
- Auscultate the lungs.
- Are a second (emergency) tracheostomy tube and obturator available?

Secure tracheostomy tubes in place using either twill tape ties or commercial tube holders. Both methods have advantages and disadvantages over the other, and both are acceptable (Smith, 2016). These devices require changing when soiled or at least daily to keep them clean, to prevent infection, and to assess TISSUE INTEGRITY under the ties. Whenever possible, use the assistance of a coworker to stabilize the tube and prevent decannulation while changing the ties or tube holder (Schreiber, 2015). A properly secured tie or holder allows space for only one finger to be placed between the tie or holder and the neck (Morris et al., 2013). Tube movement causes irritation and coughing and may lead to decannulation. Keeping the tube secure while changing the ties or holder to prevent accidental decannulation is critical. Include the patient in tracheostomy care as a step toward self-care. Fig. 28-14 shows correct placement of a tracheostomy dressing.

**FIG. 28-14** Placement of tracheostomy gauze dressing and Velcro tracheostomy tube holder. (Courtesy Dale Medical Products, Inc., Plainville, MA.)

## Nursing Safety Priority **QSEN**

### Critical Rescue

Prevent decannulation during tracheostomy care by keeping the old ties or holder on the tube while applying new ties or holder or by keeping a hand on the tube until it is securely stable. (This is best performed with the assistance of a coworker.)

### Providing Bronchial and Oral Hygiene.

Bronchial hygiene promotes a patent airway and prevents infection. Turn and reposition the patient every 1 to 2 hours, support out-of-bed activities, and encourage ambulation to promote lung expansion and GAS EXCHANGE and help remove secretions. Coughing and deep breathing, combined with the chest percussion, vibration, and postural drainage, promote pulmonary hygiene (see Chapter 30).

Good oral hygiene keeps the airway patent, prevents bacterial overgrowth, and promotes comfort. Avoid using glycerin swabs or mouthwash that contains alcohol for oral care because these products dry the mouth, change its pH, and promote bacterial growth. Instead use a sponge tooth cleaner or soft-bristle toothbrush moistened in water for mouth care. Diluted hydrogen peroxide solutions can help remove crusted matter but may break down healing tissue and should be used only if prescribed. Help the patient rinse the mouth with normal saline every 4 hours while awake or as often as he or she desires.

Examine the mouth for changes in TISSUE INTEGRITY. Ulcers and infections are treated medically. Apply lip balm or water-soluble jelly to prevent cracked lips and promote comfort. Mouth care promotes oral health and comfort. Offering an opportunity for the patient or family member to perform mouth care allows participation in care and increases self-esteem.

Oral secretions can move down the trachea and collect above the inflated cuff of the endotracheal tube. When the cuff is deflated, the secretions can move into the lungs. Some endotracheal tubes

have an extra lumen open to the area above the cuff, which allows suctioning of the airway above the cuff before deflating and reduces the risk for aspiration.

### Ensuring Nutrition.

Swallowing can be a major problem for the patient with a tracheostomy tube in place. In a normal swallow, the larynx lifts and moves forward to prevent food and saliva from entering. The tracheostomy tube sometimes tethers the larynx in place, making it unable to move effectively. The result is difficulty in swallowing. In addition, when the tracheostomy tube cuff is inflated, it can balloon backward and interfere with food passage in the esophagus because the wall separating the trachea from the esophagus is thin.

Instruct the patient to keep the head of the bed elevated for at least 30 minutes after eating. [Chart 28-5](#) outlines best practices to prevent aspiration during swallowing.

#### **Chart 28-5**

### Best Practice for Patient Safety & Quality Care

#### Preventing Aspiration During Swallowing

- Avoid serving meals when the patient is tired.
- Provide smaller and more frequent meals.
- Provide adequate time; do not “hurry” the patient.
- Provide close supervision if the patient is self-feeding.
- Keep emergency suctioning equipment close at hand and turned on.
- Avoid water and other “thin” liquids.
- Thicken all liquids, including water.
- Avoid foods that generate thin liquids during the chewing process such as fruit.
- Position the patient in the most upright position possible.
- When possible, completely (or at least partially) deflate the tube cuff during meals.
- Suction after initial cuff deflation to clear the airway and allow maximum comfort during the meal.
- Feed each bite or encourage the patient to take each bite slowly.
- Encourage the patient to “dry swallow” after each bite to clear residue from the throat.
- Avoid consecutive swallows of liquids.
- Provide controlled small volumes of liquids, using a spoon.
- Encourage the patient to “tuck” his or her chin down and move the forehead forward while swallowing.
- Allow the patient to indicate when he or she is ready for the next bite.
- If the patient coughs, stop the feeding until he or she indicates that the airway has been cleared.
- Continuously monitor tolerance to oral food intake by assessing respiratory rate, ease, pulse.

## Maintaining Communication.

The patient can speak when there is a cuffless tube, when a fenestrated tracheostomy tube is in place, and when the fenestrated tube is capped or covered. Until natural speech is feasible, teach him or her and the family about other communication means. A writing tablet, a board with pictures and letters, communication “flash cards” on a ring, hand signals, and smartphones, as well as a call light within reach, are used to promote communication and decrease frustration from not being able to speak or be understood. Concerns about infection control have been raised with techniques that involve shared equipment, such as communication boards and flash cards. Studies exploring the patient's use of his or her own smartphones for text messaging are ongoing (Bell, 2016). Phrase questions for “yes” or “no” answers to help the patient respond easily. Mark the central call light system to indicate that he or she cannot speak. For any patient with a communication problem, including a speech-language pathologist as part of the interprofessional team promotes better outcomes (Vento-Wilson et al., 2015).

**The inability to talk is a stressor for the patient. Helping communication is an important nursing action and is required by The Joint Commission's National Patient Safety Goals (NPSGs). When the patient can tolerate cuff deflation, he or she places a finger over the tracheostomy tube on exhalation, forcing air up through the larynx and mouth for speech.**

A device to facilitate speech for the patient with a tracheostomy is a one-way valve that fits over the tube and replaces the need for finger occlusion. The valve allows him or her to breathe in through the tracheostomy tube. On exhalation, the valve closes so air is forced through the vocal cords, allowing speech. For this valve to assist in speech, the patient must not be connected to a ventilator, must have the cuff deflated, and must be able to breathe around the tube. Some valves have a port for supplemental oxygen without impairing the ability to speak.

## Supporting Psychosocial Needs and Self-Concept.

Addressing psychological concerns is an important aspect of nursing care for patients recovering from a tracheostomy. Always keep in mind the emotional impact of an artificial airway. Acknowledge the patient's frustration with communication and allow sufficient time for communication. When speaking to him or her, use a normal tone of voice because hearing and understanding are not altered by the presence of a tube.

The patient may have a change in self-image because of the presence of a stoma or artificial airway, speech changes, a change in the method of eating, or difficulty with speech. Help him or her set realistic goals, starting with involvement in self-care.

Work with the caregivers to ease the patient into a more normal social environment. Provide encouragement and positive reinforcement while demonstrating acceptance and caring behaviors. Assess the caregiver(s) for the need for counseling.

After surgery the patient may feel shy and socially isolated. He or she can wear loose-fitting shirts, decorative collars, or scarves to cover the tracheostomy tube.

## Weaning.

Weaning the patient from a tracheostomy tube entails a gradual decrease in the tube size and ultimate removal of the tube. Carefully monitor this process, especially after each change. The physician or advanced practice nurse performs the steps in the process.

First, the cuff is deflated as soon as the patient can manage secretions and does not need mechanical ventilation. This change allows him or her to breathe through the tube and through the upper airway. Next, the tube is changed to an uncuffed tube. If this is tolerated, the size of the tube is gradually decreased. When a small fenestrated tube is placed, the tube is capped so all air passes through the upper airway and the fenestra, with none passing through the tube. Assess the patient to ensure adequate airflow around the tube when it is capped. The tube may be removed after he or she tolerates more than 24 hours of capping. Place a dry dressing over the stoma (which gradually heals on its own).

Another device used for the transition from tracheostomy to natural breathing is a *tracheostomy button*. The button maintains stoma patency and assists spontaneous breathing. The Kistner tracheostomy tube and Olympic tracheostomy button are examples of this type of device. To function, the button must fit properly. A disadvantage is the possibility of covert decannulation (i.e., the tube can dislodge from the trachea but remain in the neck tissues).

## Clinical Judgment Challenge 28-2

### Safety; Patient-Centered Care QSEN

Your patient is a 59-year-old man who requires a tracheostomy after being unable to wean from the ventilator. He no longer requires mechanical ventilation and has a tracheostomy collar with an FiO<sub>2</sub> of 40%.

1. Which supplies should you maintain at the bedside? Explain your choices.
2. What precautions should you take to help this patient eat with a tracheostomy tube?
3. What can you do to minimize tracheal damage?
4. The patient is concerned about communicating. What are his options at this time?

### Care Coordination and Transition Management

#### Self-Management Education.

By the time of discharge, the patient should be able to provide self-care, including tracheostomy care, nutrition care, suctioning, and communication. Although education begins before surgery, most self-care is taught in the hospital. Teach the patient and caregiver how to care for the tracheostomy tube. Review airway care, including cleaning and signs of infection or loss of TISSUE INTEGRITY. Teach clean suction technique and review the plan of care.

Instruct the patient to use a shower shield over the tracheostomy tube when bathing to prevent water from entering the airway. Teach him or her to cover the airway loosely with a small cotton cloth to protect it during the day. Covering the opening filters the air entering the stoma, keeps humidity in the airway, and enhances appearance. Attractive coverings are available as cotton scarves, decorative collars, and jewelry.

#### Home Care Management.

Teach the patient to increase humidity in the home. Tell him or her to wear a medical alert bracelet that identifies the inability to speak.

#### Health Care Resources.

The interprofessional health care team assesses specific discharge needs and makes referrals to home care agencies and durable medical equipment companies (for suction equipment and tracheostomy supplies). Follow-up visits occur early after discharge. The home care nurse initiates and coordinates the services of dietitians, nurses, speech and language pathologists, and social workers and identifies appropriate community resources.

## Considerations for Older Adults

### Patient-Centered Care QSEN

Self-managing tracheostomy care and oxygen therapy can be difficult for the older patient who has vision problems or difficulty with upper arm movement. Teach him or her to use magnifying lenses or glasses to ensure the proper setting on the oxygen gauge. Assess his or her ability to reach and manipulate the tracheostomy. If possible, work with a family member who can provide assistance during tracheostomy care.

#### ◆ Evaluation: Reflecting

Evaluate the care of the patient with a tracheostomy based on the identified priority patient problems. The expected outcomes of care are that the patient should:

- Attain and maintain GAS EXCHANGE at a level within his or her chronic baseline values

- Communicate effectively
- Achieve and maintain a body weight within 10% of his or her ideal weight
- Avoid serious respiratory infections
- Maintain TISSUE INTEGRITY of the airway mucosa and skin surrounding the tracheostomy.

# Get Ready for the NCLEX® Examination!

## Key Points

Review the following key points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Never allow water condensation in an oxygen delivery system to drain back into the system. **QSEN: Safety**
- Use sterile technique when performing endotracheal or tracheal suctioning. **QSEN: Safety**
- Assess **TISSUE INTEGRITY** of the oral mucous membranes for injury each shift for anyone who has an endotracheal tube. **QSEN: Safety**
- Keep a tracheostomy tube (and obturator) and tracheostomy insertion tray at the bedside for the first 72 hours after a tracheostomy has been created. **QSEN: Safety**
- Never use oral suctioning equipment to suction an artificial airway. **QSEN: Safety**
- Use Aspiration Precautions for any patient with an altered level of consciousness or who has an endotracheal tube (see [Chart 28-5](#)). **QSEN: Safety**
- Verify safe use of appropriate oxygen delivery systems and tracheostomy equipment. **QSEN: Safety**
- Keep the tracheal cuff pressure between 14 and 20 mm Hg to prevent injury to the **TISSUE INTEGRITY**. **QSEN: Safety**
- Teach the patient and caregivers about home management of oxygen therapy, including the avoidance of smoking or open flames in rooms in which oxygen is being used. **QSEN: Safety**
- Teach the patient and caregivers how to perform tracheostomy care (see [Chart 28-3](#)). **QSEN: Safety**

### Health Promotion and Maintenance

- Ensure that the patient and caregiver(s) know whom to contact about needed supplies and durable medical equipment. **QSEN: Patient-Centered Care**

### Psychosocial Integrity

- Provide opportunity for the patient and caregivers to express concerns about a change in breathing status or the possibility of intubation and mechanical ventilation. **QSEN: Patient-Centered Care**
- Teach caregivers and family members ways to communicate with a patient who is intubated or being mechanically ventilated. **QSEN: Patient-Centered Care**
- Reassure patients who are intubated that the loss of speech is temporary. **QSEN: Patient-Centered Care**
- Encourage patients with permanent tracheostomies to become involved in self-care. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Apply oxygen to anyone who is hypoxemic. **QSEN: Evidence-Based Practice**
- Ensure that oxygen therapy delivered to the patient is humidified appropriately. **QSEN: Evidence-Based Practice**
- Monitor arterial blood gases (ABGs) and oxygen saturation of all patients receiving oxygen therapy. **QSEN: Evidence-Based Practice**
- Assess the skin under the mask and under the plastic tubing every shift for patients receiving

oxygen by mask. **QSEN: Patient-Centered Care**

- Assess the TISSUE INTEGRITY of the nares and under the elastic band every shift for patients receiving oxygen by nasal cannula. **QSEN: Patient-Centered Care**
- Observe any patient receiving oxygen at greater than a 50% concentration for early signs and symptoms of oxygen toxicity (i.e., dyspnea, nonproductive cough, chest pain, GI upset). **QSEN: Patient-Centered Care**
- Use a manual resuscitation bag to ventilate the patient if the tracheostomy tube has dislodged or become decannulated. **QSEN: Safety**
- Assess the new tracheostomy stoma site at least once per shift for purulent drainage, redness, pain, and swelling as indicators of infection or loss of TISSUE INTEGRITY. **QSEN: Evidence-Based Practice**

## CHAPTER 29

# Care of Patients With Noninfectious Upper Respiratory Problems

M. Linda Workman

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concepts for this chapter are:**

- CELLULAR REGULATION
- GAS EXCHANGE

✚ The CELLULAR REGULATION concept exemplar for this chapter is Head and Neck Cancer, below.

**The interrelated concepts for this chapter are:**

- NUTRITION
- TISSUE INTEGRITY

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to coordinate high-quality care and promote GAS EXCHANGE for patients who have upper respiratory problems.
2. Protect patients with upper respiratory problems from hypoxia, injury, infection, and reduced GAS EXCHANGE.
3. Prioritize evidence-based care for critically ill patients with respiratory problems that decrease GAS EXCHANGE.
4. Teach the patient and family how to manage a chronic upper respiratory disorder and avoid injury and complications in the home.

### Health Promotion and Maintenance

5. Teach all adults measures to take to protect the upper respiratory system from damage and cancer (loss of CELLULAR REGULATION), including the avoidance of known environmental causative agents.
6. Identify community resources for patients requiring assistance with long-term complications of upper respiratory problems.

### Psychosocial Integrity

7. Implement nursing interventions to help the patient and family cope with the psychosocial impact caused by upper respiratory problems.

### Physiological Integrity

8. Apply knowledge of anatomy and physiology to assess patients with upper respiratory problems affecting GAS EXCHANGE.
9. Teach the patient and caregiver(s) about common drugs and other management strategies used for upper respiratory problems.
0. Prioritize the nursing care needs of the patient and family experiencing head and neck cancer.

The upper airway structures are the nose, sinuses, oropharynx, larynx, and trachea. These structures contribute to GAS EXCHANGE by providing the entrance site for air. Any problem of the upper airways can interfere with airflow and gas exchange. The nursing priority for patients with disorders of the upper respiratory tract is to promote gas exchange by ensuring a patent airway.

## Cellular Regulation Concept Exemplar Head and Neck Cancer

### Pathophysiology

Head and neck cancer can disrupt breathing (GAS EXCHANGE), eating, facial appearance, self-image, speech, and communication. This form of cancer can be devastating, even when cured. The care needs for patients with these problems are complex, requiring a coordinated interprofessional team approach. Common team members include an oncologist, surgeon, nurse, registered dietitian, speech and language pathologist, dentist, respiratory therapist, social worker, wound care specialist, clergy, occupational and physical therapists, and psychosocial counselors.

Head and neck cancers are usually squamous cell carcinomas. These slow-growing tumors are curable when diagnosed and treated at an early stage. The prognosis for those who have more advanced disease at diagnosis depends on the extent and location of the tumors. Untreated, these cancers are often fatal within 2 years of diagnosis (American Cancer Society [ACS], 2017).

The cancer begins as a loss of CELLULAR REGULATION when the mucosa is chronically irritated and becomes tougher and thicker (*squamous metaplasia*). At the same time, genes controlling cell growth are damaged, allowing excessive growth of these abnormal cells, which eventually become malignant. These lesions may then be seen as white, patchy lesions (**leukoplakia**) or red, velvety patches (**erythroplakia**).

Head and neck cancer first spreads (**metastasizes**) into local lymph nodes, muscle, and bone. Later spread is systemic to distant sites, usually to the lungs or liver.

The cancer type and stage are determined by cellular analysis. Earlier-stage cancers are described as *carcinoma in situ* and *well differentiated*. Without treatment, cancers progress to be *moderately differentiated* and, finally, *poorly differentiated*. Most head and neck cancers arise from the mucous membrane and skin, but they also can start from salivary glands, the thyroid, tonsils, or other structures. Treatment is based on tumor cell type and degree of spread at diagnosis.

### Etiology

The two most important risk factors for head and neck cancer are tobacco and alcohol use, especially in combination. Other risk factors include voice abuse, chronic laryngitis, exposure to chemicals or dusts, poor oral hygiene, long-term gastroesophageal reflux disease, and oral infection with the human papillomavirus (HPV) (ACS, 2017; McKiernan & Thom, 2016; Rettig & D'Souza, 2015).

### Incidence and Prevalence

The frequency of head and neck carcinoma is increasing in North America. About 67,200 new cases of oral, pharyngeal, and laryngeal cancers are diagnosed each year and account for more than 14,000 deaths per year (ACS, 2017; Canadian Cancer Society, 2016). They affect men twice as often as women and are most common in adults older than 60 years.

### Interprofessional Collaborative Care

Adults with head and neck cancer may be treated on an outpatient basis with radiation for early-stage disease. When surgery is needed, care starts in an acute care environment and can involve a stay of 5 days or more. Chemotherapy is usually performed in an outpatient setting.

### Assessment: Noticing

#### History.

The patient may have difficulty speaking because of hoarseness, shortness of breath, tumor bulk, and pain. Pace the interview to avoid tiring the patient.

Ask about tobacco and alcohol use, history of acute or chronic laryngitis or pharyngitis, oral sores, swallowing difficulty, and lumps in the neck. Calculate the patient's pack-years of smoking history (see Chapter 27). Ask about alcohol intake (how many drinks per day and for how many

years). Also ask about oral exposure to the human papilloma virus (Schiech, 2016).

Assess problems related to risk factors. For example, NUTRITION may be poor because of alcohol intake, impaired liver function, and difficulty swallowing. Assess dietary habits and any weight loss. Ask about chronic lung disease, which also may have an impact on GAS EXCHANGE.

### Physical Assessment/Signs and Symptoms.

Table 29-1 lists the warning signs of head and neck cancer. With laryngeal cancer, painless hoarseness may occur because of tumor size and an inability of the vocal cords to come together for normal speech. Vocal cord lesions form early in laryngeal cancer. Any adult who has a history of hoarseness, mouth sores, or a lump in the neck for 3 to 4 weeks should be evaluated for laryngeal cancer.

**TABLE 29-1**  
**Warning Signs of Head and Neck Cancer**

<ul style="list-style-type: none"><li>• Pain</li><li>• Lump in the mouth, throat, or neck</li><li>• Difficulty swallowing</li><li>• Color changes in the mouth or tongue to red, white, gray, dark brown, or black</li><li>• Oral lesion or sore that does not heal in 2 weeks</li><li>• Persistent or unexplained oral bleeding</li><li>• Numbness of the mouth, lips, or face</li><li>• Change in the fit of dentures</li><li>• Burning sensation when drinking citrus juices or hot liquids</li><li>• Persistent, unilateral ear pain</li><li>• Hoarseness or change in voice quality</li><li>• Persistent or recurrent sore throat</li><li>• Shortness of breath</li><li>• Anorexia and weight loss</li></ul>
---

Inspect the head and neck for symmetry and the presence of lumps or lesions. An advanced practice nurse or physician may perform a laryngeal examination using a laryngeal mirror or fiberoptic laryngoscope. The neck is palpated to assess for enlarged lymph nodes.

### Psychosocial Assessment.

Often the patient with head and neck cancer has a long-standing history of tobacco or alcohol use or both. Assess the adequacy of support systems and coping mechanisms. Document social and family support because the patient needs extensive assistance at home after treatment. A social worker should be a member of the patient's interprofessional team. Assess the level of education or literacy of the patient and family to plan teaching before and after surgery.

Document any family history of cancer and the patient's age, gender, occupation, and ability to perform ADLs. Ask the patient whether his or her occupation requires continual oral communication. Job retraining may be needed if treatment affects speech.

### Laboratory Assessment.

Diagnostic tests include a complete blood cell count, bleeding times, urinalysis, and blood chemistries. The patient with chronic alcoholism may have low protein and albumin levels from poor NUTRITION. Liver and kidney function tests are performed to rule out cancer spread and to evaluate the patient's ability to metabolize drugs and chemotherapy agents. A blood test for the presence of human papilloma virus (HPV) is often performed.

### Imaging Assessment.

Many types of imaging studies, including x-rays of the skull, sinuses, neck, and chest, are useful in diagnosing cancer spread, other tumors, and the extent of tumor invasion. CT with contrast medium helps evaluate the tumor's exact location. MRI can help differentiate normal from diseased tissue.

The brain, bone, and liver are evaluated with nuclear imaging, bone scans, single-photon emission computerized tomography (SPECT) scans, and positron emission tomography CT (PET-CT) scans (National Comprehensive Cancer Network [NCCN], 2016). These tests locate additional tumor sites.

### Other Diagnostic Assessment.

Other helpful tests include direct and indirect laryngoscopy, tumor mapping, and biopsy.

*Panendoscopy* (laryngoscopy, nasopharyngoscopy, esophagoscopy, and bronchoscopy) is performed with general anesthesia to define the extent of the tumor. Tumor-mapping biopsies are performed to identify tumor location. Biopsy tissues taken at the time of the panendoscopy confirm the diagnosis, tumor type, cell features, location, and stage (see [Chapter 21](#)).

### ◆**Analysis: Interpreting**

The priority collaborative problems for patients with head and neck cancer include:

1. Potential for airway obstruction due to edema and presence of tumor
2. Potential for aspiration due to edema, anatomic changes, or altered protective reflexes
3. Anxiety due to threat of death, change in role status, or change in economic status
4. Decreased self-esteem due to cancer and cancer treatment side effects

### ◆**Planning and Implementation: Responding**

#### **Preventing Airway Obstruction.**

Without treatment, head and neck cancers grow, obstruct the airway, and prevent GAS EXCHANGE. Airway obstruction also can occur as a complication of treatment modalities.

#### **Planning: Expected Outcomes.**

The patient with head and neck cancer is expected to attain and maintain adequate GAS EXCHANGE and tissue oxygenation. Indicators include:

- Arterial blood gas values within the normal range
- Rate and depth of respiration within the normal range
- Pulse oximetry within the normal range

#### **Interventions.**

The focus of treatment is to remove or eradicate the cancer while preserving as much function as possible. The oncologist presents the available treatment options. Surgery, radiation, chemotherapy, or biotherapy may be used alone or in combination, depending on the stage of the disease and the patient's general health. Considerations for treatment options include the patient's physical condition, NUTRITION status, and age; the effects of the tumor on body function; and the patient's personal choice. Treatment for laryngeal cancer may range from radiation therapy (for a small specific area or tumor) to total laryngopharyngectomy with bilateral neck dissections followed by radiation therapy, depending on the extent and location of the lesion. Voice-conservation procedures are used only if they do not risk incomplete removal of the tumor. Nursing care focuses on preoperative preparation, optimal in-hospital care, discharge planning and teaching, and extensive outpatient rehabilitation.

#### **Nonsurgical Management.**

Monitor GAS EXCHANGE and the respiratory system by assessing respiratory rate, breath sounds, pulse oximetry, and arterial blood gas values. Airway obstruction can occur from tumor growth, edema, or both. Teach the patient to use the Fowler's and semi-Fowler's positions for best gas exchange. Sitting upright in a reclining chair may promote more comfortable breathing. [Chapters 4 and 7](#) provide additional information on palliation and pain control for patients who elect not to have therapy and for those whose therapy has not been effective.

*Radiation therapy* for treatment of small cancers in specific locations has a cure rate of at least 80%. Standard therapy uses 5000 to 7500 rad (radiation absorbed dose), usually over 6 weeks and in daily or twice-daily doses. Intensity-modulated radiotherapy (IMRT) is recommended to provide higher doses directly to the tumor with less damage to surrounding normal tissues ([NCCN, 2016](#)). Radiation may be used alone or in combination with surgery and chemotherapy (see [Chapter 22](#)). It can be performed before or after surgery. Most patients have hoarseness, dysphagia, skin problems, impaired taste, and dry mouth for a few weeks after radiation therapy ([McLaughlin & Mahon, 2014a](#)).

Hoarseness may become worse during therapy. Reassure the patient that voice improves within 4 to 6 weeks after completion of radiation therapy. Urge him or her to use voice rest and alternative means of communication until the effects of radiation therapy have passed. Collaborate with the speech and language pathologist to help the patient communicate.

Most patients have a sore throat and difficulty swallowing during radiation therapy to the neck. Gargling with saline or sucking ice may decrease discomfort. Mouthwashes and throat sprays containing a local anesthetic agent such as lidocaine or diphenhydramine can provide temporary relief. Analgesic drugs may be prescribed.

The skin at the site of irradiation becomes red and tender and may peel during therapy. Instruct the patient to avoid exposing this area to sun, heat, cold, and abrasive actions such as shaving. Teach the patient to wear protective clothing made of soft cotton and to wash this area gently daily with a mild soap such as Dove. Using appropriate skin care products (approved by the radiation-oncology department) can reduce the intensity of skin reactions.

If the salivary glands are in the irradiation path, the mouth becomes dry (**xerostomia**). This effect is long term and may be permanent, and a dental consultation is needed. Some of the problems from reduced saliva include increased risk for dental caries, increased risk for oral infections, bad breath, and taste changes. Fluoride gel trays and nightly fluoride treatments can reduce the incidence of tooth deterioration. The trays can be worn during radiation therapy to prevent radiation scatter from the beam deflecting off existing metal inside the mouth. Although there is no cure for xerostomia, interventions can help reduce the discomfort. Heavy fluid intake, particularly water, and humidification can help ease the discomfort. Some patients benefit from the use of artificial saliva such as Salivart, moisturizing sprays or gels such as Mouth Kote, or saliva stimulants such as Salagen and cevimeline (cholinergic drugs).

*Chemotherapy* can be used alone or in addition to surgery or radiation for head and neck cancer. Often chemotherapy and radiation therapy (*chemoradiation*) are used at the same time. Although the exact drugs used may vary, depending on cancer cell features, most chemotherapy regimens for head and neck cancers include cisplatin (or another platinum-based drug) in combination with 5FU (NCCN, 2016). The oral cavity effects of radiation are intensified with concurrent chemotherapy. These can be uncomfortable, and patients often request breaks in the treatment regimen. However, these breaks in treatment do affect treatment outcome and should be avoided. Intense patient education before and support during treatment can improve patient adherence to the treatment plan (Mason et al., 2013). Chapter 22 discusses the general care needs of patients receiving chemotherapy.

*Biotherapy* (targeted therapy) with an epidermal growth-factor receptor inhibitor (EGFRI) such as cetuximab (Erbix) (NCCN, 2016) is used for patients whose tumors overexpress the receptor. Although it is a targeted therapy, this drug blocks EGFRs in normal tissues, as well as those in the tumor. As a result, severe skin reactions are common and difficult for the patient.

## NCLEX Examination Challenge 29-1

### Health Promotion and Maintenance

A client about to undergo radiation therapy for head and neck cancer (pharyngeal) asks what side effects are expected from this therapy. Which side effects does the nurse teach the client to expect? **Select all that apply.**

- A. Scalp and eyebrow alopecia
- B. Taste sensation loss or changes
- C. Increased risk for sinus infections
- D. Increased risk for skin breakdown
- E. Moderate weight gain
- F. Increased risk for cavities

### Surgical Management.

Tumor size, node number, and metastasis location (TNM classification) determine the type of surgery needed for the specific head and neck cancer (see [Chapter 21](#)). Very small, early-stage tumors may be removed by laser therapy or photodynamic therapy; however, few head and neck tumors are found at this stage, and most require extensive traditional surgery. Reconstruction is determined by the tumor size and amount of tissue to be resected and reconstructed. Surgical procedures for head and neck cancers include laryngectomy (total and partial), tracheotomy, and oropharyngeal cancer resections. The major types of surgery for laryngeal cancer include cord stripping, removal of a vocal cord (**cordectomy**), partial laryngectomy, and total laryngectomy. If cancer is in the lymph nodes in the neck, the surgeon performs a nodal neck dissection along with removal of the primary tumor (“radical neck”).

### Preoperative Care.

Teach the patient and family about the tumor. The surgeon explains the surgical procedure and obtains informed consent. Discuss and interpret the implications of such consent with the patient and family. [Chapter 14](#) describes general preoperative assessment and education needs.

Explain about self-management of the airway, suctioning, pain-control methods, the critical care environment (including ventilators and critical care routines), NUTRITION support, feeding tubes, and plans for discharge. The patient will need to learn new methods of speech, at least during the time that mechanical ventilation is used and, depending on surgery type, perhaps forever. Along with the speech and language pathologist, help the patient prepare for this change before surgery and practice the use of the selected form of communication (see [Chart 29-1](#) and the discussion of Maintaining Communication in [Chapter 28](#)). Determine the communication method preferred by the patient.

#### Chart 29-1

### Best Practice for Patient Safety & Quality Care QSEN

#### Communicating With a Patient Who Is Unable To Speak

- Assess the patient's reading skills and cognition.
- Determine in what language (languages) the patient is most fluent.
- Collaborate with a speech and language pathologist.
- If the patient requires vision-enhancing or hearing-enhancing devices, be sure these are available and in use.
- Provide the patient with a variety of techniques to practice before verbal skills are lost to determine with which one(s) the patient feels most comfortable. These may include:
  - Alphabet board
  - Picture board
  - Paper and pencil
  - Magic Slate
  - Hand signals/gestures
  - Computer with e-triloquist program

- Programmable speech-generating devices (text-to-speech communication aid)
- Reinforce to the patient the technique for esophageal speech presented by the speech and language pathologist and provide the time for practice.
- Use a normal tone of voice to talk with the patient (unless hearing is a pre-existing problem, a change in the ability to speak does not interfere with the patient's ability to hear).
- Ensure that the call-light board at the nurses' station indicates a nonspeaking patient.
- Teach the patient to make noise to indicate that immediate attention is needed at the bedside when he or she signals by call light. Such noises can include tapping the side rail with a spoon, making clicking noises with the tongue, using a bell, or working a noisemaker. Be sure that whatever method is selected is listed on the call-light board.
- When face-to-face with the patient:
  - Phrase questions in a “yes” or “no” format.
  - Watch the patient's face for indications of understanding or the lack of it.
  - Listen attentively to any sound the patient makes.
- If writing is selected as the method to communicate, assess whether the patient is right handed or left handed and ensure appropriate writing materials are within reach. Use the other arm for IV placement.
- Ensure that the preferred method of communication is documented in the patient record and is communicated to all care providers.
- Encourage the family to work with the patient in the use of the selected method.
- Provide praise and encouragement.
- Do not avoid talking with the patient.
- Allow the patient to set the pace for communication.

### Operative Procedures.

Table 29-2 lists specific information about the various surgical procedures for laryngeal cancer. Hemilaryngectomy (vertical or horizontal) and supraglottic laryngectomy are types of partial voice-conservation laryngectomies.

**TABLE 29-2**  
**Surgical Procedures for Laryngeal Cancer and Their Effect on Voice Quality**

PROCEDURE	DESCRIPTION	RESULTING VOICE QUALITY
Laser surgery	Tumor reduced or destroyed by laser beam through laryngoscope	Normal/hoarse

Transoral cordectomy	Tumor (early lesion) resected through laryngoscope	Normal/hoarse (high cure rate)
Laryngofissure	No cord removed (early lesion)	Normal (high cure rate)
Supraglottic partial laryngectomy	Hyoid bone, false cords, and epiglottis removed Neck dissection on affected side performed if nodes involved	Normal/hoarse
Hemilaryngectomy or vertical laryngectomy	One true cord, one false cord, and one half of thyroid cartilage removed	Hoarse
Total laryngectomy	Entire larynx, hyoid bone, strap muscles, one or two tracheal rings removed Nodal neck dissection if nodes involved	No natural voice

To protect the airway, a tracheostomy is needed. With a partial laryngectomy, the tracheostomy is usually temporary. With a total laryngectomy, the upper airway is separated from the throat and esophagus, and a permanent laryngectomy stoma in the neck is created.

Neck dissection includes the removal of lymph nodes, the sternocleidomastoid muscle, the jugular vein, the 11th cranial nerve, and surrounding soft tissue. Shoulder drop is expected after extensive surgery. Physical therapy can help the patient ease the shoulder drop by using other muscle groups.

### Postoperative Care.

Head and neck surgery often lasts 8 hours or longer, and the patient spends the immediate period after surgery in an ICU environment. Monitor airway patency, vital signs, hemodynamic status, and comfort level. Monitor for hemorrhage and other general complications of anesthesia and surgery (see [Chapter 16](#)). Take vital signs hourly for the first 24 hours and then according to agency policy until the patient is stable. After the patient is transferred from the ICU, vital signs are monitored according to agency policy.

Complications after surgery include airway obstruction, hemorrhage, wound breakdown, and tumor recurrence. *The first priorities after head and neck surgery are airway maintenance and GAS EXCHANGE.* Other priorities are wound, flap, and reconstructive tissue care; pain management; NUTRITION; and psychological adjustment, including speech and language therapy.

### Airway Maintenance and Gas Exchange.

Immediately after surgery, the patient may need ventilatory assistance. Most patients wean easily from the ventilator after this type of surgery because the thoracic and abdominal cavities are not entered. During weaning, the patient usually uses a tracheostomy collar (over the artificial airway or open stoma) with oxygen and humidity to help move mucus secretions. Secretions may remain blood tinged for 1 to 2 days. Use Standard Precautions and report any increase in bleeding to the surgeon. Humidity helps remove crusts and prevents obstruction of the tube with secretions. A laryngectomy tube is used for patients who have undergone a *total laryngectomy* and need an appliance to prevent scar tissue shrinkage of the skin-tracheal border. This tube is similar to a tracheostomy tube but is shorter and wider with a larger lumen. Laryngectomy tube care is similar to tracheostomy tube care (see [Chapter 28](#)), except that the patient can change the laryngectomy tube daily or as needed. A laryngectomy button is similar to a laryngectomy tube but is softer, has a single lumen, and is very short. A button is comfortable for the patient, is easily removed for cleaning, and is available in various sizes for a custom fit. Provide alternative communication techniques because the patient cannot speak.

Coughing and deep breathing are usually effective in clearing secretions. Instruct the patient how to cough and deep breathe to clear secretions.

Oral secretions can be suctioned by the alert patient using a Yankauer or tonsillar suction or a soft flexible catheter. Teach the patient to suction *away* from the surgical side to prevent opening the wound. Using a table mirror helps the patient see the area more clearly. Provide a clean environment for the catheter.

Stoma care after a total laryngectomy is a combination of wound care and airway care. Inspect the stoma with a flashlight. Clean the suture line with sterile saline (or a prescribed solution) to prevent secretions from forming crusts and obstructing the airway. Perform suture line care every 1 to 2 hours during the first few days after surgery and then every 4 hours. The mucosa of the stoma and trachea should be bright and shiny and without crusts, similar to the appearance of the oral mucosa.

### Wound, Flap, and Reconstructive Tissue Care.

Tissue “flaps” may be used to close the wound and improve appearance. Flaps are skin, subcutaneous tissue, and sometimes muscle, taken from other body areas used for reconstruction after head and neck resection. After neck dissection, the surgeon places a split-thickness skin graft (STSG) over the exposed carotid artery before covering it with skin flaps or reconstructive flaps.

The first 24 hours after surgery are critical. Evaluate all grafts and flaps hourly for the first 72 hours. Monitor capillary refill, color, drainage, and Doppler activity of the major blood vessel to the area. Report changes to the surgeon immediately because surgical intervention may be needed. Position the patient so the surgical flaps are not dependent.

### **Hemorrhage.**

Hemorrhage is a possible complication after any surgery, but it is uncommon with laryngectomy. The surgeon often places a closed surgical drain in the neck area to collect blood and drainage for about 72 hours after surgery. The drain also helps maintain the position of the reconstructed skin flaps. Any drain obstruction or equipment malfunction may cause a buildup of blood or fluid under the flaps that can impair blood flow and result in flap failure. A sudden stoppage of drainage may indicate drain obstruction by a clot. Monitor and record the amount and character of drainage. Check the patency and functioning of the drainage system. Report any drain malfunction or change in flap appearance to the surgeon. Depending on the surgeon's preference and the agency's policy, you may need to empty the drainage container or “milk” the drain (but avoid creasing or “stripping” the tubing).

### **Wound Breakdown.**

Wound breakdown with loss of TISSUE INTEGRITY is a complication caused by poor NUTRITION, a long smoking history, alcohol use, wound contamination, and radiation therapy before surgery. Manage wound breakdown with packing and local care as prescribed to keep the wound clean and stimulate the growth of healthy granulation tissue. Wounds may be extensive, and the carotid artery may be exposed. Split-thickness skin grafts often are placed over the carotid artery for protection in the event of wound dehiscence. As the wound heals, granulation tissue covers the artery and prevents rupture. If granulation is slow and the carotid artery is at risk, another surgical flap may be made to cover the artery and close the wound.

When the carotid artery ruptures, large amounts of bright red blood spurt quickly. It is also possible for the carotid artery to have a small leak, with continuous oozing of bright red blood. Usually a small leak leads to a complete rupture within a short time.

## **Nursing Safety Priority** QSEN

### **Critical Rescue**

Assess the patient hourly for the first several days after head and neck surgery to recognize a carotid artery leak. If you suspect a leak, respond by calling the Rapid Response Team and ***do not touch the area because additional pressure could cause an immediate rupture.*** If the carotid artery actually ruptures because of drying or infection, immediately place constant pressure over the site and secure the airway. Maintain direct manual, continuous pressure on the carotid artery and immediately transport the patient to the operating room for carotid resection. Do not leave the patient. Carotid artery rupture has a high risk for stroke and death.

### **Pain Management.**

Pain is caused by the surgical cutting or manipulation of tissue and by nerve compression. Pain should be controlled, and the patient should still be able to participate in his or her care. Morphine (Duramorph, Statex ) often is given IV by a patient-controlled analgesia (PCA) pump for the first 1 to 2 days after surgery. As the patient progresses, liquid opioid analgesics can be given by feeding tube. Oral drugs for pain and discomfort are started only after the patient can tolerate oral intake. After discharge, the patient still requires pain management, especially if he or she is receiving radiation therapy. An adjunct to the pain regimen may be liquid NSAIDs along with opioid analgesics. Tricyclic antidepressants may also be used for the lancinating pain of nerve-root involvement.

### **Nutrition.**

Many patients with head and neck cancer have taste changes and some degree of inadequate NUTRITION (malnutrition) before cancer treatment begins (McLaughlin & Mahon, 2014b). All patients

are at risk for malnutrition during treatment for head and neck cancer. A nasogastric, gastrostomy, or jejunostomy tube is placed during surgery for nutrition support while the head and neck heal. After the intestinal tract is motile, nutrients can be given via the feeding tube. The dietitian assesses the patient before surgery and is available for consultation after surgery. Replacement for calorie, protein, and water losses is calculated carefully for each patient (Ardilio, 2011).

The feeding tube usually remains in place for 7 to 10 days after surgery. Before removing the tube, assess the patient's ability to swallow if NUTRITION is to be given by mouth. Aspiration *cannot* occur after a total laryngectomy because the airway is completely separated from the esophagus. Stay with the patient during the first few swallowing attempts. Swallowing may be uncomfortable at first, and analgesics may be needed. If difficulty persists, a swallowing study may be needed.

### **Speech and Language Rehabilitation.**

The patient's voice quality and speech are altered after surgery. Although this problem has enormous effects on the patient's ability to maintain social interactions, continue employment, and maintain a desired quality of life, it is often poorly addressed while he or she is hospitalized. Working with him or her and the family toward developing an acceptable communication method during the inpatient period is essential for a satisfactory outcome.

Together with the speech and language pathologist (SLP), discuss the principles of speech therapy with the patient and family early in the course of the treatment plan (see Chart 29-1). Voice and speech differences depend on the type of surgical resection (see Table 29-2). Speech production varies with patient practice, amount of tissue removed, and radiation effects but can be very understandable. Patients have reported ongoing difficulties with speech and communication to be the most distressing problem for months to years after head and neck cancer therapy.

The speech rehabilitation plan for patients who have a total laryngectomy at first consists of writing, using a picture board, or using a computer. The patient then uses an artificial larynx and may eventually learn esophageal speech. For success, the patient needs encouragement and support from the SLP, hospital team, and family while relearning to speak. This process is time consuming and requires concentration each time the patient speaks. Having a **laryngectomee** (an adult who has had a laryngectomy) from one of the local self-help organizations visit the patient and family is often beneficial. The International Association of Laryngectomees is very supportive, as is the ACS Visitor Program.

*Esophageal speech* is attempted by most patients who have a total laryngectomy. Sound can be produced this way by "burping" the air swallowed or injected into the esophageal pharynx and shaping the words in the mouth. The voice produced is a monotone; it cannot be raised or lowered and carries no pitch. If patients do not have adequate hearing, esophageal speech will be difficult because they need to use their mouth to shape the words as they hear them. Hearing-impaired patients may need hearing aids.

Mechanical devices, called *electrolarynges*, may be used for communication. Most are battery-powered devices placed against the side of the neck or cheek (Fig. 29-1). The air inside the mouth and throat is vibrated, and the patient moves his or her lips and tongue as usual. The quality of speech generated with mechanical devices is robotlike.

**FIG. 29-1** An electrolarynx to generate speech after a laryngectomy.

Tracheoesophageal puncture (TEP) may be used if esophageal speech is ineffective and if the patient meets strict criteria. A small surgical puncture is created between the trachea and the esophagus using a special catheter. After the puncture heals, a silicone prosthesis (e.g., the Blom-Singer prosthesis or the Panje Voice Button) is inserted in place of the catheter. The patient covers the stoma and the opening of the prosthesis with a finger or with a special valve to divert air from the lungs, through the trachea, into the esophagus, and out of the mouth where lip and tongue movement produces speech.

### Surgical Procedures for Other Head and Neck Cancers.

The surgeries for other head and neck cancers are called *composite resections*. These resections are a combination of surgical procedures, including partial or total glossectomies (tongue removal), partial mandibulectomies (jaw removal) and, if needed, nodal neck dissections. Tracheostomy may be planned to provide an adequate airway. (See [Chapter 53](#) for more information about oral cancer.)

### Tracheotomy.

A **tracheotomy** is a surgical incision into the trachea for the purpose of establishing an airway (tracheostomy). It can be performed as an emergency procedure or as a scheduled surgical procedure. A tracheostomy can be temporary or permanent. [Chapter 28](#) discusses the nursing care of a patient with a tracheostomy.

### Preventing Aspiration

#### Planning: Expected Outcomes.

The patient with head and neck cancer is expected to not aspirate food, gastric contents, or oral secretions into the lungs. Indicators include that the patient often or consistently demonstrates these behaviors:

- Positions self upright for eating or drinking
- Selects foods according to swallowing ability
- Chooses liquids and foods of proper consistency

#### Interventions.

The surgical changes in the upper respiratory tract and altered swallowing mechanisms increase the patient's risk for aspiration. Aspiration can result in pneumonia, weight loss, and prolonged hospitalization. [Chart 28-5](#) lists actions for aspiration prevention.

A nasogastric (NG) feeding tube increases the risk for aspiration because it keeps the lower esophageal sphincter partially open. The one exception is the patient who has undergone a total laryngectomy. In these cases, the airway is separated from the esophagus, making aspiration impossible; and the patient is *not* at risk. Most patients who need enteral feeding supplementation have a percutaneous endoscopic gastrostomy (PEG) tube placed rather than an NG tube. See [Chapter 60](#) for care of patients receiving enteral NUTRITION by NG or PEG tube.

A dynamic swallow study, such as a barium swallow under fluoroscopy, evaluates a patient's ability to protect the airway from aspiration and helps determine the appropriate method of swallow rehabilitation (Balusik, 2014). In many cases, enteral feedings are used because of either the patient's inability to swallow or continued aspiration risk.

Swallowing can be a problem for the patient who has a tracheostomy tube. It can be normal if the cranial nerves and anatomic structures are intact. In a normal swallow, the larynx rises and moves forward to protect itself from the passing stream of food and saliva. The tracheostomy tube may fix the larynx in place, resulting in difficulty swallowing.

An inflated tracheostomy tube cuff can balloon backward into the esophagus and interfere with the passage of food. The wall between the posterior trachea and the esophagus is very thin, which allows this pushing action. The patient who is cognitively intact may adapt to eating normal food when the tracheostomy tube is small and the cuff is not inflated.

The patient who has had a partial vertical or supraglottic laryngectomy *must* be observed for aspiration. It is critical to teach the patient to use alternate methods of swallowing without aspirating. The "supraglottic" method of swallowing is especially effective after a partial laryngectomy or base-of-tongue resection (Chart 29-2). To reinforce teaching and learning, place a chart in the patient's room detailing the steps. A dynamic swallow study is performed to guide rehabilitation for swallowing and to evaluate the patient's ability to protect the airway.

### Chart 29-2

## Patient and Family Education: Preparing for Self-Management

### The Supraglottic Method of Swallowing

1. Place yourself in an upright, preferably out-of-bed, position.
2. Clear your throat.
3. Take a deep breath.
4. Place  $\frac{1}{2}$  to 1 teaspoon of food into your mouth.
5. Hold your breath or "bear down" (Valsalva maneuver).
6. Swallow twice.
7. Release your breath and clear your throat.
8. Swallow twice again.
9. Breathe normally.

This method exaggerates the normal protective mechanisms of cessation of respiration during the swallow. The double swallow attempts to clear food that may be pooling in the pharynx, vallecula, and piriform sinuses. This method is used only after a dynamic radiographic swallow study has demonstrated that it is appropriate and safe for the patient.

### Minimizing Anxiety

#### Planning: Expected Outcomes.

The patient with head and neck cancer is expected to have decreased anxiety. Indicators include that the patient often or consistently demonstrates:

- Verbalization of reduced anxiety
- Absence of distress, irritability, and facial tension
- Effective use of coping strategies

### **Interventions.**

Conferences with all members of the interprofessional care team and the general nursing staff may be beneficial. Explore the reason for anxiety (e.g., fear of the unknown, lack of teaching, fear of pain, fear of death, loss of control, uncertainty). The patient and family often benefit from further information. Before the patient is scheduled for surgery (and while still at home), home care nurses or community-sponsored programs, such as the ACS, may be able to decrease fears about the disease process and surgical interventions.

Give prescribed antianxiety drugs, such as diazepam (Valium), with caution because of the risk for respiratory depression and because some of these drugs are eliminated slowly. Shorter-duration drugs, such as lorazepam (Ativan), may have fewer respiratory side effects. The location of the tumor and the presence of other lung disease may cause some degree of airway obstruction. For anxiety in these patients, drug therapy may include lorazepam (Ativan, Novo-Lorazem) rather than a sedating agent.

### **Supporting Self-Esteem**

#### **Planning: Expected Outcomes.**

The patient with head and neck cancer is expected to accept body image changes. Indicators include that the patient often or consistently demonstrates:

- Willingness to touch and care for the affected body part
- Willingness to use strategies to enhance appearance
- Interaction with visitors, staff, and family members

#### **Interventions.**

The patient with head and neck cancer usually has a change in self-concept and self-image resulting from issues such as the presence of a stoma or artificial airway, speech changes, and a change in the method of eating. Psychosocial issues may include guilt, regret, and uncertainty. He or she may not be able to speak at all or may have permanent speech deficits. Help the patient set realistic goals, starting with involvement in self-care. Teach the patient alternative communication methods so he or she can communicate in the hospital and after discharge.

Teach the family to ease the patient into a normal social environment. Use positive reinforcement and encouragement while demonstrating acceptance and caring behaviors. The family also may benefit from counseling sessions while the patient is still in the hospital.

After surgery, the patient may feel socially isolated because of the change in voice and facial appearance. Loose-fitting, high-collar shirts or sweaters, scarves, and jewelry can be worn to cover the laryngectomy stoma, tracheostomy tube, and other changes related to surgery. Cosmetics may aid in covering disfigurement. Most surgeons try to place the incisions in the natural skinfold lines if doing so does not pose a risk for cancer recurrence.

### **Care Coordination and Transition Management**

If no complications occur, the patient is usually discharged home or to an extended-care facility within 2 weeks. At the time of discharge, he or she or a family member should be able to perform tracheostomy or stoma care and participate in NUTRITION, wound care, and communication methods.

The patient and family may feel more secure about discharge with a referral to support groups or a community health agency familiar with the care of patients recovering from head and neck cancer. Coordinate the efforts of the interprofessional team in assessing the specific discharge needs and making the appropriate referrals to home care agencies. Coordinate the scheduling for chemotherapy or radiation therapy with the patient and family.

### **Home Care Management.**

Extensive home care preparation is needed after a laryngectomy for cancer. The convalescent period is long, and airway management is complicated. The patient or family must be able to take an active role in care.

General cleanliness of the home is assessed by the home care nurse or case manager. For the patient with severe respiratory problems, home changes to allow for one-floor living may be

needed. Increased humidity is needed. A humidifier add-on to a forced-air furnace can be obtained, or a room humidifier or vaporizer may be used. Be sure to stress that meticulous cleaning of these items is needed to prevent spread of mold or other sources of infection.

A home care nurse is often an important resource for the patient and family. This nurse assesses the patient and home situation for problems in self-care, complications, adjustment, and adherence to the medical regimen. [Chart 29-3](#) lists assessment areas for the patient in the home after a laryngectomy. This nurse reinforces health care teaching, self-care teaching, and smoking-cessation regimens.

### **Chart 29-3**

## **Home Care Assessment**

### **Patients After Laryngectomy**

Assess respiratory status and effectiveness of GAS EXCHANGE:

- Observe rate and depth of respiration.
- Auscultate lungs.
- Check patency of airway.
- Examine the tracheostomy drainage for amount, color, and character.
- Examine nail beds and mucous membranes for evidence of cyanosis.
- Obtain a pulse oximetry reading.

Assess condition of wound and TISSUE INTEGRITY:

- Remove dressings (noting condition of dressings).
- Cleanse the wound.
- Compare with previous notations of wound condition:
- Presence, amount, and nature of exudate
- Presence/absence of cellulitis
- Presence/absence of odor

Assess patient's psychosocial status:

- Ask the patient about passing the time, visitors, and trips outside the house.

- Observe whether the patient communicates responses directly or whether a family member speaks for him or her.
- Observe patient and family member interactions.
- Determine which method of communication the patient has selected and observe the patient's skill with it.
- Observe whether the patient is wearing pajamas or is dressed in street clothes.
- Take the patient's temperature at each home care visit.

Assess the patient's understanding of illness and adherence to treatment:

- Manifestations to report to the health care provider
- Medication plan (correct timing and dose)
- Ambulation or positioning schedule
- Dressing changes/skin care
- Diet modifications (24-hour diet recall)
- Skill in tracheostomy or dressing care

Assess patient's NUTRITION status:

- Change in muscle mass
- Lackluster nails/sparse hair
- Recent weight loss greater than 10% of usual weight
- Impaired oral intake
- Difficulty swallowing
- Generalized edema

### **Self-Management Education.**

Education begins before surgery, and most self-care is taught in the hospital. Teach the patient and family how to care for the stoma or tracheostomy or laryngectomy tube, depending on the type of surgery performed. Review incision and airway care, including cleaning and inspecting for signs of

infection. [Chart 29-4](#) lists self-care actions for the patient after laryngeal cancer surgery. Many of these actions also apply to any surgery for head and neck cancer.

#### **Chart 29-4**

## **Patient and Family Education: Preparing for Self-Management**

### **Home Laryngectomy Care**

- Avoid swimming and use care when showering or shaving.
- Lean slightly forward and cover the stoma when coughing or sneezing.
- Wear a stoma guard or loose clothing to cover the stoma.
- Clean the stoma with mild soap and water. Lubricate the stoma with a non-oil-based ointment as needed.
- Increase humidity by using saline in the stoma as instructed, a bedside humidifier, pans of water, and houseplants.
- Obtain and wear a MedicAlert bracelet and emergency care card for life-threatening situations.

*Stoma care* teaching is focused on protection, which is needed as a result of the anatomic changes resulting from surgery. Instruct the patient to use a shower shield over the tube or stoma when bathing to prevent water from entering the airway. Teach men who use electric shavers to cover the stoma while shaving to keep hair from falling into it. Suggest that the patient wear a protective cover or stoma guard to protect the stoma during the day. Covering the opening has two benefits: (1) to filter the air entering the stoma while keeping humidity in the airway; and (2) to enhance aesthetic appearance. Attractive coverings are available in the form of scarves, crocheted collars, and jewelry.

The skill level needed to be competent at tracheostomy care can be frightening to the patient and to the caregiver. Most adults are not familiar with sterile technique and suctioning, and cleaning the tube to prevent serious consequences can be daunting (Loerzel et al., 2014). The [Quality Improvement](#) box describes the development and implementation of a pilot project designed to increase the confidence and competence of patients and caregivers in the performance of this important care in the home.

## **Quality Improvement** OSEN

### **Support and Education Reduce Caregiver Anxiety for Patients With Tracheostomies**

Loerzel, V., Crosby, W., Reising, E., & Sole, M. (2014). Developing the tracheostomy care anxiety relief through education and support (T-CARES) program. *Clinical Journal of Oncology Nursing*, 18(5), 522-527.

Permanent tracheostomies are a common method of breathing for patients who have surgery for later-stage head and neck cancer. Both the patient and the caregiver must learn proper tracheostomy care for best function and to prevent complications. The care is considered complicated by non-health care adults and creates anxiety for the patient and the caregiver; a problem with the care of the tracheostomy at home is a common reason for hospital readmission.

A group of oncology nursing experts identified one cause of anxiety to be a lack of “hands on” practice with time for education and feedback for patients with tracheostomies and their caregivers. This group developed the pilot project T-CARES program of “Tracheostomy Care Anxiety Relief through Education and Support.” The program consisted of an hour-long teaching session for tracheostomy care with an 18-minute video demonstration, group discussion with return demonstration, and assessment of 14 procedure-related skills. Instruction included basic

airway anatomy, tube function description, and demonstrations of suctioning, tube cleaning and maintenance, emergency decannulation and reinsertion procedures, and equipment/supply use. The program also used hands-on practice performance of the techniques of gloving, suctioning, and other tracheostomy care using an anatomic training dummy. After completion of the 1-hour program, participants were permitted to continue the hands-on practice.

Both state and trait anxiety levels of the participants were measured before and after completion of the program. State anxiety decreased from a preprogram score of 50.5 to a postprogram score of 34.3, which reached statistical significance. After the program, all participants demonstrated acceptable competence on at least 9 of the 14 skills assessed.

### **Commentary: Implications for Practice and Research**

Reducing anxiety in adults performing a new skill can improve competence and confidence for both the adult performing the skill and the adult who has the tracheostomy. This pilot project did not have a control group for comparison purposes. In addition, the article explaining the project did not indicate whether the participants were provided with a copy of the video to allow reinforcement of the information presented. Further research using a control group and a retest of participants 6 weeks after the initial program could help determine the utility of the T-CARES program. Another outcome to assess for program effectiveness is a comparison of the readmission rate between program participants and a control group who only receive “standard home-going instructions.”

Instruct the patient how to increase humidity in the home. Stress the importance of keeping well hydrated to prevent secretions from thickening.

*Communication* involves having the patient continue the selected communication method that began in the hospital. Instruct him or her to wear a medical alert (MedicAlert) bracelet and carry a special identification card. For patients with a laryngectomy, this card is available from the local chapters of the International Association of Laryngectomees. The card instructs the reader about providing an emergency airway or resuscitating someone who has a stoma.

*Smoking cessation* is a difficult but important issue after head and neck cancer surgery. Stress that smoking cessation can reduce the risk for developing other cancers and can increase the rate of healing from surgery. See [Chapter 27](#) for details about smoking cessation.

### **Psychosocial Preparation.**

The many changes resulting from a laryngectomy influence physical, social, and emotional functioning for both the patient and his or her significant other ([Sterba et al., 2016](#)). Patients may perceive changes in their quality of life. Begin preparing the patient and family by scheduling a visit from an adult who has adjusted to these changes.

The patient with a permanent stoma, tracheostomy tube, NG or PEG tube, and wounds has an altered body image. Stress the importance of returning to as normal a lifestyle as possible. Most patients can resume many of their usual activities within 4 to 6 weeks after surgery. A longer time is needed after a combination of radiation therapy and surgery and for patients who also have other chronic diseases. The patient may be frustrated at times while trying to adjust to the many changes resulting from treatment of head and neck cancer.

The patient with a total laryngectomy cannot produce sounds during laughing and crying. Mucus secretions may appear unexpectedly when these emotions arise or when coughing or sneezing occurs. The mucus can be embarrassing, and the patient needs to be prepared to cover the stoma with a handkerchief or gauze. The patient who has undergone composite resections has difficulty with speech *and* swallowing. He or she may need to deal with tracheostomy and feeding tubes in public places.

### **Health Care Resources.**

Inform the patient and family of community organizations (e.g., ACS) and local laryngectomee clubs, which can offer support, information, and friendships. When the patient has problems paying for health care services, equipment, and prescriptions, a visiting nurse agency and social worker may be helpful in locating available resources.

In many areas, the local unit of the ACS or Canadian Cancer Society can help provide dressing materials and NUTRITION supplements to patients in need. These organizations may also provide

transportation to and from follow-up visits or radiation therapy.

### ◆ **Evaluation: Reflecting**

Evaluate the care of the patient with head and neck cancer based on the identified priority patient problems. The expected outcomes are that the patient:

- Maintains a patent airway
- Performs self-care of the artificial airway and wound
- Performs ADLs independently or with minimal assistance
- Attains or maintains adequate NUTRITION
- Does not aspirate gastric contents or food
- Engages in desired social interactions

## **Clinical Judgment Challenge 29-1**

### **Patient-Centered Care; Teamwork and Collaboration; Evidence-Based Practice** QSEN

A 68-year-old man is diagnosed with stage 3 cancer of the larynx. He exercises daily, has never smoked, is a healthy weight, and serves as a deacon in his church. His only other health problem is asthma, which is well controlled with daily preventive drugs. He describes himself as a “social drinker” of no more than three martinis a day. His older brother died of lung cancer 3 years ago. He is very angry and states that all of his healthy living was a “waste.” He is also concerned about his ability to keep on serving as a deacon, which requires public speaking. He asks whether you think God is angry with him. He is scheduled for hemilaryngectomy surgery.

1. Which, if any, risk factors does he have for cancer of the larynx?
2. Is his concern about public speaking valid? Why or why not?
3. How will you answer his question about God?
4. Which members of the interprofessional team could be most helpful with his current concerns?

## Cancer of the Nose and Sinuses

Tumors of the nasal cavities and sinuses result from the loss of CELLULAR REGULATION. Malignant tumors are rare and are more common among adults with chronic exposure to wood dusts, dusts from textiles, leather dusts, flour, nickel and chromium dust, mustard gas, and radium. Cigarette smoking along with these exposures increases the risk (ACS, 2017).

The onset of sinus cancer is slow, and symptoms resemble sinusitis. These include persistent nasal obstruction, drainage, bloody discharge, and pain that persists after treatment of sinusitis. Lymph node enlargement often occurs on the side with tumor mass. Tumor location is identified with x-ray, CT, or MRI imaging. A biopsy is performed to confirm the diagnosis.

Surgical removal of all or part of the tumor is the main treatment for nasopharyngeal cancers. It is usually combined with radiation therapy, especially intensity-modulated radiation therapy (IMRT) (see Chapter 22). Chemotherapy may be used in conjunction with surgery and radiation for some tumors. Problems after surgery include a change in body image or speech and altered NUTRITION, especially when the maxilla and floor of the nose are involved in the surgery. Patients often also have changes in taste and smell.

Provide general postoperative care (see Chapter 16), including maintaining a patent airway, monitoring for hemorrhage, providing wound care, assessing nutrition status, and performing tracheostomy care (if needed). (See Chapter 28 for tracheostomy care.) Perform careful mouth and sinus cavity care with saline irrigations using an electronic irrigation system (e.g., Water-Pik, Sonicare) or a syringe. Assess the patient for pain and infection. Collaborate with the dietitian to help the patient make food selections that promote healing.

## Fractures of the Nose

### ❖ Pathophysiology

Nasal fractures often result from injury and can interfere with GAS EXCHANGE. If the bone or cartilage is not displaced and no complications are present, treatment may not be needed. However, displacement of either the bone or cartilage can cause airway obstruction or cosmetic deformity and is a potential source of infection.

### ❖ Interprofessional Collaborative Care

#### ◆ Assessment: Noticing

Document any nasal problem, including deviation, malaligned nasal bridge, a change in nasal breathing, crackling of the skin (*crepitus*) on palpation, bruising, and pain. Blood or clear fluid (cerebrospinal fluid [CSF]) rarely drains from one or both nares as a result of a simple nasal fracture and, if present, indicates a serious injury (e.g., skull fracture). CSF can be differentiated from normal nasal secretions because CSF contains glucose that will test positive with a dipstick test for glucose. When CSF dries on a piece of filter paper, a yellow “halo” appears as a ring at the dried edge of the fluid.

#### ◆ Interventions: Responding

The primary health care provider performs a simple **closed reduction** (moving the bones by palpation to realign them) of the nasal fracture using local or general anesthesia within the first 24 hours after injury. After 24 hours the fracture is more difficult to reduce because of edema and scar formation. Then reduction may be delayed for several days until edema is gone. Simple closed fractures may not need surgical intervention. Management focuses on pain relief and cold compresses to decrease swelling.

### Rhinoplasty.

Reduction and surgery may be needed for severe fractures or for those that do not heal properly. **Rhinoplasty** is a surgical reconstruction of the nose. It can be performed to repair a fractured nose and also to change the shape of the nose. The patient returns from surgery with packing in both nostrils, which prevents bleeding and provides support for the reconstructed nose. As long as the packing is in place, the patient cannot breathe through the nose. A “moustache” dressing (or drip pad), often a folded 2 × 2 gauze pad, is usually placed under the nose (Fig. 29-2). A splint or cast may cover the nose for better alignment and protection. Change or teach the patient to change the drip pad as necessary.

**FIG. 29-2** Immediate postoperative appearance of a patient who has undergone rhinoplasty. Note the splint and gauze drip pad (moustache dressing). (From Tardy, M. E. [1997]. *Rhinoplasty: The art and science*. Philadelphia: Saunders. Used with permission.)

After surgery observe for edema and bleeding. Check vital signs every 4 hours until the patient is discharged. The patient with uncomplicated rhinoplasty is discharged the day of surgery. Instruct him or her and the family about the routine care described in the following paragraphs.

## Nursing Safety Priority QSEN

### Action Alert

Assessing how often the patient swallows after nasal surgery is a priority because repeated swallowing may indicate posterior nasal bleeding. Use a penlight to examine the throat for bleeding and notify the surgeon if bleeding is present.

Instruct the patient to stay in a semi-Fowler's position and to move slowly. Suggest that he or she rests and uses cool compresses on the nose, eyes, and face to help reduce swelling and bruising. If a general anesthetic was used, soft foods can be eaten once the patient is alert and the gag reflex has returned. Urge the patient to drink at least 2500 mL/day.

To prevent bleeding, teach the patient to limit Valsalva maneuvers (e.g., forceful coughing or straining during a bowel movement), not to sniff upward or blow the nose, and not to sneeze with the mouth closed for the first few days after the packing is removed. Instruct the patient to avoid aspirin and other NSAIDs to prevent bleeding. Antibiotics may be prescribed to prevent infection. Recommend the use of a humidifier to prevent mucosal drying. Explain that edema lasts for weeks and that the final surgical result will be evident in 6 to 12 months.

### Nasoseptoplasty.

Nasoseptoplasty, or **submucous resection** (SMR), may be needed to straighten a deviated septum when chronic symptoms or discomfort occurs. Slight nasal septum deviation causes no symptoms. Major deviations may obstruct the nasal passages or interfere with airflow and sinus drainage. The deviated section of cartilage and bone is removed or reshaped as an ambulatory surgical procedure. Nursing care is similar to that for a rhinoplasty.

## NCLEX Examination Challenge 29-2

### Health Promotion and Maintenance

Which interventions are **most appropriate** for the nurse to teach a client with a nasal fracture to reduce bleeding from the injury? **Select all that apply.**

- A. "Avoid blowing or picking the nose."
- B. "Drink at least 2000 mL of fluid daily."
- C. "Take the antibiotics for as long as they are prescribed."
- D. "Take in only liquids and eat no solid food for at least a week."
- E. "Change the drip (moustache) dressing as soon as it becomes wet."
- F. "Use acetaminophen for pain rather than aspirin or other NSAIDs."

# Epistaxis

## ❖ Pathophysiology

**Epistaxis** (nosebleed) is a common problem because of the many capillaries within the nose. Nosebleeds occur as a result of trauma, hypertension, blood dyscrasia (e.g., leukemia), inflammation, tumor, decreased humidity, nose blowing, nose picking, chronic cocaine use, and procedures such as nasogastric suctioning. Older adults tend to bleed most often from the posterior portion of the nose.

## ❖ Interprofessional Collaborative Care

The patient often reports that the bleeding started after sneezing or blowing the nose. Document the amount and color of the blood and take vital signs. Ask about the number, duration, and causes of previous bleeding episodes.

**Chart 29-5** lists the best practices for emergency care of the patient with a nosebleed. An additional intervention for use at home or in the emergency department is a special nasal plug that contains an agent to promote blood clotting (sold by HemCon). The plug expands on contact with blood and compresses mucosal blood vessels.

### 📊 Chart 29-5

## Best Practice for Patient Safety & Quality Care QSEN

### Emergency Care of a Patient With an Anterior Nosebleed

- Maintain Standard Precautions or Body Substance Precautions.
- Position the patient upright and leaning forward to prevent blood from entering the stomach and possible aspiration.
- Reassure the patient and attempt to keep him or her quiet to reduce anxiety and blood pressure.
- Apply direct lateral pressure to the nose for 10 minutes and apply ice or cool compresses to the nose and face if possible.
- If nasal packing is necessary, loosely pack both nares with gauze or nasal tampons.
- To prevent rebleeding from dislodging clots, instruct the patient to not blow the nose for 24 hours after the bleeding stops.
- Seek medical assistance if these measures are ineffective or if the bleeding occurs frequently.

Medical attention is needed if the nosebleed does not respond to these interventions. In such cases, the affected capillaries may be cauterized with silver nitrate or electrocautery, and the nose packed. Anterior packing controls bleeding from the anterior nasal cavity.

*Posterior nasal bleeding is an emergency because it cannot be easily reached and the patient may lose a lot of blood quickly (Vacca & Poirier, 2013).* Posterior packing, epistaxis catheters (nasal pressure tubes), or gel tampons are used to stop bleeding that originates in the posterior nasal region. With packing, the primary health care provider positions a large gauze pack in the posterior nasal cavity above the throat, threads the attached string through the nose, and tapes it to the patient's cheek to prevent pack movement. Epistaxis catheters look like very short (about 6 inches) urinary catheters (**Fig. 29-3A**). These tubes have an exterior balloon along the tube length in addition to an anchoring balloon on the end. Placement of posterior packing or pressure tubes is uncomfortable; and the airway may be obstructed with reduced GAS EXCHANGE if the pack slips. **Fig. 29-3B** shows a patient with tubes in place for a posterior nasal bleed.

**FIG. 29-3** A, Ultra-Stat epistaxis catheter. B, Patient with epistaxis catheters in place to control a posterior nasal bleed. (A courtesy Invotec International, Jacksonville, FL.)

Observe the patient for respiratory distress and tolerance of the packing or tubes. Humidity, oxygen, bedrest, and antibiotics may be prescribed. Opioid drugs may be prescribed for pain. Assess patients receiving opioids at least hourly for gag and cough reflexes. Use pulse oximetry to monitor for hypoxemia. The tubes or packing is usually removed after 1 to 3 days.

For posterior bleeds that do not respond to packing or tubes, additional options include cauterizing the blood vessels, ligating the vessels, or performing an embolization of the bleeding artery with interventional radiology. Potential complications of embolization include facial pain, necrosis of skin or nasal mucosa, facial nerve paralysis, and blindness (Poetker, 2013).

After the tubes or packing is removed, teach the patient and family these interventions to use at home for comfort and safety:

- Petroleum jelly can be applied sparingly to the nares for lubrication and comfort. (Excessive application could cause inhalation of the jelly into the lungs and increase the risk for pneumonia.)
- Nasal saline sprays and humidification add moisture and prevent rebleeding.
- Avoid vigorous nose blowing, the use of aspirin or other NSAIDs, and strenuous activities such as heavy lifting for at least 1 month.

# Facial Trauma

## ❖ Pathophysiology

Facial trauma is described by the specific bones (e.g., mandibular, maxillary, orbital, nasal fractures) and the side of the face involved. Mandibular (lower jaw) fractures are the most common. *Le Fort I* is a nasoethmoid complex fracture. *Le Fort II* is a maxillary and nasoethmoid complex fracture. *Le Fort III* combines I and II plus an orbital-zygoma fracture, called *craniofacial disjunction* because the midface has no connection to the skull. The rich facial blood supply results in extensive bleeding and bruising.

## ❖ Interprofessional Collaborative Care

### ◆ Assessment: Noticing

*The priority action when caring for a patient with facial trauma is airway assessment for GAS EXCHANGE.* Signs of airway obstruction are stridor, shortness of breath, dyspnea, anxiety, restlessness, hypoxia, **hypercarbia** (elevated blood levels of carbon dioxide), decreased oxygen saturation, cyanosis, and loss of consciousness. After establishing the airway, assess the trauma site for bleeding and obvious fractures. Check for soft-tissue edema, facial asymmetry, pain, or leakage of spinal fluid through the ears or nose, indicating a skull fracture. Assess vision and eye movement because orbital and maxillary fractures can entrap the eye nerves and muscles. Check behind the ears (mastoid area) for extensive bruising, known as the “battle sign,” which is often associated with skull fracture and brain trauma. Because facial trauma can occur with spinal trauma and skull fractures, cranial CT, facial series, and cervical spine x-rays are obtained.

### ◆ Interventions: Responding

*The priority action is to establish and maintain an airway for adequate GAS EXCHANGE.* Anticipate the need for emergency intubation, tracheotomy, or cricothyroidotomy (creation of a temporary airway by making a small opening in the throat between the thyroid cartilage and the cricoid cartilage). Care at first focuses on establishing an airway to ensure GAS EXCHANGE, controlling hemorrhage, and assessing for the extent of injury. If shock is present, fluid resuscitation and identification of bleeding sites are started immediately.

Time is critical in stabilizing the patient who has head and neck trauma. Early response and treatment by special interprofessional services (e.g., trauma team, maxillofacial surgeon, general surgeon, otolaryngologist, plastic surgeon, dentist) optimize the patient's recovery.

Stabilizing the fractured jaw allows the teeth to heal in proper alignment and involves *fixed occlusion* (wiring the jaws together with the mouth in a closed position). The patient remains in fixed occlusion for 6 to 10 weeks. Treatment delay, tooth infection, or poor oral care may cause jaw bone infection. This condition may then require surgical removal of dead tissue, IV antibiotic therapy, and a longer period with the jaws in a fixed position.

Extensive jaw fractures may require open reduction with internal fixation (ORIF) procedures. Compression plates and reconstruction plates with screws may be applied. Plates may be made of stainless steel, titanium, or Vitallium. If the mandibular fracture is repaired with titanium plates, the plates are permanent and do not interfere with MRI studies.

Facial fractures may be repaired with microplating surgical systems that involve bone substitutes or commercial bone graft. Shaping plates hold the bone fragments in place until new bone growth occurs. Bone cells grow into the bone substitute and re-matrix into a stable bone support. The plates may remain in place permanently or may be removed after healing.

With inner maxillary fixation (IMF), the bones are realigned and then wired in place with the bite closed. Nondisplaced aligned fractures can be repaired in a clinic or office using local dental anesthesia. General anesthesia is used to repair displaced or complex fractures or fractures that occur with other facial bone fractures.

After surgery, teach the patient about oral care with an irrigating device such as a Water-Pik or Sonicare. If the patient has inner maxillary fixation, teach self-management with wires in place, including a dental liquid diet. If the patient vomits, watch for aspiration because of the patient's inability to open the jaws to allow ejection of the emesis. Teach him or her how to cut the wires if

vomiting occurs to maintain GAS EXCHANGE. If the wires are cut, instruct the patient to return to the surgeon for rewiring as soon as possible to reinstitute fixation.

## Nursing Safety Priority QSEN

### Action Alert

Instruct the patient to keep wire cutters with him or her at all times to prevent aspiration if vomiting occurs.

NUTRITION is important and difficult for a patient with fractures because of oral fixation, pain, and surgery. Collaborate with the dietitian for patient teaching and support.

# Obstructive Sleep Apnea

## ❖ Pathophysiology

**Obstructive sleep apnea** (OSA) is a breathing disruption during sleep that lasts at least 10 seconds and occurs a minimum of five times in an hour. The most common cause is upper airway obstruction by the soft palate or tongue. Factors that contribute to OSA include obesity, a large uvula, a short neck, smoking, enlarged tonsils or adenoids, and oropharyngeal edema.

During sleep the muscles relax, and the tongue and neck structures are displaced. As a result, the upper airway is obstructed, but chest movement is unimpaired. The apnea decreases GAS EXCHANGE, increases blood carbon dioxide levels, and decreases the pH. These blood gas changes stimulate neural centers. The sleeper awakens after 10 seconds or longer of apnea and corrects the obstruction, and respiration resumes. After he or she goes back to sleep, the cycle begins again, sometimes as often as every 5 minutes.

This cyclic pattern of disrupted sleep prevents the deep sleep needed for best rest, and the adult may have excessive daytime sleepiness, an inability to concentrate, and irritability. Long-term effects of chronic OSA include increased risk for hypertension, stroke, cognitive deficits, weight gain, diabetes, and pulmonary and cardiovascular disease (Veenstra & Untalan, 2014).

## ❖ Interprofessional Collaborative Care

### ◆ Assessment: Noticing

Patients are often unaware that they have sleep apnea. The disorder should be suspected for any adult who has persistent daytime sleepiness or reports “waking up tired,” particularly if he or she also snores heavily. Other symptoms include irritability and personality changes. Sleep apnea may be verified by family members who observe the problem when the adult sleeps. A complete assessment is performed when excessive daytime sleepiness is a problem.

A beginning assessment includes having the patient complete the STOP-Bang Sleep Apnea Questionnaire (Nations & Mayo, 2016). The patient is asked to answer yes or no to eight items (Snores, Tiredness, Observed as stopped breathing during sleep, P-treatment for high blood pressure, Body mass index >35, Age >50, Neck circumference >40 cm, and Gender-male). A yes score to fewer than three items indicates a low risk for OSA. A yes score to higher than three items indicates a high risk for OSA. This questionnaire is easy to administer and interpret and has both high reliability and validity. The results correlate well to overnight sleep study results and have some predictive value for both difficult intubations and postoperative respiratory complications (Nations & Mayo, 2016).

The most accurate test for sleep apnea is an overnight sleep study. The patient is directly observed while wearing a variety of monitoring equipment to evaluate depth of sleep, type of sleep, respiratory effort, oxygen saturation, and muscle movement. Monitoring devices include an electroencephalograph (EEG), an electrocardiograph (ECG), a pulse oximeter, and an electromyograph (EMG).

### ◆ Interventions: Responding

Changes in sleeping position or weight loss may correct mild sleep apnea and improve GAS EXCHANGE. Position-fixing devices may prevent subluxation of the tongue and reduce obstruction. Severe OSA requires additional methods to prevent obstruction.

A common method to prevent airway collapse is the use of noninvasive positive-pressure ventilation (NPPV) to hold open the upper airways. A nasal mask or full-facemask delivery system allows mechanical delivery of either bi-level positive airway pressure (BiPAP), autotitrating positive airway pressure (APAP), or nasal continuous positive airway pressure (CPAP). With BiPAP, a machine delivers a set inspiratory positive airway pressure at the beginning of each breath. As the patient begins to exhale, the machine delivers a lower end-expiratory pressure. These two pressures hold open the upper airways. With APAP, the machine adjusts continuously, resetting the pressure throughout the breathing cycle to meet the patient's needs. Nasal CPAP delivers a set positive airway pressure continuously during each cycle of inhalation and exhalation. For any positive-pressure ventilation delivered through a facemask during sleep, a small electric

compressor is required. Proper fit of the mask over the nose and mouth or just over the nose is key to successful treatment (see Fig. 28-8). Although noisy, these methods are accepted by most patients after an adjustment period.

One drug has been approved to help manage the daytime sleepiness associated with OSA (modafinil [Attenace, Provigil]) and may help patients who have *narcolepsy* (uncontrolled daytime sleep) by promoting daytime wakefulness. This drug does *not* treat the cause of OSA. Sleep-inducing sedatives also are not considered first-line therapy.

Surgical intervention may involve a simple adenoidectomy, uvulectomy, or remodeling of the entire posterior oropharynx (uvulopalatopharyngoplasty [UPP]). Both conventional and laser surgeries are used for this purpose. A tracheostomy may be needed for very severe sleep apnea that is not relieved by more moderate interventions.

## NCLEX Examination Challenge 29-3

### Safe and Effective Care Environment

With which client does the nurse anticipate complications from obstructive sleep apnea following abdominal surgery?

- A. 28-year-old who is 80 lbs (36.4 kg) overweight and has a short neck
- B. 48-year-old who has type 1 diabetes and chronic sinusitis
- C. 58-year-old who has had gastroesophageal reflux disease for 10 years
- D. 78-year-old who wears upper and lower dentures and has asthma

## Laryngeal Trauma

Laryngeal trauma and damage occur with a crushing or direct-blow injury, fracture, or prolonged endotracheal intubation. Symptoms include difficulty breathing (dyspnea), inability to produce sound (*aphonia*), hoarseness, and **subcutaneous emphysema** (air present in the subcutaneous tissue). Bleeding from the airway (**hemoptysis**) may occur, depending on the location of the trauma. The primary health care provider performs a direct visual examination of the larynx by laryngoscopy or fiberoptic laryngoscopy to determine the extent of the injury.

Management of patients with laryngeal injuries consists of assessing the effectiveness of GAS EXCHANGE and monitoring vital signs (including respiratory status and pulse oximetry) every 15 to 30 minutes. *Maintaining a patent airway is a priority.* Apply oxygen and humidification as prescribed to maintain adequate oxygen saturation. Signs of respiratory difficulty include tachypnea, nasal flaring, anxiety, sternal retraction, shortness of breath, restlessness, decreased oxygen saturation, decreased level of consciousness, and stridor.

### Nursing Safety Priority QSEN

#### Critical Rescue

Assess the patient to recognize signs of respiratory difficulty (tachypnea, nasal flaring, anxiety, sternal retraction, shortness of breath, restlessness, decreased oxygen saturation, decreased level of consciousness, stridor). If any signs are present, respond by staying with the patient and instructing other trauma team members or the Rapid Response Team to prepare for an emergency intubation or tracheotomy.

Surgical intervention is needed for lacerations of the mucous membranes, cartilage exposure, and cord paralysis. Laryngeal repair is performed as soon as possible to prevent laryngeal stenosis and to cover any exposed cartilage. An artificial airway may be needed.

# Upper Airway Obstruction

## ❖ Pathophysiology

Upper airway obstruction is the interruption of airflow through nose, mouth, pharynx, or larynx. When GAS EXCHANGE is impaired, obstruction can be a life-threatening condition. Early recognition is essential to prevent complications, including respiratory arrest. Causes of upper airway obstruction include:

- Tongue edema (surgery, trauma, angioedema as an allergic response to a drug)
- Tongue occlusion (e.g., loss of gag reflex, loss of muscle tone, unconsciousness, coma)
- Laryngeal edema
- Peritonsillar and pharyngeal abscess
- Head and neck cancer
- Thick secretions
- Stroke and cerebral edema
- Smoke inhalation edema
- Facial, tracheal, or laryngeal trauma
- Foreign-body aspiration
- Burns of the head or neck area
- Anaphylaxis

One preventable cause of airway obstruction leading to asphyxiation is *inspissated* (thickly crusted) oral and nasopharyngeal secretions. In this condition, poor oral hygiene leads to thickening and hardening of secretions that can completely block the airway and lead to death. Proper nursing care can eliminate this cause of airway obstruction. Patients at highest risk are those who have an altered mental status and level of consciousness, are dehydrated, are unable to communicate, are unable to cough effectively, or are at risk for aspiration.

## 📌 Nursing Safety Priority QSEN

### Action Alert

Assess the oral care needs of the patient with risk factors for inspissated (thickly crusted) secretions daily. Ensure that whoever provides oral care understands the importance and the correct techniques for preventing secretion buildup and airway obstruction.

## ❖ Interprofessional Collaborative Care

An acute airway obstruction from a foreign body may be managed in the community or emergency department. When chronic problems cause airway obstruction, more intensive interventions may be needed in an acute care setting.

### ◆ Assessment: Noticing

Airway obstruction is frightening, and prompt care is essential to prevent a partial obstruction from progressing to a complete obstruction. Partial obstruction produces general symptoms such as diaphoresis, tachycardia, and elevated blood pressure. Persistent or unexplained symptoms must be evaluated even though vague. Diagnostic procedures include chest or neck x-rays, laryngoscopic examination, and CT.

Observe for hypoxia and hypercarbia, restlessness, increasing anxiety, sternal retractions, a “seesawing” chest, abdominal movements, or a feeling of impending doom from air hunger. Use pulse oximetry or end-tidal carbon dioxide (ETCO<sub>2</sub> or PETCO<sub>2</sub>) for ongoing monitoring of GAS EXCHANGE. Continually assess for stridor, cyanosis, and changes in level of consciousness.

### ◆ Interventions: Responding

Assess for the cause of the obstruction. When the obstruction is caused by the tongue falling back or excessive secretions, slightly extend the patient's head and neck and insert a nasal or an oral airway. Suction to remove any obstructing secretions. If the obstruction is caused by a foreign body, perform abdominal thrusts (Fig. 29-4).

With the conscious victim standing or sitting, place your fist between the victim's lower rib cage and navel. Wrap the palm of your hand around your fist. A quick inward, upward thrust expels the air remaining in the victim's lungs, and with it the foreign body. If the first thrust is unsuccessful, repeat several thrusts in rapid succession until the foreign body is expelled or until the victim loses consciousness.

With the unconscious victim lying supine, straddle the victim's thighs. Place one hand on top of the other as shown, with the heel of the bottom hand just above the victim's navel. Quickly thrust inward and upward, toward the victim's head.

**FIG. 29-4** Abdominal thrust maneuver (formerly known as the *Heimlich maneuver*) for relief of upper airway obstruction caused by a foreign body.

Upper airway obstruction may require emergency procedures such as cricothyroidotomy, endotracheal intubation, or tracheotomy to improve GAS EXCHANGE. Laryngoscopy may be performed to determine the cause of obstruction or to remove foreign bodies.

*Cricothyroidotomy* is an emergency procedure performed by emergency medical personnel as a stab wound at the cricothyroid membrane between the thyroid cartilage and the cricoid cartilage (see Fig. 27-3). Any hollow tube—but preferably a tracheostomy tube—can be placed through the opening to hold this airway open until a tracheotomy can be performed. This procedure is used when it is the *only* way to secure an airway. Another emergency procedure to bypass an obstruction is the insertion of a 14-gauge needle or a very small endotracheal tube directly into the cricoid space to allow airflow into and out of the lungs.

*Endotracheal intubation* is performed by inserting a tube into the trachea via the nose (*nasotracheal*) or mouth (*orotracheal*) by a physician, anesthesia provider, or other specially trained personnel.

*Tracheotomy* is a surgical procedure and takes about 5 to 10 minutes to perform. It is best performed in the operating room (OR) with the patient under local or general anesthesia but can be performed at the bedside. Local anesthesia is used if there is concern that the airway will be lost during the induction of anesthesia. A tracheotomy is reserved for the patient who cannot be easily intubated with an endotracheal tube. An emergency tracheotomy can establish an airway in less than 2 minutes. See Chapter 28 for a discussion of care of the patient with a tracheotomy.

Patients receiving mechanical ventilation for upper airway obstruction or respiratory failure may require a tracheostomy after 7 or more days of continuous intubation. In such cases, a tracheotomy is performed to prevent laryngeal injury by the endotracheal tube.

# Get Ready for the NCLEX<sup>®</sup> Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Use sterile technique when performing endotracheal or tracheal suctioning. **QSEN: Safety**
- Use Standard Precautions when caring for a patient with epistaxis. **QSEN: Safety**
- Supervise care delegated to licensed practical nurses/licensed vocational nurses (LPNs/LVNs) or nursing assistants to patients who have risk factors for airway obstruction. **QSEN: Safety**
- Use Aspiration Precautions for any patient with an altered level of consciousness or who has an endotracheal tube (see [Chart 28-5](#)). **QSEN: Safety**
- Apply knowledge of anatomy to prevent aspiration in a patient with a tracheostomy. **QSEN: Safety**
- Use correct technique to suction via a tracheostomy or laryngectomy tube. **QSEN: Safety**
- Teach the patient and family how to perform tracheostomy care (see [Chart 28-3](#)). **QSEN: Safety**
- Teach family members ways to communicate with a patient who cannot speak after surgery for head and neck cancer. **QSEN: Patient-Centered Care**

### Health Promotion and Maintenance

- Assess the patient for risk factors for head and neck cancer.
- Encourage adults who smoke to quit smoking or using tobacco in any way. **QSEN: Patient-Centered Care**
- Encourage adults who use alcohol to reduce their intake of alcoholic beverages. **QSEN: Evidence-Based Practice**
- Teach patients who have had radiation therapy to the oral cavity to have dental examinations at least every 6 months. **QSEN: Patient-Centered Care**
- Teach the patient and family about home management of a laryngectomy stoma or tracheostomy. **QSEN: Patient-Centered Care**

### Psychosocial Integrity

- Allow the patient and family members the opportunity to express fear or anxiety regarding a cancer diagnosis or a change in breathing status. **QSEN: Patient-Centered Care**
- Encourage patients with permanent tracheostomies or laryngectomies to become involved in self-care and to look at the wound and touch the affected area. **QSEN: Patient-Centered Care**
- Allow the patient and family to grieve the loss of function and change in body image. **QSEN: Patient-Centered Care**
- Allow time to communicate with the patient who has voice loss. **QSEN: Patient-Centered Care**
- Refer patients and families to local chapters of the ACS or the Canadian Cancer Society after surgery for head and neck cancer. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Assess the airway patency of any patient who experiences facial or nasal trauma. **QSEN: Safety**
- Perform a focused upper respiratory assessment and re-assessment to determine adequacy of GAS EXCHANGE and tissue perfusion. **QSEN: Patient-Centered Care**
- Notify the Rapid Response Team when a patient experiences a posterior nasal bleed. **QSEN:**

### **Safety**

- Check the airway and packing at least every hour for a patient who has posterior nasal packing placed after nasal surgery or posterior epistaxis. **QSEN: Evidence-Based Practice**
- Instruct patients who have had mandibular immobilization or fixation after a mandibular fracture to keep wire cutters with them at all times. **QSEN: Safety**
- Apply oxygen to any patient who develops stridor. **QSEN: Safety**
- Use a manual resuscitation bag to ventilate the patient if the tracheostomy tube has dislodged or been decannulated. **QSEN: Safety**
- Assess the new tracheostomy stoma site at least once per shift for purulent drainage, redness, pain, and swelling as indicators of infection. **QSEN: Safety**
- Keep the tracheal cuff pressure between 14 and 20 mm Hg to prevent tissue injury. **QSEN: Evidence-Based Practice**

## CHAPTER 30

# Care of Patients With Noninfectious Lower Respiratory Problems

M. Linda Workman

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is GAS EXCHANGE.**

✚ The GAS EXCHANGE concept exemplar for this chapter is Chronic Obstructive Pulmonary Disease, p. 572.

**The interrelated concepts for this chapter are:**

- PERFUSION
- CELLULAR REGULATION

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to coordinate high-quality care and promote GAS EXCHANGE in patients with chronic lower respiratory problems.
2. Protect patients with lower respiratory problems from injury or infection.
3. Teach the patient and family how to manage a chronic lower respiratory disorder and avoid injury and complications in the home.

### Health Promotion and Maintenance

4. Teach all adults measures to take to protect the respiratory system from damage and cancer, including the avoidance of known environmental causative agents.
5. Identify community resources for patients requiring assistance with long-term GAS EXCHANGE issues related to chronic lower airway problems.

### Psychosocial Integrity

6. Implement nursing interventions to help the patient and family cope with the psychosocial impact of living with a chronic lower respiratory problem.

### Physiological Integrity

7. Apply knowledge of anatomy, physiology, and pathophysiology to assess critically ill patients with respiratory problems affecting GAS EXCHANGE OR PERFUSION.
8. Teach the patient and caregiver(s) about common drugs and other management strategies used for acute or chronic lower respiratory problems.
9. Use assessment information to identify adults at increased genetic risk for a respiratory disease that affects GAS EXCHANGE OR PERFUSION.
0. Prioritize nursing care for the patient with chest tubes.

Airflow through the entire respiratory tubular system is needed for oxygen to reach the alveolar ducts and alveoli for GAS EXCHANGE to occur. When the function of any of these structures is

reduced, both gas exchange and systemic PERFUSION are impaired. Many noninfectious lower airway problems, whether they affect airflow or gas exchange, are chronic and progressive, requiring changes in lifestyle, especially for older adults (Touhy & Jett, 2016). Chart 30-1 lists nursing issues for the older patient with a respiratory problem.

### Chart 30-1

## Nursing Focus on the Older-Adult

### Chronic Respiratory Disorder

- Provide rest periods between activities such as bathing, meals, and ambulation.
- Place the patient in an upright position for meals to prevent aspiration.
- Encourage nutritional fluid intake after the meal to promote increased calorie intake.
- Schedule drugs around routine activities to increase adherence to drug therapy.
- Arrange chairs in strategic locations to allow the patient with dyspnea to stop and rest while walking.
- Urge the patient to notify the primary health care provider promptly for any symptoms of infection.
- Encourage the patient to receive the pneumococcal vaccine and to have an annual influenza vaccination.
- For patients who are prescribed home oxygen, keep tubing coiled when walking to reduce the risk for tripping.

# Asthma

## ❖Pathophysiology

**Asthma** is a chronic disease in which reversible airway obstruction occurs intermittently, reducing airflow (Fig. 30-1). Airway obstruction occurs by both inflammation and airway tissue sensitivity (hyperresponsiveness) with bronchoconstriction. Inflammation obstructs the airway **lumens** (i.e., the insides) (Fig. 30-2). Airway hyperresponsiveness and constriction of bronchial smooth muscle narrow the tubular structure of the airways. Airway inflammation and sensitivity can trigger bronchiolar constriction, and many adults with asthma have both problems. Severe airway obstruction reduces GAS EXCHANGE and can be fatal. At least 3630 deaths from acute asthma occur in the United States each year (Centers for Disease Control and Prevention [CDC], 2015). The risk for death from asthma is higher among older adults (Arjona, 2015).

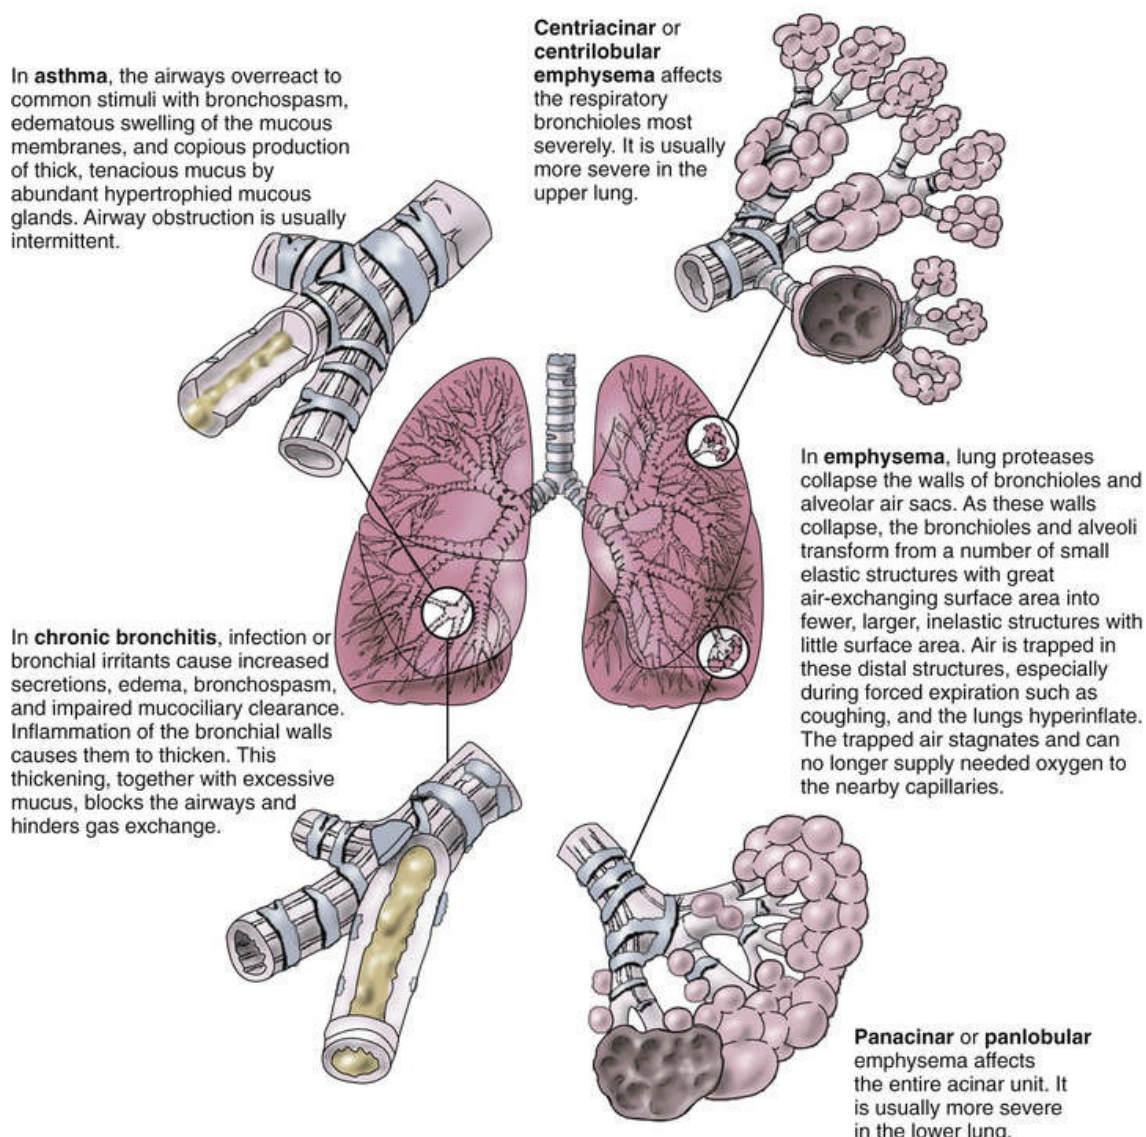

FIG. 30-1 Pathophysiology of chronic airflow limitation (CAL).

**FIG. 30-2** Causes of narrowed airways. **A**, Cross-section of a small airway showing the tissue layers. **B**, Mucosal swelling. **C**, Constriction of smooth muscle. **D**, Mucosal swelling and constriction of smooth muscle. **E**, Mucus plug.

## Etiology and Genetic Risk

Although asthma is classified into types based on what triggers the attacks, the effect on GAS EXCHANGE is the same. Inflammation of the mucous membranes lining the airways is a key event in triggering an asthma attack. It occurs in response to the presence of specific allergens; general irritants such as cold air, dry air, or fine airborne particles; microorganisms; and aspirin and other NSAIDs. Increased airway sensitivity (hyperresponsiveness) can occur with exercise or upper respiratory illness and for unknown reasons.

## Genetic/Genomic Considerations

### Patient-Centered Care QSEN

Genetic studies indicate that more than 50 gene variations are associated with asthma, although asthma is a disorder with both genetic and environmental input needed for expression (Online Mendelian Inheritance in Man [OMIM], 2015). Variation in the gene that controls the activity of beta-adrenergic receptors also has an impact on drug therapy for asthma. Adults with this mutation do not respond as expected to beta agonist drugs. Teaching these adults about why their drug therapies are different from standard recommendations is a nursing responsibility that can assist with therapy adherence.

When asthma is well controlled, airway changes are temporary and reversible. With poor control, chronic inflammation leads to airway damage and altered CELLULAR REGULATION with enlargement of the bronchial epithelial cells, including mucus-secreting cells, and changes in the bronchial smooth muscle (Lynn & Kushto-Reese, 2015). With frequent asthma attacks, even exposure to low levels of the triggering agent or event may stimulate an attack.

*Inflammation* triggers asthma for some adults when allergens bind to specific antibodies (especially immunoglobulin E [IgE]). These antibodies are attached to tissue *mast cells* and white blood cells (WBCs) called *basophils*, which are filled with chemicals that can start local inflammatory responses (see Chapters 17 and 20). Some chemicals, such as histamine, start an immediate inflammatory response, which can be blocked by drugs such as diphenhydramine (Benadryl). Others, such as leukotriene and eotaxin, are slower and cause later, prolonged inflammatory responses, which can be blocked by drugs such as montelukast (Singulair), zafirlukast (Accolate), and zileuton (Zyflo). Chemicals also attract more WBCs to the area, which then continue the responses of blood vessel dilation and capillary leak, causing mucous membrane swelling and increased mucus production (McCance et al., 2014). These responses narrow the lumens even more, which then interferes with airflow and GAS EXCHANGE. Inflammation can also occur through general irritation rather than allergic responses.

*Bronchospasm* is narrowing of the bronchial tubes by constriction of the smooth muscle around and within the bronchial walls. It can occur when small amounts of pollutants or respiratory viruses stimulate nerve fibers, causing constriction of bronchial smooth muscle. If an inflammatory response is stimulated at the same time, the chemicals released during inflammation also trigger constriction. Severe bronchospasm alone, especially in smaller bronchioles, can profoundly limit airflow to the alveoli and greatly reduce GAS EXCHANGE.

*Aspirin and other NSAIDs* can trigger asthma in some adults, although this response is not a true

allergy. It results from increased production of leukotriene when aspirin or NSAIDs suppress other inflammatory pathways.

*Gastroesophageal reflux disease (GERD)* can trigger asthma in some adults and causes asthma symptoms at night ([Global Initiative for Asthma \[GINA\], 2017](#)). With GERD, highly acidic stomach contents enter the airway and make pre-existing tissue sensitivity worse.

## Incidence and Prevalence

Asthma can occur at any age. About half of adults with asthma also had the disease in childhood. Asthma affects nearly 21 million adults in the United States and Canada (18.5 million in the United States and 2.5 million in Canada) ([CDC, 2015](#); [Statistics Canada, 2016a](#)). It is more common in urban settings than in rural settings.

## Considerations for Older Adults

### Patient-Centered Care QSEN

Asthma occurs as a new disorder in about 3% of adults older than 55 years, and another 3% of adults older than 60 years have asthma as a continuing chronic disorder (Arjona, 2015). Lung and airway changes as a part of aging make breathing problems more serious in the older adult. One problem related to aging is a decrease in the sensitivity of beta-adrenergic receptors. When stimulated, these receptors relax smooth muscle and cause bronchodilation. As these receptors become less sensitive, they no longer respond as quickly or as strongly to agonists (epinephrine, dopamine) and beta-adrenergic drugs, which are often used as rescue therapy during an acute asthma attack. Thus teaching older patients how to avoid asthma attacks and how to correctly use preventive drug therapy is a nursing priority.

### Interprofessional Collaborative Care

As a treatable chronic disorder, asthma is generally managed in the community with health care oversight ([Keep et al., 2016](#)). Acute exacerbations may require management in emergency departments or ICUs. Because asthma is a common disorder, adults admitted to the hospital for other health problems or surgery may also have asthma. For asthma control, the management plan must continue, regardless of setting.

### Assessment: Noticing

Asthma is classified on the basis of how well controlled the symptoms are and on the patient's response to asthma drugs. These classes are the basis for current asthma therapy ([Charts 30-2 and 30-3](#)).

## Chart 30-2

### Key Features

#### Levels of Asthma Control

CHARACTERISTIC	CONTROLLED (ALL OF THESE CHARACTERISTICS MUST BE PRESENT)	PARTLY CONTROLLED (THE PRESENCE OF ANY ONE OF THESE CHARACTERISTICS IS CONSIDERED PARTLY CONTROLLED)	UNCONTROLLED (THE PRESENCE OF THREE OR MORE CHARACTERISTICS FROM THE PARTLY CONTROLLED LIST IS CONSIDERED UNCONTROLLED ASTHMA)
Daytime symptoms	Symptoms occur twice per week or less	Symptoms occur more than twice per week	
Activity limitations	None	Any	
Nighttime symptoms	None	Any	
Reliever drug use	Reliever used twice per week or less	Reliever used more than twice per week	
PEF or FEV <sub>1</sub>	Normal	Less than 80% of predicted or established personal best	
Treatment action	Find and maintain lowest step level that controls symptoms	Increase step until symptoms are controlled on a regular basis and then reduce step to the lowest step level that consistently controls symptoms	Increase step (step up) until control is reached and maintained

FEV<sub>1</sub>, Forced expiratory volume in the first second; PEF, peak expiratory flow.

## Chart 30-3

### Key Features

#### The Step System for Medication Use in Asthma Control

STEP 1	STEP 2	STEP 3	STEP 4	STEP 5
As-needed rapid-acting beta <sub>2</sub> agonist (relief inhaler)	As-needed rapid-acting beta <sub>2</sub> agonist (relief inhaler)	As-needed rapid-acting beta <sub>2</sub> agonist (relief inhaler)	As-needed rapid-acting beta <sub>2</sub> agonist (relief inhaler)	As-needed rapid-acting beta <sub>2</sub> agonist (relief inhaler)
No daily drugs needed	Daily treatment involves the use of <i>one</i> of these two options:	Daily treatment involves the use of <i>one</i> of these four options:	Daily treatment involves the use of the Step 3 option that provided the best degree of control and was well tolerated along with one or more of these two options:	Daily treatment involves the use of the Step 4 option(s) that provided the best degree of control and was well tolerated along with either of these two options:
	Low-dose ICS	Low-dose ICS <i>and</i> long-acting beta <sub>2</sub> agonist	Medium-dose or high-dose ICS <i>and</i> long-acting beta <sub>2</sub> agonist	Oral glucocorticosteroid (lowest dose)
	Leukotriene modifier*	Medium-dose or high-dose ICS Low-dose ICS and leukotriene modifier Low-dose ICS and sustained-release theophylline	Leukotriene modifier and sustained-release theophylline	Anti-IgE† treatment

\*Leukotriene modifier = Leukotriene receptor antagonist or leukotriene synthesis inhibitor.

†IgE = Immunoglobulin E.

ICS, Inhaled corticosteroid.

Data compiled from Global Initiative for Asthma (GINA). (2017). *Pocket guide for asthma management and prevention*. <http://ginasthma.org/2017-pocket-guide-for-asthma-management-and-prevention/>.

### History.

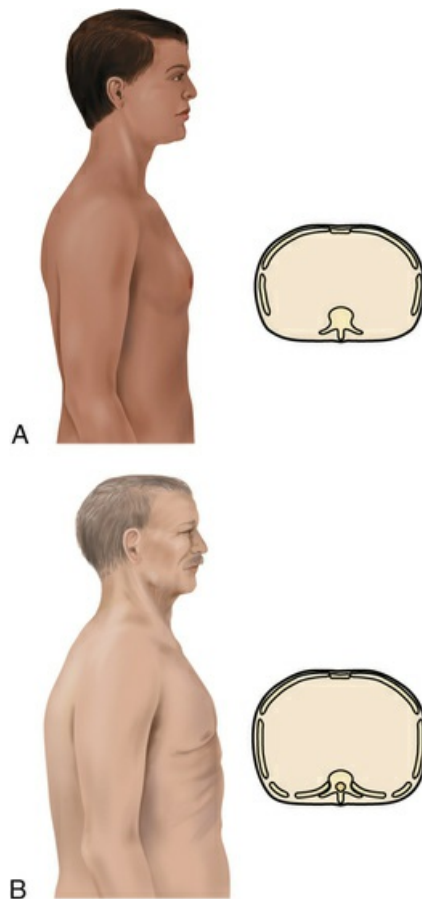

The patient with asthma usually has a pattern of intermittent episodes of **dyspnea** (shortness of breath), chest tightness, coughing, wheezing, and increased mucus production. Ask whether the symptoms occur continuously, seasonally, in association with specific activities or exposures, at work, or more frequently at night. Some patients have symptoms for 4 to 8 weeks after a cold or other upper respiratory infection. The patient with atopic (allergic) asthma also may have other allergic problems. Ask whether any family members have asthma or respiratory problems. Ask about current or previous smoking habits. If the patient smokes, use this opportunity to teach him or her about smoking cessation (see [Chart 27-2](#)). Wheezing in nonsmokers is important in the diagnosis of asthma.

### Physical Assessment/Signs and Symptoms.

The patient with mild-to-moderate asthma may have no symptoms between asthma attacks. During an acute episode, common symptoms are an audible wheeze and increased respiratory rate. At first the wheeze is louder on exhalation. When inflammation occurs with asthma, coughing may increase.

The patient may use accessory muscles to help breathe during an attack. Observe for muscle retraction at the sternum and the suprasternal notch and between the ribs. The patient with long-standing, severe asthma may have a "barrel chest," caused by air trapping ([Fig. 30-3](#)). The anteroposterior (AP) diameter (diameter between the front and the back of the chest) increases with air trapping, giving the chest a rounded rather than an oval shape. The normal chest is about 1.5 times as wide as it is deep. In severe, chronic asthma, the AP diameter may equal or exceed the lateral diameter ([Jarvis, 2016](#)). Compare the chest AP diameter with the lateral diameter. Chronic air trapping also flattens the diaphragm and increases the space between the ribs.

**FIG. 30-3** **A**, Normal adult. The thorax has an oval shape with an anteroposterior-to-transverse diameter of 1 : 1.5 or 5 : 7. **B**, Barrel chest. Note equal anteroposterior-to-transverse diameter and that ribs are horizontal instead of the normal downward slope. This is associated with chronic obstructive pulmonary disease and severe asthma as a result of hyperinflation of the lungs. (From Jarvis, C. [2016]. *Physical examination and health assessment* [7th ed.]. Philadelphia: Saunders.)

Along with an audible wheeze, the breathing cycle is longer, with prolonged exhalation, and requires more effort. The patient may be unable to speak more than a few words between breaths. Hypoxia occurs with severe attacks. Pulse oximetry shows **hypoxemia** (poor blood oxygen levels). Examine the oral mucosa and nail beds for cyanosis. Other indicators of hypoxemia include changes in the level of cognition or consciousness and tachycardia.

### Laboratory Assessment.

Laboratory tests can determine asthma type and the degree of breathing impairment. Arterial blood gas (ABG) levels show the effectiveness of GAS EXCHANGE (see [Chapter 12](#) for discussion of ABGs). The arterial oxygen level ( $\text{PaO}_2$ ) may decrease during an asthma attack. Early in the attack, the arterial carbon dioxide level ( $\text{PaCO}_2$ ) may be decreased as the patient increases the breathing rate and depth. Later in an asthma episode,  $\text{PaCO}_2$  rises, indicating carbon dioxide retention. Allergic asthma often occurs with elevated serum eosinophil counts and immunoglobulin E (IgE) levels. The sputum may contain eosinophils and mucus plugs with shed epithelial cells (Curschmann's spirals).

### Pulmonary Function Tests.

The most accurate tests for measuring airflow in asthma are the pulmonary function tests (PFTs) using spirometry. Baseline PFTs are obtained for all patients diagnosed with asthma. The most important PFTs for a patient with asthma are the forced vital capacity (FVC), the forced expiratory volume in the first second ( $\text{FEV}_1$ ), and the peak expiratory flow (PEF), sometimes called *peak expiratory rate flow (PERF)* (Lynn & Kushto-Reese, 2015). Definitions of PFTs are listed in [Chapter 27](#). A decrease in either the  $\text{FEV}_1$  or the PEF (PERF) of 15% to 20% below the expected value for age, gender, and size is common for the patient with asthma. Asthma is diagnosed when these values

increase by 12% or more after treatment with bronchodilators. Airway responsiveness is tested by measuring the PEF and FEV<sub>1</sub> before and after the patient inhales the drug *methacholine*, which induces bronchospasm in susceptible adults.

### ◆Interventions: Responding

The purposes of asthma therapy are to control and prevent episodes, improve airflow and GAS EXCHANGE, and relieve symptoms. Asthma is best controlled when the patient is an active partner in the management plan. Priority nursing actions focus on patient education about using his or her personal asthma action plan, which includes drug therapy and lifestyle management strategies to help him or her understand the disease and its management (GINA, 2017).

### Self-Management Education.

Asthma often has intermittent overt symptoms. With guided self-care, patients can co-manage this disease, increasing symptom-free periods and decreasing the number and severity of attacks. Good management decreases hospital admissions and increases participation in patient-chosen work and leisure activities. Self-care requires extensive education for the patient to be able to self-assess respiratory status, self-manage (by adjusting the frequency and dosage of prescribed drugs), and know when to consult the primary health care provider (Keep et al., 2016).

Ideally a personal asthma action plan is developed by the health care provider and the patient. The plan is tailored to meet the patient's personal triggers, asthma symptoms, and drug responses. It includes:

- The prescribed daily controller drug(s) schedule and prescribed reliever drug directions
- Patient-specific daily asthma control assessment questions
- Directions for adjusting the daily controller drug schedule
- When to contact the primary health care provider (in addition to regularly scheduled visits)
- Emergency actions to take when asthma is not responding to controller and reliever drugs

Teach the patient to assess asthma severity at least daily with a peak flow meter (Fig. 30-4) and to adjust drugs according to his or her personal asthma action plan to prevent or relieve symptoms. Chart 30-4 describes the correct method for using the peak flow meter. The patient first establishes a baseline or "personal best" peak expiratory flow (PEF) by measuring his or her PEF twice daily for 2 to 3 weeks when asthma is well controlled and recording the results. This way, the patient will know when his or her peak flow is reduced to the point that more drugs are needed or that emergency assistance is needed. When the patient has established a "personal best," all other readings are compared with this value. Some meters are color coded to help the patient interpret the results. Green zone readings are at least 80% of or above the "personal best." This is the ideal range for asthma control and indicates that no increases in drug therapy are needed. Yellow is a range between 50% and 80% of personal best. When a patient has a reading in this range, he or she needs to use the prescribed reliever drug. Within a few minutes after using the reliever drug, another PEF reading should be made to determine whether it is working. *Frequent readings in the yellow zone or increasing use of reliever drugs indicates the need to reassess the asthma plan for the need to change controller drugs.* Red is a range below 50% of the patient's personal best, indicating serious respiratory obstruction.

**FIG. 30-4** Typical peak flow meter. This model will show faster exhalation rates in *green*, reduced exhalation rates in *yellow*, and seriously reduced exhalation rates in *red*. (From Aehlert, B. [2011]. *Paramedic practice today: Above and beyond*. St. Louis: Mosby.)

### Chart 30-4

## Patient and Family Education: Preparing for Self-Management

### Using a Peak Flow Meter

- Set the peak flow meter at zero.
- Use a standing position, without leaning or supporting yourself on anything, if possible.
- Take as deep a breath as you can.
- Place the mouthpiece of the meter in your mouth, taking care to wrap your lips tightly around it.
- Blow your breath out through the mouthpiece as hard and as fast as you are able. (If you cough, sneeze, or have any type of interruption while you exhale, reset the meter and perform the test again.)
- Reset and perform the test two additional times.
- The highest reading of the three is your current peak flow rate.
- Keep a record or graph of your peak flow rates and examine these for trends.

### Nursing Safety Priority QSEN

#### Action Alert

Teach the patient that, if a red zone reading occurs when using the peak flow meter, to immediately use the reliever drugs and seek emergency help.

Teach the patient to keep a symptom and intervention diary to learn specific triggers of asthma, early cues for impending attacks, and personal response to drugs. Stress the importance of proper use of his or her personal asthma action plan for any severity of asthma. [Chart 30-5](#) lists areas to emphasize when teaching the patient with asthma.

## Chart 30-5

# Patient and Family Education: Preparing for Self-Management

## Asthma Management

- Avoid potential environmental asthma triggers, such as smoke, fireplaces, dust, mold, and weather changes of warm to cold.
- Avoid drugs that trigger your asthma (e.g., aspirin, NSAIDs, beta blockers).
- Avoid food that has been prepared with monosodium glutamate (MSG) or metabisulfite.
- If you have exercise-induced asthma, use your bronchodilator inhaler 30 minutes before exercise to prevent or reduce bronchospasm.
- Be sure that you know the proper technique and correct sequence when you use metered dose inhalers.
- Get adequate rest and sleep.
- Reduce stress and anxiety; learn relaxation techniques; adopt coping mechanisms that have worked for you in the past.
- Wash all bedding with hot water to destroy dust mites.
- Monitor your peak expiratory flow rates with a flow meter at least twice daily.
- Seek immediate emergency care if you experience any of these:
  - Gray or blue fingertips or lips
  - Difficulty breathing, walking, or talking
  - Retractions of the neck, chest, or ribs
  - Nasal flaring
  - Failure of drugs to control worsening symptoms
  - Peak expiratory rate flow (PERF) declining steadily after treatment, or a flow rate 50% below your usual flow rate

### Drug Therapy.

Pharmacologic management of adults with asthma is based on the step category for severity and treatment (see [Charts 30-2](#) and [30-3](#)) (GINA, 2017). **Control therapy drugs** are used to reduce airway sensitivity (responsiveness) to prevent asthma attacks from occurring to maintain GAS EXCHANGE. *They are used every day, regardless of symptoms.* **Reliever drugs** (also called *rescue drugs*) are used to actually stop an attack once it has started. Some patients may need drug therapy only during an asthma episode. For others, daily drugs are needed to keep asthma episodic rather than a more frequent problem. Therapy involves the use of bronchodilators and various drug types to reduce inflammation. Some drugs reduce the asthma response, and other drugs actually prevent it. Combination drugs are two agents from different classes combined together for better response.

Chart 30-6 lists the most common preferred drugs in each class for control and relief therapy of asthma. The actions and interventions for most drugs within a single class are similar. Be sure to consult a drug handbook for information on a specific drug.

### Chart 30-6

## Common Examples of Drug Therapy

### Asthma Prevention and Treatment

DRUG	NURSING IMPLICATIONS
<b>Bronchodilators</b> —Cause bronchodilation through relaxing bronchiolar smooth muscle by binding to and activating pulmonary beta <sub>2</sub> receptors.	
<b>Short-Acting Beta<sub>2</sub> Agonist (SABA)</b> —Primary use is a fast-acting reliever (rescue) drug to be used either during an asthma attack or just before engaging in activity that usually triggers an attack.	
Albuterol (ProAir, Proventil, Ventolin) (inhaled drug)	Teach patients to carry drug with them at all times because it can stop or reduce life-threatening bronchoconstriction.
Levalbuterol (Xopenex)	Teach patient to monitor heart rate because excessive use causes tachycardia and other systemic symptoms. When taking any of these drugs with other inhaled drugs, teach patient to use it at least 5 minutes before the other inhaled drugs to allow the bronchodilation effect to increase the penetration of the other inhaled drugs. Teach patient the correct technique for using the MDI or DPI to ensure that the drug reaches the site of action.
<b>Long-Acting Beta<sub>2</sub> Agonist (LABA)</b> —Causes bronchodilation through relaxing bronchiolar smooth muscle by binding to and activating pulmonary beta <sub>2</sub> receptors. Onset of action is slow with a long duration. Primary use is prevention of an asthma attack.	
Salmeterol (Serevent) (inhaled drug)	Teach patient to not use these drugs as reliever drugs because they have a slow onset of action and do not relieve acute symptoms. Teach patient the correct technique for using the MDI or DPI to ensure that the drug reaches the site of action.
Indacaterol (Arcapta Neohaler) (COPD only) (inhaled drug)	
Formoterol (Perforomist) Arformoterol (Brovana) (COPD only)	
<b>Cholinergic Antagonist</b> —Causes bronchodilation by inhibiting the parasympathetic nervous system, allowing the sympathetic system to dominate, releasing norepinephrine that activates beta <sub>2</sub> receptors. Purpose is to both relieve and prevent asthma and improve GAS EXCHANGE.	
Ipratropium (Atrovent, Apo-Ipratvent) (inhaled drug)	If patient is to use any of these as a reliever drug, teach him or her to carry it at all times because it can stop or reduce life-threatening bronchoconstriction.
Tiotropium (Spiriva)	Teach patient to shake MDI well before using because the drugs separate easily. Teach patient to increase daily fluid intake because the drugs cause mouth dryness. Teach patient to observe for and report blurred vision, eye pain, headache, nausea, palpitations, tremors, inability to sleep as these are systemic symptoms of overdose and require intervention. Teach patient the correct technique for using the MDI or DPI to ensure that the drug reaches the site of action.
<b>Anti-Inflammatories</b> —All of these drugs help improve bronchiolar airflow and increase GAS EXCHANGE by decreasing the inflammatory response of the mucous membranes in the airways. They do not cause bronchodilation.	
<b>Corticosteroids</b> —Disrupt production pathways of inflammatory mediators. The main purpose is to prevent an asthma attack caused by inflammation or allergies (controller drug).	
Fluticasone (Ellipta) (MDI inhaled drug)	Teach patient to use the drug daily, even when no symptoms are present, because maximum effectiveness requires continued use for 48-72 hr and depends on regular use.
Beclomethasone (Qvar) (MDI inhaled drug)	Teach patient to use good mouth care and to check mouth daily for lesions or drainage because these drugs reduce local immunity and increase the risk for local infections, especially Candida albicans (yeast).
Budesonide (Pulmicort) (MDI inhaled drug)	Teach patient to not use these drugs as reliever drugs because they have a slow onset of action and do not relieve acute symptoms. Teach patient the correct technique for using the MDI to ensure that the drug reaches the site of action.
Prednisone (oral drug)	Teach patient about expected side effects because knowing which side effects to expect may reduce anxiety when they appear. Teach patient to avoid anyone who has an upper respiratory infection because the drug reduces all protective inflammatory responses, increasing the risk for infection. Teach patient to avoid activities that lead to injury because blood vessels become more fragile, leading to bruising and petechiae. Teach patient to take drug with food to help reduce the side effect of GI ulceration. Teach patient not to suddenly stop taking the drug for any reason because the drug suppresses adrenal production of corticosteroids, which are essential for life.
<b>Cromone</b> —Stabilizes the membranes of mast cells and prevents the release of inflammatory mediators. Purpose is to prevent asthma attack triggered by inflammation or allergens.	
Nedocromil (Tilade) (inhaled drug)	Teach patient to use the drug daily, even when no symptoms are present, because maximum effectiveness requires continued use for 48-72 hr and depends on regular use. Teach patient to not use this drug as a reliever drug because it has a slow onset of action and does not relieve acute symptoms. Teach patient the correct technique for using the MDI to ensure that the drug reaches the site of action.
<b>Leukotriene Modifier</b> —Blocks the leukotriene receptor, preventing the inflammatory mediator from stimulating inflammation. Purpose is to prevent asthma attack triggered by inflammation or allergens.	
Montelukast (Singulair) (oral drug)	Teach patient to use the drug daily, even when no symptoms are present, because maximum effectiveness requires continued use for 48-72 hr and depends on regular use. Teach patient not to decrease the dose or stop taking any other asthma drugs unless instructed by the health care professional because this drug is for long-term asthma control and does not replace other drugs, especially corticosteroids and reliever (rescue) drugs.

COPD, Chronic obstructive pulmonary disease; DPI, dry powder inhaler; MDI, metered dose inhaler.

(2017). *Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease*. <http://goldcopd.org/wp-content/uploads/2016/12/wms-GOLD-2017-Pocket-Guide.pdf>.

### Bronchodilators.

Bronchodilators cause bronchiolar smooth muscle relaxation but have no effect on inflammation. Thus, for patients who have airflow obstruction by both bronchospasm and inflammation, at least two types of drug therapy are needed. Bronchodilators include beta<sub>2</sub> agonists and cholinergic antagonists.

Beta<sub>2</sub> agonists bind to and stimulate the beta<sub>2</sub>-adrenergic receptors in the same way that epinephrine and norepinephrine do. This causes an increase in smooth muscle relaxation. Short-acting beta<sub>2</sub> agonists (SABAs) provide rapid but short-term relief. These inhaled drugs are most useful when an attack begins (as relief) or as premedication when the patient is about to begin an activity that is likely to induce an attack (GINA, 2017). Such agents include albuterol (ProAir,

Proventil, Ventolin), levalbuterol (Xopenex), and terbutaline (Brethaire). Teach the patient the correct technique for using an inhaled drug with a metered dose inhaler (MDI) (Chart 30-7). Fig. 30-5 shows a patient using a “spacer” with an MDI. Spacer use increases the amount of drug that is delivered to the lungs. Chart 30-8 describes the care and use of a dry powder inhaler (DPI).

### **Chart 30-7**

## **Patient and Family Education: Preparing for Self-Management**

### **How to Use an Inhaler Correctly**

#### **With a Spacer (Preferred Technique)**

1. Before each use, remove the caps from the inhaler and the spacer.
2. Insert the mouthpiece of the inhaler into the nonmouthpiece end of the spacer.
3. Shake the whole unit vigorously three or four times.
4. Fully exhale and then place the mouthpiece into your mouth, over your tongue, and seal your lips tightly around it.
5. Press down firmly on the canister of the inhaler to release one dose of medication into the spacer.
6. Breathe in slowly and deeply. If the spacer makes a whistling sound, you are breathing in too rapidly.
7. Remove the mouthpiece from your mouth; and, keeping your lips closed, hold your breath for at least 10 seconds and then breathe out slowly.
8. Wait at least 1 minute between puffs.
9. Replace the caps on the inhaler and the spacer.

. At least once a day, clean the plastic case and cap of the inhaler by thoroughly rinsing in warm, running tap water; at least once a week, clean the spacer in the same manner.

#### **Without a Spacer**

1. Before each use, remove the cap and shake the inhaler according to the instructions in the package insert.
2. Tilt your head back slightly and breathe out fully.
3. Open your mouth and place the mouthpiece 1 to 2 inches away.
4. As you begin to breathe in deeply through your mouth, press down firmly on the canister of the inhaler to release one dose of medication.
5. Continue to breathe in slowly and deeply (usually over 5-7 sec).
6. Hold your breath for at least 10 seconds to allow the medication to reach deep into the lungs and then breathe out slowly.
7. Wait at least 1 minute between puffs.

8. Replace the cap on the inhaler.
  9. At least once a day, remove the canister and clean the plastic case and cap of the inhaler by thoroughly rinsing in warm, running tap water.
- . Avoid spraying in the direction of the eyes.

**FIG. 30-5** Patient using an aerosol metered dose inhaler with a spacer.

### **Chart 30-8**

## **Patient and Family Education: Preparing for Self-Management**

### **How to Use a Dry Powder Inhaler (DPI)**

#### **For Inhalers Requiring Loading**

- First load the drug by:
  - Turning the device to the next dose of drug, *or*
  - Inserting the capsule into the device, *or*
  - Inserting the disk or compartment into the device

#### **After Loading the Drug and for Inhalers That Do Not Require Drug Loading**

- Read your doctor's instructions for how fast you should breathe for your particular inhaler.
- Exhale fully away from the inhaler.
- Place your lips over the mouthpiece and breathe in forcefully (there is no propellant in the inhaler; only your breath pulls the drug in).
- Remove the inhaler from your mouth as soon as you have breathed in.
- *Never exhale (breathe out) into your inhaler.* Your breath will moisten the powder, causing it to clump and not be delivered accurately.

- *Never wash or place the inhaler in water.*
- *Never shake your inhaler.*
- Keep your inhaler in a dry place at room temperature.
- If the inhaler is preloaded, discard it after it is empty.
- Because the drug is a dry powder and there is no propellant, you may not feel, smell, or taste it as you inhale.

## Nursing Safety Priority QSEN

### Action Alert

Teach the patient with asthma to always carry the relief drug inhaler with him or her and to ensure that enough drug remains in the inhaler to provide a quick dose when needed.

Dry powder inhalers indicate the amount of remaining drug. Most aerosol inhalers (MDIs) now have meters that indicate the number of doses left in the canister, but some do not. It is recommended that the patient count the number of doses as they are used; however, many patients have difficulty keeping the dose count accurate.

Long-acting beta<sub>2</sub> agonists (LABAs) are also delivered by inhaler directly to the site of action—the bronchioles. Proper use of the long-acting agonists decreases the need to use reliever drugs as often. Unlike short-acting agonists, long-acting drugs need time to build up an effect, but the effects are longer lasting. These drugs are useful in *preventing* an asthma attack but cannot stop an acute attack. Therefore teach patients not to use LABAs alone to relieve symptoms of an attack or when wheezing is getting worse but, instead, to use a SABA. Examples of LABAs include formoterol (Perforomist, Zenhale ) and salmeterol (Serevent). Both drugs are associated with increased asthma deaths, especially when used as the only therapy for asthma, and have a black box warning from the Food and Drug Administration (FDA).

## Nursing Safety Priority QSEN

### Drug Alert

LABAs should never be prescribed as the *only* drug therapy for asthma and are not to be used during an acute asthma attack or bronchospasm. Teach the patient to use these control drugs daily as prescribed, even when no symptoms are present, and to use a SABA to relieve acute symptoms. Any patient using these drugs must be monitored closely.

*Cholinergic antagonists*, also called *anticholinergic drugs* or *long-acting muscarinic antagonists* (LAMAs), are similar to atropine and block the parasympathetic nervous system. This action increases bronchodilation and decreases secretions. The main drug in this class is ipratropium (Apo-Ipravent , Atrovent), which is used as an inhalant. Most cholinergic antagonists are short acting and are used several times a day. Long-acting agents such as tiotropium (Spiriva) are used once a day.

*Xanthines* such as theophylline and aminophylline are used rarely, only when other types of management are ineffective. These drugs are given systemically, and the dosage that is effective is close to the dosage that produces many dangerous side effects. Blood levels must be monitored closely to ensure that the drug level is within the therapeutic range.

### Anti-Inflammatory Agents.

Anti-inflammatory agents decrease airway inflammation. The inhaled forms have fewer systemic side effects than those taken systemically. *All of the anti-inflammatory drugs, whether inhaled or taken orally, are controller drugs only.*

## Nursing Safety Priority QSEN

### Drug Alert

Anti-inflammatory drug therapy for asthma is for prevention or control of asthma. They are *not* effective in reversing symptoms during an asthma attack and should not be used alone as reliever drugs. Teach patients to take anti-inflammatory asthma drugs on a scheduled basis, even when no symptoms are present.

*Corticosteroids* decrease inflammation mainly by reducing the production of inflammatory chemicals. Inhaled corticosteroids (ICSs) can be helpful in controlling asthma symptoms. High-potency steroid inhalers, such as fluticasone (Flovent), budesonide (Pulmicort), and mometasone (Asmanex), may be used once per day for maintenance. Newer approved drugs for asthma control include those that are combinations of an inhaled corticosteroid and an inhaled beta<sub>2</sub> agonist, such as Breo Elipta (fluticasone and vilanterol). This combination comes in different strengths and is used once daily.

Systemic corticosteroids, because of severe side effects, are avoided for mild-to-moderate intermittent asthma and are used on a short-term basis for moderate asthma. For some patients with severe asthma, daily oral corticosteroids may be needed.

*Cromones*, either inhaled or taken orally, are useful as *controller* asthma therapy when taken on a scheduled basis. These agents reduce airway inflammation by either inhibiting the release of inflammatory chemicals (nedocromil [Tilade]) or preventing mast cell membranes from opening when an allergen binds to IgE (cromolyn sodium [Intal]).

*Leukotriene modifiers* are oral drugs that work in several ways to control asthma when taken on a scheduled basis. Montelukast (Singulair) and zafirlukast (Accolate) block the leukotriene receptor. Zileuton (Zyflo) prevents leukotriene synthesis.

### Exercise and Activity.

Regular exercise is a recommended part of asthma therapy to maintain cardiac health, strengthen muscles, and promote GAS EXCHANGE and PERFUSION. Teach patients to examine the conditions that trigger an attack and adjust the exercise routine as needed. Some may need to use an inhaled SABA before beginning activity. For others, adjusting the environment may be needed (e.g., changing from outdoor ice-skating in cold, dry air to indoor ice-skating).

### Oxygen Therapy.

Supplemental oxygen by mask or nasal cannula is often used during an acute asthma attack. High-flow delivery may be needed when bronchospasms are severe and limit flow of oxygen through the bronchiole tubes (see [Chapter 28](#) for high-flow delivery systems).

## Nursing Safety Priority QSEN

### Action Alert

Ensure that no open flames (e.g., cigarette smoking, fireplaces, burning candles) or other combustion hazards are in rooms where oxygen is in use.

### Status Asthmaticus.

Status asthmaticus is a severe, life-threatening acute episode of airway obstruction that intensifies once it begins and often does not respond to usual therapy. The patient arrives in the emergency department with extremely labored breathing and wheezing. Use of accessory muscles for breathing and distention of neck veins are observed. *If the condition is not reversed, the patient may develop pneumothorax and cardiac or respiratory arrest.* IV fluids, potent systemic bronchodilators, steroids, epinephrine, and oxygen are given immediately to reverse the condition. Magnesium sulfate also may be used. Prepare for emergency intubation. Sudden absence of wheezing indicates complete airway obstruction and requires a tracheotomy. When breathing improves, management

is similar to that for any patient with asthma.

## NCLEX Examination Challenge 30-1

### Health Promotion and Maintenance

A client newly diagnosed with moderate asthma asks whether he can just take salmeterol instead of salmeterol and albuterol, because he has read that they are both beta agonists. What is the nurse's **best** advice?

- A. Yes; both of these drugs have the same action, and you only need one.
- B. Yes, because they both need to be used daily whether you are having symptoms or not; just take a little more of the salmeterol and don't take any of the albuterol.
- C. No; albuterol is used to relieve the symptoms during an actual asthma attack, and salmeterol is used to prevent an attack. Both are needed."
- D. No; albuterol is taken through the use of an aerosol inhaler, and salmeterol is an oral drug (tablet) that is activated in the stomach. Both are needed."

## Gas Exchange Concept Exemplar Chronic Obstructive Pulmonary Disease

### Pathophysiology

Chronic obstructive pulmonary diseases (COPD) interfere with airflow and GAS EXCHANGE. These disorders include emphysema and chronic bronchitis. Although these are separate disorders with different pathologic processes, many patients with emphysema also have chronic bronchitis (Fig. 30-6).

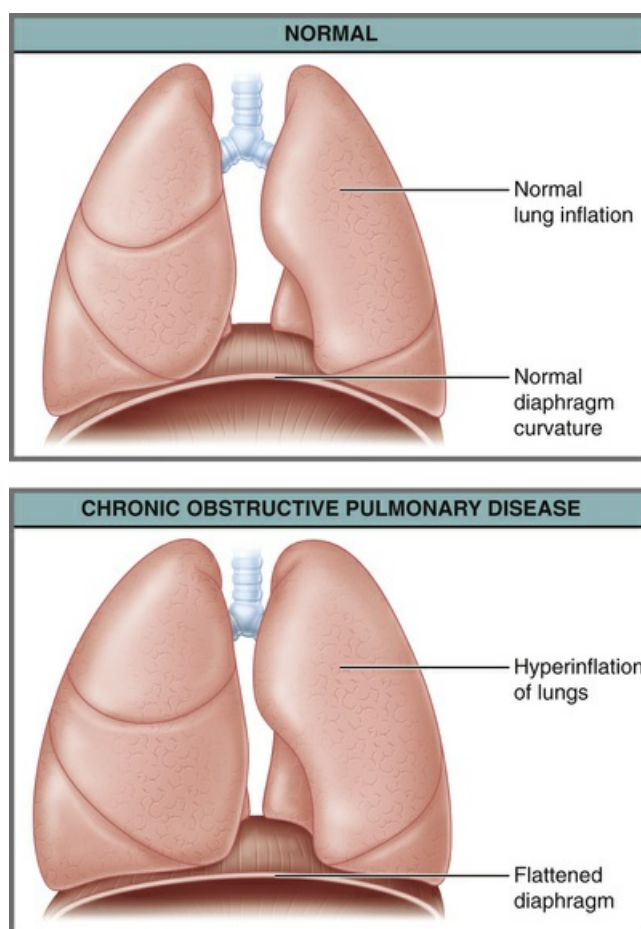

**FIG. 30-6** The interaction of chronic bronchitis and emphysema in chronic obstructive pulmonary disease (COPD).

### Emphysema

The two major changes that occur with emphysema are loss of lung elasticity and hyperinflation of the lung (see Fig. 30-1). These changes result in dyspnea, reduced GAS EXCHANGE, and the need for an increased respiratory rate.

In the healthy lung, enzymes called *proteases* are present to destroy and eliminate particulates inhaled during breathing. Cigarette smoking triggers increased synthesis of these enzymes. When these proteases are present in higher-than-normal levels, they damage the alveoli and the small airways by breaking down elastin. Over time, alveolar sacs lose their elasticity, and the small airways collapse or narrow. Some alveoli are destroyed, and others become large and flabby, with less area for GAS EXCHANGE.

An increased amount of air is trapped in the lungs. Causes of air trapping are loss of elastic recoil in the alveolar walls, overstretching and enlargement of the alveoli into air-filled spaces called *bullae*, and collapse of small bronchioles. These changes greatly increase the work of breathing and interfere with airflow to the lungs. The hyperinflated lung flattens the diaphragm (Fig. 30-7), weakening the effectiveness of this muscle. As a result, the patient with emphysema needs to use accessory muscles in the neck, chest wall, and abdomen to inhale and exhale. This increased effort increases the need for oxygen, making the patient have an “air hunger” sensation. Inhalation starts before exhalation is completed, resulting in an uncoordinated breathing pattern.

**FIG. 30-7** Diaphragm shape and lung inflation in the normal patient and in the patient with chronic airflow limitation (CAL), especially chronic obstructive pulmonary disease (COPD).

GAS EXCHANGE is affected by the increased work of breathing and the loss of alveolar tissue. Although some alveoli enlarge, the curves of alveolar walls decrease, and less surface area is available for gas exchange. Often the patient adjusts by increasing the respiratory rate, so arterial blood gas (ABG) values may not show gas exchange problems until the patient has advanced disease. Then carbon dioxide is produced faster than it can be eliminated, resulting in carbon dioxide retention and chronic respiratory acidosis (see [Chapter 12](#)). The patient with late-stage emphysema also has a low arterial oxygen ( $\text{PaO}_2$ ) level because it is difficult for oxygen to move from diseased alveoli into the blood.

Emphysema is classified as *panlobular*, *centrilobular*, or *paraseptal*, depending on the pattern of destruction and dilation of the gas-exchanging units (acini) (see [Fig. 30-1](#)). Each type can occur alone or in combination in the same lung. Most are associated with smoking or chronic exposure to other inhaled particles such as wood smoke and biomass fuels ([Global Initiative for Chronic Obstructive Lung Disease \[GOLD\], 2017](#)).

### Chronic Bronchitis

Bronchitis is an inflammation of the bronchi and bronchioles caused by exposure to irritants, especially cigarette smoke. The irritant triggers inflammation, vasodilation, mucosal edema, congestion, and bronchospasm. Bronchitis affects only the airways, not the alveoli.

Chronic inflammation increases the number and size of mucus-secreting glands, which produce large amounts of thick mucus. The bronchial walls thicken and impair airflow. This thickening, along with excessive mucus, blocks some of the smaller airways and narrows larger ones. The increased mucus provides a breeding ground for organisms and leads to chronic infection.

Chronic bronchitis impairs airflow and GAS EXCHANGE because mucus plugs and infection narrow the airways. As a result, the  $\text{PaO}_2$  level decreases (hypoxemia), and the arterial carbon dioxide ( $\text{PaCO}_2$ ) level increases (respiratory acidosis).

## Etiology and Genetic Risk

*Cigarette smoking* is the greatest risk factor for COPD. The patient with a 20-pack-year history or longer often has early-stage COPD with changes in pulmonary function tests (PFTs).

The inhaled smoke triggers the release of excessive proteases in the lungs. These enzymes break down elastin, the major component of alveoli. By impairing the action of cilia, smoking also inhibits the cilia from clearing the bronchi of mucus, cellular debris, and fluid.

*Alpha<sub>1</sub>-antitrypsin deficiency* is a less common but important risk factor for COPD, although it is often underrecognized (Kessenich & Bacher, 2015). The enzyme alpha<sub>1</sub>-antitrypsin (AAT) is normally present in the lungs. AAT inhibits excessive protease activity so the proteases only break down inhaled pollutants and organisms and do not damage lung structures.

The production of normal amounts of AAT depends on the inheritance of a pair of normal gene alleles for this protein. The AAT gene is recessive. Thus if one of the pair of alleles is faulty and the other allele is normal, the adult makes enough AAT to prevent COPD unless there is significant exposure to cigarette smoke or other inhalation irritants. However, this adult is a carrier for AAT deficiency. When both alleles are faulty, COPD develops at a fairly young age even when the person is not exposed to cigarette smoke or other irritants.

About 100,000 Americans have severe AAT deficiency, and many more have mild-to-moderate deficiencies. Although an AAT deficiency also can cause problems in the skin and liver, lung diseases are more common (Kessenich & Bacher, 2014).

## Genetic/Genomic Considerations

### Patient-Centered Care QSEN

The gene for AAT has many known variations, and some increase the risk for emphysema. Different variations result in different levels of AAT deficiency, which is why the disease is more severe for some adults than for others (OMIM, 2016b). The most serious variation for emphysema risk is the Z mutation, although others also increase the risk but to a lesser degree. Table 30-1 shows the most common AAT mutations increasing the risk for emphysema. Urge patients who have any AAT deficiency to avoid smoking and other environmental pollutants.

**TABLE 30-1**

**Characteristics Associated With the Most Common Alpha<sub>1</sub>-Antitrypsin Gene Mutations**

MUTATION GENOTYPE	LEVEL OF SERUM ALPHA <sub>1</sub> -ANTITRYPSIN (% OF NORMAL)	DISEASE SEVERITY
M/S	80%	No detectable disease
S/S	50%-60%	Minimal to no disease expression
M/Z	50%-55%	Minimal to no disease expression
S/Z	30%-35%	Pulmonary disease, early age
Z/Z	10%-15%	Severe COPD, extrapulmonary involvement

*COPD*, Chronic obstructive pulmonary disease.

In addition to genetic and environmental factors, asthma also appears to be a risk factor for COPD. The incidence of COPD is reported to be 12 times greater among adults with asthma than among adults without asthma after adjusting for smoking history (GOLD, 2017).

## Incidence and Prevalence

The prevalence of chronic bronchitis and emphysema in the United States has been estimated at about 15.8 million and 800,000 in Canada (CDC, 2016; Statistics Canada, 2016b). More than 10% of nursing home residents have COPD. COPD is the fourth leading cause of morbidity and mortality in the United States (GOLD, 2017).

## Complications

COPD affects GAS EXCHANGE and the oxygenation of all tissues. Complications include hypoxemia, acidosis, respiratory infection, cardiac failure, dysrhythmias, and respiratory failure.

*Hypoxemia and acidosis* occur because the patient with COPD has reduced gas exchange, leading to decreased oxygenation and increased carbon dioxide levels. These problems reduce cellular

function.

*Respiratory infection* risk increases because of the increased mucus and poor GAS EXCHANGE. Bacterial infections are common and make COPD symptoms worse by increasing inflammation and mucus production and inducing more bronchospasm. Airflow becomes even more limited, the work of breathing increases, and dyspnea results.

*Cardiac failure*, especially **cor pulmonale** (right-sided heart failure caused by pulmonary disease), occurs with bronchitis or emphysema. Air trapping, airway collapse, and stiff alveolar walls increase the lung tissue pressure and narrow lung blood vessels, making blood flow more difficult. The increased pressure creates a heavy workload on the right side of the heart, which pumps blood into the lungs. To pump blood through the narrowed vessels, the right side of the heart generates high pressures. In response to this heavy workload, the right chambers of the heart enlarge and thicken, causing right-sided heart failure with backup of blood into the general venous system. [Chart 30-9](#) lists key features of cor pulmonale.

### Chart 30-9

## Key Features

### Cor Pulmonale

<ul style="list-style-type: none"><li>• Hypoxia and hypoxemia</li><li>• Increasing dyspnea</li><li>• Fatigue</li><li>• Enlarged and tender liver</li><li>• Warm, cyanotic hands and feet, with bounding pulses</li><li>• Cyanotic lips</li><li>• Distended neck veins</li><li>• Right ventricular enlargement (hypertrophy)</li></ul>	<ul style="list-style-type: none"><li>• Visible pulsations below the sternum</li><li>• GI disturbances such as nausea or anorexia</li><li>• Dependent edema</li><li>• Metabolic and respiratory acidosis</li><li>• Pulmonary hypertension</li></ul>
---	---

*Cardiac dysrhythmias* are common in patients with COPD. They result from hypoxemia (from decreased oxygen to the heart muscle), other cardiac disease, drug effects, or acidosis.

## Health Promotion and Maintenance

The incidence and severity of COPD would be greatly reduced by smoking cessation. Urge all adults who smoke to quit smoking. [Chart 27-2](#) provides tips to teach adults about smoking cessation. In addition, as described in [Chapter 27](#), teach all adults specific actions to take to avoid exposure to other inhalation irritants.

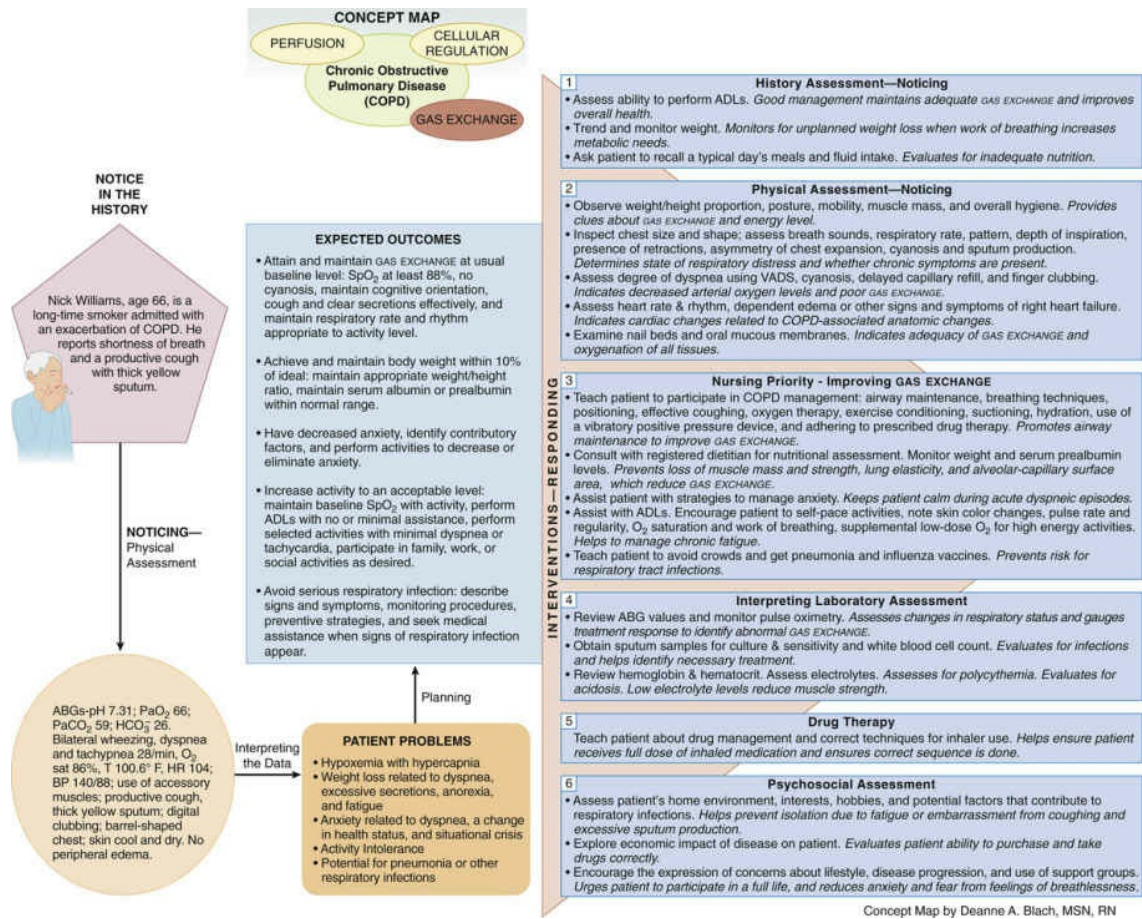

## ❖ Interprofessional Collaborative Care

Although COPD is a life-limiting chronic disorder, most patients live decades in the community, although management is continuous. Acute infections and other complications often require hospital stays. Adults with COPD may be admitted to the hospital for other health problems or surgery and require continued COPD management.

COPD can affect every aspect of a patient's life, and care is best provided by an interprofessional team. In addition to primary health care providers and nurses, other professionals important to ensuring optimal management include registered dietitians, pharmacists, respiratory therapists, occupational therapists, physical therapists, social workers, patient navigators, community health workers, and mental health practitioners ([Bracken, 2016](#)). Like many chronic disorders, COPD management is most effective when the patient and family are full partners with the health care team.

The [Concept Map](#) addresses interprofessional care issues related to COPD.

## ◆ Assessment: Noticing

### History.

Ask about risk factors such as age, gender, and occupational history. COPD is seen more often in older men. Some types of emphysema occur in families, especially those with alpha<sub>1</sub>-antitrypsin (AAT) deficiency.

Obtain a thorough smoking history, because tobacco use is a major risk factor. Ask about the length of time the patient has smoked and the number of packs smoked daily. Use these data to determine the pack-year smoking history.

Ask the patient to describe the breathing problems and assess whether he or she has any difficulty breathing while talking. Does he or she speak in complete sentences, or is it necessary to take a breath between every one or two words? Ask about the presence, duration, or worsening of wheezing, coughing, and shortness of breath. Determine which activities trigger these problems. Assess any cough, and ask whether sputum is clear or colored and how much is produced each day. Ask about the time of day when sputum production is greatest. Smokers often have a productive cough when they get up in the morning; nonsmokers generally do not.

Ask the patient to compare the activity level and shortness of breath now with those of a month ago and a year ago. Ask about any difficulty with eating and sleeping. Many patients sleep in a semi-sitting position because breathlessness is worse when lying down (**orthopnea**). Ask about any difficulty with ADLs or sexual activity. Document this assessment to personalize the intervention plan.

Weigh the patient and compare this weight with previous weights. Unplanned weight loss is likely when COPD severity increases, because the work of breathing increases metabolic needs. Dyspnea and mucus production often result in poor food intake and inadequate nutrition. Ask the patient to recall a typical day's meals and fluid intake. When heart failure is present with COPD, general edema with weight gain may occur.

## Physical Assessment/Signs and Symptoms.

*General appearance* can provide clues about respiratory status and energy level. Observe weight in proportion to height, posture, mobility, muscle mass, and overall hygiene. The patient with increasingly severe COPD is thin, with loss of muscle mass in the extremities, although the neck muscles may be enlarged. He or she tends to be slow moving and slightly stooped. The patient often sits in a forward-bending posture with the arms held forward, a position known as the *orthopneic* or *tripod position* (Fig. 30-8). When dyspnea becomes severe, activity intolerance may be so great that bathing and general grooming are neglected.

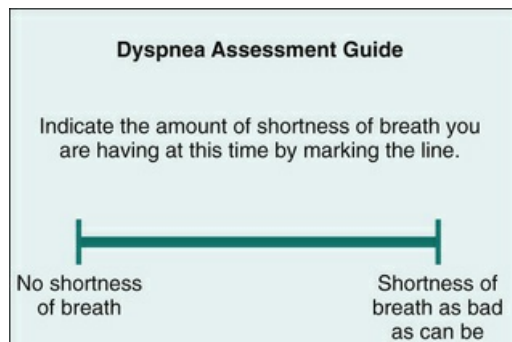

**FIG. 30-8** Orthopnea positions that patients with chronic obstructive pulmonary disease (COPD) often assume to ease the work of breathing.

*Respiratory changes* occur as a result of obstruction, changes in chest size, and fatigue. Inspect the chest and assess the breathing rate and pattern. The patient with respiratory muscle fatigue breathes with rapid, shallow respirations and may have an abnormal breathing pattern in which the abdominal wall is sucked in during inspiration or may use accessory muscles in the abdomen or neck. During an acute exacerbation, the respiratory rate could be as high as 40 to 50 breaths/min and requires immediate medical attention. As respiratory muscles become fatigued, respiratory movement is jerky and appears uncoordinated.

Check the patient's chest for retractions and asymmetric chest expansion. The patient with emphysema has limited diaphragmatic movement (excursion) because the diaphragm is flattened and below its usual resting state. Chest vibration (fremitus) is often decreased, and the chest sounds hyperresonant on percussion because of trapped air (Jarvis, 2016).

Auscultate the chest to assess the depth of inspiration and any abnormal breath sounds. Wheezes and other abnormal sounds often occur on inspiration and expiration, although crackles are usually not present. Reduced breath sounds are common, especially with emphysema. Note the pitch and location of the sound and the point in the respiratory cycle at which the sound is heard. A silent chest may indicate serious airflow obstruction or pneumothorax.

Assess the degree of dyspnea using a visual analog dyspnea scale (VADS), which is a straight line with verbal anchors at the beginning and end of a 100-mm line (Fig. 30-9). Ask the patient to place a mark on the line to indicate his or her breathing difficulty. Document and use this scale to determine the therapy effectiveness and pace the patient's activities.

**FIG. 30-9** Visual analog scale to assess dyspnea. (Modified from Gift, A. [1989]. A dyspnea assessment guide. *Critical Care Nurse*, 9[8], 79. Used with permission.)

Examine the patient's chest for the presence of a “barrel chest” (see Fig. 30-3). With a barrel chest, the ratio between the anteroposterior (AP) diameter of the chest and its lateral diameter is 1 : 1 rather than the normal ratio of 1 : 1.5, as a result of lung overinflation and diaphragm flattening (Jarvis, 2016).

The patient with chronic bronchitis often has a cyanotic, or blue-tinged, dusky appearance and has excessive sputum production. Assess for cyanosis, delayed capillary refill, and finger clubbing (Fig. 30-10), which indicate chronically decreased arterial oxygen levels and poor GAS EXCHANGE.

**FIG. 30-10** Late digital clubbing (on left) compared with a normal digit (on right). (From Swartz, M. H. (2009). *Textbook of physical diagnosis: History and examination* [6th ed.]. Philadelphia: Saunders.)

*Cardiac changes* occur as a result of the anatomic changes associated with COPD. Assess the patient's heart rate and rhythm. Check for swelling of the feet and ankles (dependent edema) or other signs of right-sided heart failure. Examine nail beds and oral mucous membranes. In late-stage emphysema the patient may have pallor or cyanosis and is usually underweight.

### Psychosocial Assessment.

COPD affects all aspects of a patient's life. He or she may be isolated because dyspnea causes fatigue or because of embarrassment from coughing and excessive sputum production.

Ask the patient about interests and hobbies to assess whether socialization has decreased or whether hobbies cause exposure to irritants. Ask about home conditions for exposure to smoke or crowded living conditions that promote transmission of respiratory infections.

Economic status may be affected by the disease through changes in income and health insurance coverage. Drugs, especially the metered dose inhalers (MDIs) and dry powder inhalers (DPIs), are expensive, and many patients with limited incomes may use them only during exacerbations and not as prescribed on a scheduled basis.

Anxiety and fear from feelings of breathlessness may reduce the patient's ability to participate in a full life. Work, family, social, and sexual roles can be affected. Encourage the patient and family to express their feelings about the limitations on lifestyle and disease progression. Assess their use of support groups and community services.

### Laboratory Assessment.

Arterial blood gas (ABG) values identify abnormal GAS EXCHANGE, oxygenation, ventilation, and acid-base status. Compare repeated ABG values to assess changes in respiratory status. Once baseline ABG values are obtained, pulse oximetry can gauge treatment response. As COPD

worsens, the amount of oxygen in the blood decreases (**hypoxemia**), and the amount of carbon dioxide increases (**hypercarbia**). Chronic respiratory acidosis (increased arterial carbon dioxide [PaCO<sub>2</sub>]) then results; metabolic alkalosis (increased arterial bicarbonate) occurs as compensation by kidney retention of bicarbonate. This change is seen on ABGs as an elevation of HCO<sub>3</sub><sup>-</sup> although pH remains lower than normal. Not all patients with COPD are CO<sub>2</sub> retainers, even when hypoxemia is present, because CO<sub>2</sub> diffuses more easily across lung membranes than does oxygen. Hypercarbia is a problem in advanced emphysema (because the alveoli are affected) rather than in bronchitis (in which the airways are affected).

Sputum samples are obtained for culture from hospitalized patients with an acute respiratory infection. The infection is treated on the basis of symptoms and the common bacterial organisms in the local community. A WBC count helps confirm the presence of infection.

Other blood tests include hemoglobin and hematocrit to determine *polycythemia* (a compensatory increase in red blood cells [RBCs] and iron in the chronically hypoxic patient). Serum electrolyte levels are examined because acidosis can change electrolyte values. Low phosphate, potassium, calcium, and magnesium levels reduce muscle strength. In patients with a family history of COPD, serum AAT levels may be drawn.

### Imaging Assessment.

Chest x-rays are used to rule out other lung diseases and to check the progress of patients with respiratory infections or chronic disease. With advanced emphysema, chest x-rays show hyperinflation and a flattened diaphragm.

### Other Diagnostic Assessments.

COPD is classified from mild to very severe on the basis of symptoms and pulmonary function test (PFT) changes (Table 30-2; see Table 27-6). Airflow rates and lung volume measurements help distinguish airway disease (obstructive diseases) from interstitial lung disease (restrictive diseases). PFTs determine lung volumes, flow volume curves, and diffusion capacity. Each test is performed before and after the patient inhales a bronchodilator agent. Encourage the patient to express his or her feelings about testing and the potential impact of the results. Explain the preparations for the procedures (if any), whether pain or discomfort will be involved, and any needed follow-up care.

**TABLE 30-2**  
**Gold Classification of COPD Severity**

CLASS	PULMONARY FUNCTION TEST RESULTS
GOLD 1: Mild	FEV <sub>1</sub> ≥80% of predicted
GOLD 2: Moderate	FEV <sub>1</sub> 50% to 79% of predicted
GOLD 3: Severe	FEV <sub>1</sub> 30% to 49% of predicted
GOLD 4: Very severe	FEV <sub>1</sub> <30% of predicted

*COPD*, Chronic obstructive pulmonary disease; *FEV*<sub>1</sub>, volume of air blown out as hard and fast as possible during the first second of the most forceful exhalation after the greatest full inhalation; *FVC*, functional vital capacity.

Data from Global Initiative for Chronic Obstructive Lung Disease (GOLD). (2017). *Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease*. <http://goldcopd.org/wp-content/uploads/2016/12/wms-GOLD-2017-Pocket-Guide.pdf>.

Although the severity classification in Table 30-2 can help clinicians determine overall disease severity, it does not predict how well the patient can manage his or her activity on a daily basis and how likely an acute exacerbation could occur. So this classification was modified in 2017 to include the severity indications based on symptom scores obtained with the patient responses to the COPD Assessment Test (CAT) (GOLD, 2017). This 8-item test requires the patient to rate his or her specific symptoms on a 0 (no symptom) to a 5 (worst symptom) scale. Scores can range from 0 to 40, with lower scores indicating less severe problems. As a result, each of the GOLD classes also can contain an ABCD designation for actual symptom severity as an indicator of risk for exacerbation. An *A* designation indicates a low risk for exacerbation, even when the patient has a GOLD class of 4 (very severe disease), whereas a *D* designation indicates a high risk for exacerbation (and need for hospitalization), even if the patient meets PFT results associated with a GOLD class of 1 (mild disease). It is hoped that use of the new classification can help clinicians better recognize when interventions are needed to prevent an acute exacerbation.

The lung volumes measured for COPD are vital capacity (VC), residual volume (RV), forced expiratory volume (FEV), and total lung capacity (TLC). Although all volumes and capacities change to some degree in COPD, the RV is most affected, with increases reflecting the trapped, stale air remaining in the lungs that interferes with GAS EXCHANGE.

A diagnosis of COPD is based mostly on the FEV<sub>1</sub> (the FEV in the first second of exhalation). FEV<sub>1</sub> can also be expressed as a percentage of the forced vital capacity (FVC). As the disease progresses, the ratio of FEV<sub>1</sub> to FVC becomes smaller.

The diffusion test measures how well a test gas (carbon monoxide) diffuses across the alveolar-capillary membrane and combines with hemoglobin. In emphysema, alveolar wall destruction decreases the large surface area for diffusion of gas into the blood, leading to a decreased diffusion capacity. In bronchitis alone, the diffusion capacity is usually normal.

The patient with COPD has decreased oxygen saturation, often much lower than 90%. Changes in SpO<sub>2</sub> below the patient's usual saturation require medical attention. Patients who have been managing COPD for a long time often are aware of their usual SpO<sub>2</sub> values.

Peak expiratory flow meters are used to monitor the effectiveness of drug therapy to relieve obstruction. Peak flow rates increase as obstruction resolves. Teach the patient to self-monitor the peak expiratory flow rates at home and adjust drugs as needed.

### ◆**Analysis: Interpreting**

The priority collaborative problems for patients with chronic obstructive pulmonary disease (COPD) include:

1. Decreased GAS EXCHANGE due to alveolar-capillary membrane changes, reduced airway size, ventilatory muscle fatigue, excessive mucus production, airway obstruction, diaphragm flattening, fatigue, and decreased energy
2. Weight loss due to dyspnea, excessive secretions, anorexia, and fatigue
3. Anxiety due to a change in health status, and situational crisis
4. Decreased endurance due to fatigue, dyspnea, and an imbalance between oxygen supply and demand
5. Potential for pneumonia or other respiratory infections due to presence of thick secretions and the immunosuppressive effects of some drugs

### ◆**Planning and Implementation: Responding**

#### **Improving Gas Exchange and Reducing Carbon Dioxide Retention**

##### **Planning: Expected Outcomes.**

The patient with COPD is expected to attain and maintain GAS EXCHANGE at his or her usual baseline level. Indicators include that the patient:

- Maintains SpO<sub>2</sub> of at least 88%
- Remains free from cyanosis
- Maintains cognitive orientation
- Coughs and clears secretions effectively
- Maintains a respiratory rate and rhythm appropriate to his or her activity level

##### **Interventions.**

Most patients with COPD use nonsurgical management to improve or maintain GAS EXCHANGE. Surgical management requires that the patient meet strict criteria.

##### **Nonsurgical Management.**

Nursing management for patients with COPD focuses on airway maintenance, monitoring, breathing techniques, positioning, effective coughing, oxygen therapy, exercise conditioning,

suctioning, hydration, and use of a vibratory positive-pressure device. A nursing priority is to teach the patient how to be a partner in COPD management by participating in therapies to improve GAS EXCHANGE and by adhering to prescribed drug therapy.

Before any intervention, assess the breathing rate, rhythm, depth, and use of accessory muscles. The accessory muscles are less efficient than the diaphragm, and the work of breathing increases. Determine whether any factors are contributing to the increased work of breathing, such as respiratory infection. *Airway maintenance is the most important focus of interventions to improve GAS EXCHANGE.*

### Monitoring.

Monitoring for changes in respiratory status is key to providing prompt interventions to reduce complications. Assess the hospitalized patient with COPD at least every 2 hours, even when the purpose of hospitalization is not COPD management. Apply prescribed oxygen, assess the patient's response to therapy, and prevent complications.

If the patient's condition worsens, more aggressive therapy is needed. Noninvasive ventilation (NIV) may be useful for patients with stable, very severe COPD and daytime hypercapnia (GOLD, 2017). Intubation and mechanical ventilation may be needed for patients in respiratory failure.

### Breathing Techniques.

Diaphragmatic or abdominal and pursed-lip breathing may be helpful for managing dyspneic episodes. Teach the patient to use these techniques, shown in Chart 30-10, during all activities to reduce the amount of stale air in the lungs and manage dyspnea. Teach these techniques when the patient has less dyspnea.

## Chart 30-10

# Patient and Family Education: Preparing for Self-Management

## Breathing Exercises

### Diaphragmatic or Abdominal Breathing

- If you can do so comfortably, lie on your back with your knees bent. If you cannot lie comfortably, perform this exercise while sitting in a chair.
- Place your hands or a book on your abdomen to create resistance.
- Begin breathing from your abdomen while keeping your chest still. You can tell if you are breathing correctly if your hands or the book rises and falls accordingly.

### Pursed-Lip Breathing

- Close your mouth and breathe in through your nose.
- Purse your lips as you would to whistle. Breathe out slowly through your mouth, without puffing your cheeks. Spend at least twice the amount of time it took you to breathe in.

- Use your abdominal muscles to squeeze out every bit of air you can.
- Remember to use pursed-lip breathing during any physical activity. Always inhale before beginning the activity and exhale while performing it. Never hold your breath.

In diaphragmatic breathing, the patient consciously increases movement of the diaphragm. Lying on the back allows the abdomen to relax. Breathing through pursed lips creates mild resistance, which prolongs exhalation and increases airway pressure. This technique delays airway compression and reduces air trapping.

### Positioning.

Placing the patient in an upright position with the head of the bed elevated can help alleviate dyspnea by increasing chest expansion and keeping the diaphragm in the proper position to contract. This position conserves energy by supporting the patient's arms and upper body. Help the patient who can tolerate sitting in a chair to get out of bed for 1-hour periods two to three times a day.

### Effective Coughing.

Coughing effectively can improve GAS EXCHANGE by helping increase airflow in the larger airways. The patient with COPD has difficulty removing secretions, which results in poor gas exchange. Excessive mucus increases the risk for infections.

Controlled coughing is helpful in removing excessive mucus. Teach the patient to cough on arising in the morning to eliminate mucus that collected during the night. Coughing to clear mucus before mealtimes may make meals more pleasant. Coughing before bedtime may help clear lungs for a less interrupted night's sleep.

For effective coughing, teach the patient to sit in a chair or on the side of a bed with feet placed firmly on the floor. Instruct him or her to turn the shoulders inward and to bend the head slightly downward, hugging a pillow against the stomach. The patient then takes a few breaths, attempting to exhale more fully. After the third to fifth breath (in through the nose, out through pursed lips), instruct him or her to take a deeper breath and bend forward slowly while coughing two or three times ("mini" coughs) from the same breath. On return to a sitting position, the patient takes a comfortably deep breath. The entire coughing procedure is repeated at least twice.

### Oxygen Therapy.

Oxygen is prescribed for relief of hypoxemia and hypoxia. The need for oxygen therapy and its effectiveness can be determined by arterial blood gas (ABG) values and oxygen saturation. The patient with COPD may need an oxygen flow of 2 to 4 L/min via nasal cannula or up to 40% via Venturi mask. Ensure that there are no open flames in rooms in which oxygen is in use. See [Chapter](#)

28 for information on oxygen therapy.

In the past, the patient with COPD was thought to be at risk for extreme hypoventilation with oxygen therapy because of a decreased drive to breathe as blood oxygen levels rose. However, this concern has not been shown to be evidence based and has been responsible for ineffective management of hypoxia in patients with COPD. All hypoxic patients, even those with COPD and hypercarbia, should receive oxygen therapy at rates appropriate to reduce hypoxia and bring SpO<sub>2</sub> levels up between 88% and 92% (Burt & Corbridge, 2013; Makic et al., 2013).

### Drug Therapy.

Drugs used to manage COPD are the same drugs as for asthma and include beta-adrenergic agents, cholinergic antagonists, xanthines, corticosteroids, and cromones (see Chart 30-6). The focus is on long-term control therapy with longer-acting drugs, such as arformoterol (Brovana); indacaterol (Arcapta Neohaler); tiotropium (Spiriva); aclidinium bromide (Tudorza Pressair); olodaterol (Striverdi); and the combination drugs, such as fluticasone/vilanterol (BREQ ELLIPTA), olodaterol/tiotropium (STIOLTO RESPIMAT), and vilanterol/umeclidinium (ANORO ELLIPTA). The patient with COPD is more likely to be taking systemic agents in addition to inhaled drugs. Another drug class for COPD is the mucolytics, which thin the thick secretions, making them easier to cough up and expel. Nebulizer treatments with normal saline or a mucolytic agent such as acetylcysteine (Mucosil, Mucomyst) or dornase alfa (Pulmozyme) and normal saline help thin secretions. Guaifenesin (Organidin, Naldecon Senior EX) is a systemic mucolytic that is taken orally. A combination of guaifenesin and dextromethorphan (Mucinex DM) also raises the cough threshold.

Stepped therapy, which adds drugs as COPD progresses, is recommended for patients with chronic bronchitis or emphysema, although the patient's response to drug therapy is the best indicator of when drugs or their dosages need changing. Ideally the patient notices changes and participates in management strategies. Teach patients and family members the correct techniques for using inhalers and to care for them properly.

Many inhalers for COPD drug therapy are dry powder inhalers (DPIs). These often require having the patient "load in" each dose. The steps for this process involve opening the inhaler's capsule chamber, removing the dry powder capsule from a separate blister pack, placing the capsule in the chamber, closing the inhaler until it clicks and punctures the capsule, and then using the inhaler. Often the patient with severe COPD is older, has muscle weakness, has poor manual dexterity, and may have some problems with cognition. All of these issues can be barriers to proper use of a DPI inhaler for COPD management.

### Exercise Conditioning.

Exercise for conditioning and pulmonary rehabilitation can improve function and endurance in patients with COPD. Patients often respond to the dyspnea of COPD by limiting their activity, even basic ADLs. Over time, the muscles used in breathing weaken, resulting in increased dyspnea with lower activity levels.

Pulmonary rehabilitation involves education and exercise training to prevent muscle deconditioning. Each patient's exercise program is personalized to his or her current limitations and planned outcomes. The simplest plan is having the patient walk (indoors or outdoors) daily at a self-paced rate until symptoms limit further walking, followed by a rest period, and then continue walking until 20 minutes of actual walking has been accomplished. As the time during rest periods decreases, the patient can add 5 more minutes of walking time. Teach patients whose symptoms are severe to modify the exercise by using a walker with wheels or, if needed, to use oxygen while exercising. Exercise needs to be performed at least two or three times weekly for best improvement. Formal pulmonary rehabilitation programs can be beneficial even for patients who are severely impaired. Additional exercise techniques to retrain ventilatory muscles include isocapnic hyperventilation and resistive breathing. Isocapnic hyperventilation, in which the patient hyperventilates into a machine that controls the levels of oxygen and carbon dioxide, increases endurance. In resistive breathing the patient breathes against a set resistance. Resistive breathing increases respiratory muscle strength and endurance.

### Suctioning.

Perform suctioning only when needed—not routinely. Nasotracheal suction is used only for

patients with a weak cough, weak pulmonary muscles, and inability to expectorate effectively. Assess for dyspnea, tachycardia, and dysrhythmias during the procedure. Assess for improved breath sounds after suctioning. Suctioning is discussed in detail in [Chapter 28](#).

### Hydration.

Maintaining hydration may thin the thick, tenacious (sticky) secretions, making them easier to remove by coughing. Unless hydration needs to be avoided for other health problems, teach the patient with COPD to drink at least 2 L/day. Humidifiers may be useful for those living in a dry climate or those who use dry heat during the winter.

### Vibratory Positive Expiratory Pressure Device.

The use of a vibratory positive expiratory pressure device can help patients remove airway secretions. The device is a small, handheld plastic pipe with a short, fat stem and a perforated lid over the bowl ([Fig. 30-11](#)). A movable steel ball is inside the bowl. The patient inhales deeply and then exhales through the device, causing the ball to move and set up vibrations that are transmitted to the chest and airways. The vibrations loosen secretions and allow them to be coughed out more easily.

**FIG. 30-11** The FLUTTER® valve mucus clearance device, a type of vibratory positive-pressure device. (Courtesy Axcan Pharma, Mont-Saint-Hilaire, Quebec, Canada.)

### Surgical Management.

Lung transplantation and lung reduction surgery can improve GAS EXCHANGE in the patient with COPD. Transplantation is a relatively rare procedure because of cost and the scarce availability of donor lungs. The more common surgical procedure for patients with emphysema is lung reduction surgery.

The purpose of lung reduction surgery is to improve GAS EXCHANGE through removal of hyperinflated lung tissues that are filled with stagnant air containing little, if any, oxygen. The level of carbon dioxide is the same as that in the capillary, and no gas exchange occurs. Successful lung reduction results in increased forced expiratory volume and decreased total lung capacity and residual volume. Activity tolerance increases, and oxygen therapy may no longer be needed.

### Preoperative Care.

Patients who are selected for this procedure have end-stage emphysema, minimal chronic bronchitis, and stable cardiac function. They also must be ambulatory; not ventilator dependent; free of pulmonary fibrosis, asthma, or cancer; and not have smoked for at least 6 months. The patient must be rehabilitated to the stage that he or she is able to walk, without stopping, for 30 minutes at 1 mile/hr and maintain a 90% or better oxygen saturation level.

In addition to standard preoperative testing, tests to determine the location of greatest lung hyperinflation and poorest lung blood flow are performed. These tests include pulmonary plethysmography, gas dilution, and PERFUSION scans.

### Operative Procedures.

Usually lung reduction is performed on both lungs, most often by the minimally invasive surgical technique of video-assisted thoracoscopic surgery (VATS) ([GOLD, 2016](#)). Each lung is examined for areas of hyperinflation. The surgeon removes as much of the hyperinflated tissue as possible.

### Postoperative Care.

After lung reduction surgery, the patient needs close monitoring for continuing respiratory problems and usual postoperative complications. Bronchodilator and mucolytic therapies are maintained. Pulmonary hygiene includes incentive spirometry 10 times per hour while awake, chest physiotherapy starting on the first day after surgery, and hourly pulmonary assessment.

## Preventing Weight Loss

### Planning: Expected Outcomes.

The patient with COPD is expected to achieve and maintain a body weight within 10% of ideal. Indicators include that the patient:

- Maintains an appropriate weight/height ratio
- Maintains serum albumin or prealbumin within the normal range

### Interventions.

The patient with COPD often has nausea, *early satiety* (feeling too “full” to eat), poor appetite, and meal-related dyspnea. The work of breathing raises calorie and protein needs, which can lead to protein-calorie malnutrition. Malnourished patients lose muscle mass and strength, lung elasticity, and alveolar-capillary surface area, all of which reduce GAS EXCHANGE and PERFUSION.

Identify patients at risk for or who have this complication and collaborate with a registered dietitian to perform a nutrition assessment. Monitor weight and other indicators of nutrition, such as serum prealbumin levels.

*Dyspnea management* is needed because shortness of breath interferes with eating. Teach the patient to plan the biggest meal of the day for the time when he or she is most hungry and well rested. Four to six small meals a day may be preferred to three larger ones. Remind patients to use pursed-lip and abdominal breathing and to use the prescribed bronchodilator 30 minutes before the meal to reduce bronchospasm.

*Food selection* can help prevent weight loss. Abdominal bloating and a feeling of fullness often prevent the patient from eating a complete meal. Collaborate with the dietitian to teach about foods that are easy to chew and not gas-forming. Advise the patient to avoid dry foods that stimulate coughing and caffeine-containing drinks that increase urine output and may lead to dehydration.

Urge the patient to eat high-calorie, high-protein foods. Supplements such as Pulmocare provide nutrition with reduced carbon dioxide production. If early satiety is a problem, advise him or her to avoid drinking fluids before and during the meal and to eat smaller, more frequent meals.

## NCLEX Examination Challenge 30-2

### Health Promotion and Maintenance

Which interventions are important for the nurse to teach a client with severe chronic obstructive pulmonary disease (COPD) to help ensure adequate nutrition? **Select all that apply.**

- A. Avoid eating gas-producing foods.
- B. Cough to clear mucus right before eating.
- C. Drink plenty of fluid with every meal.
- D. Eat smaller meals more frequently.
- E. Rest immediately following a meal.
- F. Eat more raw fruits and vegetables.
- G. Use your bronchodilator about 30 minutes before each meal.

### Minimizing Anxiety

### Planning: Expected Outcomes.

The patient with COPD is expected to have decreased anxiety. Indicators include that the patient consistently demonstrates these behaviors:

- Identifies factors that contribute to anxiety
- Identifies activities to decrease anxiety
- States that anxiety is reduced or absent

### Interventions.

Patients with COPD become anxious during acute dyspneic episodes, especially when excessive secretions are present. Anxiety also may cause dyspnea.

Help the patient understand that anxiety can increase dyspnea and have a plan for dealing with anxiety. Together with the patient, develop a written plan that states exactly what he or she should do if symptoms flare. Having a plan provides confidence and control in knowing what to do, which often helps reduce anxiety. Stress the use of pursed-lip and diaphragmatic breathing techniques during periods of anxiety or panic.

Family, friends, and support groups can be helpful. Recommend professional counseling, if needed, as a positive suggestion. Stress that talking with a counselor can help identify techniques to maintain control over dyspnea and panic.

Explore other approaches to help the patient manage dyspneic episodes and panic attacks, such as progressive relaxation, hypnosis therapy, and biofeedback. For some patients, antianxiety drug therapy may be needed for severe anxiety.

## Improving Endurance

### Planning: Expected Outcomes.

The patient with COPD is expected to increase activity to a level acceptable to him or her. Indicators include that the patient:

- Maintains his or her baseline SpO<sub>2</sub> with activity
- Performs ADLs with no or minimal assistance
- Participates in family, work, or social activities as desired

### Interventions.

The patient with COPD often has chronic fatigue. During acute exacerbations, he or she may need extensive help with the ADLs of eating, bathing, and grooming. As the acute problem resolves, encourage the patient to pace activities and perform as much self-care as possible. Teach him or her to not rush through morning activities, because rushing increases dyspnea, fatigue, and hypoxemia. As activity gradually increases, assess the patient's response by noting skin color changes, pulse rate and regularity, oxygen saturation, and work of breathing. Suggest the use of oxygen during periods of high energy use such as bathing or walking.

*Energy conservation* is the planning and pacing of activities for best tolerance and minimum discomfort. Ask the patient to describe a typical daily schedule. Help him or her divide each activity into its smaller parts to determine whether that task can be performed in a different way or at a different time. Teach about planning and pacing daily activities with rest periods between activities. Help the patient develop a chart outlining the day's activities and planned rest periods.

Encourage the patient to avoid working with the arms raised. Activities involving the arms decrease exercise tolerance because the accessory muscles are used to stabilize the arms and shoulders rather than to assist breathing. Many activities involving the arms can be done sitting at a table leaning on the elbows. Teach the patient to adjust work heights to reduce back strain and fatigue. Remind him or her to keep arm motions smooth and flowing to prevent jerky motions that waste energy. Work with the occupational therapist to teach about the use of adaptive tools for housework, such as long-handled dustpans, sponges, and dusters, to reduce bending and reaching.

Suggest organizing work spaces so items used most often are within easy reach. Measures such as dividing laundry or groceries into small parcels that can be handled easily, using disposable plates to save washing time, and letting dishes dry in the rack also conserve energy. Teach the patient to not talk when engaged in other activities that require energy, such as walking. In addition, teach him or her to avoid breath holding while performing any activity.

## Preventing Respiratory Infection

### Planning: Expected Outcomes.

The patient with COPD is expected to avoid serious respiratory infection. Indicators include that the patient consistently demonstrates these behaviors:

- Describes signs and symptoms of respiratory infection
- Describes respiratory infection-monitoring procedures
- Uses prevention activities such as pneumonia and influenza vaccination and crowd avoidance
- Seeks medical assistance when signs of respiratory infection first appear

### Interventions.

Pneumonia is a common complication of COPD, especially among older adults. Patients who have excessive secretions are at increased risk for respiratory tract infections. Teach patients to avoid crowds and stress the importance of receiving a pneumonia vaccination and a yearly influenza vaccine.

## Care Coordination and Transition Management

### Home Care Management.

Most patients with COPD are managed in the ambulatory care setting and cared for at home. When pneumonia or a severe exacerbation develops, the patient often returns home after hospitalization. For those with advanced disease, 24-hour care may be needed for ADLs and for monitoring. If home care is not possible, placement in a long-term care setting may be needed.

Patients with hypoxemia may use oxygen at home either as needed or continually. Continuous, long-term oxygen therapy can reverse tissue hypoxia and improve cognition and well-being. For more information on home oxygen therapy, see [Chapter 28](#).

Collaborate with the case manager to obtain the equipment needed for care at home. Patient needs may include oxygen therapy, a hospital-type bed, a nebulizer, a tub transfer bench or shower chair, and scheduled visits from a home care nurse for monitoring and evaluation.

The patient with COPD faces a lifelong disease with remissions and exacerbations. Explain to the patient and family that he or she may have periods of anxiety, depression, and ineffective coping. The patient who was a smoker may also have self-directed anger.

### Self-Management Education.

Patients with COPD need to know as much about the disease as possible so they can better manage it and themselves. Patients and families should be able to discuss drug therapy, signs of infection, avoidance of respiratory irritants, the nutrition therapy regimen, and activity progression. Instruct them to identify and avoid stressors that can worsen the disease.

Reinforce the techniques of pursed-lip breathing, diaphragmatic breathing, positioning, relaxation therapy, energy conservation, and coughing and deep breathing. Teaching about all of the needed topics may require coordination with the home care or clinic staff.

### Health Care Resources.

Provide appropriate referrals as needed. Home care visits may be needed, especially when home oxygen therapy is first prescribed. [Chart 30-11](#) lists assessment areas for the patient with COPD at home. Referral to assistance programs, such as Meals on Wheels, can be helpful. Provide a list of support groups and Better Breather clubs sponsored by the American Lung Association. If the patient wants to quit smoking, make the appropriate referrals.

### Chart 30-11

## Home Care Assessment

### The Patient With Chronic Obstructive Pulmonary Disease

Assess respiratory status and adequacy of GAS EXCHANGE.

- Measure rate, depth, and rhythm of respirations.
- Examine mucous membranes and nail beds for evidence of hypoxia.
- Determine use of accessory muscles.
- Examine chest and abdomen for paradoxical breathing.
- Count number of words patient can speak between breaths.
- Determine need and use of supplemental oxygen. (How many liters per minute is the patient using?)
- Determine level of consciousness and presence/absence of confusion.
- Auscultate lungs for abnormal breath sounds.
- Measure oxygen saturation by pulse oximetry.
- Determine sputum production, color, and amount.
- Ask about activity level.
- Observe general hygiene.
- Measure body temperature.

Assess cardiac status for adequate PERFUSION.

- Measure rate, quality, and rhythm of pulse.
- Check dependent areas for edema.
- Check neck veins for distention with the patient in a sitting position.
- Measure capillary refill.

Assess nutritional status.

- Check weight maintenance, loss, or gain.
- Determine food and fluid intake.

- Determine use of nutritional supplements.
- Observe general condition of the skin.

Assess patient's and caregiver's adherence and understanding of illness and treatment, including:

- Correct use of supplemental oxygen
- Correct use of inhalers
- Drug schedule and side effects
- Symptoms to report to the primary health care provider indicating the need for acute care
- Increasing severity of resting dyspnea
- Increasing severity of usual symptoms
- Development of new symptoms associated with poor GAS EXCHANGE
- Respiratory infection
- Failure to obtain the usual degree of relief with prescribed therapies
- Unusual change in condition
- Use of pursed-lip and diaphragmatic breathing techniques
- Scheduling of rest periods and priority activities
- Participation in rehabilitation activities

#### ◆ **Evaluation: Reflecting**

Evaluate the care of the patient with COPD based on the identified priority patient problems. The expected outcomes of care are that the patient will:

- Attain and maintain GAS EXCHANGE at a level within his or her chronic baseline values
- Achieve an effective breathing pattern that decreases the work of breathing
- Maintain a patent airway
- Achieve and maintain a body weight within 10% of his or her ideal weight
- Have decreased anxiety
- Increase activity to a level acceptable to him or her
- Avoid serious respiratory infections

### **Clinical Judgment Challenge 30-1**

## Patient-Centered Care; Teamwork and Collaboration **QSEN**

A 60-year-old patient has recently been diagnosed with GOLD 2 class COPD. He is a current smoker and has only had COPD symptoms for the past year. He and his wife, a retired registered nurse, are attending a class on COPD management. Before the class starts, he complains to you that his wife is pressuring him to make some big changes. First she wants him to stop smoking, which he has agreed to do and has started on pharmacologic therapy to assist in this process. She wants to sell their current home (where they have lived for 25 years) and move to a one-story house. She has started mowing the lawn, which has always been his job, and which he wants to continue to do. She also has asked him to stop his hobby of refinishing furniture to avoid the fumes. He says, "I'm not dying yet, and I don't want to give up any of these things." She says, "I'm just thinking of your best interests and am planning ahead." She then asks you to support her suggestions (demands).

1. How should you respond to her request to support her suggestions? What do you think her motive(s) is (are)?
2. Is there justification for any or all of these suggested changes? Provide a rationale for your responses.
3. Should you continue this conversation with both of them together or separately? Provide a rationale for your choice.
4. Which members of the interprofessional team for COPD management would be helpful in this situation? Provide a rationale for your choices.

# Cystic Fibrosis

## ❖ Pathophysiology

Cystic fibrosis (CF) is a genetic disease that affects many organs and lethally impairs lung function. Although CF is present from birth and usually is first seen in early childhood, almost half of patients with CF in the United States are adults ([Cystic Fibrosis Foundation \[CFF\], 2015](#)).

The underlying problem of CF is blocked chloride transport in the cell membranes. Poor chloride transport causes the formation of mucus that has little water content and is thick. The thick, sticky mucus causes problems in the lungs, pancreas, liver, salivary glands, and testes. The mucus plugs up the airways in the lungs and the glandular tissues in nonpulmonary organs, causing atrophy and organ dysfunction. Nonpulmonary problems include pancreatic insufficiency, malnutrition, intestinal obstruction, poor growth, male sterility, and cirrhosis of the liver. Additional problems of CF in young adults include osteoporosis and diabetes mellitus. Respiratory failure is the main cause of death. Improved management has increased life expectancy, even among those with severe disease, to about 40 years ([CFF, 2015](#)).

The pulmonary problems of CF result from the constant presence of thick, sticky mucus and are the most serious complications of the disease. The mucus narrows airways, reducing airflow and interfering with GAS EXCHANGE. The constant presence of mucus results in chronic respiratory tract infections, chronic bronchitis, and dilation of the bronchioles (bronchiectasis). Lung abscesses are common. Over time, the bronchioles distend, and mucus-producing cells have increased numbers (hyperplasia) and increased size (hypertrophy). Complications include pneumothorax, arterial erosion and hemorrhage, and respiratory failure.

CF is most common among whites, and about 4% are carriers ([CFF, 2015](#)). It is rare among African Americans and Asians. Males and females are affected equally.

## ❖ Genetic/Genomic Consideration

### Patient-Centered Care QSEN

CF is an autosomal-recessive disorder in which both gene alleles must be mutated for the disease to be expressed. The CF gene (*CFTR*) produces a protein that controls chloride movement across cell membranes. The severity of CF varies; however, life expectancy is always reduced, with an average of 40 years. Adults with one mutated allele are carriers and have few or no symptoms of CF but can pass the abnormal allele on to their children. More than 1700 different mutations have been identified, which is responsible for variation in disease severity (OMIM, 2016c). Help patients understand why their symptoms may be more or less severe than others with the disease.

## ❖ Interprofessional Collaborative Care

### ◆ Assessment: Noticing

Usually, but not always, CF is diagnosed in childhood. The major diagnostic test is sweat chloride analysis ([Pagana et al., 2017](#)). The sweat chloride test is positive for CF when the chloride level in the sweat ranges between 60 and 200 mEq/L (mmol/L), compared with the normal value of less than 40 mEq/L (mmol/L) ([CFF, 2015](#)). Values of 40 to 59 mEq/L (mmol/L) are considered borderline. Genetic testing can be performed to determine which specific mutation an adult may have. Different mutations result in different degrees of disease severity.

*Nonpulmonary symptoms* include abdominal distention, gastroesophageal reflux, rectal prolapse, foul-smelling stools, and **steatorrhea** (excessive fat in stools). The patient is often malnourished and has many vitamin deficiencies, especially of the fat-soluble vitamins (e.g., vitamins A, D, E, K). As pancreatic function decreases, diabetes mellitus develops with loss of insulin production. The adult with severe CF is usually smaller and thinner than average. Another problem seen in adults with CF is the early onset of osteoporosis and osteopenia, with a greatly increased risk for bone fracture ([CFF, 2015](#)).

*Pulmonary symptoms* caused by CF are progressive. Respiratory infections are frequent or chronic with exacerbations. Patients usually have chest congestion, limited exercise tolerance, cough,

sputum production, use of accessory muscles, and decreased pulmonary function (especially forced vital capacity [FVC] and forced expiratory volume in the first second of exhalation [FEV<sub>1</sub>]). Chest x-rays show infiltrate and an increased anteroposterior (AP) diameter.

During an acute exacerbation or when the disease progresses to end stage, the patient has increased chest congestion, reduced activity tolerance, increased crackles, increased cough, increased sputum production (often with hemoptysis), and severe dyspnea with fatigue. Arterial blood gas (ABG) studies show acidosis (low pH), greatly reduced arterial oxygen (PaO<sub>2</sub>) levels, increased arterial carbon dioxide (PaCO<sub>2</sub>) levels, and increased bicarbonate levels.

With infection, the patient has fever, an elevated white blood cell count, and decreased oxygen saturation. Other symptoms of infection include tachypnea, tachycardia, intercostal retractions, weight loss, and increased fatigue.

### ◆Interventions: Responding

The patient with CF needs daily therapy to slow disease progress and enhance GAS EXCHANGE. There is no cure for CF.

### Nonsurgical Management.

The management of the patient with CF is complex and lifelong. Nutrition management focuses on weight maintenance, vitamin supplementation, diabetes management, and pancreatic enzyme replacement. Pulmonary management focuses on preventive maintenance and management of exacerbations. Priority nursing interventions focus on teaching about drug therapy, infection prevention, pulmonary hygiene, nutrition, and vitamin supplementation.

*Preventive/maintenance therapy* involves the use of positive expiratory pressure, active cycle of breathing technique, and an individualized exercise program. Daily chest physiotherapy with postural drainage is beneficial for the patient with CF. This therapy uses chest percussion, chest vibration, and dependent drainage to loosen secretions and promote drainage. Increasingly the use of a chest physiotherapy (CPT) vest is recommended (Fig. 30-12). This system uses an inflatable vest that rapidly fills and deflates, gently compressing and releasing the chest wall up to 25 times per second, a process called high-frequency chest wall oscillation (HFCWO). The action creates mini-coughs that dislodge mucus from the bronchial walls, increase mobilization, and move it toward central airways where it can be removed by coughing or suctioning. HFCWO also thins secretions, making them easier to clear. Pulmonary function tests are monitored regularly. Daily drugs include bronchodilators, anti-inflammatories, mucolytics, and antibiotics.

**FIG. 30-12** Inflatable chest physiotherapy vest for high-frequency chest wall oscillation (HFCWO).  
(Modified ©2015 Hill-Rom Services, Inc. Reprinted with permission—all rights reserved.)

*Exacerbation therapy* is needed when the patient with CF has increased chest congestion, reduced activity tolerance, increased or new-onset crackles, and a 10% decrease in FEV<sub>1</sub>. Other symptoms include increased sputum production with bloody or purulent sputum, increased coughing, decreased appetite, weight loss, fatigue, decreased SpO<sub>2</sub>, and chest muscle retractions. Often infection is present, with fever, increased lung infiltrate on x-ray, and an elevated white blood cell count.

Every attempt is made to avoid mechanical ventilation for the patient with CF. Bi-level positive

airway pressure (BiPAP) may be a part of daily therapy for the patient with advanced disease (see [Chapter 28](#) for information on BiPAP). Management focuses on airway clearance, increased GAS EXCHANGE, and antibiotic therapy. Supplemental oxygen is prescribed on the basis of SpO<sub>2</sub> levels. The respiratory therapist initiates airway clearance techniques four times a day. Bronchodilator and mucolytic therapies are intensified. Steroidal agents are started or increased.

Depending on the severity of the exacerbation, a 14- to 21-day course of oral antibiotics may be prescribed. Antibiotic choice is based on which bacteria are found in the patient's sputum. If antibiotics are not effective or if the exacerbation is very severe, IV antibiotics are used, usually an aminoglycoside such as tobramycin and colistin, or meropenem (Merrem).

A serious bacterial infection for patients with CF is *Burkholderia cepacia*. The organism lives in the respiratory tracts of patients with CF and is often resistant to antibiotic therapy. It is spread by casual contact from one CF patient to another. It is possible for *B. cepacia* to be transmitted to a CF patient during clinic and hospital visits; thus special infection control measures that limit close contact between adults with CF are needed. These measures include separating infected CF patients from noninfected CF patients on hospital units and seeing them in the clinic on different days. Strict CFF-approved procedures are used to clean clinic rooms and respiratory therapy equipment. Drug therapy for this infection usually includes co-trimoxazole (a combination of trimethoprim and sulfamethoxazole [Bactrim, Septra]) along with the usual drugs used for exacerbation therapy.

Teach patients about protecting themselves by not routinely shaking hands or kissing in social settings. Handwashing is critical because the organism also can be acquired indirectly from contaminated surfaces such as sinks and tissues.

As life span increases for patients with CF, other problems, such as bronchiole bleeding from lung arteries, may develop. Interventional radiology may be needed to embolize the bleeding arterial branches. Patients with CF may undergo this procedure repeatedly to control hemoptysis. See [Chapter 36](#) for information on interventional radiology vascular procedures.

Other problems that occur with CF over time include severe gastroesophageal reflux disease (GERD), osteoporosis, and sensory hearing loss. Osteoporosis increases the risk for bone fractures.

*Gene therapy* for CF is available for use in patients with specific gene mutations ([Nakano & Tluczek, 2014](#)). The drug ivacaftor (Kalydeco) has been found to be of value to patients with CF who have any one of the following specific mutations in the *CFTR* gene: G551D, G1244E, G1349D, G178R, G551S, S1251N, S1255P, S549N, or S549R. A newly approved combination drug, lumacaftor/ivacaftor (Orkambi), is effective for patients whose CF is caused by the F508del mutation, the most common mutation involved in CF. For patients with the involved mutations, the oral drugs specifically target and potentiate the CFTR channel opening so this transporter can move chloride ions across the cell membrane. This action reduces sodium and fluid absorption so mucus is less thick and sticky. These drugs have no effect in patients whose *CFTR* gene does not have the specific mutations described.

### **Surgical Management.**

The surgical management of the patient with CF is lung transplantation. The patient has greatly reduced symptoms but is at continuing risk for lethal pulmonary infections, especially with anti-rejection drug therapy. The nonpulmonary problems are not helped by this treatment. Transplantation extends life for 1 to 15 years with an average of 7 years; but the transplant rejection rate is high, possibly caused by poor GI absorption of anti-rejection drugs ([CFF, 2015](#)).

Fewer lung transplants are performed compared with transplantation of other solid organs because of the scarcity of available lungs. In addition, many patients who could benefit from lung transplantation have serious problems in other organs that make the procedure even more dangerous.

Lung transplant procedures include two lobes or single-lung transplantation, as well as double-lung transplantation. The type of procedure is determined by the patient's overall condition and the life expectancy after transplantation. Usually the patient with CF has a bilateral lobe transplant from either a cadaver donor or a living-related donor.

### **Preoperative Care.**

Many factors are considered before lung transplantation surgery. Recipient and donor criteria vary from one program to another, but some criteria are universal.

*Recipient criteria* for the patient with CF include that he or she must have severe, irreversible lung

damage and still be well enough to survive the surgery. Common exclusion criteria include a cancer diagnosis, systemic infection, HIV/AIDS, and irreversible heart, kidney, or liver disease.

*Donor criteria*, regardless of whether the lung tissue is obtained from a cadaver or from a living-related donor, include that the donor be infection free and cancer free, have healthy lung tissue, be a close tissue match with the recipient, and have the same blood type as the recipient. When the donor is a living relative, additional criteria include an age restriction and that he or she has healthy organs and has not had previous chest surgery.

The two nursing priorities before surgery are teaching the patient the expected regimen of pulmonary hygiene to be used in the period immediately after surgery and assisting him or her in a pulmonary muscle strengthening/conditioning regimen.

### Operative Procedures.

The patient may or may not need to be placed on cardiopulmonary bypass, depending on the exact procedure. Those having single-lung or lobe transplantation usually do not need bypass; those having double-lung transplantation usually do.

The most common incision used for lung transplantation is a transverse thoracotomy (“clamshell”). The diseased lung or lungs are removed. The new lobes, lung, or lungs are placed in the chest cavity with proper connections made to the trachea, bronchi, and blood vessels. Usually lung transplantation surgery is completed within 4 to 6 hours.

### Postoperative Care.

The patient is intubated for at least 48 hours, and chest tubes and arterial lines are in place. The care needed is the same as that for any thoracic surgery.

Major problems after lung transplantation are bleeding, infection, and transplant rejection. The patient usually remains in the ICU for several days after transplantation. Postoperative chest physiotherapy often is performed with high-frequency chest wall oscillation (HFCWO) at this time.

Anti-rejection drug regimens are started immediately after surgery, which increases the risk for infection. Combination therapy with the anti-rejection drugs, described in [Chapter 17](#), is used for the rest of the patient's life. Corticosteroids are avoided in the first 10 to 14 days after surgery because of their negative impact on the healing process.

After transplantation, patients have more energy and usually feel very good. The drug regimen for nonpulmonary CF problems is continued for the rest of the patient's life or until after a pancreatic transplant is performed. Exercise is gradually increased; and some patients even participate in intense activities, such as jogging, running, skiing, skating, and swimming.

## NCLEX Examination Challenge 30-3

### Psychosocial Integrity

A client with CF who is 2 months postoperative from a bilateral lung transplant wants to begin riding his bicycle again, as his pulmonary specialist has said he can do, but his wife is concerned that this will “wear out” his new lungs faster. How will the nurse advise this couple?

- A. Remind the wife that activity does not damage or “wear out” the lungs and that exercise will reduce the risk for other health complications.
- B. Tell the wife that, because the client has a reduced life expectancy, she should allow him to do whatever he wants.
- C. Remind the client that this is the “honeymoon phase” of recovery and that he will not feel well for very long.
- D. Advise the client to protect his lungs at all cost.

# Pulmonary Arterial Hypertension

## ❖ Pathophysiology

General pulmonary hypertension can occur as a complication of other lung disorders. Primary pulmonary arterial hypertension (PAH) (also known as *idiopathic pulmonary hypertension*) occurs in the absence of other lung disorders, and its cause is unknown; however, exposure to some drugs, such as fenfluramine/phentermine (Pondimin or “Fen-Phen) or dasatinib (Sprycel), increase the risk. The disorder is rare and occurs mostly in women between the ages of 20 and 40 years (McCance et al., 2014). The familial PAH form appears to be transmitted in an autosomal-dominant pattern with reduced penetrance (OMIM, 2016d).

The pathologic problem in PAH is blood vessel constriction with increasing vascular resistance in the lung. Pulmonary blood pressure rises, and blood flow decreases through the lungs, leading to poor PERFUSION and GAS EXCHANGE with hypoxemia. Eventually the right side of the heart fails (*cor pulmonale*) from the continuous workload of pumping against the high pulmonary pressures. Without treatment, death usually occurs within 2 years after diagnosis.

## ⌘ Genetic/Genomic Considerations

### Patient-Centered Care QSEN

About 50% of patients with pulmonary arterial hypertension have a genetic mutation in the BMPR2 gene, which codes for a growth factor receptor. Excessive activation of this receptor allows increased growth of arterial smooth muscle in the lungs, making these arteries thicker. Many more adults have mutations in this gene than have PAH. It is thought that these mutations increase the susceptibility to PAH when other, often unknown, environmental factors also are present. Mutations in other genes, such as the PPH1 gene and the SMAD9 gene, are also associated with thickening of lung arteries and increased risk for PAH (OMIM, 2016d).

Often PAH is not diagnosed until late in the disease process when the lungs and heart have already been damaged significantly. Teach adults, especially women, who have a first-degree relative (parent or sibling) with PAH to have regular health checks and to consult a primary health care provider whenever pulmonary problems are present.

## ❖ Interprofessional Collaborative Care

### ◆ Assessment: Noticing

The most common early symptoms are dyspnea and fatigue in an otherwise healthy adult. Some patients also have angina-like chest pain. Table 30-3 lists the classification of PAH.

**TABLE 30-3**

**Severity Classification for Primary Pulmonary Arterial Hypertension**

CLASS SYMPTOMS	
I	Pulmonary hypertension diagnosed by pulmonary function tests and right-sided cardiac catheterization No limitation of physical activity Moderate physical activity does not induce dyspnea, fatigue, chest pain, or light-headedness
II	No symptoms at rest Mild-to-moderate physical activity induces dyspnea, fatigue, chest pain, or light-headedness
III	No or slight symptoms at rest Mild (less than ordinary) activity induces dyspnea, fatigue, chest pain, or light-headedness
IV	Dyspnea and fatigue present at rest Unable to carry out any level of physical activity without symptoms Symptoms of right-sided heart failure apparent (dependent edema, engorged neck veins, enlarged liver)

Diagnosis is made from the results of right-sided heart catheterization showing elevated pulmonary pressures. Other test results suggesting PAH include abnormal ventilation-perfusion scans, pulmonary function tests (PFTs) showing reduced functional pulmonary volumes with reduced diffusion capacity, and an abnormal appearance on CT.

### ◆ Interventions: Responding

Drug therapy can reduce pulmonary pressures and slow the development of cor pulmonale by dilating pulmonary vessels and preventing clot formation. Warfarin (Coumadin) is taken daily to achieve an international normalized ratio (INR) of 1.5 to 2.0. Calcium channel blockers have been used to dilate blood vessels. The three classes of drugs that have been shown to be most effective in the treatment of PAH are the endothelin-receptor antagonists, prostacyclin agents, and guanylate cyclase stimulators.

*Endothelin-receptor agonists*, such as bosentan (Tracleer), induce blood vessel relaxation and decrease pulmonary arterial pressure. However, these agents cause general vessel dilation and some degree of hypotension. Another endothelin receptor antagonist drug, macitentan (Opsumit), is an oral agent taken once daily. Teach patients to take the drug with a glass of water; and teach them not to break, chew, or crush the tablet.

Because macitentan can cause birth defects, its use is contraindicated for women who are pregnant or breast-feeding. Instruct women who are sexually active and within childbearing age to use two reliable methods of contraception while taking this drug. In addition, the drug can harm the liver, and patients should avoid drinking alcoholic beverages while taking it.

*Natural and synthetic prostacyclin agents* provide the best specific dilation of pulmonary blood vessels. Continuous infusion of epoprostenol (Flolan, Veletri) or treprostinil (Remodulin) through a small IV pump reduces pulmonary pressures and increases lung blood flow. Treprostinil also can be delivered by continuous subcutaneous infusion. These continuous infusions of prostacyclin drugs can be performed by the patient at home and in other settings. These drugs also are continued when the patient is hospitalized for any reason. The unusual continuous infusion, the need to keep an IV line dedicated strictly to prostacyclin infusion, and the varied dosages of the different brands of prostacyclins contribute to a high drug error rate when infusing this drug.

The prostacyclin agents iloprost (Ilomedin, Ventavis, Ventavis) and treprostinil (Tyvaso) can be delivered by inhalation. A new oral prostacyclin agonist is selexipag (Uptravi) (Aschenbrenner, 2016). A drug given along with prostacyclins is oral or IV sildenafil (Revatio, Viagra).

*Guanylate cyclase stimulators* increase the amount an intracellular substance (cGMP) in endothelial cells that induces relaxation and vasodilation. The oral agent in this class is riociguat (Adempas). It is usually used in combination with other classes of drugs for PAH. Riociguat is known to cause birth defects.

Although most patients with PAH need to stay on prostacyclin drugs until lung transplantation or disease progression to death, a small percentage have been successfully weaned off prostacyclin drug therapy. These patients are maintained on oral bosentan, sildenafil, and warfarin therapy (Demerouti et al., 2013).

## Nursing Safety Priority QSEN

### Action Alert

A critical nursing priority for a patient undergoing therapy with IV prostacyclin agents is to ensure that the drug therapy is never interrupted. Deaths have been reported if the drug delivery is interrupted even for a matter of minutes. Teach the patient to always have backup drug cassettes and battery packs. If these are not available or if the line is disrupted, the patient should go to the emergency department immediately.

Another critical priority is helping the patient receiving IV prostacyclin agents prevent sepsis. The central line IV setup provides an access for organisms to enter the bloodstream directly. Teach the patient to use strict aseptic technique for all aspects of the drug delivery system. Also teach him or her to notify the pulmonologist at the first sign of any infection.

When the heart has undergone hypertrophy and cardiac output has fallen, the patient may be started on a regimen of digoxin (Lanoxin) and diuretics. Oxygen therapy is used when dyspnea is uncomfortable. This therapy improves function and reduces symptoms but does not cure PAH.

Surgical management of PAH involves lung transplantation. When cor pulmonale also is present, the patient may need combined heart-lung transplantation. It is not known whether the process of pulmonary vasoconstriction can begin again in the transplanted lungs.

## NCLEX Examination Challenge 30-4

### Safe and Effective Care Environment

A client with pulmonary artery hypertension on a continuous IV epoprostenol infusion is in the emergency department with symptoms of possible sepsis. The primary health care provider prescribes a broad-spectrum antibiotic to be administered IV immediately. What is the nurse's **best** action?

- A. Request a prescription for an oral antibiotic.
- B. Start a peripheral IV line and administer the antibiotic.
- C. Administer the IV antibiotic through the continuous infusion's side port.
- D. Stop the epoprostenol infusion for 15 minutes to administer the IV antibiotic.

# Idiopathic Pulmonary Fibrosis

## ❖ Pathophysiology

Idiopathic pulmonary fibrosis is a common restrictive lung disease. The patient usually is an older adult with a history of cigarette smoking, chronic exposure to inhalation irritants, or exposure to the drugs amiodarone (Cordarone) or ambrisentan (Letairis, Volibris). Most patients have progressive disease with few remission periods. Even with proper treatment, most patients usually survive less than 5 years after diagnosis.

Pulmonary fibrosis is an example of excessive wound healing with loss of CELLULAR REGULATION. Once lung injury occurs, inflammation begins tissue repair. The inflammation continues beyond normal healing time, causing fibrosis and scarring. These changes thicken alveolar tissues, making GAS EXCHANGE difficult.

## ❖ Interprofessional Collaborative Care

The onset is slow, with early symptoms of mild dyspnea on exertion. Pulmonary function tests show decreased forced vital capacity (FVC). High-resolution computed tomography (HRCT) shows a “honeycomb” pattern in affected lung tissue. As the fibrosis progresses, the patient becomes more dyspneic, and hypoxemia becomes severe. Eventually he or she needs high levels of oxygen and often is still hypoxemic. Respirations are rapid and shallow.

Therapy focuses on slowing the fibrotic process and managing dyspnea. Corticosteroids and other immunosuppressants are the mainstays of therapy. Immunosuppressant drugs include cytotoxic drugs such as cyclophosphamide (Cytoxan, Neosar, Procytox ♣), azathioprine (Imuran), chlorambucil (Leukeran), or methotrexate (Folex). These drugs have many side effects, including increased infection risk, nausea, and lung and liver damage and have shown limited benefit. Studies using the combination therapy of corticosteroids, azathioprine, interferon gamma 1b, and *N*-acetylcysteine show promise of slowing disease progression. Newer approved drugs include nintedanib (Ofev), a tyrosine kinase inhibitor, and pirfenidone (Esbriet), an antifibrotic agent. Both drugs help improve CELLULAR REGULATION of fibrous cell growth.

Starting any drug therapy early is critical, even though not all patients respond to therapy. Even among those who have a response to therapy, the disease eventually continues to progress and leads to death by respiratory failure. Lung transplantation is a curative therapy; however, the selection criteria, cost, and availability of organs make this option unlikely for most patients.

The patient and family need support and help with community resources. Nursing care focuses on helping the patient and family understand the disease process and maintaining hope for fibrosis control. It is important to prevent respiratory infections. Teach the patient and family about the symptoms of infection and to avoid respiratory irritants, crowds, and people who are ill.

Home oxygen is needed by the time the patient has dyspnea because significant fibrosis has already occurred and GAS EXCHANGE is reduced. Teach about oxygen use as a continuous therapy. Fatigue is a major problem. Teach the patient and family about energy conservation measures (see the discussion of activity intolerance in the [Chronic Obstructive Pulmonary Disease](#) section). These measures and rest help reduce the work of breathing and oxygen consumption. Encourage the patient to pace activities and accept assistance as needed.

In the later stages of the disease, the focus is to reduce the sensation of dyspnea. This is often accomplished with the use of oral, parenteral, or nebulized morphine. Provide information about hospice, which supports and coordinates resources to meet the needs of the patient and family when the prognosis for survival is less than 6 months (see [Chapter 7](#)).

# Lung Cancer

## ❖Pathophysiology

Lung cancer is a leading cause of cancer-related deaths worldwide. In North America, more deaths from lung cancer occur each year than from prostate cancer, breast cancer, and colon cancer combined. In the United States, more than 243,000 new cases are diagnosed each year, and more than 160,000 deaths occur from lung cancer annually ([American Cancer Society \[ACS\], 2017](#)). In Canada, more than 26,600 new cases are diagnosed each year, and more than 20,900 deaths from lung cancer occur annually ([Canadian Cancer Society, 2016](#)). The overall 5-year survival for all patients with lung cancer is only 16%. This poor long-term survival is because most lung cancers are diagnosed at a late stage, when metastasis is present. Only 15% of patients have small tumors and localized disease at the time of diagnosis. The 5-year survival rate for this population is 52% ([ACS, 2017](#)).

The prognosis for advanced lung cancer remains poor. Treatment often focuses on relieving symptoms or increasing survival time (**palliation**) rather than cure.

Most primary lung cancers arise as a result of failure of CELLULAR REGULATION in the bronchial epithelium. These cancers are collectively called *bronchogenic carcinomas*. Lung cancers are classified as small cell lung cancer (SCLC) and non-small cell lung cancer (NSCLC). [Chapter 21](#) discusses the general mechanisms and processes of cancer development.

*Metastasis* (spread) of lung cancer occurs by direct extension, through the blood, and by invading lymph glands and vessels. Tumors in the bronchial tubes can grow and obstruct the bronchus partially or completely. Tumors in other areas of lung tissue can grow so large that they can compress and obstruct the airway. Compression of the alveoli, nerves, blood vessels, and lymph vessels can occur and also interfere with GAS EXCHANGE. Lung cancer can spread to the lung lymph nodes; distant lymph nodes; and other tissues, including bone, liver, brain, and adrenal glands.

Additional symptoms, known as *paraneoplastic syndromes*, complicate certain lung cancers. The paraneoplastic syndromes are caused by hormones secreted by tumor cells and occur most commonly with SCLC. [Table 30-4](#) lists the endocrine paraneoplastic syndromes that may occur.

**TABLE 30-4**  
**Endocrine Paraneoplastic Syndromes Associated With Lung Cancer**

ECTOPIC HORMONE	SYMPTOMS
Adrenocorticotropic hormone (ACTH)	Cushing's syndrome
Antidiuretic hormone	Syndrome of inappropriate antidiuretic hormone (SIADH) Weight gain General edema Dilution of serum electrolytes
Follicle-stimulating hormone (FSH)	Gynecomastia
Parathyroid hormone	Hypercalcemia
Ectopic insulin	Hypoglycemia

*Staging* of lung cancer is performed to assess the size and extent of the disease. These factors are related to survival. Lung cancer staging is based on the TNM system (T, primary **t**umor; N, number of regional lymph **n**odes; M, distant **m**etastasis). See [Table 21-5](#) for a cancer staging system. Higher numbers represent later stages and less chance for cure or long-term survival.

## Incidence and Prevalence

Lung cancers occur as a result of repeated exposure to inhaled substances that cause chronic tissue irritation or inflammation interfering with CELLULAR REGULATION of cell growth. Cigarette smoking is the major risk factor and is responsible for 85% of all lung cancer deaths ([ACS, 2017](#)). The risk for lung cancer is directly related to the total exposure to cigarette smoke as determined by the number of years of smoking and number of packs of cigarettes smoked per day (pack-years). Pipe and cigar smoking also increase risk.

## Etiology and Genetic Risk

Nonsmokers exposed to “secondhand” or “thirdhand” smoke also have a greater risk for lung cancer than do nonsmokers who are minimally exposed to cigarette smoke ([Sherry, 2017](#)). See [Chapter 27](#) for a discussion of passive smoking risks.

Other lung cancer risk factors include chronic exposure to asbestos, beryllium, chromium, coal distillates, cobalt, iron oxide, mustard gas, petroleum distillates, radiation, tar, nickel, and uranium (Held-Warmkessel & Schiech, 2014). Air pollution with benzopyrenes and hydrocarbons also increases the risk for lung cancer.

## Genetic/Genomic Considerations

### Patient-Centered Care QSEN

Lung cancer development varies among adults with similar smoking histories, suggesting that genetic factors can influence susceptibility. Genome-wide association studies have found specific variations in a variety of genes that increase the susceptibility to lung cancer development (OMIM, 2016a). Differences in a gene that regulates cell division, the Tp53 gene, may be the most important genetic susceptibility link for lung cancer development. Mutations in the alleles of this gene are known to increase the susceptibility to a wide variety of cancers both with and without exposure to environmental risks, including lung cancer development among smokers and nonsmokers. Help patients understand that lung cancer susceptibility varies by both genetic issues and exposure to carcinogens.

## Health Promotion and Maintenance

Primary prevention for lung cancer is directed at reducing tobacco smoking. Chapter 27 discusses strategies for helping adults reduce smoking and ways to protect lungs from other exposures to inhalation irritants linked to lung cancer development.

Secondary prevention by early detection involves screening adults at high risk for lung cancer development. Annual CT scans can detect cancers at stage I, when cure is probable and long-term survival (longer than 5 years) is very likely (ACS, 2016; Qiu et al., 2016).

## Interprofessional Collaborative Care

### Assessment: Noticing

#### History.

Ask the patient about risk factors, including smoking, hazards in the workplace, and warning signals (Table 30-5). Calculate the pack-year smoking history as described in Chapter 27.

**TABLE 30-5**

### Warning Signals Associated With Lung Cancer

- Hoarseness
- Change in respiratory pattern
- Persistent cough or change in cough
- Blood-streaked sputum
- Rust-colored or purulent sputum
- Frank hemoptysis
- Chest pain or chest tightness
- Shoulder, arm, or chest wall pain
- Recurring episodes of pleural effusion, pneumonia, or bronchitis
- Dyspnea
- Fever associated with one or two other signs
- Wheezing
- Weight loss
- Clubbing of the fingers

Ask about the presence of lung cancer symptoms, such as hoarseness, cough, sputum production, hemoptysis, shortness of breath, or change in endurance. Assessing for and documenting these symptoms provide information about the extent of nursing care and teaching the patient needs now and can be used later to determine therapy effectiveness. Symptoms often have been present for years. Ask the patient to describe any recent symptom changes or if position affects them.

Assess for chest pain or discomfort, which can occur at any stage of tumor development. Chest pain may be localized or on just one side and can range from mild to severe. Ask about any sensation of fullness, tightness, or pressure in the chest, which may suggest obstruction. A piercing chest pain or pleuritic pain may occur on inspiration. Pain radiating to the arm results from tumor invasion of nerve plexuses in advanced disease.

### Physical Assessment/Signs and Symptoms—Pulmonary.

Symptoms of lung cancer are often nonspecific and appear late in the disease. Specific symptoms depend on tumor location. Chills, fever, and cough may be related to pneumonitis or bronchitis that occurs with obstruction. Assess sputum quantity and character. Blood-tinged sputum may occur with bleeding from a tumor. Hemoptysis is a later finding in the course of the disease. If infection or necrosis is present, sputum may be purulent and copious.

Breathing may be labored or painful. Obstructive breathing may occur as prolonged exhalation alternating with periods of shallow breathing. Rapid, shallow breathing occurs with pleuritic chest pain and an elevated diaphragm. Look for and document abnormal retractions, the use of accessory muscles, flared nares, stridor, and asymmetric diaphragmatic movement on inspiration. Dyspnea and wheezing may be present with airway obstruction. Ask about dyspnea severity at rest, with activity, and in the supine position. Assess how much the dyspnea interferes with the patient's participation in ADLs, work, recreational activities, and family responsibilities. Ask him or her to compare participation in activities during the past week with that of a month ago and a year ago.

Areas of tenderness or masses may be felt when palpating the chest wall. Increased vibrations felt on the chest wall (**fremitus**) indicate areas of the lung where air spaces are replaced with tumor or fluid. Fremitus is decreased or absent when the bronchus is obstructed. The trachea may be displaced from midline if a mass is present in the area.

Lung areas with masses sound dull or flat rather than hollow or resonant on chest percussion. Breath sounds may change with the presence of a tumor. Wheezes indicate partial obstruction of airflow in passages narrowed by tumors. Decreased or absent breath sounds indicate complete obstruction of an airway by a tumor or fluid. Increased loudness or sound intensity of the voice while listening to breath sounds indicates increased density of lung tissue from tumor compression. A pleural friction rub may be heard when inflammation is present.

### Physical Assessment/Signs and Symptoms—Nonpulmonary.

Many other systems can be affected by lung cancer and have changes at the time of diagnosis. Heart sounds may be muffled by a tumor or fluid around the heart (*cardiac tamponade*). Dysrhythmias may occur as a result of hypoxemia or direct pressure of the tumor on the heart. Cyanosis of the lips and fingertips or clubbing of the fingers may be present (see [Fig. 30-10](#)).

Bones lose density with tumor invasion and break easily. The patient may have bone pain or pathologic fractures. Handle him or her carefully. Thin bones can fracture with little pressure and without trauma. Even heavy coughing can break a rib.

Late symptoms of lung cancer usually include fatigue, weight loss, anorexia, dysphagia, and nausea and vomiting. *Superior vena cava syndrome may result from tumor pressure in or around the vena cava. This syndrome is an emergency (see Chapter 22) and requires immediate intervention.* The patient may have confusion or personality changes from brain metastasis. Bowel and bladder tone or function may be affected by tumor spread to the spine and spinal cord, which can change gait.

### Psychosocial Assessment.

The poor prognosis for lung cancer has made it a much-feared disease. Dyspnea and pain add to the patient's fear and anxiety. The patient with a history of cigarette smoking may feel guilt and shame. Convey acceptance and interact with the patient in a nonjudgmental way. Encourage the patient and family to express their feelings about the possible diagnosis of lung cancer.

### Diagnostic Assessment.

The diagnosis of lung cancer is made by examination of cancer cells. Cytologic testing of early-morning sputum specimens may identify tumor cells; however, cancer cells may not be present in the sputum. When pleural effusion is present, fluid is obtained by thoracentesis for cytology.

Most commonly, lung lesions are first identified on chest x-rays. CT scans are then used to identify the lesions more clearly and guide biopsy procedures.

A thoracoscopy to directly view lung tissue may be performed through a video-assisted thoracoscope entering the chest cavity via small incisions through the chest wall. Spread to mediastinal lymph nodes is assessed with a mediastinoscopy through a small chest incision.

Other diagnostic studies may be needed to determine how widely the cancer has spread. Such tests include needle biopsy of lymph nodes, direct surgical biopsy, and thoracentesis with pleural

biopsy. MRI and radionuclide scans of the liver, spleen, brain, and bone help determine the location of metastatic tumors. Pulmonary function tests (PFTs) and arterial blood gas (ABG) analysis help determine the overall respiratory status. Positron emission tomography (PET) scanning is becoming the most thorough way to locate metastases. These tests help determine the extent of the cancer and the best methods to treat it.

### ◆Interventions: Responding

#### Interventions for Cure.

Interventions for the patient with lung cancer can have the purposes of curing the disease, increasing survival time, and enhancing quality of life through palliation. Both nonsurgical and surgical interventions are used to achieve these purposes. Some patients with lung cancer may undergo interventions for all three purposes at different stages in the disease process. Cure is most likely for patients who undergo treatment for stage I or II disease. Cure is rare for patients who undergo treatment for stage III or IV disease, although survival time is increasing.

#### Nonsurgical Management.

*Chemotherapy* is often the treatment of choice for lung cancers, especially small cell lung cancer (SCLC). It may be used alone or as adjuvant therapy in combination with surgery for non-small cell lung cancer (NSCLC). The combination of drugs used depends on tumor response and the overall health of the patient; however, most include platinum-based agents.

Side effects that occur with chemotherapy for lung cancer include chemotherapy-induced nausea and vomiting (CINV), **alopecia** (hair loss), open sores on mucous membranes (**mucositis**), immunosuppression with neutropenia, anemia, **thrombocytopenia** (decreased numbers of platelets), and peripheral neuropathy. Consult [Chapter 22](#) for a thorough discussion of the nursing care needs for patients who have these side effects.

Immunosuppression with neutropenia, which greatly increases the risk for infection, is the major dose-limiting side effect of chemotherapy for lung cancer. It can be managed by the use of growth factors to stimulate bone marrow production of immune system cells. Teach the patient and family about precautions to take to reduce the patient's risk for infection (see [Chart 22-4](#)). (See [Chapter 22](#) for information about chemotherapy and associated nursing care.)

*Targeted therapy* is common in the treatment of non-small cell lung cancer (NSCLC). These agents take advantage of one or more differences in cancer cell growth or metabolism that is either not present or only slightly present in normal cells. Agents used as targeted therapies work to disrupt cancer cell division in one of several ways. However, these agents only work when the cancer cell has the particular target or specific genetic mutation. Therefore testing of the cancer cells is needed before therapy begins, and not all cancers of the same type express the target. Some of these drugs are used alone for metastatic NSCLC, and others are used in combination with chemotherapy. These agents are increasing survival time for patients with NSCLC but do not lead to a cure. [Table 30-6](#) lists targeted agents and indications. [Chapter 22](#) describes general issues with targeted therapy agents.

**TABLE 30-6**  
**Targeted Agents for Non–Small Cell Lung Cancer (NSCLC)**

Agent and Route of Administration	Specific Indications or Targets
afatinib (Gilotrif) Oral	First-line therapy for metastatic NSCLC that is positive for a mutation in the EGFR gene of either exon 19 deletion or exon 21 L858R substitution mutations
alectinib (Alecensa) Oral	Second-line therapy for metastatic NSCLC that has progressed after initial treatment and is ALK-positive
bevacizumab (Avastin) IV	First-line treatment of unresectable, locally advanced, recurrent, or metastatic nonsquamous NSCLC in combination with carboplatin and paclitaxel
crizotinib (Xalkori) Oral	First-line treatment of metastatic NSCLC that is ALK-positive
erlotinib (Tarceva) Oral	First-line treatment of metastatic NSCLC with EGFR exon 19 deletions or exon 21 (L858R) substitution mutations
neclitumumab (Portrazza) IV	First-line treatment of metastatic squamous NSCLC in combination with gemcitabine and cisplatin
nivolumab (Opdivo) IV	Second-line treatment of metastatic NSCLC, with progression on or after platinum-based chemotherapy and after progression on EGFR- or ALK-targeted therapy
ramucirumab (Cyramza) IV	Second-line treatment of metastatic NSCLC in combination with docetaxel, with disease progression on or after platinum-based chemotherapy

ALK, Anaplastic lymphoma kinase *EGFR*, epidermal growth factor receptor.

*Radiation therapy* can be an effective treatment for locally advanced lung cancers confined to the

chest. Best results are seen when radiation is used in addition to surgery or chemotherapy. Radiation may be performed before surgery to shrink the tumor and make resection easier.

Usually radiation therapy for lung cancer is performed daily for a 5- to 6-week period. Only the areas thought to have cancer are positioned in the radiation path. The immediate side effects of this treatment are skin irritation and peeling, fatigue, nausea, and taste changes. Some patients have esophagitis during therapy, making nutrition more difficult. Collaborate with a dietitian to teach patients to eat foods that are soft, bland, and high in calories. Suggest that the patient drink liquid nutrition supplements between meals to maintain weight and energy levels.

Skin care in the radiation-treated area can be difficult, and consultation with a wound care specialist may be needed. Because skin in the radiation path is more sensitive to sun damage, advise patients to avoid direct skin exposure to the sun during treatment and for at least 1 year after radiation is completed. See [Chapter 22](#) for other nursing care issues associated with radiation therapy.

*Photodynamic therapy* (PDT) may be used to remove small bronchial tumors when they are accessible by bronchoscopy. The patient is first injected with an agent that sensitizes cells to light. This drug enters all cells but leaves normal cells more rapidly than cancer cells. Usually, within 48 to 72 hours, most of the drug has collected in high concentrations in cancer cells. At this time, the patient goes to the operating room where, under anesthesia and intubation, a laser light is focused on the tumor. The light activates a reaction that causes irreversible damage to the cells retaining the sensitizing drug. Some cells die and slough immediately; others continue to slough for several days.

With PDT, the patient may require a stay in the ICU for airway management. Sloughing tissue and airway edema from inflammation can block the airways. The patient is at risk for bronchial hemorrhage, fistula formation, and hemoptysis.

### **Surgical Management.**

Surgery is the main treatment for stage I and stage II NSCLC. Total tumor removal may result in a cure. If complete resection is not possible, the surgeon removes the bulk of the tumor. The specific surgery depends on the stage of the cancer and the patient's overall health. Lung cancer surgery may involve removal of the tumor only, removal of a lung segment, removal of a lobe (**lobectomy**), or removal of the entire lung (**pneumonectomy**). These procedures can be performed by open thoracotomy or by minimally invasive surgery in select patients.

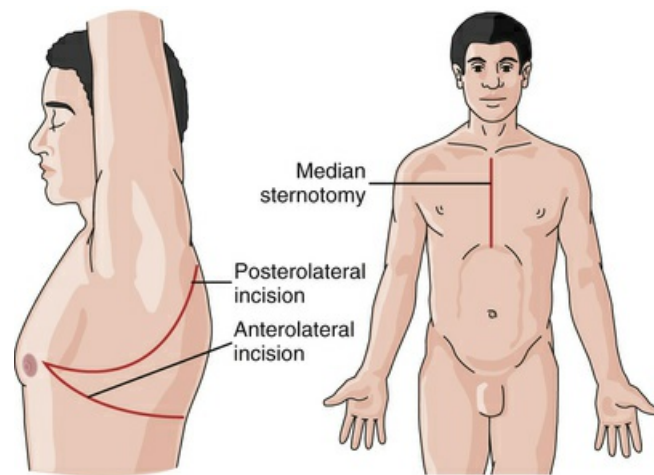

### **Preoperative Care.**

The focus of nursing care before surgery is to relieve anxiety and promote the patient's participation (see [Chapter 14](#) for routine preoperative care). Encourage the patient to express fears and concerns, reinforce the surgeon's explanation of the procedure, and provide education related to what is expected after surgery. Teach about the probable location of the surgical incision or thoracoscopy openings, shoulder exercises, and the chest tube and drainage system (except after pneumonectomy).

### **Operative Procedures.**

Three types of incisions can be made, depending on the location of the cancer: posterolateral, anterolateral, and median sternotomy ([Fig. 30-13](#)). The incisions are large and are held open with retractors during surgery, contributing to pain after surgery.

**FIG. 30-13** Common incision locations for partial or total pneumonectomy.

Surgery may consist of a lobectomy, pneumonectomy, segmental resection, or wedge resection. A segmental resection is a lung resection that includes the bronchus, pulmonary artery and vein, and tissue of the involved lung segment or segments of a lobe. A **wedge resection** is removal of the peripheral portion of small, localized areas of disease.

A lobe or entire lung can be removed through video-assisted thoracoscopic surgery (VATS), which is minimally invasive, in select patients. The procedure involves making three small incisions in the chest for placement of the instruments. These same openings are used later for placement of drains and chest tubes. The lung section, lobe, or lung then is isolated from its airway, which is surgically closed. The lobe or the lung is closed off from the rest of the lung using a double-stapling technique. The tissue is sealed in a bag to prevent leakage of tumor tissue and possible seeding of the cancer. The bagged lung is then removed whole through one of the small incisions.

### Postoperative Care.

Care after surgery for patients who have undergone thoracotomy (except for pneumonectomy) requires closed-chest drainage to drain air and blood that collect in the pleural space. A **chest tube**, a drain placed in the pleural space, allows lung re-expansion (Fig. 30-14). The chest tube also prevents air and fluid from returning to the chest. The drainage system consists of one or more chest tubes or drains, a collection container placed below the chest level, and a water seal to keep air from entering the chest. The drainage system may be a stationary, disposable, self-contained system (Fig. 30-15); or a smaller, portable, disposable, self-contained system that requires no connection to a vacuum source (Fig. 30-16). The nursing care priorities for the patient with a chest tube are to ensure the integrity of the system, promote comfort, ensure chest tube patency, and prevent complications.

**FIG. 30-14** Chest tube placement.

**FIG. 30-15** A, Pleur-evac drainage system, a commercial three-chamber chest drainage device. B, Schematic of the drainage device.

**FIG. 30-16** Portable chest drainage system. (Courtesy Atrium Medical Corporation, Hudson, NH.)

### Chest Tube Placement and Care.

The tip of the tube used to drain air is placed near the front lung apex (see Fig. 30-14). The tube that drains liquid is placed on the side near the base of the lung. After lung surgery, two tubes, anterior and posterior, are used. The wounds are covered with airtight dressings.

The chest tube is connected by about 6 feet of tubing to a collection device placed below the chest, which allows gravity to drain the pleural space. The tubing allows the patient to turn and move without pulling on the chest tube. When two chest tubes are inserted, they are joined by a Y-connector near the patient's body; the 6 feet of tubing is attached to the Y-connector.

*Stationary chest tube drainage systems* use a water-seal mechanism that acts as a one-way valve to prevent air or liquid from moving back into the chest cavity. The Pleur-evac system is a common device using a one-piece disposable plastic unit with three chambers. The three chambers are connected to one another. The tube(s) from the patient is (are) connected to the first chamber in the series of three. This chamber is the drainage collection container. The second chamber is the water seal to prevent air from moving back up the tubing system and into the chest. The third chamber, when suction is applied, is the suction regulator.

In setting up the system, chamber one (nearest to the patient) does not at first have fluid in it. The tubing from the patient penetrates shallowly into this chamber, as does the tube connecting chamber one with chamber two.

Chamber one collects the fluid draining from the patient. This fluid is measured hourly during the first 24 hours. *The fluid in chamber one must never fill to the point that it comes into contact with any tubes! If the tubing from the patient enters the fluid, drainage stops and can lead to a tension pneumothorax.*

Chamber two is the water seal that prevents air from re-entering the patient's pleural space. As the trapped air leaves the pleural space, it will pass through chamber one (drainage collection chamber) before entering chamber two (the water-seal chamber), which should always contain at least 2 cm of water to prevent air from returning to the patient. As trapped air from the patient's pleural space passes through the water seal, which serves as a one-way valve, the water will bubble. Once all the air has been evacuated from the pleural space, bubbling of the water seal stops.

### **Nursing Safety Priority** QSEN

#### Action Alert

For a water-seal chest tube drainage system, 2 cm of water is the minimum needed in the water seal to prevent air from flowing backward into the patient. Check the water level every shift and add sterile water to this chamber to the level marked on the indicator (specified by the manufacturer of the drainage system).

The bubbling of the water in the water-seal chamber indicates air drainage from the patient. Bubbling is seen when intrathoracic pressure is greater than atmospheric pressure, such as when the patient exhales, coughs, or sneezes. When the air in the pleural space has been removed, bubbling stops. A blocked or kinked chest tube also can cause bubbling to stop (Muzzy & Butler, 2015). Excessive bubbling in the water-seal chamber (chamber two) may indicate an air leak. The water in the narrow column of the water-seal chamber normally rises 2 to 4 inches during inhalation and falls during exhalation, a process called *tidaling*. An absence of fluctuation may mean that the lung has fully re-expanded or that there is an obstruction in the chest tube.

Chamber three is the suction control of the system. There are different types of suction, most commonly wet or dry. With wet suction, the fluid level in chamber three is prescribed by the primary health care provider (usually -20 cm water). The chamber is connected to wall suction, which is turned up until there is gentle bubbling in the chamber. With dry suction, the primary health care provider prescribes the suction level to be dialed in on the device. When connected to wall suction, the regulator is set to the amount indicated by the device's manufacturer. For either type of suction, the amount of suction in the system is determined not by the wall suction unit but by the chest tube drainage device.

Chart 30-12 summarizes best safety practices when caring for a patient with a water-seal chest tube drainage system. Check hourly to ensure the sterility and patency of the drainage system. Tape tubing junctions to prevent accidental disconnections and keep an occlusive dressing at the chest tube insertion site. Keep sterile gauze at the bedside to cover the insertion site immediately if the chest tube becomes dislodged. Also keep padded clamps at the bedside for use if the drainage system is interrupted. Position the drainage tubing to prevent kinks and large loops of tubing, which can block drainage and prevent lung re-expansion.

## Chart 30-12

### Best Practice for Patient Safety & Quality Care QSEN

#### Management of Chest Tube Drainage Systems

##### Patient

- Ensure that the dressing on the chest around the tube is tight and intact. Depending on agency policy and the surgeon's preference, reinforce or change loose dressings.
- Assess for difficulty breathing.
- Assess breathing effectiveness by pulse oximetry.
- Listen to breath sounds for each lung.
- Check alignment of trachea.
- Check tube insertion site for condition of the skin. Palpate area for puffiness or crackling that may indicate subcutaneous emphysema.
- Observe site for signs of infection (redness, purulent drainage) or excessive bleeding.
- Check to see if tube "eyelets" are visible.
- Assess for pain and its location and intensity and administer drugs for pain as prescribed.
- Assist patient to deep breathe, cough, perform maximal sustained inhalations, and use incentive spirometry.
- Reposition the patient who reports a "burning" pain in the chest.

##### Drainage System

- Do not “strip” the chest tube.
- Keep drainage system lower than the level of the patient's chest.
- Keep the chest tube as straight as possible from the bed to the suction unit, avoiding kinks and dependent loops. Extra tubing can be loosely coiled on the bed.
- Ensure that the chest tube is securely taped to the connector and that the connector is taped to the tubing going into the collection chamber.
- Assess bubbling in the water-seal chamber; should be gentle bubbling on patient's exhalation, forceful cough, position changes.
- Assess for “tidaling” (rise and fall of water in chamber three with breathing).
- Check water level in the water-seal chamber and keep at the level recommended by the manufacturer.
- Check water level in the suction control chamber and keep at the level prescribed by the surgeon (unless dry suction system is used).
- Clamp the chest tube only for brief periods to change the drainage system or when checking for air leaks.
- Check and document amount, color, and characteristics of fluid in the collection chamber as often as needed according to the patient's condition and agency policy.
- Empty collection chamber or change the system before the drainage makes contact with the bottom of the tube.
- When a sample of drainage is needed for culture or other laboratory test, obtain it from the chest tube; after cleaning chest tube, use a 20-gauge (or smaller) needle and draw up specimen into a syringe.

### Immediately Notify Physician or Rapid Response Team for:

- Tracheal deviation
- Sudden onset or increased intensity of dyspnea
- Oxygen saturation less than 90%
- Drainage greater than 70 mL/hr
- Visible eyelets on chest tube
- Chest tube falls out of the patient's chest (first, cover the area with dry, sterile gauze)
- Chest tube disconnects from the drainage system (first, put end of tube in a container of sterile water and keep below the level of the patient's chest)
- Drainage in tube stops (in the first 24 hours)

If any tube manipulation is needed, gentle hand-over-hand “milking” of the tube, stopping between each handhold, is used to move blood clots and prevent obstruction. Follow surgeon prescriptions and agency policies and guidelines on this action.

## Nursing Safety Priority QSEN

### Action Alert

Manipulation of the chest tube should be kept to a minimum. Do not vigorously “strip” the chest tube because this can create up to -400 cm of water negative pressure and damage lung tissue.

Assess the respiratory status and document the amount and type of drainage hourly on the collection chamber. Notify the surgeon if more than 70 mL/hr of drainage occurs. After the first 24 hours, assess drainage at least every 8 hours. Usually the drainage in chamber one is not emptied unless it is so full that the fluid is in danger of coming into contact with the chest drainage tube.

Check the water-seal chamber for unexpected bubbling created by an air leak in the system. Bubbling is normal during forceful expiration or coughing because air in the chest is being expelled. Continuous bubbling indicates an air leak (Muzzy & Butler, 2015). Notify the primary health care provider if bubbling occurs continuously in the water-seal chamber. With a prescription, gently apply a padded clamp briefly on the drainage tubing close to the occlusive dressing. If the bubbling stops, the air leak may be at the chest tube insertion site or within the chest, requiring physician intervention. Bubbling that does not stop when a padded clamp is applied indicates that the air leak is between the clamp and the drainage system. Release the clamp as soon as this assessment is made.

*Mobile or portable chest tube drainage systems* are “dry” chest drainage systems without a water seal to prevent air from re-entering the patient’s lung through the chest tube. Instead, these lightweight devices use a dynamic control “flutter” valve that prevents backflow of air. When the patient exhales, air is forced from the chest cavity into the chest tube under pressure. This pressure forces the soft flutter valve open, and air moves into the harder surrounding tube shell (which has a vent for air). Portable units allow the patient to ambulate and go home with chest tubes still in place.

*Chest tube removal* is performed when drainage is minimal and lung expansion is stable, as confirmed by x-ray. Usually the primary health care provider removes the chest tube at the bedside. Most patients find chest tube removal painful during the actual procedure. After removal, the site is dressed and sealed with an occlusive dressing and observed for drainage. Assess the patient hourly for respiratory distress for the first few hours after chest tube removal. Respiratory distress may signal lung collapse and the need for chest tube reinsertion.

### **Pain Management.**

Most patients have intense pain after an open thoracotomy. Pain is considerably less for the patient after surgery using minimally invasive techniques. However, pain control is needed in either case for patient comfort and to help him or her participate in techniques to reduce the risk for complications, such as incentive spirometry, coughing, deep breathing, and ambulating. Give the prescribed drugs for pain and assess the patient’s responses to them. Teach patients using patient-controlled analgesia (PCA) devices to self-administer the drug before pain intensity becomes too severe. Monitor vital signs before and after giving opioid analgesics, especially for the patient who is not being mechanically ventilated. Plan care activities around the timing of analgesia to reduce pain.

### **Respiratory Management.**

Immediately after surgery the patient is mechanically ventilated. See [Chapter 32](#) for nursing care of the patient receiving mechanical ventilation.

*Once the patient is breathing on his or her own, the priorities are to maintain a patent airway, ensure adequate ventilation, and prevent complications.* Assess the patient at least every 2 hours for adequacy of ventilation and GAS EXCHANGE. Check the alignment of the trachea. Assess oxygen saturation and the rate and depth of respiration. Listen to breath sounds in all lobes on the nonoperative side, particularly noting the presence of crackles. Assess the oral mucous membranes for cyanosis and the nail beds for rate of capillary refill. Perform oral suctioning as necessary.

Usually the patient receives oxygen by mask or nasal cannula for the first 2 days after surgery. Warm and humidify the oxygen. Assist the patient to a semi-Fowler’s position or up in a chair as soon as possible. Encourage him or her to use the incentive spirometer every hour while awake. If coughing is permitted, help him or her cough by splinting any incision and ensuring that the chest tube does not pull with movement. Ensuring that pain is well managed increases the patient’s ability to cough and deep breathe effectively.

## NCLEX Examination Challenge 30-5

### Safe and Effective Care Environment

The chest tube of a client who is 12 hours postoperative from a lobectomy separates from the drainage system. What is the nurse's best **first** action?

- A. Immediately call the surgeon or rapid response team.
- B. Notify respiratory therapy to set up a new drainage system.
- C. Cover the insertion site with a sterile occlusive dressing and tape down on three sides.
- D. Place the end of the disconnected tube into a container of sterile water positioned below the chest.

### Pneumonectomy Care.

After pneumonectomy, the pleural cavity on the affected side is an empty space. The surgeon sometimes inserts a clamped chest tube for only a day. Serous fluid collection in the empty space creates adhesions that help reduce mediastinal shift toward the affected side. Closed-chest drainage is not usually used.

Complications of a pneumonectomy include *empyema* (purulent material in the pleural space) and development of a bronchopleural *fistula* (an abnormal duct that develops between the bronchial tree and the pleura). Positioning of the patient after pneumonectomy varies according to surgeon preference and the patient's comfort. Some surgeons want the patient placed on the nonoperative side immediately after a pneumonectomy to reduce stress on the bronchial stump incision. Others prefer to place the patient on the operative side to allow fluids to fill in the now empty space.

### Interventions for Palliation.

*Oxygen therapy* is prescribed when the patient is hypoxemic. Even if the hypoxemia is not severe, humidified oxygen may be prescribed to relieve dyspnea and anxiety. (See [Chapter 28](#) for issues related to home oxygen therapy.)

*Drug therapy* with bronchodilators and corticosteroids is prescribed for the patient with bronchospasm to decrease bronchospasm, inflammation, and edema. Mucolytics may help ease removal of thick mucus and sputum. Bacterial infections are treated with antibiotic therapy.

*Radiation therapy* can help relieve hemoptysis, obstruction of the bronchi and great veins (superior vena cava syndrome), difficulty swallowing from esophageal compression, and pain from bone metastasis. Radiation for palliation uses higher doses for shorter periods. Skin care issues and fatigue are the same as those occurring with radiation therapy for cure.

*Thoracentesis* is performed when pleural effusion is a problem for the patient with lung cancer. The excess fluid increases dyspnea, discomfort, and the risk for infection. The purpose of treatment is to remove pleural fluid and prevent its formation. **Thoracentesis** is fluid removal by suction after the placement of a large needle or catheter into the intrapleural space. Fluid removal temporarily relieves hypoxia; however, the fluid can rapidly re-form in the pleural space. When fluid development is continuous and uncomfortable, a continuously draining catheter may be placed into the intrapleural space to collect the fluid.

*Dyspnea management* is needed because the patient with lung cancer tires easily and is often most comfortable resting in a semi-Fowler's position. Dyspnea is reduced with oxygen, use of a continuous morphine infusion, and positioning for comfort. The severely dyspneic patient may be most comfortable sitting in a lounge chair or reclining chair.

*Pain management* may be needed to help the patient be as pain free and comfortable as possible. Pain may be present in the chest or in almost any area when bone metastasis occurs. Perform a complete pain assessment with attention to onset, intensity, quality, duration, and the patient's description of the pain.

Pharmacologic management with opioid drugs as oral, parenteral, or transdermal preparations is needed. Analgesics are most effective when given around the clock. Additional PRN analgesics are used for breakthrough pain. Ongoing evaluation of pain control effectiveness is a primary nursing

responsibility.

*Hospice care* can be beneficial for the patient in the terminal phase of lung cancer. Hospice programs provide support to the terminally ill patient and the family, meet physical and psychosocial needs, adjust the palliative care regimen as needed, make home visits, and provide volunteers for errands and respite care. (See [Chapter 7](#) for a more complete discussion of end-of-life issues.) Family and significant others who are caregivers also have many needs and require support during this time. The American Cancer Society or the Canadian Cancer Society may provide assistance through support groups for patients and families or through the use of equipment such as a hospital bed or bedside commode.

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Ensure there are no open flames or combustion hazards in rooms where oxygen is in use. **QSEN: Safety**
- Ensure that oxygen therapy delivered to the patient is humidified. **QSEN: Safety**
- Protect the patient with cystic fibrosis from hospital-acquired pulmonary infections. **QSEN: Safety**
- Ensure proper function of chest tube drainage equipment. **QSEN: Safety**

### Health Promotion and Maintenance

- Teach patients who come into contact with inhalation irritants in their workplaces or leisure-time activities to use a mask to avoid respiratory contact with these substances. **QSEN: Safety**
- Teach adults who smoke that smoking increases the risk for development of many pulmonary problems. **QSEN: Evidence-Based Practice**
- Teach patients with asthma to develop a management plan based on their identified personal best on peak expiratory rate flow testing. **QSEN: Patient-Centered Care**
- Encourage all patients older than 50 years and anyone with a respiratory problem to receive a yearly influenza vaccination. **QSEN: Patient-Centered Care**
- Teach all patients who smoke the warning signs of lung cancer. **QSEN: Evidence-Based Practice**
- Help patients and families contact community support agencies such as the American Cancer Society and the Canadian Cancer Society. **QSEN: Patient-Centered Care**

### Psychosocial Integrity

- Encourage the patient and family to express their feelings regarding the diagnosis of a chronic respiratory disease or cancer and about management/treatment regimens. **QSEN: Patient-Centered Care**
- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for tests. **QSEN: Patient-Centered Care**
- Help patients use strategies to improve their appearance when alopecia occurs. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Assess the airway and effectiveness of GAS EXCHANGE for any patient who experiences shortness of breath or any change in mental status. **QSEN: Evidence-Based Practice**
- Assess the degree to which breathing problems interfere with the patient's ability to perform ADLs, work, and leisure-time activities. **QSEN: Patient-Centered Care**
- Apply oxygen to anyone who is hypoxemic. **QSEN: Evidence-Based Practice**
- Monitor arterial blood gases and oxygen saturation of all patients receiving oxygen therapy. **QSEN: Evidence-Based Practice**
- Teach patients receiving radiation therapy how to care for the skin in the radiation path (see [Chart 22-2](#)). **QSEN: Patient-Centered Care**
- Collaborate with respiratory therapists, registered dietitians, and social workers to meet the hospital and home care needs of patients with chronic lower respiratory problems. **QSEN:**

### **Teamwork and Collaboration**

- Remind patients with lung cancer that targeted therapies can be used only for tumors that express the targets and cancer cell testing is needed to identify these. **QSEN: Patient-Centered Care**
- Instruct patients with asthma or COPD who are prescribed to use inhalers how to use and care for them properly. **QSEN: Patient-Centered Care**
- Instruct patients with asthma to carry a reliever inhaler with them at all times. **QSEN: Safety**
- Teach patients receiving chemotherapy for lung cancer the signs and symptoms of infection. **QSEN: Patient-Centered Care**

## CHAPTER 31

# Care of Patients With Infectious Respiratory Problems

---

Meg Blair

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concepts for this chapter are:**

- GAS EXCHANGE
- IMMUNITY

✚ The GAS EXCHANGE concept exemplar for this chapter is Pneumonia, p. 598.

✚ The IMMUNITY concept exemplar for this chapter is Pulmonary Tuberculosis, p. 605.

**The interrelated concept for this chapter is COGNITION.**

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to coordinate high-quality care and promote GAS EXCHANGE in patients with infectious respiratory problems.
2. Teach the patient and caregiver(s) about home safety affected by infectious respiratory problems.
3. Prioritize evidence-based care for patients with common infectious respiratory problems affecting GAS EXCHANGE.

### Health Promotion and Maintenance

4. Identify community resources for patients with infectious respiratory problems.
5. Teach adults how to decrease the risk for respiratory infections.

### Psychosocial Integrity

6. Implement nursing interventions to help the patient and family cope with the psychosocial impact caused by respiratory infection.

### Physiological Integrity

7. Apply knowledge of pathophysiology to assess patients with common respiratory infections that impair GAS EXCHANGE.
8. Teach the patient and caregiver(s) about common drugs used for pneumonia, tuberculosis, and other respiratory infections.

## Seasonal Influenza

### ❖Pathophysiology

Seasonal influenza, or “flu,” is a highly contagious acute viral respiratory infection that can occur at any age. Epidemics are common and lead to complications of pneumonia or death, especially in older adults or immunocompromised patients. Between 5% and 20% of the U.S. population get influenza each year, and up to 49,000 deaths in a single year have been caused by the flu ([Centers for Disease Control and Prevention \[CDC\], 2015k](#)). Most patients are treated at home, but hospitalization may be needed when symptoms are severe or the patient develops complications such as pneumonia. Influenza may be caused by one of several virus families, referred to as A, B, and C.

The patient with influenza often has a rapid onset of severe headache, muscle aches, fever, chills, fatigue, and weakness. Adults are contagious from 24 hours before symptoms occur and up to 5 days after they begin. Sore throat, cough, and watery nasal discharge can also occur. Infection with influenza strain B can lead to nausea, vomiting, and diarrhea. Most patients feel fatigued for 1 to 2 weeks after the acute episode has resolved.

### Health Promotion and Maintenance

**Vaccinations for the prevention of influenza are widely available and are recommended for adults by The Joint Commission's National Patient Safety Goals (NPSGs).** The vaccine is changed every year based on which specific viral strains are most likely to cause illness during the influenza season (i.e., late fall and winter in the Northern Hemisphere). Usually the vaccines contain antigens for the three or four expected viral strains. The recommended influenza vaccination for all adults is an IM injection (Fluvirin, Fluzone). The intranasal vaccine was found to be ineffective and is no longer available ([CDC, 2016](#)). An annual vaccination is especially important for those older than 50 years, adults with chronic illness or immune compromise, those living in institutions, adults living with or caring for adults with health problems that put them at risk for severe complications of influenza, and health care personnel providing direct care to patients ([CDC, 2015f](#)). Nurses have an opportunity to urge vaccination in the community and can show support for this action by receiving annual vaccinations themselves ([Wiley, 2015](#)).

Teach the patient who is sick to reduce the risk for spreading the flu by thoroughly washing hands, especially after nose blowing, sneezing, coughing, rubbing the eyes, or touching the face. Other precautions include staying home from work, school, or crowded places; covering the mouth and nose with a tissue when sneezing or coughing; disposing properly of used tissues immediately; and avoiding close contact with other people ([Wiley, 2015](#)). Although handwashing is a good way to prevent transmitting the virus, many people cannot wash their hands immediately after sneezing. The technique recommended by the CDC for controlling flu spread is to sneeze or cough into the upper sleeve rather than into the hand ([CDC, 2015c](#)). (Respiratory droplets on the hands can contaminate surfaces and be transmitted to others.)

### ❖Interprofessional Collaborative Care

Tests for influenza are available; however, in a community that has already seen the disease, the diagnosis is usually based on the patient's reported symptoms. The rapid influenza diagnostic test (RIDT) is common but has high false-negative rates, and the patient should be treated if influenza is suspected even if the RIDT is negative. Other tests, including cultures, are usually recommended only in specific situations.

Viral infections do not respond to antibiotic therapy. Antiviral agents such as oseltamivir (Tamiflu), zanamivir (Relenza), and peramivir (Rapivab) have been effective in the prevention and treatment of some strains of influenza A and B. They can be given to adults at high risk for complications who have been exposed to influenza but have not yet been vaccinated. These drugs also shorten the duration of influenza. The drugs prevent viral spread in the respiratory tract by inhibiting a viral enzyme that allows the virus to penetrate respiratory cells. To be effective as treatment, they must be taken within 24 to 48 hours after symptoms begin. Zanamivir should be used with caution in patients who have chronic obstructive pulmonary disease (COPD) or asthma

and in older adults. Peramivir is available only as an IV drug. Patients older than 65 years should be treated with antiviral drugs as soon as possible to reduce their risks for hospitalization, complications, and disability (CDC, 2015d).

The patient should rest for several days and increase fluid intake unless another problem requires fluid restriction. Saline gargles may ease sore throat pain. Antihistamines may reduce the rhinorrhea. Other supportive measures are the same as those for acute rhinitis.

## NCLEX Examination Challenge 31-1

### Health Promotion and Maintenance

A nurse is providing community education on seasonal influenza. What information will the nurse include in this presentation? **Select all that apply.**

- A. Adults older than 65 years should get the Prevnar-13 vaccination annually.
- B. All adults older than 49 years should receive a Fluzone immunization annually.
- C. Sneeze into a disposable tissue or into your sleeve instead of your hand.
- D. Avoid large crowds during spring and summer to limit the chance for getting the flu.
- E. Wash your hands frequently and after blowing your nose, coughing, or sneezing.
- F. Call your primary health care provider for an antiviral prescription within 3 days of getting symptoms.

# Pandemic Influenza

## ❖Pathophysiology

Many viral infections in animals and birds are not usually transmitted to humans. A few historic exceptions have occurred when these animal and bird viruses mutated and became highly infectious to humans. These infections are termed **pandemic** because they have the potential to spread globally and because the virus is new to humans who have no IMMUNITY to it. Such pandemics include the 1918 “Spanish” influenza that resulted in 40 million to 100 million deaths worldwide. This virus, the H1N1 strain, also known as *swine flu*, mutated and became highly infectious to humans. Most recently it caused a pandemic in 2009, spreading to 215 countries. In the United States, the number of people infected during the pandemic was estimated at 61 million with more than 12,000 deaths (CDC, 2015e). A vaccine was developed in 2009 and was administered separately from the seasonal influenza vaccine. Now the seasonal vaccine contains the H1N1 antigen.

A new avian virus is the H5N1 strain, known as “avian influenza” or “bird flu.” This virus has infected millions of birds, especially in Asia, and now has started to spread by human-to-human contact. World health officials are concerned that this strain could become a pandemic and spread worldwide, leading to very high mortality rates. Another avian strain, H7N9, has appeared in China, resulting in several deaths. This virus seems to be able to spread from person to person in limited situations. Travelers have brought the virus outside of China, but there are no cases originating outside of that country (CDC, 2015e).

## Health Promotion and Maintenance

*The prevention of a worldwide influenza pandemic of any virus is the responsibility of everyone.* Health officials have been monitoring human outbreaks and testing both wild and domestic bird species throughout the world. A vaccine (Vepacel) is available in case of H5N1 outbreaks, but it is stockpiled and not part of general influenza vaccination. The recommended approach for any potential pandemic is early recognition of cases and implementing community and personal quarantine. Social-distancing behaviors also will help to reduce viral exposure.

Plans to prevent and contain pandemic flu in North America have been developed with the cooperation of the United States and Canadian governments. When a cluster of cases is discovered in an area, the stockpiled vaccine will be made available for immunization. Vepacel requires two injections 28 days apart.

The antiviral drugs oseltamivir (Tamiflu) and zanamivir (Relenza) should be widely distributed. These drugs may reduce the severity of the infection and the mortality rate. Infected patients must be cared for in strict isolation. All nonessential public activities in the area should be stopped, including public gatherings of any type, attendance at schools, religious services, shopping, and many types of employment. Adults should stay home and use the food, water, and drugs they have stock-piled to last at least 2 weeks per person (see Chapter 10). Travel to and from this area should be stopped.

Urge all adults to pay attention to public health announcements and early warning systems for disease outbreaks. Teach them the importance of starting prevention behaviors as soon as an outbreak is announced. They should also have a battery-powered radio (and batteries) to keep informed of updates. See Chapter 10 for more information on items to have ready in the home for disaster preparedness. *An influenza pandemic is a disaster, and containing it requires the cooperation of all adults.*

## ❖Interprofessional Collaborative Care

*The care priorities for the patient with avian or any pandemic influenza are supporting the patient and preventing spread of the disease. Both are equally important.* The initial signs and symptoms of avian influenza are similar to those of other respiratory infections—cough, fever, and sore throat. These progress rapidly to shortness of breath and pneumonia. In addition, diarrhea, vomiting, abdominal pain, and bleeding from the nose and gums can occur. *Ask any patient with these symptoms if he or she has recently (within the past 10 days) traveled to areas of the world affected by H5N1. If such travel has*

*occurred, coordinate with the health care team to place the patient in an airborne isolation room with negative air pressure. These precautions remain until the diagnosis of H5N1 is ruled out or the threat of contagion is over.* Diagnosis is made based on signs and symptoms and positive testing. Rapid influenza diagnostic testing is available along with other measures such as cultures.

When caring for the patient with avian influenza, personal protective equipment is essential. Anyone entering the patient's room for any reason needs to wear a fit-tested respirator. Use other Airborne, Droplet, and Contact Precautions as described in [Chapter 23](#). Teach others to monitor themselves for illness, especially respiratory infection, for at least a week after the last contact with the patient. Use the antiviral drug *oseltamivir* (Tamiflu) or *zanamivir* (Relenza) within 48 hours of contact with the infected patient. All health care personnel working with patients suspected of having avian influenza should receive the vaccine in the recommended two-step process.

No effective treatment for this infection currently exists. Interventions are supportive to allow the patient's own immune system to fight the infection. Oxygen is given when hypoxia, breathlessness, or a sudden change in COGNITION is present. Respiratory treatments to dilate the bronchioles and move respiratory secretions are used. If hypoxemia is not improved with oxygen therapy, intubation and mechanical ventilation may be needed. Antibiotics are used to treat a bacterial pneumonia that may occur with H5N1.

In addition to the need for respiratory support, the patient with H5N1 may have severe diarrhea and need fluid therapy. Transmission Precautions may prevent using a scale to weigh the patient. Monitor his or her hydration status, and carefully measure intake and output. The type of fluid therapy varies with the patient's cardiovascular status and blood osmolarity. Two important areas to monitor during rehydration are pulse rate and quality and urine output.

## Middle East Respiratory Syndrome (MERS)

Middle East respiratory syndrome (MERS) is another example of a disease that could cause a pandemic. MERS is caused by a “novel” or new virus from the large family of coronaviruses. Viruses from this family cause many respiratory illnesses such as the common cold. They also can cause critical infections such as severe acute respiratory syndrome (SARS). There have been 1611 confirmed cases of MERS since 2012 and 575 deaths. MERS was first identified in Saudi Arabia and has now been reported in 26 countries. The most recent outbreak started in 2015 in the Republic of Korea (“South Korea”). Only two cases of MERS have been confirmed in North America, and both patients were health care workers who lived in Saudi Arabia and traveled to North America (WHO, 2015b).

Patients with MERS typically report respiratory symptoms (cough and shortness of breath) along with fever. Pneumonia is common. GI problems, such as diarrhea, have also been reported. Symptoms may be mild or progress rapidly to multi-system organ failure, sepsis, and death. With severe distress, arterial blood gas analysis is performed to determine the need for oxygen therapy and possible ventilation support.

The only tests available for MERS are through the CDC. To be tested, patients must have symptoms of MERS and have either traveled to areas where MERS has been reported or have had close contact with someone who was confirmed to have MERS. Other patients considered for testing may be part of a cluster of cases of severe, unknown respiratory disease that is being investigated. The CDC test uses the reverse-transcriptase polymerase chain reaction assay (rRT-PCR). It is also possible to test a patient for a prior infection by assessing for MERS antibodies.

There is no specific treatment for MERS. Supportive care is used to manage and prevent complications. The patient may need mechanical ventilation and fluids. If kidney function is severely reduced, dialysis is performed. Hemorrhage from disseminated intravascular coagulation is managed with blood products. (See Chapter 37 for management of septic shock.) “Convalescent serum,” which is the serum taken from a patient who has recovered from the disease, is a potential treatment but requires that the patient have the same blood type as the convalescent patient. This therapy was used successfully with a few patients during the 2014 Ebola outbreak. Patients being treated for MERS must be maintained in Contact and Airborne Precautions (CDC, 2015g).

### Nursing Safety Priority QSEN

#### Action Alert

When performing procedures for the patient with a pandemic influenza that normally induce coughing or promote aerosolization of particles (e.g., suctioning, using a positive-pressure facemask, obtaining a sputum culture, or giving aerosolized treatments), protect yourself and other health care workers. Wear a disposable particulate mask respirator and protective eyewear during the procedures. Keep the door to the patient's room closed. Avoid touching your face with contaminated gloves. Wash your hands after you remove the gown, gloves, eyewear, and face shield and whenever you leave the patient's room. Wear gloves when disinfecting contaminated surfaces or equipment.

### NCLEX Examination Challenge 31-2

#### Physiological Integrity

A nurse is caring for a client who suddenly developed acute respiratory distress after returning home from an extended business trip in a foreign country. Which actions by the nurse are **most appropriate** before the cause of the problem is identified? **Select all that apply.**

- A. Ask the client where the travel specifically occurred and whether he or she was exposed to anyone who was ill.
- B. Use Contact Precautions with this client and use gloves and gown for care.

- C. Prepare to administer isoniazid (INH) as soon as the first dose is available.
- D. Monitor the results of the client's blood urea nitrogen (BUN), creatinine, and liver function studies.
- E. Collaborate with the interprofessional team to obtain arterial blood gases and prepare to intubate the client.
- F. Assist with obtaining sputum cultures for acid-fast bacilli to send to the laboratory for analysis.

# Gas Exchange Concept Exemplar Pneumonia

## Pathophysiology

**Pneumonia** is excess fluid in the lungs from an inflammatory process. This disease can seriously reduce gas exchange. GAS EXCHANGE is oxygen transport to the cells and carbon dioxide transport away from cells through ventilation and diffusion. See Chapter 2 for a discussion that summarizes the concept of gas exchange.

Inflammation causing pneumonia can be triggered by infectious organisms and by inhaling irritating agents. Inflammation occurs in the interstitial spaces, the alveoli, and often the bronchioles. The process begins when organisms penetrate the airway mucosa and multiply in the alveolar spaces. White blood cells (WBCs) migrate to the area of infection, causing local capillary leak, edema, and exudate. These fluids collect in and around the alveoli, and the alveolar walls thicken. Both events seriously reduce GAS EXCHANGE by interfering with diffusion in the lungs. This leads to hypoxemia, which has the potential to cause death. Red blood cells (RBCs) and fibrin move into the alveoli, and capillary leak spreads the infection to other areas of the lung. If the organisms move into the bloodstream, septicemia results; if the infection extends into the pleural cavity, **empyema** (a collection of pus in the pleural cavity) results.

The fibrin and edema stiffen the lung, reducing compliance and decreasing the vital capacity. Alveolar collapse (atelectasis) reduces GAS EXCHANGE even more. As a result, arterial oxygen levels fall, causing hypoxemia.

Pneumonia may occur as *lobar pneumonia* with **consolidation** (solidification, lack of air spaces) in a segment or an entire lobe of the lung or as *bronchopneumonia* with diffusely scattered patches around the bronchi. The extent of lung involvement depends on the host defenses. Bacteria multiply quickly in a person whose immune system is compromised. Tissue necrosis results when an abscess forms and perforates the bronchial wall.

## Etiology

Pneumonia develops when a patient's IMMUNITY cannot overcome the invading organisms (Arsbad et al., 2016). Organisms from the environment (especially after natural disasters), from invasive devices, equipment and supplies, or other people can invade the body. Risk factors are listed in Table 31-1. Pneumonia can be caused by bacteria, viruses, mycoplasmas, fungi, rickettsiae, protozoa, and helminths (worms). Noninfectious causes of pneumonia include inhalation of toxic gases, chemical fumes, and smoke and aspiration of water, food, fluid (including saliva), and vomitus. Pneumonia can be categorized as community-acquired (CAP), hospital-acquired (HAP), health care–acquired (HCAP) or ventilator-associated (VAP) (see Table 31-2).

**TABLE 31-1**

### Risk Factors for Pneumonia

<p><b>Community-Acquired Pneumonia</b></p> <ul style="list-style-type: none"> <li>• Is an older adult</li> <li>• Has never received the pneumococcal vaccination or received it more than 5 years ago</li> <li>• Did not receive the influenza vaccine in the previous year</li> <li>• Has a chronic health problem or other coexisting condition that reduces IMMUNITY</li> <li>• Has recently been exposed to respiratory viral or influenza infections</li> <li>• Uses tobacco or alcohol or is exposed to high amounts of secondhand smoke</li> </ul> <p><b>Health Care–Acquired Pneumonia</b></p> <ul style="list-style-type: none"> <li>• Is an older adult</li> <li>• Has a chronic lung disease</li> <li>• Has presence of gram-negative colonization of the mouth, throat, and stomach</li> <li>• Has an altered level of consciousness</li> <li>• Has had a recent aspiration event</li> <li>• Has presence of endotracheal, tracheostomy, or nasogastric tube</li> <li>• Has poor nutritional status</li> <li>• Has reduced IMMUNITY (from disease or drug therapy)</li> <li>• Uses drugs that increase gastric pH (histamine [H<sub>2</sub>] blockers, antacids) or alkaline tube feedings</li> <li>• Is currently receiving mechanical ventilation (ventilator-associated pneumonia [VAP])</li> </ul>
--

**TABLE 31-2**

### Differentiation of Types of Pneumonia

TYPE OF PNEUMONIA	DEFINITION	MANAGEMENT CONSIDERATIONS
Community-	Contracted outside a health care setting; acquired in the	Most common bacterial agents: <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i>

acquired	community	Most common viral agents: influenza, respiratory syncytial virus (RSV) Antibiotics are often empirical based on multiple patient and environmental factors Treatment length: minimum of 5 days Prompt initiation of antibiotics required; in ED setting, first dose given before patient leaves unit for inpatient bed or within 6 hours of presentation to the ED
Health care-associated	Onset/diagnosis of pneumonia occurs <48 hours after admission in patient with specific risk factors: <ul style="list-style-type: none"> <li>• In hospital for &gt;48 hours in the past 90 days</li> <li>• Living in nursing home or assisted-living facility</li> <li>• Received IV therapy, wound care, antibiotics, chemotherapy in the past 30 days</li> <li>• Seen at a hospital or dialysis clinic within the past 30 days</li> </ul>	May have multidrug-resistant organisms Hand hygiene critical
Hospital-acquired	Onset/diagnosis of pneumonia >48 hours after admission to hospital	Encourage pulmonary hygiene and progressive ambulation Provide adequate hydration Assess risk for aspiration using an evidence-based tool Monitor for early signs of sepsis Hand hygiene is critical Provide vigorous oral care
Ventilator-associated	Onset/diagnosis of pneumonia within 48-72 hours after endotracheal intubation	Presence of ET tube increases risk for pneumonia by bypassing protective airway mechanisms and allowing aspiration of secretions from the oropharynx and stomach; dental plaque also increases risk Initiate ventilator bundle order set, including: Elevate HOB at least 30 degrees Daily sedation "vacation" and weaning assessment DVT prophylaxis Oral care regimen Stress ulcer prophylaxis Suctioning, either as needed or continuous subglottal suction Hand hygiene is critical

DVT, Deep vein thrombosis; ED, emergency department; ET, endotracheal; HOB, head of bed.

Data from Sopena, N., Heras, E., Casas, I., Bechini, J., Gausch, I., Pedro-Botet, et al. (2014). Risk factors of hospital-acquired pneumonia outside the intensive care unit. *American Journal of Infection Control*, 42, 38-42; Peyrani, P. (2013). A three-step critical pathway for community-acquired pneumonia reduces duration of hospital stay and intravenous antibiotic use by 2 days. *Evidence-Based Nursing*, 16 (2), 48-49; Driver, C., (2014). The common causes of community-acquired pneumonia. *Nursing in Residential Care*, 16(4), 202-205; Quinn, B., & Baker, D.L. (2015). Comprehensive oral care helps prevent hospital non-ventilator acquired pneumonia. *American Nurse Today*, 10(3), 18-23; Gianakis, A., McNett, M., Belle, J., Moran, C., & Grimm, D. (2015). Risk factors for ventilator-associated pneumonia. *Journal of Trauma Nursing*, 22(3), 125-113; Liao, Yu-Mei, Tsai, Jung-Rung; & Chou, Fan-Hao. (2015). The effectiveness of an oral health program for preventing ventilator-associated pneumonia. *Nursing in Critical Care*, 10(2), 89-97.

## Incidence and Prevalence

In the United States 2 to 5 million cases of pneumonia occur annually. About 1 million people are hospitalized for treatment, and more than 50,000 deaths result from the disease (CDC, 2015k). In Canada, influenza and pneumonia incidence and deaths are reported together; and both disorders are common, accounting for about 6000 deaths annually (Statistics Canada, 2015). The rate of pneumonia is higher among older adults, nursing home residents, hospitalized patients, patients with neurological problems or difficulty swallowing, and those being mechanically ventilated. CAP is more common than HAP and occurs most often in late fall and winter, frequently as a complication of influenza.

## Health Promotion and Maintenance

**Patient education about vaccination is important in the prevention of pneumonia (Chart 31-1).**

**The Joint Commission National Patient Safety Goals [NPSGs] recommend that nurses especially encourage adults older than 65 years and those with a chronic health problem to receive immunization against pneumonia.** There are two pneumonia vaccines: pneumococcal polysaccharide vaccine (PPSV 23), known as *Pneumovax*; and pneumococcal conjugate vaccine (PCV-13), known as *Prevnar 13*. The CDC recommends that adults older than 65 years be vaccinated with both, first with Prevnar 13 followed by Pneumovax about 6 to 12 months later. Adults who have already received the Pneumovax should have Prevnar 13 about a year or more later. These recommendations also apply to adults between 19 and 64 years of age who have specific risk factors such as chronic illnesses (CDC, 2015j). Because pneumonia often follows influenza, especially among older adults, urge all adults to receive the seasonal vaccination annually.

### Chart 31-1

## Patient and Family Education: Preparing for Self-Management

### Preventing Pneumonia

- Know whether you are at risk for pneumonia (older than 65 years, have a chronic health problem)

[especially a respiratory problem], or have limited mobility and are confined to a bed or chair during your waking hours).

- Have the annual influenza vaccine after discussing appropriate timing of the vaccination with your primary health care provider.
- Discuss the pneumococcal vaccine with your primary health care provider and have the vaccination as recommended.
- Avoid crowded public areas during flu and holiday seasons.
- If you have a mobility problem, cough, turn, move about as much as possible, and perform deep-breathing exercises.
- If you are using respiratory equipment at home, clean the equipment as you have been taught.
- Avoid indoor pollutants, such as dust, secondhand (passive) smoke, and aerosols.
- If you do not smoke, do not start.
- If you smoke, seek professional help on how to stop (or at least decrease) your habit.
- Be sure to get enough rest and sleep on a daily basis.
- Eat a healthy, balanced diet.
- Drink at least 3 L (quarts) of nonalcoholic fluids each day (unless fluid restrictions are needed because of another health problem).

Vaccination for pneumonia is now available at the hospital for patients admitted for any other condition. **The Joint Commission's NPSGs include that all inpatients should have their pneumonia vaccination status checked and, if needed, be vaccinated while on in-patient status.** Although this is now a Core Measure, compliance has remained less than desirable. See the [Quality Improvement box](#) to learn about one hospital's program to increase the compliance with this core measure.

## Quality Improvement QSEN

### Enhancing Interprofessional Collaboration Toward Reaching a Core Measure

Michaels, K., & Sidone, L. (2014). Adhering to The Joint Commission's pneumonia core measure. *Nursing*, 44(2), 20-22.

Because of the high morbidity and mortality associated with community-acquired pneumonia, one of The Joint Commission's core measures for hospitalized patients is pneumonia, with vaccination receipt as the outcome measure. This Quality Improvement project was an interprofessional process improvement project at Suburban Hospital in Maryland to meet this core measure.

Before the project, Suburban hospital's nurse-driven pneumonia vaccination program gave nurses the authority to screen patients and implement standing orders for the pneumonia vaccine based on patient eligibility. The patients were screened and then vaccinated on the day of discharge. On audit, the compliance rate for this activity was only 47%.

After a thorough investigation into the practice by a multidisciplinary team, it was determined that vaccination on the day of discharge was the probable barrier. Reasons for this included patients being in a hurry to leave and not wanting to wait or having other concerns and questions during the discharge process.

The team established a pilot program in which nurses screened patients for vaccine eligibility when they were admitted and a pharmacist administered the vaccination on the second or third day of the hospital stay. The pharmacist was responsible for obtaining a prescription from the provider and securing the vaccine, which had been removed from the medication dispensing units

on the floors.

The program included educating nurses and pharmacists about the changes, generating new reports that contained vaccination information for each patient, collaborating with other members of the health care team (social workers, unit managers, and staff educators), and a protocol for determining vaccine status from patients admitted from long-term care facilities.

After the program was implemented, Suburban Hospital's program demonstrated compliance rates of 95% to 99% for vaccination.

### Commentary: Implications for Practice and Research

This Quality Improvement project demonstrates the value of creative, out-of-the-box thinking and interprofessional collaboration. Identification of a probable barrier to consistently attaining 100% compliance was found to be short (<24 hour) hospital admissions. The team is implementing a new process in which the reports on vaccine eligibility are reviewed twice a day.

Other prevention techniques include strict handwashing to avoid spreading organisms and avoiding crowds during cold and flu season. Teach the patient who has a cold or the flu to see his or her primary health care provider if fever lasts more than 24 hours, if the problem lasts longer than 1 week, or if symptoms worsen.

Respiratory therapy equipment must be well maintained and decontaminated or changed as recommended. Use sterile water rather than tap water in GI tubes and institute Aspiration Precautions as indicated, including screening patients for aspiration risk.

VAP is on the rise, but the risk can be reduced with conscientious assessment and meticulous nursing care. The preventive care for VAP is discussed in detail in [Chapter 32](#).

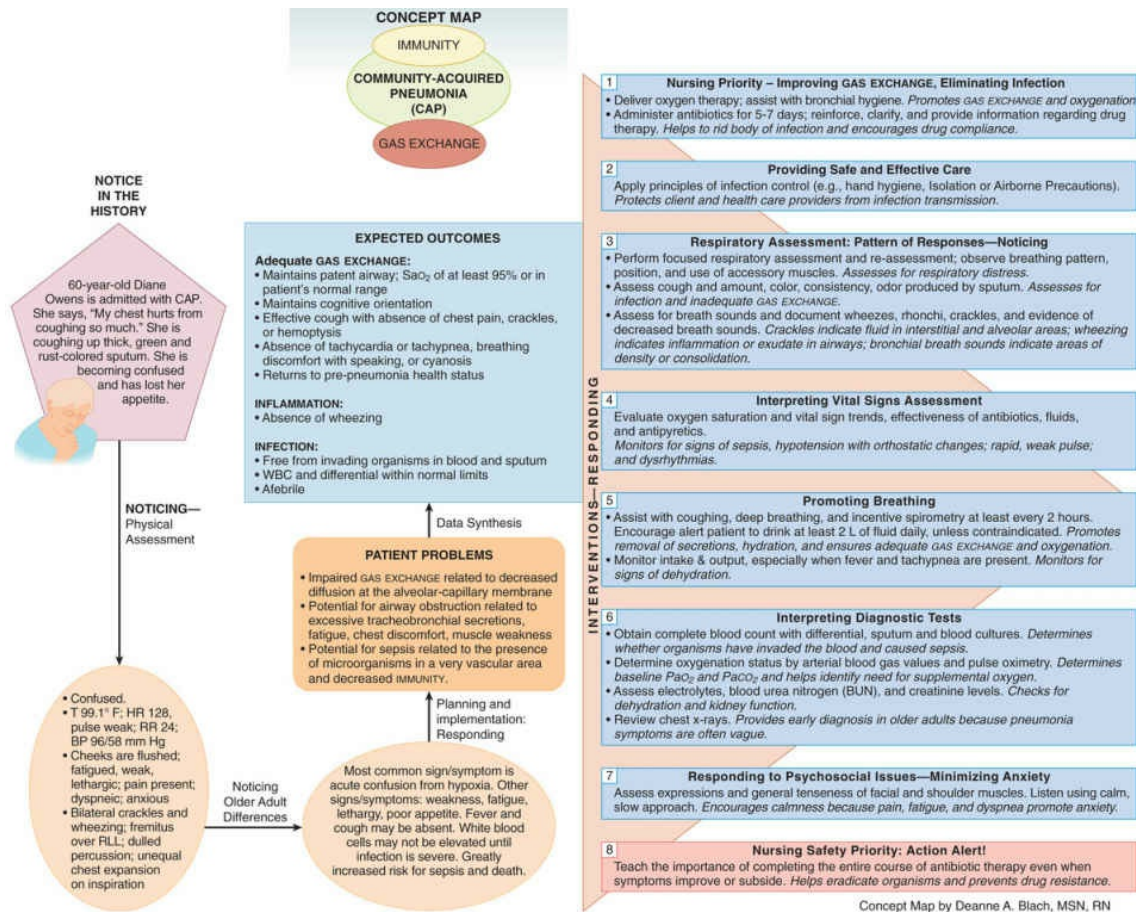

## Nursing Safety Priority QSEN

### Action Alert

Because pneumonia is a frequent cause of sepsis, use a sepsis screening tool to monitor patients who have pneumonia. For patients with pneumonia, always check oxygen saturation with vital signs.

## ❖ Interprofessional Collaborative Care

Depending on the patient's overall health status, the specific cause of the pneumonia, and the severity of hypoxemia, patients may be cared for in the home or other residential setting or may need acute hospital care. The [Concept Map](#) addresses assessment and nursing care issues related to patients who have pneumonia. Signs and symptoms of pneumonia differ in older patients compared with younger patients.

## ◆ Assessment: Noticing

### History.

Assess for the risk factors for infection (see [Table 31-1](#)). Document age; living, work, or school environment; diet, exercise, and sleep routines; swallowing problems; presence of a nasogastric tube; tobacco and alcohol use; and past and current use of or addiction to “street” drugs. Remember that often aspiration is “silent” with no signs or symptoms. Ask about past respiratory illnesses and whether the patient has been exposed to influenza or pneumonia or has had a recent viral infection.

If the patient has chronic respiratory problems, ask whether respiratory equipment is used in the home. Assess whether the patient's home cleaning routine is adequate to prevent infection. Ask when he or she received the last influenza or pneumococcal vaccine. Ask family members whether they have noticed a change in the patient's COGNITION.

### Physical Assessment/Signs and Symptoms.

Observe the general appearance. Many patients with pneumonia have flushed cheeks and an anxious expression. The patient may have chest pain or discomfort, myalgia, headache, chills, fever, cough, tachycardia, dyspnea, tachypnea, hemoptysis, and sputum production. Severe chest muscle weakness also may be present from sustained coughing.

Observe the patient's breathing pattern, position, and use of accessory muscles. The patient with hypoxia and reduced GAS EXCHANGE may be uncomfortable in a lying position and will sit upright, balancing with the hands (“tripod position”). Assess the cough and the amount, color, consistency, and odor of sputum produced.

Crackles are heard with auscultation when fluid is in interstitial and alveolar areas, and breath sounds may be diminished. Wheezing may be heard if inflammation or exudate narrows the airways. Bronchial breath sounds are heard over areas of density or consolidation. Fremitus is increased over areas of pneumonia, and percussion is dulled. Chest expansion may be diminished or unequal on inspiration.

In evaluating vital signs, compare the results with baseline values. The patient with pneumonia, especially the older adult, is often hypotensive with orthostatic changes because of vasodilation and dehydration. A rapid, weak pulse may indicate hypoxemia, dehydration, or impending sepsis and shock. Dysrhythmias may occur from cardiac tissue hypoxia. Common pneumonia signs and symptoms and their causes are listed in [Table 31-3](#).

**TABLE 31-3**  
**Pathophysiology of Common Signs and Symptoms of Pneumonia**

SIGN OR SYMPTOM	PATHOPHYSIOLOGY
Increased respiratory rate/dyspnea	Stimulation of chemoreceptors Increased work of breathing as a result of decreased lung compliance Stimulation of J receptors Anxiety Pain
Hypoxemia	Alveolar consolidation Pulmonary capillary shunting
Cough	Fluid accumulation in the receptors of the trachea, bronchi, and bronchioles
Purulent, blood-tinged, or rust-colored sputum	A result of the inflammatory process in which fluid from the pulmonary capillaries and red blood cells moves into the alveoli
Fever	Phagocytes release pyrogens that cause the hypothalamus to increase body temperature
Pleuritic chest discomfort	Inflammation of the parietal pleura causes pain on inspiration

Use an evidence-based pneumonia severity scale to help determine where the patient should be managed. Two such tools are the Pneumonia Severity Index (PSI) and the CURB-65. The PSI uses four risk categories (demographics, comorbid conditions, physical examination, and selected laboratory values) to determine a score that shows the severity of the patient's pneumonia. The CURB-65 relies on laboratory values (blood urea nitrogen [BUN], age, respiration, blood pressure, and presence of confusion).

## Considerations for Older Adults

### Patient-Centered Care QSEN

The older adult with pneumonia has weakness, fatigue (which can lead to falls), lethargy, confusion, and poor appetite. Fever and cough may be absent, but hypoxemia is often present. The most common symptom of pneumonia in the older-adult patient is a change in COGNITION with acute confusion from hypoxia. The WBC count may not be elevated until the infection is severe. Waiting to treat the disease until more typical symptoms appear greatly increases the risk for sepsis and death (Touhy & Jett, 2016).

### Psychosocial Assessment.

The patient with pneumonia often has pain, fatigue, and dyspnea, all of which promote anxiety. Assess anxiety by looking at his or her facial expression and general tenseness of facial and shoulder muscles. Listen to the patient carefully, and use a calm approach. Because of airway obstruction and muscle fatigue, the patient with dyspnea speaks in broken sentences. Keep the interview short if severe dyspnea or breathing discomfort is present.

### Laboratory Assessment.

Sputum is obtained and examined by Gram stain, culture, and sensitivity testing; however, the responsible organism often is not identified. A sputum sample is easily obtained from the patient who can cough into a specimen container. Extremely ill patients may need suctioning to obtain a sputum specimen. In these situations, a specimen is obtained by sputum trap ([Fig. 31-1](#)) during suctioning. A complete blood count (CBC) is obtained to assess for an elevated WBC count, which is a common finding except in older adults. Blood cultures may be performed to determine whether the organism has entered the bloodstream.

**FIG. 31-1** Lukens tube for collection of sterile sputum/mucus specimens. (Courtesy Covidien, AG, Switzerland.)

In severely ill patients, arterial blood gases (ABGs) may be assessed to determine baseline arterial oxygen and carbon dioxide levels and to help identify a need for supplemental oxygen. Serum electrolyte, blood urea nitrogen (BUN), and creatinine levels also are assessed. A high BUN level may occur as a result of dehydration. Hypernatremia (high blood sodium levels) occurs with dehydration. A lactate level may be ordered to help assess for sepsis.

### Imaging Assessment.

Chest x-ray is the most common diagnostic test for pneumonia but may not show changes until 2 or more days after symptoms are present. It usually appears on chest x-ray as an area of increased density. It may involve a lung segment, a lobe, one lung, or both lungs. *In the older adult, the chest x-ray is essential for early diagnosis because pneumonia symptoms are often vague* (Touhy & Jett, 2016).

### Other Diagnostic Assessments.

Pulse oximetry is used to assess for hypoxemia. Thoracentesis is used in patients who have an accompanying pleural effusion.

#### ◆Analysis: Interpreting

The priority collaborative problems for patients with pneumonia include:

1. Decreased GAS EXCHANGE due to decreased diffusion at the alveolar-capillary membrane
2. Potential for airway obstruction due to excessive pulmonary secretions, fatigue, muscle weakness
3. Potential for sepsis due to the presence of microorganisms in a very vascular area and decreased IMMUNITY.
4. Potential for pulmonary empyema due to spread of infectious organisms from the lung into the pleural space.

#### ◆Planning and Implementation: Responding

##### Improving Gas Exchange

##### Planning: Expected Outcomes.

The patient with pneumonia is expected to have adequate GAS EXCHANGE and oxygenation. Indicators of adequacy are:

- Maintenance of SaO<sub>2</sub> of at least 95% or in the patient's normal range
- Absence of crackles and wheezes on auscultation

- Absence of cyanosis
- Maintenance of cognitive orientation

#### Interventions.

Interventions to improve GAS EXCHANGE are similar to those for the patient with asthma or chronic obstructive pulmonary disease (see [Chapter 30](#)). Nursing priorities include delivery of oxygen therapy and assisting the patient with bronchial hygiene.

*Oxygen therapy* is usually delivered by nasal cannula or mask unless the hypoxemia does not improve with these devices. The patient who is confused may not tolerate a facemask. Check the skin under the device and under the elastic band, especially around the ears, for areas of redness or skin breakdown. Actions for oxygen therapy are listed in [Chart 28-1](#).

*Incentive spirometry* is used to improve inspiratory muscle action and prevent or reverse atelectasis (alveolar collapse). Instruct the patient to sit up if possible; exhale fully; place the mouthpiece in his or her mouth; take a long, slow, deep breath, raising the piston as high as possible; and then hold the breath for 2 to 4 seconds before slowly exhaling. Evaluate technique and record the volume of air inspired. Teach the patient to perform 5 to 10 breaths per session every hour while awake.

### Preventing Airway Obstruction

#### Planning: Expected Outcomes.

The patient with pneumonia is expected to maintain a patent airway. Indicators are:

- Effective cough
- Absence of pallor or cyanosis
- Pulse oximetry at or above 95%

#### Interventions.

Interventions to improve GAS EXCHANGE by avoiding airway obstruction in pneumonia are similar to those for chronic obstructive pulmonary disease (COPD) or asthma. Because of fatigue, muscle weakness, chest discomfort, and excessive secretions, the patient often has difficulty clearing secretions. Help him or her cough and deep breathe at least every 2 hours. The alert patient may use an incentive spirometer to facilitate deep breathing and stimulate coughing. Encourage the alert patient to drink at least 2 L of fluid daily to prevent dehydration and to thin secretions unless another health problem requires fluid restriction. Monitor intake and output; oral mucus membranes; and skin turgor to assess hydration status, especially when fever and tachypnea are present.

Bronchodilators, especially beta<sup>2</sup> agonists (see [Chart 30-6](#)), are prescribed when bronchospasm is present. They can be given by nebulizer or metered-dose inhaler. Inhaled or IV steroids are used with acute pneumonia when airway swelling is present. Expectorants such as guaifenesin (Mucinex) may be used.

### Preventing Sepsis

#### Planning: Expected Outcomes.

The patient with pneumonia is expected to be free of the invading organism and to return to a pre-pneumonia health status. Indicators are:

- Absence of fever
- Absence of pathogens in blood and sputum cultures
- WBC count and differential within normal limits

#### Interventions.

Eliminating the infecting organism is key to treating pneumonia and preventing sepsis. When sepsis occurs with pneumonia, the risk for death is high. Anti-infectives are given for all types of pneumonias except those caused by viruses. Which drugs and the route of delivery prescribed are based on how the pneumonia was acquired (i.e., CAP, HAP, or HCAP), how ill the patient is, which organism is involved, and whether the patient has conditions that increase the risk for

complications, especially reduced IMMUNITY. The primary health care provider must consider drug resistance in the specific geographic area and in that hospital setting. Drug resistance is becoming increasingly common, especially for infections with *Streptococcus pneumoniae* (drug-resistant *S. pneumoniae* [DRSP]). Usually anti-infectives are used for 5 to 7 days for a patient with uncomplicated CAP and up to 21 days for a patient with severely impaired immunity or one with HAP.

For pneumonia caused by aspiration of food or stomach contents, interventions focus on preventing lung damage and treating the infection. Aspiration of acidic stomach contents can cause widespread inflammation, leading to acute respiratory distress syndrome (ARDS) and permanent lung damage. See [Chapter 32](#) for a discussion of ARDS.

### Managing Empyema.

When pulmonary empyema occurs as a result of pneumonia, further interventions are needed. **Pulmonary empyema** is a collection of pus in the pleural space most commonly caused by pulmonary infection. When empyema is present, GAS EXCHANGE can be impaired by both reduced lung diffusion and reduced effective ventilation.

Empyema is suspected when chest wall motion is reduced, fremitus is reduced or absent, percussion is flat, and breath sounds are decreased. Abnormal breath sounds, including bronchial breath sounds, egophony, and whispered pectoriloquy, also may be present. Diagnosis is made by chest x-ray or CT scan and a sample of the pleural fluid (obtained via thoracentesis). Empyema fluid is thick, opaque, exudative, and foul smelling.

Treatment includes draining the empyema cavity, re-expanding the lung, and controlling the infection. Appropriate antibiotics are prescribed. A chest tube(s) to closed-chest drainage is used to promote lung expansion and drainage. The tube is removed when the lung is fully expanded and the infection is under control. Chest surgery may be needed for thick pus or excessive pleural thickening. Nursing interventions are similar to those for patients with a pleural effusion, pneumothorax, or infection. [Chapters 30](#) and [32](#) discuss these interventions in more detail.

## NCLEX Examination Challenge 31-3

### Safe and Effective Care Environment

When reviewing the laboratory values for a client admitted with pneumonia, which result will cause the nurse to collaborate quickly with the primary health care provider?

- A. White blood cell (WBC) count of  $14,526 \text{ mm}^3$
- B.  $\text{PaO}_2$  68 mm Hg
- C.  $\text{PaCO}_2$  46 mm Hg
- D. Blood glucose 146 mg/dL

### Care Coordination and Transition Management

The patient needs to continue the anti-infective drugs as prescribed. An important nursing role is to reinforce, clarify, and provide information to the patient and family as needed.

### Home Care Management.

No special changes are needed in the home. If the home has a second story, the patient may prefer to stay on one floor for a few weeks, because stair climbing can be tiring. Toileting needs may be met by using a bedside commode if a bathroom is not located on the level the patient is using. Home care needs depend on the patient's level of fatigue, dyspnea, and family and social support.

The long recovery phase, especially in the older adult, can be frustrating. Fatigue, weakness, and a residual cough can last for weeks. Some patients fear they will never return to a "normal" level of functioning. Prepare them for the disease course and offer reassurance that complete recovery will occur. After discharge a home nursing assessment may be helpful. [Chart 31-2](#) details the assessment

of a patient recovering from pneumonia.

### **Chart 31-2**

## **Focused Assessment**

### **The Patient Recovering from Pneumonia**

Ask whether the patient has had any of these:

- New-onset confusion
- Chills
- Fever
- Persistent cough
- Dyspnea
- Wheezing
- Hemoptysis
- Increased sputum production
- Chest discomfort
- Increasing fatigue
- Any other symptoms that have failed to resolve

Assess the patient for:

- Fever
- Diaphoresis
- Cyanosis, especially around the mouth or conjunctiva
- Dyspnea, tachypnea, or tachycardia
- Adventitious or abnormal breath sounds
- Weakness

### **Self-Management Education.**

Review all drugs with the patient and family and emphasize the importance of completing anti-infective therapy. Teach the patient to notify the primary health care provider if chills, fever, persistent cough, dyspnea, wheezing, hemoptysis, increased sputum production, chest discomfort, or increasing fatigue returns or fails to go away completely. Instruct him or her to get plenty of rest and increase activity gradually.

An important aspect of education for the patient and family is avoiding upper respiratory tract infections and viruses. Teach him or her to avoid crowds (especially in the fall and winter when viruses are prevalent), people who have a cold or flu, and exposure to irritants such as smoke. A balanced diet and adequate fluid intake are essential.

### Health Care Resources.

Inform patients who smoke that smoking is a risk factor for pneumonia. **Provide them with information on local smoking-cessation classes and nicotine replacement options as recommended by The Joint Commission's NPSGs** (see [Chapter 27](#)). Teach about pneumonia and urge the patient who has not already been vaccinated against influenza or pneumonia to get these vaccinations after the pneumonia has resolved. Vaccinations will boost IMMUNITY to these diseases.

## Nursing Safety Priority QSEN

### Drug Alert

Warn the patient using nicotine patches or supplements of the danger of myocardial infarction if smoking is continued while using other forms of nicotine.

### ◆ Evaluation: Reflecting

Evaluate the care of the patient with pneumonia based on the identified priority patient problems. The expected outcomes are that he or she:

- Attains or maintains adequate GAS EXCHANGE
- Maintains patent airways
- Is free of the invading organism
- Avoids empyema
- Returns to his or her pre-pneumonia health status

## Immunity Concept Exemplar Pulmonary Tuberculosis

### Pathophysiology

**Tuberculosis (TB)** is a highly communicable disease caused by *Mycobacterium tuberculosis*. It is one of the most common bacterial infections worldwide. The organism is transmitted via **aerosolization** (i.e., an airborne route) (Fig. 31-2). When a person with active TB coughs, laughs, sneezes, whistles, or sings, infected respiratory droplets become airborne and may be inhaled by others. Far more adults are infected with the bacillus than actually develop active TB. This is because the normal protection of **IMMUNITY** prevents full development of TB in the healthy person. **Immunity** is the body's physiologic defense mechanisms that protect from illness or disease. See Chapter 2 for a discussion that summarizes the concept of immunity.

**FIG. 31-2** Primary TB infection with progression to secondary infection and active disease. *HIV*, Human immune deficiency virus; *M. tuberculosis*, *Mycobacterium tuberculosis*; *TB*, tuberculosis. (Illustration from Workman, M. L., & LaCharity, L. (2016). *Understanding pharmacology* (2nd ed.). St. Louis: Saunders; photo from Kumar, V., Abbas, A., & Aster, J. (2015). *Robbins and Cotran pathologic basis for disease* [9th ed.]. Philadelphia: Saunders.)

The bacillus multiplies freely when it reaches a susceptible site (bronchi or alveoli). An exudative response occurs, causing pneumonitis. With the development of acquired **IMMUNITY** to TB, further growth of bacilli is controlled in most cases. The lesions usually resolve and leave little or no residual bacilli. Only a small percentage of adults infected with the bacillus ever develop active TB.

Cell-mediated **IMMUNITY** against TB develops 2 to 10 weeks after infection and is manifested by a positive reaction to a tuberculin test. The primary infection may be so small that it does not appear on a chest x-ray. The process of infection occurs in this order:

1. The granulomatous inflammation created by the TB bacillus in the lung becomes surrounded by collagen, fibroblasts, and lymphocytes.
2. **Caseation necrosis**, which is necrotic tissue being turned into a granular mass, occurs in the center of the lesion. If this area shows on x-ray, it is the *primary* lesion.

Areas of caseation then undergo resorption, degeneration, and fibrosis. These necrotic areas may calcify (*calcification*) or liquefy (*liquefaction*). If liquefaction occurs, this material then empties into a bronchus, and the emptied area becomes a cavity (*cavitation*). Bacilli continue to grow in the necrotic cavity wall and spread through the lymph channels into new areas of the lung.

A lesion also may grow by direct extension if bacilli multiply rapidly during inflammation. The lesions can extend through the pleura, resulting in pleural or pericardial effusion. **Miliary** or **hematogenous TB** is the spread of TB throughout the body when a large number of organisms

enter the blood. Many tiny nodules scattered throughout the lung are seen on chest x-ray. Other body areas can become infected as a result of this spread.

*Initial infection* is seen more often in the middle or lower lobes of the lung. The local lymph nodes are infected and enlarged. An asymptomatic period usually follows the primary infection and can last for years or decades before clinical symptoms develop. This is called *latent TB*. *An infected person is not contagious to others until symptoms of disease occur.*

*Secondary TB* is a reactivation of the disease in a previously infected person. It is more likely when defenses are lowered and IMMUNITY is reduced. This is seen in older adults, those with chronic diseases, and especially those with HIV disease. The upper lobes are common sites of reactivation.

## Etiology

*M. tuberculosis* is a slow-growing, acid-fast rod transmitted via the airborne route. Adults most often infected are those having repeated close contact with an infectious person who has not yet been diagnosed with TB. The risk for transmission is reduced after the infectious person has received proper drug therapy for 2 to 3 weeks, clinical improvement occurs, and acid-fast bacilli (AFB) in the sputum are reduced.

## Incidence and Prevalence

Worldwide, 9.5 million people were diagnosed, and an additional 1.45 million people died from TB in 2012 (WHO, 2016). About one-third of the entire world population has latent TB (WHO, 2015a). In the United States, there were over 9000 new cases of TB in 2014 (CDC, 2015m). The incidence of TB has been steadily decreasing in North America, although increases in incidence are seen in many other countries (WHO, 2015a). In North America, the adults who are at greatest risk for development of TB are:

- Those in constant, frequent contact with an untreated person
- Those who have reduced IMMUNITY or HIV
- Adults who live in crowded areas such as long-term care facilities, prisons, homeless shelters, and mental health facilities
- Older homeless adults
- Abusers of injection drugs or alcohol
- Lower socioeconomic groups
- Foreign immigrants (WHO, 2015a)

## Health Promotion and Maintenance

Many adults who acquire TB have risk factors such as homelessness, living in very crowded conditions, or substance abuse with malnutrition. These risk factors are best managed on a societal level. Communities need to work toward providing adequate housing, substance-abuse programs that are accessible, and feeding centers or food banks for those in need. On a personal level, many health conditions make it more likely to contract TB if exposed. Adults with these health conditions should avoid people who are ill, stay well nourished, and practice good handwashing. Any adult who works with people at high risk of having TB should be screened annually.

## ❖ Interprofessional Collaborative Care

### ◆ Assessment: Noticing

Early detection of TB depends on subjective patient reports rather than observable signs or symptoms. TB has a slow onset, and patients are not aware of problems until the disease is advanced. *TB should be considered for any patient with a persistent cough or other symptoms of TB, such as unintended weight loss, anorexia, night sweats, hemoptysis, shortness of breath, fever, or chills.*

### History.

Assess the patient's past exposure to TB. Ask about his or her country of origin and travel to foreign countries where incidence of TB is high. It is important to ask about the results of any previous tests for TB. Also ask whether the patient has had bacille Calmette-Guérin (BCG) vaccine (often given in

childhood overseas), which contains attenuated tubercle bacilli. *Anyone who has received BCG vaccine within the previous 10 years will have a positive skin test that can complicate interpretation.* Usually the size of the skin response decreases each year after BCG vaccination. These patients should be evaluated for TB with a chest x-ray or the QuantiFERON-TB Gold test (CDC, 2015l).

### Physical Assessment/Signs and Symptoms.

The patient with TB has progressive fatigue, lethargy, nausea, anorexia, weight loss, irregular menses, and a low-grade fever. Symptoms may have been present for weeks or months. Night sweats may occur with the fever. A cough with mucopurulent sputum, which may be streaked with blood, is present. Chest tightness and a dull, aching chest pain occur with the cough. Ask about, assess for, and document the presence of any of these symptoms to help with diagnosis, establish a baseline, and plan nursing interventions.

When assessing the patient, you may note dullness with percussion over the involved lung fields, bronchial breath sounds, crackles, and increased transmission of spoken or whispered sounds. Partial obstruction of a bronchus from the disease or compression by lymph nodes may produce localized wheezing.

### Psychosocial Assessment.

Tuberculosis is a frightening diagnosis. Explain the disease thoroughly, including the need to maintain good hygiene and avoid infecting others. The patient may feel isolated and shunned. Take time to listen to him or her and help to resolve any concerns. The family and friends of the patient may have similar concerns as well. Often close contacts will be afraid they have contracted the illness. Encourage all close contacts to get tested. Help the patient notify his or her employer if needed about required time off. Directly observed therapy may feel threatening. Explain how this helps improve adherence to the long treatment schedule.

### Diagnostic Assessment.

There are several methods to test for TB. In addition to chest x-ray, sputum cultures of blood or respiratory secretions can be tested. The most accurate and rapid test for TB is the fully automated nucleic acid amplification test (NAAT) used on respiratory secretions. Results are available in less than 2 hours.

*Sputum culture* confirms the diagnosis. Enhanced TB cultures take up to 4 weeks for a valid result. After drug therapy is started, sputum samples are obtained at intervals to determine therapy effectiveness. Cultures are usually negative after 3 months of effective treatment (CDC, 2015l).

*Blood analysis* can be done with interferon-gamma release assays, or IGRAs. The two available tests are the QuantiFERON-TB Gold In-Tube test and the T-SPOT TB test. Both tests show how the patient's immune system responds to the TB bacterium. A positive result means that the person is infected with TB but does not indicate whether the infection is latent or active. Another blood test, the Xpert MTB/RIF can detect drug-resistant strains of TB and is also recommended for testing people with HIV infection. A new test (GeneXpert Omni) will be available in the future for point-of-care testing (WHO, 2015a).

*The tuberculin test* (Mantoux test) is the most commonly used reliable screening test for TB. A small amount (0.1 mL) of purified protein derivative (PPD) is placed intradermally in the forearm. The test is "read" in 48 to 72 hours. An area of **induration** (localized swelling with hardness of soft tissue), not just redness, measuring 10 mm or greater in diameter, indicates exposure to and possible infection with TB (Fig. 31-3). In certain adults, such as those with decreased IMMUNITY, induration of 5 mm is a positive result. If possible, the site is re-evaluated after 72 hours because false-negative readings occur more often after only 48 hours (CDC, 2015l). *A positive reaction indicates exposure to TB or the presence of inactive (dormant) disease, not active disease. A reduced skin reaction or a negative skin test does not rule out TB disease or infection of the very old or anyone who has severely reduced IMMUNITY.* Failure to have a skin response because of reduced immunity when infection is present is called **anergy**.

**FIG. 31-3** Positive tuberculin skin test with induration. (From Zitelli, B. J., McIntire, S. C., & Nowalk, A. J. (2012). *Zitelli and Davis' atlas of pediatric physical diagnosis* (6th ed.). Philadelphia: Saunders; courtesy Kenneth Schuitt, MD.)

Annual screening is needed for anyone who comes into contact with people who may be infected with TB, including some health care workers. Screening is very important for foreign-born people and migrant workers. Participation in screening programs is higher when programs are delivered in a culturally sensitive and nonthreatening manner. Urge anyone who is considered high risk to have an annual TB screening test.

### Imaging Assessment.

Once a person's skin test is positive for TB, a chest x-ray is used to detect active TB or old, healed lesions. Caseation and inflammation may be seen on the x-ray if the disease is active. The chest x-rays of HIV-infected patients may be normal or may show infiltrates in any lung zone and lymph node enlargement.

#### ◆Analysis: Interpreting

The priority collaborative problems for patients with tuberculosis include:

1. Potential for airway obstruction due to thick secretions and weak cough effort
2. Potential for development of drug-resistant disease and spread of infection due to inadequate adherence to therapy regimen
3. Anxiety due to diagnosis
4. Weight loss due to inadequate intake and nausea from therapy regimen
5. Fatigue due to lengthy illness, poor GAS EXCHANGE, and increased energy demands

#### ◆Planning and Implementation: Responding

##### Promoting Airway Clearance

###### Planning: Expected Outcomes.

The patient with TB is expected to maintain a patent and adequate airway. Indicators of adequacy are:

- Effective cough
- Able to expectorate secretions
- Adequate GAS EXCHANGE
- Absence of cyanosis

###### Interventions.

Interventions to maintain a patent airway are similar to those for pneumonia and COPD. Instruct the patient to drink plenty of fluids unless another condition requires restriction. Teach him or her to take a deep breath before coughing. An incentive spirometer may facilitate effective coughing.

##### Decreasing Drug Resistance and Infection Spread

## Planning: Expected Outcomes.

The patient with TB is expected to become free of active disease and not spread the disease to others.

## Interventions.

Interventions to help the patient become disease free include antimicrobial therapy.

*Combination drug therapy* is the most effective method of treating TB and preventing transmission. Active TB is treated with a combination of drugs to which the organism is sensitive. Therapy continues until the disease is under control. Multiple-drug regimens destroy organisms as quickly as possible and reduce the emergence of drug-resistant organisms. First-line therapy uses isoniazid (INH, Nidrazid), rifampin (Rifadin), pyrazinamide, and ethambutol (Myambutol) for the first 8 weeks, which is called *the initial phase of treatment*. The continuation phase lasts another 18 weeks, and the patient takes INH and rifampin either daily or twice a week (CDC, 2015) (Chart 31-3). These drugs are now available in two- or three-drug combinations. One example is Rifater, which combines isoniazid, pyrazinamide, and rifampin. Variations of the first-line drugs along with other drug types are used when the patient does not tolerate the standard first-line therapy. Nursing interventions focus on patient teaching for drug therapy adherence and infection control.

### Chart 31-3

## Common Examples of Drug Therapy

### First-Line Treatment for Tuberculosis

DRUG	NURSING IMPLICATIONS
<b>Isoniazid (INH, Hydraside, PDP-Isoniazid)</b> Kills actively growing mycobacteria outside the cell and inhibits the growth of dormant bacteria inside macrophages and caseating granulomas	Instruct the patient to avoid antacids and to take the drug on an empty stomach (1 hour before or 2 hours after meals) to prevent slowing of drug absorption in the GI tract. Teach the patient to take a daily multiple vitamin that contains the B-complex vitamins while on this drug because the drug can deplete the body of this vitamin. Remind the patient to avoid drinking alcoholic beverages while on this drug because the liver-damaging effects of this drug are potentiated by drinking alcohol. Tell the patient to report darkening of the urine, a yellow appearance to the skin or whites of the eyes, and an increased tendency to bruise or bleed, which are signs and symptoms of liver toxicity or failure.
<b>Rifampin (RIF, Rifadin, Rimactane, Rofact)</b> Kills slower-growing organisms, even those that reside inside macrophages and caseating granulomas	Warn patients to expect an orange-reddish staining of the skin and urine, and all other secretions to have a reddish-orange tinge; also, soft contact lenses will become permanently stained because knowing the expected side effects decreases anxiety when they appear. Instruct sexually active women using oral contraceptives to use an additional method of contraception while taking this drug and for 1 month after stopping it because this drug reduces the effectiveness of oral contraceptives. Remind the patient to avoid drinking alcoholic beverages while on this drug because the liver-damaging effects of this drug are potentiated by drinking alcohol. Tell the patient to report darkening of the urine, a yellow appearance to the skin or whites of the eyes, and an increased tendency to bruise or bleed, which are signs and symptoms of liver toxicity or failure. Ask the patient about all other drugs in use because this drug interacts with many other drugs.
<b>Pyrazinamide (PZA)</b> Can effectively kill organisms residing within the very acidic environment of macrophages (which is where the tuberculosis bacillus sequesters) Available only in combination with other anti-TB drugs	Ask whether the patient has ever had gout because the drug increases uric acid formation and will make gout worse. Instruct patients to drink at least 8 ounces of water when taking this tablet and to increase fluid intake to prevent uric acid from precipitating, making gout or kidney problems worse. Teach the patient to wear protective clothing, a hat, and sunscreen when going outdoors in the sunlight because the drug causes photosensitivity and greatly increases the risk for sunburn. Remind the patient to avoid drinking alcoholic beverages while on this drug because the liver-damaging effects of this drug are potentiated by drinking alcohol. Tell the patient to report darkening of the urine, a yellow appearance to the skin or whites of the eyes, and an increased tendency to bruise or bleed, which are signs and symptoms of liver toxicity or failure.
<b>Ethambutol (EMB, Etibi, Myambutol)</b> Inhibits bacterial RNA synthesis, thus suppressing bacterial growth Slow acting and bacteriostatic rather than bactericidal; thus it must be used in combination with other anti-TB drugs	Instruct patients to report any changes in vision, such as reduced color vision, blurred vision, or reduced visual fields, immediately to his or her primary health care provider because the drug can cause optic neuritis, especially at high doses, and can lead to blindness. Minor eye problems are usually reversed when the drug is stopped. Remind the patient to avoid drinking alcoholic beverages while on this drug because the drug induces severe nausea and vomiting when alcohol is ingested. (At one time ethambutol was used as drug therapy to help alcoholic patients stop drinking because of the drug's side effects in association with alcohol.) Ask whether the patient has ever had gout because the drug increases uric acid formation and will make gout worse. Instruct patients to drink at least 8 ounces of water when taking this drug and to increase fluid intake to prevent uric acid from precipitating, making gout or kidney problems worse.

Bedaquiline fumarate (Sirturo) is specifically targeted to multidrug-resistant TB. Side effects of this drug can be life threatening, so it is not used when other drugs will work. It should be given through directly observed therapy. Several other drugs for multidrug-resistant TB are in different phases of clinical trials.

*Strict adherence to the prescribed drug regimen is crucial for suppressing the disease.* Adherence is difficult because of the long duration of treatment. (Duration of therapy is often 26 weeks but can be as long as 2 years for multidrug-resistant [MDR] TB.) Thus your major role is teaching the patient about drug therapy and stressing the importance of taking each drug regularly, exactly as prescribed, for as long as it is prescribed. Provide accurate information in multiple formats, such as pamphlets, videos, and drug-schedule worksheets. To determine whether the patient understands how to take the drugs, ask him or her to describe the treatment regimen, side effects, and when to call the health care agency and physician.

## Nursing Safety Priority QSEN

### Drug Alert

The first-line drugs used as therapy for TB all can damage the liver. Warn the patient to not drink any alcoholic beverages for the entire duration of TB therapy. Bedaquiline fumarate can prolong the QT interval, cause ventricular dysrhythmias, and lead to sudden death. Patients on this drug need to have regular electrocardiograms (ECGs) and serum electrolyte evaluations.

The patient with TB often has concerns about the disease prognosis. Offer a positive outlook for the patient who adheres to the drug regimen. *However, with current resistant strains of TB, emphasize that not taking the drugs as prescribed could lead to an infection that is drug resistant.*

Some *multidrug-resistant TB* (MDR TB) strains are emerging as extensively drug-resistant (XDR TB). MDR TB is an infection that resists INH and rifampin. XDR TB is resistant not only to the first-line anti-tuberculosis drugs but also to the second-line antibiotics, including the fluoroquinolones and at least one of the aminoglycosides. The WHO estimates that 3.5% of all TB cases are drug resistant. The most common cause of MDR TB and XDR TB is mismanagement of drug therapy, either from inappropriate selection or use of antibiotics. Patients with acquired immune deficiency syndrome (AIDS) also often have MDR TB (WHO, 2015a). Drug therapy for MDR TB and XDR TB is more limited than standard first-line therapy and requires higher doses for longer periods. Patients who contract TB from a person with a resistant strain will also have a resistant strain of TB. So teaching patients to adhere to their drug regimens will also help them prevent the spread of the disease in both forms.

## Nursing Safety Priority QSEN

### Action Alert

Warn patients with extensively drug-resistant TB that absolute adherence to therapy is critical for survival and cure of the disease. These patients should receive directly observed therapy (DOT) (described under the “Self-Management Education” section).

The hospitalized patient with active TB is placed on Airborne Precautions (see Chapter 23) in a well-ventilated room that has at least six exchanges of fresh air per minute. All health care workers must use a personal respirator when caring for the patient. Use Standard Precautions with appropriate protection as with all patients. **In accordance with The Joint Commission's NPSGs, perform handwashing before and after patient care.** Precautions are discontinued when the patient is no longer contagious.

*Other care issues* for the patient with TB include teaching about infection prevention and what to expect about disease monitoring and participating in activities. TB is often treated outside the acute care setting, with the patient convalescing at home. Airborne Precautions are not necessary in this setting because family members have already been exposed; however, all members of the household need to undergo TB testing. Teach the patient to cover the mouth and nose with a tissue when coughing or sneezing, to place used tissues in plastic bags, and to wear a mask when in contact with crowds until the drugs suppress infection.

Tell the patient that sputum specimens are needed usually every 2 to 4 weeks once drug therapy is initiated. When the results of three consecutive sputum cultures are negative, the patient is no longer infectious (contagious) and may return to former activities. Remind him or her to avoid exposure to any inhalation irritants because these can cause further lung damage.

## NCLEX Examination Challenge 31-4

### Health Promotion and Maintenance

Which information is **most important** for a nurse to include when teaching a client with tuberculosis about the prescribed first-line drug therapy?

- A. "Report darkening or reddening of the urine while taking Rifampin."
- B. "Do not drink alcohol in any quantity while taking Isoniazid."
- C. "Restrict fluid intake to 2 quarts of liquid a day on pyrazinamide."
- D. "Temporary visual changes while taking ethambutol are not serious."

## Managing Anxiety

### Planning: Expected Outcomes.

The patient with TB is expected to have adequate knowledge about the disease and report decreased anxiety. Indicators of decreased anxiety include:

- Patient report of reduced anxiety
- Relaxed facial features and muscles
- Ability to listen and retain information

### Interventions.

The nurse can provide many interventions to decrease anxiety if present. First assess the patient for subjective reports of anxiety and work with him or her to determine the source. Most patients will need education regarding the disease. When teaching the patient and family with either MDR TB or XDR TB, stress that it is the organism, not the patient, that is drug resistant because that can sometimes be misunderstood. Patients may be anxious about isolation if hospitalized or about spreading the disease to housemates or visitors. They may also be concerned about contacting an employer. Provide education and support. Refer the patient to social services if he or she does not have sick leave and will lose pay during the time off work.

## Improving Nutrition

### Planning: Expected Outcomes.

The patient with TB is expected to have improved nutrition. Indicators of improved nutrition include:

- Weight gain
- Improvement in laboratory values indicating nutritional status
- Improved stamina
- Reports eating a healthy, balanced diet

### Interventions.

The patient with TB often has a long-standing history of malnutrition. Conduct a nutrition assessment using an evidence-based tool. Determine patient likes/dislikes, the ability to buy healthy food, condition of teeth or dentures, weight and body mass index, and history of substance abuse. When inadequate nutrition is a problem, be sure to include a registered dietitian as part of the interprofessional team.

Drugs to treat TB often cause nausea. If this happens, instruct the patient to take once-a-day drugs at night. Antiemetics can also be prescribed. If food doesn't interfere with the drug absorption (check the label), taking pills with a small snack of simple carbohydrates may help. Refer the patient to Meals on Wheels or other meal-delivery service. Instruct him or her about good oral hygiene, which makes food taste better. Weigh the patient once a week at the primary health care provider's office or, if he or she is receiving home health care services, have the agency weigh the patient and report the results to the provider.

For best healing, the patient should eat a diet with quality protein; iron; vitamins A, B, C, and E; and abundant fresh produce. Educate him or her about nutrition in consultation with a registered dietitian. Tell the patient to avoid alcohol. Alcohol can cause liver damage, and so can most of the antituberculosis drugs. Alcohol is also a source of "empty calories," and adults who abuse alcohol often are malnourished. An adult who gets a large number of calories from alcohol will not feel hungry. A special problem for this group of patients is lack of phosphorus, which is part of the

cellular energy compound ATP. With low phosphorus, the patient will lack energy. Refer the patient to support groups if alcoholism or other substance abuse is present. Improved nutrition will improve IMMUNITY.

## Managing Fatigue

### Planning: Expected Outcomes.

The patient with TB is expected to have improved stamina and less fatigue. Indicators of improved fatigue include:

- Patient report of increased energy
- Increased activity and activity tolerance
- Increased ability to concentrate

### Interventions.

Many of the interventions for fatigue will be the same as those for improving nutrition. Poor nutrition can lead directly to fatigue. Encourage the patient to resume activities slowly and get plenty of rest. Reassure him or her that the fatigue will improve as therapy progresses. Assess the patient's sleep-wake habits and encourage a full night's sleep with short day-time naps. Help him or her develop a healthy bed-time ritual if needed. Mental stamina may be decreased as a result of the lengthy convalescence. Reassure the patient that, by taking drugs as directed, the disease will be cured and energy levels will increase.

## Care Coordination and Transition Management

### Home Care Management.

Most patients with TB are managed outside the hospital; however, patients may be diagnosed with TB while in the hospital for another problem. Discharge may be delayed if the living situation is high risk or if nonadherence is likely. Ensure collaboration with other members of the interprofessional team, including the case manager or social service worker in the hospital or the community health nursing agency, to ensure that the patient is discharged to the appropriate environment with continued supervision.

### Self-Management Education.

Teach the patient to follow the drug regimen exactly as prescribed and always to have a supply on hand. Teach about side effects and ways of reducing them to promote adherence. Remind him or her that the disease is usually no longer contagious after drugs have been taken for 2 to 3 consecutive weeks and clinical improvement is seen; however, *he or she must continue with the prescribed drugs for 6 months or longer as prescribed*. **Directly observed therapy (DOT)**, in which a health care professional watches the patient swallow the drugs, may be indicated in some situations. This practice leads to more treatment successes, fewer relapses, and less drug resistance.

The patient who has weight loss and severe lethargy should gradually resume usual activities. Proper nutrition is needed to prevent infection recurrence.

Provide the patient with information about how TB can be spread to others. A key to preventing transmission is identifying those in close contact with the infected person so they can be tested and treated if needed. Identified contacts are assessed with a TB test and possibly a chest x-ray to determine infection status. Multidrug therapy may be indicated to prevent TB in heavily exposed individuals or for those who have other health problems that reduce IMMUNITY.

### Health Care Resources.

Teach the patient to receive follow-up care by a primary health care provider for at least 1 year after active treatment. The American Lung Association (ALA) can provide free information to the patient about the disease and its treatment. In addition, Alcoholics Anonymous (AA) and other health care resources for patients with alcoholism are available if needed. Assist the patient who uses illicit drugs to locate a drug-treatment program. **In accordance with The Joint Commission's NPSGs, urge smokers to quit and help them find an appropriate smoking-cessation program** (see [Chapter 27](#)).

### ◆**Evaluation: Reflecting**

Evaluate the care of the patient with TB based on the identified priority patient problems. The expected outcomes are that he or she:

- Effectively clears his or her airways
- Is free of the invading organism and does not spread the infection
- Has reduced anxiety
- Demonstrates improved nutrition
- Reports decreased fatigue and increased energy
- Returns to his or her pre-tuberculosis health status

# Rhinosinusitis

## ❖ Pathophysiology

**Rhinosinusitis** is an inflammation of the mucous membranes of one or more of the sinuses and is usually seen with rhinitis, especially the common cold (coryza). Anything that interferes with sinus drainage (e.g., deviated nasal septum, nasal polyps or tumors, inhaled air pollutants or cocaine, allergies, facial trauma, and dental infection) can lead to rhinosinusitis. Even when the problem starts with a noninfectious cause such as seasonal allergies, swelling usually blocks the flow of secretions from the sinuses, which may then become infected.

Most episodes of rhinosinusitis are caused by viruses and usually develop in the maxillary and frontal sinuses, although bacterial infections also can occur. Complications include cellulitis, abscess, and meningitis.

Diagnosis is made based on the patient's history and symptoms, but other tests in complicated cases include endoscopic examination and CT scans. Plain x-rays are not helpful in viewing sinuses and are not recommended. Purulent drainage, fever, and lack of response to decongestants can indicate a bacterial infection. Cultures are not usually necessary but may be useful in patients who do not respond to therapy or who develop complications.

## ❖ Interprofessional Collaborative Care

Overwhelmingly rhinosinusitis is managed as an outpatient problem. Even when sinus surgery is needed, it usually takes place in an ambulatory surgical setting.

Assess for signs and symptoms of rhinosinusitis. Common symptoms include pain over the cheek radiating to the teeth, tenderness to percussion over the sinuses, referred pain to the temple or back of the head, and general facial pain that is worse when bending forward. Additional symptoms in bacterial infection include purulent nasal drainage with postnasal drip, sore throat, fever, erythema, swelling, fatigue, dental pain, and ear pressure.

Management focuses on symptom relief and patient education. Teach him or her about correct use of the drug therapy prescribed.

*Drug therapy* commonly includes decongestants and intranasal steroid spray. *Antihistamines*, *leukotriene inhibitors*, and *mast cell stabilizers* block or reduce the amount of chemical mediators in nasal and sinus tissues and prevent local edema and itching. *Decongestants* constrict blood vessels and decrease edema. *Antipyretics* are given if fever is present, and analgesics may be given for pain.

## 📌 Considerations for Older Adults

### 📌 Patient-Centered Care QSEN

First-generation antihistamines are potentially inappropriate drugs for use in older adults. In this population, problems with these drugs include reduced drug clearance, higher risk for confusion, and anticholinergic effects such as dry mouth and constipation. Common drugs in this category include chlorpheniramine (Chlor-Trimeton), diphenhydramine (Aller-Aid 🍀, Allerdryl 🍀, Benadryl), and hydroxyzine (Vistaril). Educate older adults that they should not take these drugs.

Treatment for bacterial rhinosinusitis includes broad-spectrum antibiotics (e.g., amoxicillin [Amoxil, Novamoxin 🍀]), decongestants (e.g., phenylephrine [Neo-Synephrine]), and antipyretics. In some cases, nasal steroids or systemic steroids may be prescribed. If no improvement is seen within 48 hours, the patient may need further evaluation. Endoscopic sinus surgery to relieve obstruction and promote sinus drainage may be needed if nonsurgical management fails to provide relief.

## 📌 Nursing Safety Priority QSEN

### 📌 Action Alert

Teach patients with any bacterial infection the importance of completing the entire antibiotic prescription, even when symptoms improve or subside. This will help eradicate the organism and prevents development of resistant bacterial strains.

*Supportive therapy* such as humidification, nasal irrigation, and applying hot wet packs over the sinus area can increase the patient's comfort and help prevent spread of the infection. Instruct the patient about the importance of rest (8 to 10 hours a day) and fluid intake of at least 2000 mL/day unless other health problems require fluid restriction. Humidifying the air helps relieve congestion. Humidity can be increased with a room humidifier or by breathing steamy air in the bathroom after running hot shower water. Nasal saline irrigation is an inexpensive treatment with few side effects. Sleeping with the head of the bed elevated and avoiding cigarette smoke may reduce discomfort. If the condition is caused by allergies, limiting exposure to the offending agent is helpful (see [Chapter 20](#)).

Teach patients to reduce the risk for spreading infections by thoroughly washing hands, especially after nose blowing, sneezing, coughing, rubbing the eyes, or touching the face. Other precautions include staying home from work, school, or other crowded places; covering the mouth and nose with a tissue when sneezing or coughing; disposing properly of used tissues immediately; and avoiding close contact with others.

## Peritonsillar Abscess

**Peritonsillar abscess (PTA)** is a rare complication of acute tonsillitis. The infection spreads from the tonsil to the surrounding tissue and forms an abscess. The most common cause of PTA is group A beta-hemolytic *Streptococcus*, although the abscess often contains multiple organisms (Shah, 2014).

Signs and symptoms include a collection of pus behind the tonsil causing swelling on one side of the throat, pushing the uvula toward the unaffected side. The patient may have severe throat pain radiating to the ear or teeth, a muffled voice, fever, and difficulty swallowing. He or she may also have a tonic contraction of the muscles of chewing (trismus) and difficulty breathing. Bad breath is present, and lymph nodes on the affected side are swollen. Diagnosis is usually made based on the patient's symptoms, but needle aspiration and culture of pus collected is the preferred test.

Most patients can be treated as outpatients with antibiotics. However, antibiotics alone are often ineffective. The patient may need steroids to reduce the swelling, and some may need drainage of the abscess. Pain control is important; drugs may include topical anesthetics, over-the-counter analgesics, and opioids. The patient may need liquid drugs because of swallowing difficulty. *Stress the importance of completing the antibiotic regimen and coming to the emergency department quickly if symptoms of obstruction (drooling and stridor) appear.* Hospitalization is needed when the airway is endangered or when the infection does not respond to antibiotic therapy. A tonsillectomy may be performed to prevent recurrence.

# Inhalation Anthrax

## ❖Pathophysiology

Inhalation anthrax (respiratory anthrax) is a bacterial infection caused by the gram-positive organism *Bacillus anthracis*. This organism lives as a spore in soil where grass-eating animals live and graze. Most cases of anthrax are on the skin (cutaneous). Inhalation anthrax accounts for only about 5% of cases, and GI anthrax accounts for about 1% of cases of the disease. When infection occurs through the lungs, the disease is nearly 100% fatal without treatment (CDC, 2015b). Inhalation anthrax is rare in North America and is not spread by person-to-person contact. It is an occupational hazard of veterinarians; farmers; taxidermists; and others who frequently contact animal wool, hides, bone meal, and skin (CDC, 2015a).

## 📌Nursing Safety Priority QSEN

### Action Alert

Because inhalation anthrax is so rare, any occurrence in a person who does not have an occupational risk is considered an intentional act of bioterrorism. Report the presence of symptoms consistent with inhalation anthrax to hospital authorities immediately.

This organism first forms a **spore** (i.e., an encapsulated organism that is inactive). Spores can live for years, even decades. When many spores are inhaled deeply into the lungs, macrophages engulf them. Once inside the macrophage, the organism leaves its capsule and replicates. The active bacteria produce several toxins that are released into the infected tissues and the blood that make the infection worse. Massive edema occurs along with hemorrhage and destruction of lung cells. Infected macrophages carry the organisms to the lymph nodes; and the organisms spread rapidly, causing bacteremia, sepsis and meningitis. Lethal toxins produced by the bacteria are the most common cause of death (CDC, 2015b).

## ❖Interprofessional Collaborative Care

Inhalation anthrax has two stages: prodromal (or incubation period) and fulminant (with active disease). Symptoms take up to 8 weeks to develop after exposure (Chart 31-4).

### 📌Chart 31-4

## Key Features

### Inhalation Anthrax

PRODROMAL STAGE (EARLY)	FULMINANT STAGE (LATE)
<ul style="list-style-type: none"><li>• Fever</li><li>• Fatigue</li><li>• Mild chest pain</li><li>• Dry cough</li><li>• No signs or symptoms of upper respiratory infection</li><li>• Mediastinal "widening" on chest x-ray</li></ul>	<ul style="list-style-type: none"><li>• Sudden onset of breathlessness</li><li>• Dyspnea</li><li>• Diaphoresis</li><li>• Stridor on inhalation and exhalation</li><li>• Hypoxia</li><li>• High fever</li><li>• Mediastinitis</li><li>• Pleural effusion</li><li>• Hypotension</li><li>• Septic shock</li></ul>

The *prodromal stage* is early and difficult to distinguish from influenza or pneumonia. Symptoms include low-grade fever, fatigue, mild chest pain, and a dry, harsh cough. A *special feature of inhalation anthrax* is that it is **not** accompanied by upper respiratory symptoms of sore throat or rhinitis. Usually the patient starts to feel better and symptoms improve in 2 to 4 days.

If the patient begins appropriate antibiotic therapy at this stage, the likelihood of survival is high. Diagnosis can be made with a Gram stain of blood or a chest x-ray. After several days, blood cultures may be positive for the organism. Genetic material of the bacteria may be found with

polymerase chain reaction (PCR) done on serum. Positive results may not be evident until the disease has progressed to the fulminant stage.

The *fulminant stage* begins after the patient feels a little better. Usually there is a sudden onset of severe illness, including respiratory distress, hematemesis (bloody vomit), dyspnea, diaphoresis, stridor, chest pain, and cyanosis. The patient has a high fever. Hemorrhagic mediastinitis and pleural effusions develop. The patient may have a decreased level of consciousness or frank shock. The disease spreads through the blood, causing septic shock and hemorrhagic meningitis. Death often occurs within 24 to 36 hours even if antibiotics are started in this stage (CDC, 2015b).

The organism found naturally in the environment is sensitive to common antibiotics; however, organisms grown for bioterrorism may have been altered to be resistant to these antibiotics. Therefore the antibiotics used for suspected or diagnosed inhalation anthrax include a combination of drugs (Chart 31-5). The same drugs are used to prevent illness when adults have been exposed to inhalation anthrax but do not yet have symptoms. A new monoclonal antibody drug has been approved to neutralize the toxins produced by the organisms.

### Chart 31-5

## Common Examples of Drug Therapy

### Prophylaxis and Treatment of Inhalation Anthrax

PROPHYLAXIS	TREATMENT
Ciprofloxacin (Cipro) 500 mg orally twice daily	Ciprofloxacin (Cipro IV) 400 mg IV every 12 hr
<i>or</i>	<i>or</i>
Doxycycline (Vibramycin) 100 mg orally twice daily	Doxycycline (Doxy 100) 100 mg IV every 12 hr
<i>or (if organism is proven susceptible to penicillin)</i>	<b>Plus one or two of the following secondary agents (parenteral form (IV); dosage based on patient's weight and age):</b>
Amoxicillin (Amoxil, Trimox) 500 mg orally every 8 hr or 875 mg orally twice daily	Rifampin (RIF)
	Clindamycin (Cleocin)
	Vancomycin (Vancocin, Vancoled)
Prophylaxis must continue for 60 days (or longer if exposure was heavy).	Treatment with IV drugs continues for at least 7 days. When the response is good and the patient improves, IV drugs are changed to oral agents and continued for at least 60 days.

A vaccine is available to be used *before* exposure occurs, but distribution is limited to specific at-risk adults. The CDC also recommends that it be considered for patients after exposure and before symptoms appear, but this requires special approval. A new vaccine is currently being tested for postexposure use.

Teach patients with any type of lower respiratory infection to be especially vigilant for changes after they think they are getting well. They need to seek medical attention immediately on having a setback that starts with breathlessness.

## Pertussis

Pertussis is a respiratory infection caused by the bacterium *Bordetella pertussis*. It is highly contagious and spreads easily from person to person via respiratory droplets. Once considered a childhood disease, is it making a comeback in adults, perhaps because of decreasing IMMUNITY from childhood vaccinations over time (Massetia & Krishnarajah, 2015). In 1976 there were only 1010 reported cases. In 2014 that number jumped to 32,971 (CDC, 2015h; CDC, 2015i).

The disease has three distinct phases. During the first (*catarrhal*) phase, the patient has symptoms resembling the common cold, including a mild cough. After 1 to 2 weeks, the *paroxysmal* stage begins, and the patient has severe coughing "fits" lasting several minutes. During the coughing spasms the patient may turn red and/or vomit. He or she is frequently exhausted by the coughing. The distinct "whooping" sound common in children at the end of a cough may not be present in adults. There is a bloody, purulent, thick exudate in the small airways that can lead to atelectasis and pneumonia. This stage can last up to 10 weeks. The recovery (*convalescent*) stage lasts for months.

The diagnosis of pertussis can be made based on the patient's reported symptoms, but sputum cultures (obtained by deep suctioning) and PCR laboratory testing are also available. Blood cultures are negative. The CDC recommends testing for anyone who has a cough lasting longer than 3 weeks.

## Coccidioidomycosis

Coccidioidomycosis is a fungal infection caused by the *Coccidioides* organism common in the desert southwest regions of the United States, Mexico, and Central and South America. It is also known as *valley fever* and is becoming more prevalent. The organism is present in the soil as inactive and nonreproducing microfilaments. When the soil is disturbed by excavation or dust storms, the microfilaments become airborne. When the microfilaments are inhaled, they change into the reproductively active spore form of the organism. This can lead to development of an actual pulmonary infection within 1 to 4 weeks after exposure (Buhrow, 2013).

Symptoms of coccidioidomycosis resemble other respiratory infections with fever, cough, headache, muscle aches, chest pain, and night sweats. Bone and joint pain indicates more severe infection. Often the disorder is misdiagnosed and mistreated as influenza or pneumonia. Neither antibacterial drugs nor antiviral drugs are effective therapy. The disease can become widespread and cause symptoms of hemoptysis, meningitis, and involvement of the skin, adrenal glands, liver, and spleen. It also can become chronic and debilitating.

Depending on the health and IMMUNITY of the infected person and the number of spores present in the respiratory tract, the resulting infection can be mild, moderate, severe, or widely disseminated. Most younger healthy adults recover from the infection without treatment. For moderate infection, oral therapy with antifungal agents such as fluconazole (Diflucan), ketoconazole (Nizoral), voriconazole (Vfend) is needed. For those with severe disease or women who are pregnant, IV amphotericin B may be needed. Because the infection is not spread from person to person, Isolation Precautions are not required.

In endemic areas, adults at highest risk are those who work in or around soil, such as farm workers or construction workers. Older adults, anyone who has reduced IMMUNITY, and pregnant women also are at increased risk for developing more severe disease. Because the areas that naturally harbor this organism are often winter vacation destinations, always ask anyone with respiratory infection symptoms whether they have visited endemic regions so the possibility of coccidioidomycosis is considered.

### Clinical Judgment Challenge 31-1

#### Patient-Centered Care, Evidence-Based Practice QSEN

A patient has been admitted with an obvious problem with GAS EXCHANGE. The patient's room air ABGs are: pH 7.12, PO<sub>2</sub> 62 mm Hg, PCO<sub>2</sub> 66 mm Hg, HCO<sub>3</sub> 22 mm Hg. The patient's oxygen saturation is 84%, and you assess coarse lung sounds with some wheezing in all fields. The patient is anxious and reports feeling very short of breath. The patient is febrile at 102.3° F (39° C); pulse is 148 beats/min, respirations 38 breaths/min, and blood pressure is 98/52 mm Hg.

1. Which immediate care actions do you anticipate?
2. After addressing the patient's GAS EXCHANGE needs, which care priorities should you focus on next?
3. The primary health care provider leaves the following prescriptions for the patient. In what order should you accomplish them?
  - a. Start gentamycin (Garamycin) 500 mg IVPB now
  - b. Obtain sputum and blood cultures
  - c. Insert indwelling urinary catheter
  - d. Administer acetaminophen 1000 mg orally once for rib pain

e. Increase rate of IV infusion to 150 mL/hr

4. Which member(s) of the interprofessional team would be most helpful in this situation and why?

5. Which other assessments should you perform?

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Limit transmission of respiratory infections by washing hands after blowing the nose or using a tissue. **QSEN: Safety**
- Receive a yearly influenza vaccination because you are more likely to care for infected people and because you could spread influenza to adults who have reduced IMMUNITY. **QSEN: Safety**
- Use Airborne Precautions and Isolation Precautions for any patient who has tuberculosis (TB) symptoms until proven otherwise. **QSEN: Safety**
- If possible, place the patient with a respiratory infection in a private room. **QSEN: Safety**
- Keep the door to the room of any patient with a respiratory infection closed until the cause of the infection is identified. **QSEN: Safety**
- Teach adults living with patients who have TB to ensure good ventilation of the home with open windows whenever possible. **QSEN: Safety**
- Administer humidified oxygen therapy to patients with inadequate GAS EXCHANGE and hypoxemia. **QSEN: Evidence-Based Practice**
- Assess the skin under and around a facemask or nasal cannula for evidence of skin breakdown at least every 8 hours. **QSEN: Patient-Centered Care**
- Identify patients who may require a directly observed therapy (DOT) program in which they must be directly observed by a health care professional while swallowing the drug. **QSEN: Safety**

### Health Promotion and Maintenance

- Teach everyone the “etiquette” of sneezing or coughing into the upper sleeve rather than the hand when a tissue is not available. **QSEN: Evidence-Based Practice**
- Urge all adults older than 50 years, anyone who has a chronic respiratory problem, anyone who has reduced IMMUNITY, and anyone who lives with a person who is older or immunocompromised or has a chronic respiratory disease to receive the pneumonia vaccine and yearly influenza vaccinations. **QSEN: Evidence-Based Practice**
- Urge all adults to quit smoking or using tobacco in any form. **QSEN: Patient-Centered Care**
- Teach all adults to be prepared for an emergency or disaster by having sufficient food, water, and prescribed drugs for at least 2 weeks (see [Chapter 10](#)). **QSEN: Patient-Centered Care**
- Teach all adults to follow community infection containment procedures if there is a possible outbreak of any pandemic influenza virus. **QSEN: Patient-Centered Care**

### Psychosocial Integrity

- Assess older patients with acute confusion for pneumonia (cough and fever may not be present). **QSEN: Evidence-Based Practice**
- Assure the family of an older-adult patient with pneumonia who is confused that the new-onset confusion is temporary. **QSEN: Patient-Centered Care**
- Teach adults who may be afraid of contracting inhalational anthrax that this disease is not transmitted by person-to-person contact. **QSEN: Patient-Centered Care**
- Inform patients who have a positive TB test that far more adults are infected with the bacillus than have active TB disease. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Assess the respiratory status of any adult suspected of having a respiratory infection by taking vital signs, noting color of nail beds and mucous membranes, measuring oxygen saturation, determining ease of ventilation, determining cognition, and auscultating lung fields. **QSEN: Evidence-Based Practice**
- Ask any patient with a respiratory infection if he or she is from a foreign country or has recently visited a foreign country. **QSEN: Patient-Centered Care**
- Ask patients from other countries whether they have had BCG as a vaccination against TB. For patients who have had BCG, the PPD skin test is a less reliable indicator of TB. **QSEN: Safety**
- Educate the family and the patient with tuberculosis who lives at home about the side effects of anti-TB therapy and when to notify the primary health care provider. **QSEN: Patient-Centered Care**
- Urge patients to complete the anti-infective drug therapy course for any respiratory infection. **QSEN: Patient-Centered Care**
- Assess the patient receiving first-line drug therapy for TB for any symptoms of liver impairment (dark urine, clay-colored stools, anorexia, jaundiced sclera or hard palate). **QSEN: Patient-Centered Care**
- Teach sexually active women taking rifampin or rifapentine as drug therapy for TB that these drugs reduce the effectiveness of oral contraceptives and an additional form of birth control should be used while on this therapy. **QSEN: Patient-Centered Care**

## CHAPTER 32

# Care of Critically Ill Patients With Respiratory Problems

Harry Rees

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is GAS EXCHANGE.**

✚ The GAS EXCHANGE concept exemplar for this chapter is Pulmonary Embolism, below.

**The interrelated concepts for this chapter are:**

- PERFUSION
- CLOTTING

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to coordinate high-quality care and promote GAS EXCHANGE in critically ill patients with respiratory problems.
2. Teach the patient and caregiver(s) about how decreased GAS EXCHANGE and impaired PERFUSION affect home safety.
3. Prioritize evidence-based care for critically ill patients with respiratory problems that decrease GAS EXCHANGE.

### Health Promotion and Maintenance

4. Identify community resources for patients requiring assistance with long-term complications of severe respiratory problems.
5. Teach adults how to decrease the risk for severe respiratory damage or disease.

### Psychosocial Integrity

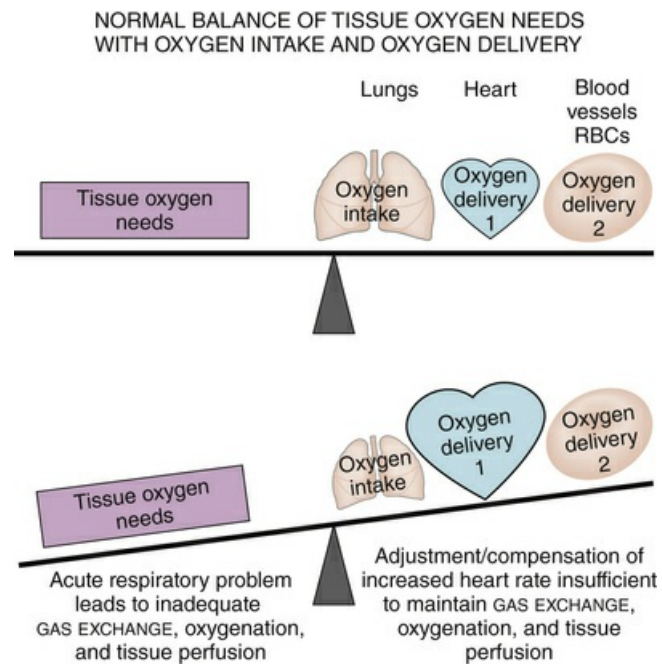

6. Implement nursing interventions to help the patient and family cope with the psychosocial impact caused by severe respiratory problems.

### Physiological Integrity

7. Apply knowledge of anatomy, physiology, and pathophysiology to assess critically ill patients with respiratory problems affecting GAS EXCHANGE or PERFUSION.
8. Teach the patient and caregiver(s) about common drugs and other management strategies used for respiratory problems.
9. Implement evidence-based nursing interventions to prevent complications of pulmonary embolism, mechanical ventilation, or any other critical respiratory problem.

Although chronic respiratory problems are more common, acute problems do arise that can interfere with GAS EXCHANGE and tissue PERFUSION to such a degree that death can occur quickly. These problems tax the cardiac system by forcing the heart to work harder to compensate for lung-related impairment of gas exchange (Fig. 32-1). *Thus prompt recognition and interventions are needed to prevent serious complications and death.* Such emergencies include pulmonary embolism, acute respiratory failure, acute respiratory distress syndrome, and chest trauma. The emergent nature of these problems and the potential for fatal outcomes present challenges in caring for these critically

ill patients.

**FIG. 32-1** Rapid-onset acute respiratory problems overwhelm the ability of the cardiac oxygen delivery system to adapt and restore balance. The red blood cell (RBC) oxygen delivery system cannot begin to adapt to the acute respiratory problem.

## Gas Exchange Concept Exemplar Pulmonary Embolism

### ❖ Pathophysiology

A **pulmonary embolism (PE)** is a collection of particulate matter (solids, liquids, or air) that enters venous circulation and lodges in the pulmonary vessels. Large emboli obstruct pulmonary blood flow, leading to reduced GAS EXCHANGE, reduced oxygenation, pulmonary tissue hypoxia, decreased PERFUSION, and potential death. Any substance can cause an embolism, but a blood clot is the most common (McCance et al., 2014; Rali et al., 2016). PE is common and may account for as many as 100,000 deaths each year in the United States (Centers for Disease Control and Prevention [CDC], 2015). It may be the most common preventable death in hospitalized patients but is often misdiagnosed, and patients at risk may not be provided the appropriate preventive measures.

Most often, a PE occurs when inappropriate blood CLOTTING forms a venous thromboembolism (VTE) (also known as a deep vein thrombosis [DVT]) in a vein in the legs or the pelvis and a clot breaks off and travels through the vena cava into the right side of the heart. The clot then lodges in the pulmonary artery or within one or more of its branches. Platelets collect on the embolus, triggering the release of substances that cause blood vessel constriction. Widespread pulmonary vessel constriction and pulmonary hypertension impair GAS EXCHANGE and tissue PERFUSION. Deoxygenated blood moves into arterial circulation, causing **hypoxemia** (low arterial blood oxygen level), although some patients with PE do *not* have hypoxemia.

Major risk factors for VTE leading to PE are:

- Prolonged immobility
- Central venous catheters
- Surgery
- Obesity
- Advancing age
- Conditions that increase blood CLOTTING
- History of thromboembolism

Smoking, pregnancy, estrogen therapy, heart failure, stroke, cancer (particularly lung or prostate), and trauma increase the risk for VTE and PE (McCance et al., 2014).

Fat, oil, air, tumor cells, amniotic fluid and fetal debris, foreign objects (e.g., broken IV catheters), injected particles, and infected clots can enter a vein and cause PE. Fat emboli can occur with fracture of the femur, and oil emboli can occur from diagnostic procedures. These have a mortality rate of about 10% (Moore, 2016). Fat emboli do not impede lung blood flow; instead, they injure blood vessels and cause acute respiratory distress syndrome (ARDS) (discussed as a disorder later in this chapter). Septic clots often arise from a pelvic abscess, an infected IV catheter, and injections of illegal drugs. The effects of sepsis are more serious than the venous blockage.

### Health Promotion and Maintenance

Although pulmonary embolism (PE) can occur in healthy people without warning, certain conditions increase the risk for occurrence. Thus prevention of conditions that lead to PE is a major nursing concern. Preventive actions for PE are those that also prevent venous stasis and VTE. Best nursing practices for PE prevention are outlined in [Chart 32-1](#). Also see [Chapter 14](#) for more information about core measures during the surgical experience for VTE prevention.

#### Chart 32-1

### Best Practice for Patient Safety & Quality Care QSEN

#### Prevention of Pulmonary Embolism

- Start passive and active range-of-motion exercises for the extremities of immobilized and

postoperative patients.

- Ambulate patients soon after surgery.
- Use anti-embolism and pneumatic compression stockings and devices after surgery.
- Evaluate patient for criteria indicating the need for anticoagulant therapy.
- Avoid the use of tight garters, girdles, and constricting clothing.
- Prevent pressure under the popliteal space (e.g., do not place a pillow under the knee; instead, use alternating pressure mattress).
- Perform a comprehensive assessment of peripheral circulation.
- Elevate the affected limb 20 degrees or more above the level of the heart to improve venous return, as appropriate.
- Change patient position every 2 hours or ambulate as tolerated.
- Prevent injury to the vessel lumen by preventing local pressure, trauma, infection, or sepsis.
- Refrain from massaging leg muscles.
- Instruct patient not to cross legs.
- Administer prescribed prophylactic low-dose anticoagulant and antiplatelet drugs.
- Teach the patient to avoid activities that result in the Valsalva maneuver (e.g., breath-holding, bearing down for bowel movements, coughing).
- Administer prescribed drugs, such as stool softeners, that will prevent episodes of the Valsalva maneuver.
- Teach the patient and family about precautions.
- Encourage smoking cessation.

Lifestyle changes can help reduce the risk for PE. Tobacco use narrows blood vessels and increases the risk for clot formation. Hormone-based contraceptives also increase blood CLOTTING. Urge patients to stop smoking cigarettes, especially women who use hormone-based contraceptives. Reducing weight and becoming more physically active can reduce risk for PE. Teach patients who are traveling for long periods to drink plenty of water, change positions often, avoid crossing their legs, and get up from the sitting position at least 5 minutes out of every hour to prevent stasis and clot formation.

For patients known to be at risk for PE, small doses of heparin or low-molecular-weight heparin (enoxaparin [Lovenox]), an indirect thrombin inhibitor, may be prescribed every 8 to 12 hours. Oral direct thrombin inhibitors may be used instead of heparin for VTE prevention in patients who have nonvalvular atrial fibrillation.

For adults who have an ongoing risk for VTE and PE, prevention may include preoperative placement of a retrievable inferior vena cava (IVC) filter. This placement occurs before any surgery in which the patient is expected to be confined to bed for more than just a few days and is retrieved when the patient is fully ambulatory.

### ❖ **Interprofessional Collaborative Care**

The patient who has a pulmonary embolism (PE) is critically ill and at risk for life-threatening complications. Initial management occurs in an acute care environment, most often an ICU. In addition to medical and nursing care providers, pharmacists and respiratory therapists are key interprofessional team members.

Some patients have ongoing issues or residual problems that impair GAS EXCHANGE and PERFUSION

after the acute problems have resolved. These changes may be permanent. Then continuing care occurs in the home or residential setting.

The interprofessional team for ongoing issues includes a variety of specialists for optimal patient function. A pulmonary health care provider in addition to a primary health care provider is needed for continual assessment and management of any reduced lung function. Respiratory therapists assist with prescribed oxygen therapy and delivery needs. Physical therapists can help the patient maintain muscle conditioning. Occupational therapists provide information and home set-up suggestions to help patients conserve energy when endurance is affected. Registered dietitians assess patients' caloric and protein needs and plan personalized interventions to meet these needs. Pastoral care workers and clergy may help patients who experience spiritual distress with this life-altering condition. Social workers together with home care nurses determine which types of home modifications and durable supplies would be most helpful in maintaining functional ability for self-management of ADLs. When significant lifestyle changes are needed, mental health professionals can help the patient and family cope with adjustments.

### ◆**Assessment: Noticing**

Signs and symptoms range from vague, nonspecific discomforts to hemodynamic collapse and death. *It is important to remember that many patients with PE do not have the “classic” symptoms.* This variability in symptoms often leads to PEs being overlooked.

### **Physical Assessment/Signs and Symptoms.**

*Respiratory symptoms* are outlined in [Chart 32-2](#) and are mostly related to decreased GAS EXCHANGE. Assess the patient for difficulty breathing (dyspnea) and pleuritic chest pain (sharp, stabbing-type pain on inspiration) ([Wilbeck & Evans, 2015](#)). Other symptoms vary depending on the size and type of embolism. Breath sounds may be normal or include crackles, wheezes, or a pleural friction rub. A dry or productive cough may be present; **hemoptysis** (bloody sputum) may result from pulmonary infarction.

## ▶**Chart 32-2**

### **Key Features**

#### **Pulmonary Embolism**

##### **Classic Symptoms**

- Dyspnea, sudden onset
- Sharp, stabbing chest pain
- Apprehension, restlessness
- Feeling of impending doom
- Cough
- Hemoptysis

##### **Signs**

- Tachypnea
- Crackles
- Pleural friction rub
- Tachycardia
- S<sub>3</sub> or S<sub>4</sub> heart sound

- Diaphoresis
- Fever, low-grade
- Petechiae over chest and axillae
- Decreased arterial oxygen saturation (SaO<sub>2</sub>)

*Cardiac symptoms* related to decreased tissue PERFUSION include tachycardia, distended neck veins, **syncope** (fainting or loss of consciousness), cyanosis, and hypotension. Systemic hypotension results from acute pulmonary hypertension and reduced forward blood flow. Abnormal heart sounds, such as an S<sub>3</sub> or S<sub>4</sub>, may occur. Electrocardiogram (ECG) changes are nonspecific and transient. T-wave and ST-segment changes may occur as can left-axis or right-axis deviations. Right ventricular dysfunction and failure are extreme complications. The patient may have cardiac arrest or frank shock.

## Nursing Safety Priority QSEN

### Critical Rescue

Monitor patients at risk to recognize signs and symptoms of PE (e.g., shortness of breath, chest pain, and/or hypotension without an obvious cause). If such symptoms are present, respond by notifying the Rapid Response Team. If PE is strongly suspected, prompt categorization and management strategies are started before diagnostic studies have been completed.

#### Psychosocial Assessment.

Symptoms of PE often occur abruptly, and the patient is anxious. Hypoxemia may stimulate a sense of impending doom and cause increased restlessness. The life-threatening nature of PE and admission to an ICU increase the patient's anxiety and fear.

#### Laboratory Assessment.

The hyperventilation triggered by hypoxia and pain first leads to respiratory alkalosis, indicated by low partial pressure of arterial carbon dioxide (PaCO<sub>2</sub>) on arterial blood gas (ABG) analysis. The PaO<sub>2</sub>-Fio<sub>2</sub> (fraction of inspired oxygen) ratio falls as a result of “shunting” of blood from the right side of the heart to the left without picking up oxygen from the lungs. Shunting causes the PaCO<sub>2</sub> level to rise, resulting in respiratory acidosis (McCance et al., 2014). Later, metabolic acidosis results from buildup of lactic acid caused by tissue hypoxia. (See Chapter 12 for a more detailed discussion of acidosis.)

*Even if ABG studies and pulse oximetry show hypoxemia, these results alone are not sufficient for the diagnosis of PE (McCance et al., 2014). A patient with a small embolus may not be hypoxemic, and PE is not the only cause of hypoxemia.*

Other laboratory studies performed when PE is suspected include a general metabolic panel, troponin, brain natriuretic peptide (BNP), and a D-dimer. The D-dimer, a fibrin split product, rises with fibrinolysis. When the value is normal or low, it can rule out a PE. However, even if the value is high, other diagnostic testing is needed to determine whether a PE has occurred (Pagana et al., 2017).

## Genetic/Genomic Considerations

### Patient-Centered Care QSEN

Factor V Leiden (also known as activated protein C resistance) is an inherited abnormal tendency to develop blood clots. In this disorder, the gene coding for blood clotting factor V (the F5 gene) has a mutation that changes the nature of the factor V produced. With this genetic alteration, factor V functions normally but is more slowly degraded; and clotting activity continues longer than usual, which increases the risk for developing abnormal blood clots (Lee, 2014). People can inherit

either one or both abnormal gene alleles. The risk for developing clots is three to eight times greater in those who inherit only one abnormal allele and up to 80 times greater with two abnormal alleles (United States National Library of Medicine, 2016). The risk for developing DVT, PE, or thrombotic strokes increases greatly when both abnormal gene alleles are present, especially in smokers and those who use hormone-based contraceptives. Testing for factor V Leiden is recommended for people who develop a VTE without a precipitating event and for those who have a first-degree relative with the disorder (Online Mendelian Inheritance in Man [OMIM], 2015).

### Imaging Assessment.

Pulmonary angiography is the “gold standard” diagnostic test but is not available in all settings. Computed tomography pulmonary angiography (CT-PA) or helical CT may also be used, which has the added advantage of diagnosing other pulmonary abnormalities causing the patient’s symptoms. Ventilation-perfusion (V/Q) scans are not as widely used anymore but may be considered in certain circumstances (e.g., allergy to contrast dye). A chest x-ray may diagnose other conditions that mimic acute PE. Doppler ultrasound may be used to document the presence of VTE and to support a diagnosis of PE (York et al., 2015).

### ◆Analysis: Interpreting

The priority collaborative problems for patients with PE include:

1. Hypoxemia due to mismatch of lung PERFUSION and alveolar GAS EXCHANGE with oxygenation
2. Hypotension due to inadequate circulation to the left ventricle
3. Potential for excessive bleeding due to anticoagulation or fibrinolytic therapy causing inadequate CLOTTING
4. Anxiety due to hypoxemia and life-threatening illness

### ◆Planning and Implementation: Responding

#### Managing Hypoxemia.

*When a patient has a sudden onset of dyspnea and chest pain, immediately notify the Rapid Response Team. Reassure the patient and elevate the head of the bed. Prepare for oxygen therapy and blood gas analysis while continuing to monitor and assess for other changes.*

#### Planning: Expected Outcomes.

The patient with PE is expected to have adequate tissue PERFUSION in all major organs. Indicators of adequate PERFUSION are that the patient has:

- ABGs within normal limits
- Pulse oximetry above 92%
- Cognitive status unimpaired compared with baseline
- Absence of pallor and cyanosis

#### Interventions.

Nonsurgical management of PE is most common. In some cases invasive procedures also may be needed. Best care practices for the patient with PE are listed in Chart 32-3. Rapid categorization of PE severity and prompt management are required (Table 32-1).

### ©Chart 32-3

## Best Practice for Patient Safety & Quality Care QSEN

### Care of the Patient With a Pulmonary Embolism

- Apply oxygen by nasal cannula or mask.

- Reassure patient that the correct measures are being taken.
- Place patient in high-Fowler's position.
- Apply telemetry monitoring equipment.
- Obtain an adequate venous access.
- Assess oxygenation continuously with pulse oximetry.
- Assess respiratory status at least every 30 minutes by:
  - Listening to lung sounds.
  - Measuring the rate, rhythm, and ease of respirations.
  - Checking skin color and capillary refill.
  - Checking position of trachea.
- Assess cardiac status by:
  - Comparing blood pressures in right and left arms.
  - Checking pulse for quality.
  - Checking cardiac monitor for dysrhythmias.
  - Checking for distention of neck veins.
- Ensure that prescribed chest imaging and laboratory tests are obtained immediately (may include complete blood count with differential, platelet count, prothrombin time, partial thromboplastin time, D-dimer level, arterial blood gases).
- Examine the thorax for presence of petechiae.
- Administer prescribed anticoagulants.
- Assess for bleeding.
- Handle patient gently.
- Institute Bleeding Precautions.

**TABLE 32-1**  
**Pulmonary Embolism (PE) Severity and Management Options**

CATEGORY	POSSIBLE SYMPTOMS	MANAGEMENT OPTIONS
<b>Massive PE</b> Mortality may be as high as 65%	Severe hypotension (SBP <90 mm Hg for at least 15 minutes) Cardiac arrest/cardiopulmonary collapse Severe bradycardia Shock Severe dyspnea/respiratory distress	CPR Inotropic and/or vasopressor support; fluids Fibrinolytic therapy Tissue plasminogen activator (tPA) Alteplase (Activase) Unfractionated heparin initial treatment
<b>Submassive PE</b>	Normotension RV dysfunction on echocardiography RV dilation on echocardiography or CT Right bundle branch block ST elevation or depression	Treatment is controversial; some agents not approved for this group Must weigh benefits of thrombolytic therapy against risk for bleeding Thrombolytics may be preferred if patient appears to be decompensating or if there is RV dysfunction (hypokinesia) or elevation in BNP or troponin LMWH preferred agent

	T-wave inversion Elevated BNP or troponin	Fondaparinux (Arixtra) Unfractionated heparin
Low-risk PE Mortality ranges from 1% to 8%	Normotension No RV dysfunction No elevation in BNP or troponin	Thrombolytics not warranted because of risk for bleeding LMWH Rivaroxaban (Xarelto)

BNP, Brain natriuretic peptide; CPR, cardiopulmonary resuscitation; CT, computed tomography; LMWH, low-molecular-weight heparin; RV, right ventricle; SBP, systolic blood pressure.

Adapted from Jaff, M. R., McMurtry, M. S., & Archer, S. L. (2011). The use of fibrinolytics in patients with acute pulmonary embolism. *Circulation*, 123, 1788-1830.

## Nonsurgical Management.

Management activities for PE focus on increasing GAS EXCHANGE and oxygenation, improving lung PERFUSION, reducing risk for further clot formation, and preventing complications. Priority nursing interventions include implementing oxygen therapy, administering anticoagulation or fibrinolytic therapy to improve tissue perfusion, monitoring the patient's responses to the interventions, and providing psychosocial support (York et al., 2015).

*Oxygen therapy* is critical for the patient with PE. The severely hypoxemic patient may need mechanical ventilation and close monitoring with ABG studies. In less severe cases oxygen may be applied by nasal cannula or mask. Use pulse oximetry to monitor oxygen saturation and hypoxemia.

*Monitor* the patient continually for any changes in status. Check vital signs, lung sounds, and cardiac and respiratory status at least every 1 to 2 hours. Document increasing dyspnea, dysrhythmias, distended neck veins, and pedal or sacral edema. Assess for crackles and other abnormal lung sounds along with cyanosis of the lips, conjunctiva, oral mucosa, and nail beds.

*Drug therapy* begins immediately with anticoagulants to prevent embolus enlargement and more CLOTTING. Unfractionated heparin, low-molecular-weight heparin (enoxaparin [Lovenox]), or fondaparinux (Arixtra) is used unless the PE is massive or occurs with hemodynamic instability. Review the patient's partial thromboplastin time (PTT)—also called *activated partial thromboplastin time (aPTT)*—before therapy is started and thereafter according to facility policy. Therapeutic PTT values usually range between 1.5 and 2.5 times the control value for this health problem. Factor anti-Xa levels may be used instead of PTT or aPTT.

Fibrinolytic drugs, such as alteplase (Activase, tPA), are used for treatment of PE when specific criteria are met such as shock, hemodynamic collapse, or instability. Fibrinolytic drugs are used to break up the existing clot. (See Chapter 38 for a discussion of fibrinolytic therapy.)

Both heparin and fibrinolytic drugs are *high-alert drugs*. These drugs have an increased risk to cause harm if given at too high a dose, at too low a dose, or to the wrong patient. Because of the high risk for bleeding, patients receiving fibrinolytic therapy are monitored in an ICU setting.

## Nursing Safety Priority QSEN

### Drug Alert

Heparin comes in a variety of concentrations in vials that have differing amounts, which contributes to possible medication errors. In accordance with The Joint Commission's National Patient Safety Goals (NPSGs), check the prescribed dose carefully and ensure that the correct concentration is being used to prevent overdosing or underdosing.

Heparin therapy usually continues for 5 to 10 days. Most patients are started on an oral anticoagulant, such as warfarin (Coumadin, Jantoven, Warfilone ) , on day one or two of heparin therapy. Therapy with both heparin and warfarin continues until the international normalized ratio (INR) reaches 2.0 to 3.0. Heparin is usually infused for at least 5 days and continues for 24 hours after the INR is greater than 2. Monitor the platelet count and INR during this time. A low-molecular-weight heparin (e.g., dalteparin [Fragmin], enoxaparin [Lovenox]) or a direct thrombin inhibitor (e.g., rivaroxaban [Xarelto]) is often used instead of warfarin. Oral anticoagulant use continues for 3 to 6 weeks, but some patients may take it indefinitely. Charts 32-4 and 32-5 list common drugs used and the laboratory tests to monitor in a patient with PE. These drugs and the associated nursing care are discussed in Chapters 36, 38, and 39.

## Chart 32-4

# Common Examples of Drug Therapy

## Pulmonary Embolism

DRUG	NURSING IMPLICATIONS
<b>Heparins and Heparinoids</b> —These drugs are used to begin anticoagulation to minimize growth of existing clots and prevent the development of additional clots. They bind to and increase the activity of antithrombin III (AT III). By activating AT III, coagulation factor Xa (thrombin) is indirectly inhibited.	
Heparin sodium (Hepalean) Enoxaparin (Lovenox)	Monitor PTT (or factor anti-Xa) and know expected therapeutic PTT range for each patient to <i>detect side effects and prevent complications</i> . Monitor patient for bleeding or bruising, <i>which are indications of a prolonged PTT and a harbinger of excessive bleeding</i> . Have <i>protamine sulfate</i> available <i>because it is an antidote to heparin and can prevent hemorrhage when anticoagulation is too great</i> . Avoid puncturing the skin and apply pressure to venipuncture and IM injection sites to <i>prevent excessive bruising and bleeding</i> . Monitor platelet counts to <i>assess for the complication of heparin-induced thrombocytopenia (HIT)</i> .
<b>Vitamin K Antagonists (VKAs)</b> —These drugs decrease the synthesis of vitamin K in the intestinal tract, which then reduces the production of vitamin K–dependent CLOTTING factors II, VII, IX, and X, along with the anticoagulant proteins C and S. When the clotting factors are reduced, anticoagulation results. It is used for long-term anticoagulation in at-risk patients to prevent the development of future clots.	
Warfarin sodium (Coumadin, Jantoven, Warfilone  )	Monitor INR and know expected therapeutic INR range for each patient to <i>ensure drug effectiveness and identify drug overdose</i> . Consult the pharmacist about potential drug interactions <i>because this drug affects the activity of many other drugs</i> . Teach patients to check with a pharmacist before taking any other prescribed or over-the-counter drug <i>because this drug affects the activity of many other drugs</i> . Have <i>vitamin K (phytonadione)</i> available <i>because it is the antidote to be used in case of warfarin overdose</i> . Avoid puncturing the skin and apply pressure to venipuncture and IM injection sites to <i>prevent excessive bruising and bleeding</i> . Teach patients which foods are sources of vitamin K (e.g., leafy dark green vegetables, herbs, spring onions, Brussels sprouts, broccoli, cabbage, asparagus), <i>because they will reduce the effectiveness of warfarin if eaten in excess</i> .
<b>Fibrinolytics</b> —These drugs selectively break down fibrin threads present in formed blood clots by activating tissue protein <i>plasminogen</i> to its active form, <i>plasmin</i> , which then directly attacks and degrades the fibrin molecule. Fibrinolytics are used to promote lysis of large pulmonary emboli in patients who are hemodynamically unstable.	
Alteplase (tissue plasminogen activator, recombinant; tPA; Activase)	Assess hourly for internal and external bleeding while the patient is receiving the drug and for 8 hours after <i>because hemorrhage is the most common complication</i> . To administer, reconstitute with sterile water that contains no preservative immediately before use to <i>ensure drug stability</i> . Administer with caution to patients who have been receiving aspirin, dipyridamole, heparin, or other anticoagulants <i>because these drugs also increase the risk for bleeding</i> .

INR, International normalized ratio; PTT, partial thromboplastin time.

## Chart 32-5

# Laboratory Profile

## Blood Tests Used to Monitor Anticoagulation Therapy

TEST	NORMAL RANGE	SIGNIFICANCE OF ABNORMAL FINDINGS
Partial thromboplastin time (PTT, aPTT [APTT])	Normal values for each local laboratory may vary. When activator reagents are used by the laboratory, the normal CLOTTING time is shortened. Common normal ranges are 20–30 sec in some laboratories and 30–40 sec in others. Therapeutic range for PE is 1.5–2.5 times the normal value (e.g., if normal is 20–30 sec, therapeutic range is 40–75 sec).	<i>Subtherapeutic times</i> may signify that the patient is not receiving enough heparin to prevent extension of the blood clot. An increase in the dosage or rate of infusion is usually indicated. <i>Therapeutic times</i> mean that the clotting time is increased from normal but this increase is indicated in the case of PE. <i>Prolonged times</i> in patients with PE (i.e., >75 sec) indicate that the patient is at risk for serious spontaneous bleeding. Heparin is usually held or decreased until the PTT drops back into the therapeutic range.
Prothrombin time (pro time, PT)	Common normal range is 11–12.5 sec. Therapeutic range for anticoagulant therapy in PE is 1.5–2.0 times the normal or control value in seconds. Control values can vary day to day because reagents used may vary.	<i>Subtherapeutic values</i> may signify that the patient is not receiving enough warfarin. An increase in the dosage is usually indicated. <i>Therapeutic values</i> mean that the pro time is increased from normal but this increase is indicated in the case of PE. <i>Prolonged values</i> in the treatment of PE indicate that the patient is at risk for reduced CLOTTING and increased bleeding. The warfarin dose is usually decreased or held, the patient is instructed to eat foods high in vitamin K, or an injection of vitamin K may be given.
International normalized ratio (INR)	The common normal range is 0.8–1.1. The therapeutic range for PE is 2.5–3.0, or 3.0–4.5 for recurrent PE.	<i>Subtherapeutic values</i> may signify that the patient is not receiving enough warfarin. An increase in the dosage is usually indicated. <i>Therapeutic values</i> mean that the INR is increased from normal but this increase is indicated in the case of PE. <i>Prolonged values</i> (higher than 4.5) in the treatment of PE indicate that the patient is at risk for bleeding. The warfarin dose is usually decreased or held, the patient is instructed to eat foods high in vitamin K, or an injection of vitamin K may be given.

aPTT or APTT, Activated partial thromboplastin time; INR, international normalized ratio; PE, pulmonary embolism.

Data from Pagana, K., Pagana, T. J., & Pagana, T. N. (2017). *Mosby's diagnostic and laboratory test reference* (13th ed.). St. Louis: Mosby; and Pagana, K., Pagana, T., & Pike-MacDonald, S. (2013). *Mosby's Canadian manual of diagnostic and laboratory tests*. St. Louis: Mosby.

## Genetic/Genomic Considerations

### Patient-Centered Care OSEN

Many agencies perform genetic tests before starting warfarin therapy to check for variation in two specific genes. One gene, *VKORC1*, produces an enzyme that alters vitamin K so it can help activate the vitamin K–dependent clotting factors. Warfarin interferes with the activity of this enzyme. Patients who have a variation in the enzyme are resistant to the effects of warfarin, and much higher doses are needed to achieve coagulation. On the other hand, the gene *CYP2C19* produces an enzyme that metabolizes warfarin and prepares it for elimination. Patients who have a variation in this gene do not metabolize warfarin well, so higher blood levels remain and more severe side

effects are possible. The dosage of warfarin needs to be much lower in patients with this gene variation. When a patient's CLOTTING response to warfarin is either greater than expected or much less than expected, consider the possibility of a gene mutation.

Anticoagulation and fibrinolytic therapy can lead to excessive bleeding. *The antidote for heparin is protamine sulfate; the antidote for warfarin is vitamin K1, which is available as an injectable drug, phytonadione (AquaMEPHYTON, Mephyton). Antidotes for fibrinolytic therapy include clotting factors, fresh frozen plasma, and aminocaproic acid (Amicar).* Antidotes to anticoagulant drugs and fibrinolytic drugs should be readily available either on the unit, from the pharmacy, or from the blood bank for patients undergoing these therapies. Based on hospital policy, blood banks may require that a blood type and screen be completed every 72 hours. This action minimizes delays if a transfusion is indicated.

## NCLEX Examination Challenge 32-1

### Safe and Effective Care Environment

Which laboratory values are **most important** for a nurse to monitor for a client who is receiving a heparin infusion for treatment of a pulmonary embolism when warfarin is added to the drug therapy? **Select all that apply.**

- A. Activated partial thromboplastin time
- B. Albumin levels
- C. Factor V levels
- D. Hepatic function tests
- E. International normalized ratio
- F. Platelet count
- G. Serum osmolarity

### Surgical Management.

Two surgical procedures for the management of PE are embolectomy and inferior vena cava filtration.

*Embolectomy* is the surgical or percutaneous removal of the embolus. It may be performed when fibrinolytic therapy cannot be used for a patient who has massive or multiple large pulmonary emboli with shock or bleeding complications.

*Inferior vena cava filtration* with placement of a retrievable vena cava filter prevents further emboli from reaching the lungs in patients with ongoing risk for PE. Patients for whom filter placement is considered less risky than drug therapy include those with recurrent or major bleeding while receiving anticoagulants, those with septic PE, and those undergoing pulmonary embolectomy. Placement of a vena cava filter is detailed in [Chapter 36](#).

### Managing Hypotension

#### Planning: Expected Outcomes.

The patient with PE is expected to have adequate circulation and tissue PERFUSION. Indicators of adequate circulation are:

- Maintenance of pulse rate and blood pressure within the normal ranges
- Maintenance of a urine output of at least 0.5 to 1 mL/kg/hr
- Absence of cyanosis

#### Interventions.

In addition to the interventions used for hypoxemia, IV fluid therapy and drug therapy are used to increase cardiac output and maintain blood pressure.

*IV fluid therapy* involves giving crystalloid solutions to restore plasma volume and prevent shock (see [Chapter 37](#)). Continuously monitor the ECG and pulmonary artery and central venous/right atrial pressures of the patient receiving IV fluids because increased fluids can worsen pulmonary hypertension and lead to right-sided heart failure. Also monitor indicators of fluid adequacy, including urine output, skin turgor, and moisture of mucous membranes.

*Drug therapy* with vasopressors is used when hypotension persists despite fluid resuscitation. Commonly used agents include norepinephrine (Levophed), epinephrine (adrenalin), or dopamine (Intropin). Agents that increase myocardial contractility (**positive inotropic agents**), including milrinone (Primacor) and dobutamine (Dobutrex), may be considered. Vasodilators, such as nitroprusside (Nipride, Nitropress), may be used to decrease pulmonary artery pressure if it is impeding cardiac contractility. Assess the patient's cardiac status hourly during therapy with any of these drugs.

## Minimizing Bleeding

### Planning: Expected Outcomes.

The patient with PE is expected to have appropriate CLOTTING and remain free from bleeding. Indicators include that the patient:

- Does not have bruising or petechiae
- Maintains hematocrit, hemoglobin, and platelet count within the normal range

### Interventions.

Drug therapy that disrupts clots or prevents their formation impairs the patient's ability to start and continue the blood-CLOTTING cascade when injured, increasing the risk for bleeding. Priority nursing actions are ensuring that appropriate antidotes are present on the nursing unit, protecting the patient from situations that could lead to bleeding, ensuring correct drug therapy, assessing laboratory values, and monitoring the amount of bleeding that occurs.

Assess for evidence of bleeding (e.g., oozing, bruises that cluster, petechiae, or purpura) at least every 2 hours. Examine all stools, urine, drainage, and vomitus for gross blood; and test for occult blood. Measure any blood loss as accurately as possible. Measure the patient's abdominal girth every 8 hours (increasing girth can indicate internal bleeding). Best practices to prevent bleeding are listed in [Chart 32-6](#).

## Chart 32-6

### Best Practice for Patient Safety & Quality Care QSEN

#### Prevention of Injury for the Patient Receiving Anticoagulant, Fibrinolytic, or Antiplatelet Therapy

- Handle the patient gently.
- Use and teach UAP to use a lift sheet when moving and positioning the patient in bed.
- Avoid IM injections and venipunctures.
- When injections or venipunctures are necessary, use the smallest-gauge needle for the task.
- Apply firm pressure to the needlestick site for 10 minutes or until the site no longer oozes blood.
- Apply ice to areas of trauma.
- Test all urine, vomitus, and stool for occult blood.
- Assess IV sites at least every 4 hours for bleeding.

- Instruct alert patients to notify nursing personnel immediately if any trauma occurs and if bleeding or bruising is noticed.
- Avoid trauma to rectal tissues:
- Do not administer enemas.
- If suppositories are prescribed, lubricate liberally and administer with caution.
- Instruct the patient and UAP to use an electric shaver rather than a razor.
- When providing mouth care or supervising others in providing mouth care:
- Use a soft-bristled toothbrush or tooth sponges.
- Do not use floss.
- Check to make certain that dentures fit and do not rub.
- Instruct the patient not to blow the nose forcefully or insert objects into the nose.
- Ensure that the patient wears shoes with firm soles whenever he or she is ambulating.
- Ensure that antidotes to anticoagulation therapy are on the unit.

*UAP, Unlicensed assistive personnel.*

Monitor laboratory values daily. Review the complete blood count (CBC) results to determine the risk for impaired CLOTTING and whether actual blood loss has occurred. If the patient has severe blood loss, packed red blood cells may be prescribed (see Transfusion Therapy in [Chapter 40](#)). Monitor the platelet count. A decreasing count may indicate ongoing CLOTTING or heparin-induced thrombocytopenia (HIT) caused by the formation of anti-heparin antibodies.

### Minimizing Anxiety

#### Planning: Expected Outcomes.

The patient with PE is usually anxious and fearful as a result of the life-threatening nature of the problem. He or she is expected to have anxiety reduced to an acceptable level. Indicators include that he or she consistently demonstrates these behaviors:

- States that anxiety is reduced
- Has no distress, irritability, or facial tension
- Uses coping strategies effectively

#### Interventions.

The patient with PE is anxious and fearful and often has pain. Interventions for reducing anxiety in those with PE include oxygen therapy (see Interventions discussion in the [Managing Hypoxemia](#) section), communication, and drug therapy.

*Communication* is critical in allaying anxiety. Acknowledge the anxiety and the patient's perception of a life-threatening situation. Stay with him or her and speak calmly and clearly, providing assurances that appropriate measures are being taken. Explain the rationale and share information when giving drugs, changing position, taking vital signs, or assessing the patient. Coordinate with pastoral care to help provide spiritual comfort.

*Drug therapy* with an antianxiety drug may be prescribed if the patient's anxiety interferes with

diagnostic testing, management, or adequate rest. Unless he or she is mechanically ventilated, sedating agents are avoided to reduce the risk for hypoventilation. Pharmacologic therapy is used for pain management. Care is taken to avoid suppressing the respiratory response.

### Care Coordination and Transition Management

The patient with a PE is discharged when hypoxemia and hemodynamic instability are resolved and adequate anticoagulation has been achieved. Anticoagulation therapy usually continues after discharge.

#### Home Care Management.

Some patients are discharged to home with minimal risk for recurrence and no permanent physiologic changes. Others have heart or lung damage that requires home and lifestyle modification.

Patients with extensive lung damage may have activity intolerance from reduced GAS EXCHANGE and become fatigued easily. The living arrangements may need to be modified so patients can spend most of the time on one floor and avoid climbing stairs. Depending on the degree of impairment, patients may require varying amounts of assistance with ADLs. Coordinate with members of the interprofessional team as described earlier in the Interprofessional Collaborative Care section to ensure optimal patient function.

#### Self-Management Education.

The patient with a PE may continue anticoagulation therapy for weeks, months, or years after discharge, depending on the risks for PE, and have impaired CLOTTING. Teach him or her and the family about Bleeding Precautions, activities to reduce the risk for venous thromboembolism (VTE) and recurrence of PE, complications, and the need for follow-up care ([Chart 32-7](#)).

### Chart 32-7

## Patient and Family Education: Preparing for Self-Management

### Preventing Injury and Bleeding

During the time you are taking anticoagulants:

- Use an electric shaver.
- Use a soft-bristled toothbrush and do not floss.
- Do not have dental work performed without consulting your health care provider.
- Do not take aspirin or any aspirin-containing products. Read the label to be sure that the product does not contain aspirin or salicylates.
- Do not participate in contact sports or any activity likely to result in your being bumped, scratched, or scraped.
- If you are bumped, apply ice to the site for at least 1 hour.
- Avoid hard foods that would scrape the inside of your mouth.
- Eat warm, cool, or cold foods to avoid burning your mouth.
- Check your skin and mouth daily for bruises, swelling, or areas with small, reddish-purple marks that may indicate bleeding.
- Notify your health care provider if you:

- Are injured and persistent bleeding results
- Have excessive menstrual bleeding
- See blood in your urine or bowel movement
- Avoid anal intercourse.
- Take a stool softener to prevent straining during a bowel movement.
- Do not use enemas or rectal suppositories.
- Do not wear clothing or shoes that are tight or that rub.
- Avoid blowing your nose forcefully or placing objects in your nose. If you must blow your nose, do so gently without blocking either nasal passage.
- Avoid playing musical instruments that raise the pressure inside your head, such as brass wind instruments and woodwinds or reed instruments.
- Keep all appointments for laboratory tests.

#### Health Care Resources.

Patients using anticoagulation therapy with warfarin are usually seen in a clinic or primary health care provider's office frequently for blood tests. Those who are homebound may have a visit from a home care nurse to perform these tests. Enoxaparin (Lovenox) and newer anticoagulation agents (dabigatran [Pradaxa], rivaroxaban [Xarelto], and apixaban [Eliquis]) do not require laboratory monitoring. Patients with severe dyspnea may need home oxygen therapy. Respiratory therapy treatments can be performed in the home. The nurse or case manager coordinates arrangements for oxygen and other respiratory therapy equipment to be available if needed at home. See [Chart 32-8](#) for a home care assessment guide.

#### Chart 32-8

### Home Care Assessment

#### The Patient After Pulmonary Embolism

Assess respiratory status:

- Observe rate and depth of ventilation.
- Auscultate lungs.
- Examine nail beds and mucous membranes for evidence of cyanosis, indicating reduced GAS EXCHANGE.
- Take a pulse oximetry reading.
- Ask the patient if chest pain or shortness of breath is experienced in any position.

- Ask the patient about the presence of sputum and its color and character.

Assess cardiovascular status:

- Take vital signs, including apical pulse, pulse pressure; assess for presence or absence of orthostatic hypotension and quality and rhythm of peripheral pulses.
- Note presence or absence of peripheral edema.
- Examine hand vein filling in the dependent position.
- Examine neck vein filling in the recumbent and sitting positions.

Assess lower extremities for deep vein thrombosis:

- Examine lower legs and compare with each other for:
  - General edema
  - Calf swelling
  - Surface temperature
  - Presence of red streaks or cordlike, palpable structure
  - Measure calf circumference.

Assess for evidence of bleeding:

- Examine the mouth and gums for oozing or frank bleeding.
- Examine all skin areas, especially old puncture sites and wounds, for bleeding, bruising, or petechiae.
- If the patient voids during the visit, test the urine for occult blood.

Assess cognition and mental status:

- Check level of consciousness.
- Check orientation to time, place, and person.
- Can the patient accurately read a seven-word sentence containing no

words with more than three syllables?

Assess the patient's understanding of illness and adherence to treatment:

- Symptoms to report to health care provider
- Drug therapy plan (correct timing and dose)
- Bleeding Precautions
- Prevention of venous thromboembolism

◆ **Evaluation: Reflecting**

Evaluate the care of the patient with PE on the basis of the identified priority patient problems. The expected outcomes are that he or she:

- Attains and maintains adequate GAS EXCHANGE and oxygenation
- Does not experience hypovolemia and shock
- Remains free from bleeding episodes
- States that the level of anxiety is reduced
- Uses effective coping strategies

 **Clinical Judgment Challenge 32-1**

**Patient-Centered Care; Safety; Teamwork and Collaboration** USEN

The patient is a 53-year-old woman who had major abdominal surgery for a bowel resection 2 days ago. She is a current smoker with a 40 pack-year smoking history. She also has chronic obstructive pulmonary disease and had a right upper lobe lung removal in the past. The nursing assistant calls you to the patient's room because her pulse oximeter is alarming and indicates an SpO<sub>2</sub> of 50%. The patient reports mild shortness of breath, and her blood pressure is 76/42.

1. What should be your first actions? Provide a rationale for your choice(s).
2. The primary health care provider asks you to send a D-dimer laboratory test. Is this test diagnostic for a PE? Why or why not?
3. The primary health care provider believes that the patient has a PE and wants to start anticoagulation before a CT scan is performed for confirmation. Is this an appropriate intervention action? Why or why not?
4. Which other interprofessional team members now would be helpful to involve in this patient's care and why?
5. Your patient does have a PE and has completed her inpatient therapy. She is to be discharged to home on warfarin therapy. Which important issues should be included in the discharge plan?

# Acute Respiratory Failure

## ❖ Pathophysiology

A near match in the lungs between air movement or ventilation (V) and blood flow or PERFUSION (Q) is needed for adequate pulmonary GAS EXCHANGE. When either ventilation or perfusion is mismatched with the other in a lung or lung area, gas exchange is reduced, and respiratory failure can result (Lamba et al., 2016).

Acute respiratory failure (ARF) can be *ventilatory failure*, *oxygenation (GAS EXCHANGE) failure*, or a *combination of both ventilatory and oxygenation failure* and is classified by abnormal blood gas values. The critical values are:

- Partial pressure of arterial oxygen (PaO<sub>2</sub>) less than 60 mm Hg (hypoxemic/oxygenation failure)
- or Partial pressure of arterial carbon dioxide (PaCO<sub>2</sub>) more than 45 mm Hg occurring with acidemia (pH <7.35) (hypercapnic/ventilatory failure)
- and Arterial oxygen saturation (SaO<sub>2</sub>) less than 90% in both cases

Whatever the underlying problem, the patient in acute respiratory failure is always **hypoxemic** (has low arterial blood oxygen levels).

## Ventilatory Failure

Ventilatory failure is a problem in oxygen intake (air movement or ventilation) and blood flow (PERFUSION) that causes a ventilation-perfusion (V/Q) mismatch in which blood flow (perfusion) is normal but air movement (ventilation) is inadequate. It occurs when the chest pressure does not change enough to permit air movement into and out of the lungs. As a result, too little oxygen reaches the alveoli, and carbon dioxide is retained. Perfusion is wasted in this area of no air movement from either inadequate oxygen intake or excessive carbon dioxide retention, leading to poor GAS EXCHANGE and hypoxemia.

Ventilatory failure usually results from any of these problems: a physical problem of the lungs or chest wall; a defect in the respiratory control center in the brain; or poor function of the respiratory muscles, especially the diaphragm. The problem is defined by a PaCO<sub>2</sub> level above 45 mm Hg plus acidemia (pH < 7.35) in patients who have otherwise healthy lungs.

Many disorders can result in ventilatory failure. Causes are either **extrapulmonary** (involving nonpulmonary tissues but affecting respiratory function) or **intrapulmonary** (disorders of the respiratory tract). Table 32-2 lists causes of ventilatory failure.

**TABLE 32-2**

**Common Causes of Ventilatory Failure**

Extrapulmonary Causes	Intrapulmonary Causes
<ul style="list-style-type: none"> <li>• Neuromuscular disorders:               <ul style="list-style-type: none"> <li>• Myasthenia gravis</li> <li>• Guillain-Barré syndrome</li> <li>• Poliomyelitis</li> <li>• Spinal cord injuries affecting nerves to intercostal muscles</li> </ul> </li> <li>• Central nervous system dysfunction:               <ul style="list-style-type: none"> <li>• Stroke</li> <li>• Increased intracranial pressure</li> <li>• Meningitis</li> </ul> </li> <li>• Chemical depression:               <ul style="list-style-type: none"> <li>• Opioid analgesics, sedatives, anesthetics</li> <li>• Kyphoscoliosis</li> <li>• Massive obesity</li> <li>• Sleep apnea</li> </ul> </li> <li>• External obstruction/constriction</li> </ul>	<ul style="list-style-type: none"> <li>• Airway disease:               <ul style="list-style-type: none"> <li>• Chronic obstructive pulmonary disease (COPD), asthma</li> </ul> </li> <li>• Ventilation-perfusion (V/Q)mismatch:               <ul style="list-style-type: none"> <li>• Pulmonary embolism</li> </ul> </li> <li>• Pneumothorax</li> <li>• Acute respiratory distress syndrome (ARDS)</li> <li>• Amyloidosis</li> <li>• Pulmonary edema</li> <li>• Interstitial fibrosis</li> </ul>

## Oxygenation (Gas Exchange) Failure

In oxygenation (GAS EXCHANGE) failure, chest pressure changes are normal, and air moves in and out without difficulty but does not oxygenate the pulmonary blood sufficiently. It occurs in the type of V/Q mismatch in which air movement and oxygen intake (ventilation) are normal but lung blood flow (PERFUSION) is decreased.

Many lung disorders can cause oxygenation failure. Problems include impaired diffusion of oxygen at the alveolar level, right-to-left shunting of blood in the pulmonary vessels, V/Q

mismatch, breathing air with a low oxygen level, and abnormal hemoglobin that fails to bind oxygen. In one type of V/Q mismatch, areas of the lungs still have PERFUSION, but GAS EXCHANGE does not occur, which leads to hypoxemia. An extreme example of V/Q mismatch is when systemic venous blood (oxygen-poor) passes through the lungs without being oxygenated and is “shunted” to the left side of the heart and into the systemic arterial system. Normally less than 5% of cardiac output contains venous blood that has bypassed oxygenation. With poor oxygenation in the lungs or a shunt that allows venous blood to bypass the lungs, even more arterial blood is not oxygenated, and applying 100% oxygen does not correct the problem. A classic cause of such a V/Q mismatch is acute respiratory distress syndrome (ARDS). Table 32-3 lists specific causes of oxygenation failure.

**TABLE 32-3**  
**Common Causes of Oxygenation Failure**

<ul style="list-style-type: none"> <li>• Low atmospheric oxygen concentration:</li> <li>• High altitudes, closed spaces, smoke inhalation, carbon monoxide poisoning</li> <li>• Pneumonia</li> <li>• Congestive heart failure with pulmonary edema</li> <li>• Pulmonary embolism (PE)</li> <li>• Acute respiratory distress syndrome (ARDS)</li> <li>• Interstitial pneumonitis-fibrosis</li> <li>• Abnormal hemoglobin</li> <li>• Hypovolemic shock</li> <li>• Hypoventilation</li> <li>• Complications of nitroprusside therapy:</li> <li>• Thiocyanate toxicity, methemoglobinemia</li> </ul>
--

### Combined Ventilatory and Oxygenation Failure

Combined ventilatory and oxygenation failure involves **hypoventilation** (poor respiratory movements). Impaired GAS EXCHANGE at the alveolar-capillary membrane results in poor diffusion of oxygen into arterial blood and carbon dioxide retention. The condition may or may not include poor lung perfusion. When lung PERFUSION is not adequate, V/Q mismatch occurs, and both ventilation and perfusion are inadequate. This type of respiratory failure leads to a more profound hypoxemia than either ventilatory failure or oxygenation failure alone.

A combination of ventilatory failure and oxygenation (GAS EXCHANGE) failure occurs in patients who have abnormal lungs, such as those who have any form of chronic bronchitis, emphysema, or cystic fibrosis or are having an asthma attack. The bronchioles and alveoli are diseased (causing oxygenation failure), and the work of breathing increases until the respiratory muscles cannot function effectively, causing ventilatory failure leading to acute respiratory failure (ARF). ARF can also occur in patients who have cardiac failure along with ventilatory failure and is made worse because the cardiac system cannot adapt to the hypoxia by increasing the cardiac output.

### ❖ Interprofessional Collaborative Care

#### ◆ Assessment: Noticing

The symptoms of ARF are related to the systemic effects of hypoxia, hypercapnia, and acidosis. Assess for **dyspnea** (perceived difficulty breathing)—the hallmark of respiratory failure. Evaluate dyspnea on the basis of how breathless the patient becomes while performing common tasks. Depending on the nature of the underlying problem, the patient might not be aware of changes in the work of breathing.

Dyspnea is more intense when it develops rapidly. Slowly progressive respiratory failure may first be noticed as dyspnea on exertion (DOE) or when lying down. The patient may have **orthopnea**, finding it easier to breathe in an upright position (Bull, 2014). With chronic respiratory problems, a minor increase in dyspnea may represent severe GAS EXCHANGE problems.

Assess for a change in the patient's respiratory rate or pattern and changes in lung sounds. Pulse oximetry (SpO<sub>2</sub>) may show decreased oxygen saturation, but end-tidal CO<sub>2</sub> (ETCO<sub>2</sub> or PETCO<sub>2</sub>) monitoring may be more valuable for monitoring the patient with ARF (Carlisle, 2014). His or her pulse oximetry may show adequate oxygen saturation but, because of increased ETCO<sub>2</sub>, the patient may be close to respiratory failure. Arterial blood gas (ABG) studies are reviewed to most accurately identify the degree of hypoxia and hypercarbia.

Other symptoms of hypoxic respiratory failure include restlessness, irritability or agitation, confusion, and tachycardia. Symptoms of hypercapnic failure may include decreased level of

consciousness (LOC), headache, drowsiness, lethargy, and seizures. The effects of acidosis may lead to decreased LOC, drowsiness, confusion, hypotension, bradycardia, and weak peripheral pulses.

### ◆ **Interventions: Responding**

*Oxygen therapy is appropriate for any patient with acute hypoxemia.* It is used in acute respiratory failure to keep the arterial oxygen (PaO<sub>2</sub>) level above 60 mm Hg while treating the cause of the respiratory failure. Oxygen therapy is discussed in detail in [Chapter 28](#). If oxygen therapy does not maintain acceptable PaO<sub>2</sub> levels, indicating adequate GAS EXCHANGE, mechanical ventilation (invasive or noninvasive) may be needed.

Drugs given systemically, by nebulizer, or by metered dose inhaler (MDI) may be prescribed to dilate the bronchioles and decrease inflammation to promote GAS EXCHANGE. Corticosteroids may be used, but their benefit has not been demonstrated conclusively. Analgesics are needed if the patient has pain. If the patient requires mechanical ventilation, he or she may need neuromuscular blockade drugs for optimal ventilator effect. Other management strategies depend on the underlying condition(s) that predisposed the patient to ARF development, which may include diuretic therapy or antibiotic therapy.

Help the patient find a position of comfort that allows easier breathing (i.e., usually a more upright position). To decrease the anxiety occurring with dyspnea, help him or her use relaxation, diversion, and guided imagery. Start energy-conserving measures, such as minimal self-care and no unnecessary procedures. Encourage deep breathing and other breathing exercises.

# Acute Respiratory Distress Syndrome

## ❖ Pathophysiology

**Acute respiratory distress syndrome (ARDS)** is acute respiratory failure with these features:

- Hypoxemia that persists even when 100% oxygen is given (**refractory hypoxemia**, a cardinal feature)
- Decreased pulmonary compliance
- Dyspnea
- Noncardiac-associated bilateral pulmonary edema
- Dense pulmonary infiltrates on x-ray (ground-glass appearance)

Often ARDS occurs after an *acute lung injury (ALI)* in people who have no pulmonary disease as a result of other conditions such as sepsis, burns, pancreatitis, trauma, and transfusion. Other terms for ARDS include *adult respiratory distress syndrome* and *shock lung*.

Despite different causes of ALI in ARDS, the trigger is a systemic inflammatory response. As a result, ARDS symptoms are similar regardless of the cause. The main site of injury in the lung is the alveolar-capillary membrane, which normally is permeable only to small molecules. It can be injured during sepsis, pulmonary embolism, shock, aspiration, or inhalation injury. When injured, this membrane becomes more permeable to large molecules, which allows debris, proteins, and fluid into the alveoli. Lung tissue normally remains relatively dry, but in patients with ARDS lung fluid increases and contains more proteins.

Other changes occur in the alveoli and respiratory bronchioles. Normally the type II pneumocytes produce surfactant, a substance that increases lung **compliance** (elasticity) and prevents alveolar collapse. Surfactant activity is reduced in ARDS because type II pneumocytes are damaged and because the surfactant is diluted by excess lung fluids. As a result, the alveoli become unstable and tend to collapse unless they are filled with fluid. These fluid-filled and collapsed alveoli cannot participate in GAS EXCHANGE. Edema then forms around terminal airways, which are compressed and closed and can be destroyed. Lung volume and compliance are further reduced. As fluid continues to leak in more lung areas, fluid, protein, and blood cells collect in the alveoli and in the spaces between the alveoli. Lymph channels are compressed, and more fluid collects. Poorly inflated alveoli receive blood but cannot oxygenate it, increasing the shunt. Hypoxemia and ventilation-perfusion V/Q mismatch result.

Transfusion-related acute lung injury (TRALI) is the sudden onset (within 6 hours of a transfusion) of hypoxemic lung disease along with infiltrates on x-ray without cardiac problems. TRALI is associated with the activation of the inflammatory response caused by a recent transfusion of plasma-containing blood products such as packed red blood cells (PRBCs), platelets, and fresh frozen plasma. Other lung complications of transfusion include transfusion-associated circulatory overload (TACO) and transfusion-related immunomodulation (TRIM).

## Etiology and Genetic Risk

ALI leading to ARDS has many causes (Table 32-4). Some causes result in direct injury to lung tissue; other causes do not directly involve the lungs. As a result of sepsis, pancreatitis, trauma, and other conditions, inflammatory mediators spread to the lungs, causing damage (McCance et al., 2014).

---

**TABLE 32-4**

### Common Causes of Acute Lung Injury

---

<ul style="list-style-type: none"><li>• Shock</li><li>• Trauma</li><li>• Serious nervous system injury</li><li>• Pancreatitis</li><li>• Fat and amniotic fluid emboli</li><li>• Pulmonary infections</li><li>• Sepsis</li><li>• Inhalation of toxic gases (smoke, oxygen)</li></ul>
<ul style="list-style-type: none"><li>• Pulmonary aspiration (especially of stomach contents)</li><li>• Drug ingestion (e.g., heroin, opioids, aspirin)</li><li>• Hemolytic disorders</li><li>• Multiple blood transfusions</li><li>• Cardiopulmonary bypass</li></ul>

ARDS also can occur from direct lung injury. Aspiration of acidic gastric contents, pneumonia, drowning, or inhaling toxic fumes are examples of conditions causing direct lung injury. With such events, surfactant production is impaired, and the remaining surfactant is diluted. This situation leads to atelectasis, decreased lung compliance, and shunting (movement of blood in the lungs without GAS EXCHANGE and oxygenation) (McCance et al., 2014).

## Genetic/Genomic Considerations

### Patient-Centered Care QSEN

An increased genetic risk is suspected in the development and progression of ARDS. Variations in the genes responsible for surfactant production appear to increase the predisposition to developing ARDS, as does variation in the genes responsible for cytokine production during inflammatory events associated with sepsis. Ask about the patient's previous responses to infection or injury. If the patient has consistently had greater-than-expected inflammatory responses, he or she may be at increased risk for ARDS after ALI and should be monitored for symptoms of the disorder.

### Incidence and Prevalence

The actual incidence of ARDS is unknown because it is part of other health problems and is not systematically reported as a separate disorder. According to the ARDS Foundation, about 150,000 cases of ARDS occur yearly in North America, although many health care professionals believe this estimate to be low. The mortality rate is estimated at 42% (ARDS Foundation, 2016).

### Health Promotion and Maintenance

*The nursing priority in the prevention of ARDS is early recognition of patients at high risk for the syndrome.* Because patients who aspirate gastric contents are at great risk, closely assess and monitor those receiving tube feedings (because the tube keeps the gastric sphincter open) and those with problems that impair swallowing and gag reflexes. As required by The Joint Commission's NPSGs to prevent ARDS, follow meticulous infection control guidelines, including handwashing, invasive catheter and wound care, and Contact Precautions. Teach unlicensed assistive personnel (UAP) the importance of always adhering to infection control guidelines. Carefully observe patients who are being treated for any health problem associated with ARDS.

### Interprofessional Collaborative Care

ARDS is a life-threatening health problem that may result in permanent impairment of lung function requiring major changes in lifestyle. For optimum patient function, a comprehensive interprofessional team approach is needed. Essential team members are the same as those described for pulmonary embolism (see the exemplar earlier in this chapter).

### Assessment: Noticing

#### Physical Assessment/Signs and Symptoms.

Assess the breathing of any patient at increased risk for ARDS. Determine whether increased work of breathing is present, as indicated by hyperpnea, noisy respiration, cyanosis, pallor, and retraction **intercostally** (between the ribs) or **substernally** (below the ribs). Document sweating, respiratory effort, and any change in mental status. *Abnormal lung sounds are **not** heard on auscultation because the edema occurs first in the interstitial spaces and not in the airways.* Assess vital signs at least hourly for hypotension, tachycardia, and dysrhythmias.

Many patients with ARDS have an altered core body temperature on admission. Those with a temperature elevation early in the course of ARDS appear to have a better outcome with lower mortality than do those who have hypothermia (Schell-Chaple et al., 2015).

#### Diagnostic Assessment.

The diagnosis of ARDS is established by a lowered partial pressure of arterial oxygen (PaO<sub>2</sub>) value (decreased GAS EXCHANGE and oxygenation), determined by arterial blood gas (ABG) measurements.

Because a widening alveolar oxygen gradient (i.e., increased fraction of inspired oxygen [ $\text{FiO}_2$ ] does not lead to increased  $\text{PaO}_2$  levels) develops with increased shunting of blood, the patient has a progressive need for higher levels of oxygen. He or she develops refractory hypoxemia and often needs intubation and mechanical ventilation. Sputum cultures obtained by bronchoscopy and transtracheal aspiration are used to determine if a lung infection also is present.

The chest x-ray may show diffuse haziness or a “whited-out” (ground-glass) appearance of the lung. An ECG rules out cardiac problems and usually shows no specific changes. Although hemodynamic monitoring with a pulmonary artery catheter has been used in the past to help diagnose ARDS, such invasive monitoring has not shown any benefit and is no longer recommended.

## ◆Interventions: Responding

### Management Overview.

General management of the patient with ARDS focuses on the three phases of ARDS. Timing of the phases varies from patient to patient.

*Exudative phase.* This phase includes early changes of dyspnea and tachypnea resulting from the alveoli becoming fluid filled and from pulmonary shunting and atelectasis. Early interventions focus on supporting the patient and providing oxygen.

*Fibroproliferative phase.* Increased lung injury leads to pulmonary hypertension and fibrosis. The body attempts to repair the damage, and increasing lung involvement reduces GAS EXCHANGE and oxygenation. Multiple organ dysfunction syndrome (MODS) can occur. Interventions focus on delivering adequate oxygen, preventing complications, and supporting the lungs.

*Resolution phase.* Usually occurring after 14 days, resolution of the injury can occur; if not the patient either dies or has chronic disease. Fibrosis may or may not occur. Patients surviving ARDS often have neuropsychological deficits.

### Specific Management.

The patient with ARDS often needs intubation and mechanical ventilation with positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP). Best practice involves using “open lung” and lung protective ventilation strategies. Low tidal volumes (6 mL/kg of body weight) have been shown to prevent lung injury. PEEP is started at 5 cm  $\text{H}_2\text{O}$  and increased to keep oxygen saturation adequate. PEEP levels may need to be high. Pressure-controlled ventilation is preferred over volume-controlled ventilation to promote the nonfunctional alveoli to participate in GAS EXCHANGE. Because one of the side effects of PEEP is tension pneumothorax, assess lung sounds hourly and suction as often as needed to maintain a patent airway.

Airway pressure-release ventilation (APRV) and high-frequency oscillatory ventilation (HFOV) are alternative modes of mechanical ventilation that improve GAS EXCHANGE with oxygenation and ventilation in patients with moderate-to-severe ARDS. The airway pressure for both APRV and HFOV are significantly higher than for conventional mechanical ventilation. Sedation and paralysis may be needed for adequate ventilation and to reduce tissue oxygen needs, especially with HFOV. Sedation and paralysis are not required with APRV but may be needed to prevent patient disruption of mechanical ventilation. APRV does not allow for spontaneous breathing between mandatory breaths (see the [Modes of Ventilation](#) section).

Positioning may be important in promoting GAS EXCHANGE, but the exact position is controversial. Some patients do better in the prone position, especially if it is started early in the disease course ([Drahnak & Custer, 2015](#); [Senecal, 2015](#)). Prone positioning may be achieved using a mechanical turning device, although the turning equipment is awkward and care in the prone position is more difficult. Automated kinetic beds are available to assist with turning. Manually turning the patient every 2 hours has been shown to improve PERFUSION; however, this intervention often is not performed as frequently as needed. Early progressive mobility also has demonstrated benefit in reducing ventilator needs, days on the ventilator, and mortality. Automatic turning appears to have a slight advantage of decreasing some pulmonary complications but has not yet shown secondary benefits such as decreased lengths of stay, reduced ICU mortality, or decreased ventilator days.

For severe ARDS, extracorporeal membrane oxygenation (ECMO) using heart-lung bypass equipment has been a successful life support technique when the patient does not improve with more traditional management ([Schulman et al., 2014](#)). However, the proper timing of ECMO and

standardization of this therapy for best outcomes have not been established.

### Drug and Fluid Therapy.

Antibiotics are used to treat infections when organisms are identified. Other drugs are used to manage any underlying cause. Currently no treatments reverse the pathologic changes in the lungs, although many interventions that modify the inflammatory responses and reduce oxidative stress are under investigation. These agents include vitamins C and E, *N*-acetylcysteine, nitric oxide, and surfactant replacement (Chudow et al., 2015; Howe et al., 2015).

Research shows that patients with ARDS who receive conservative fluid therapy have improved lung function and a shorter duration of mechanical ventilation and ICU length of stay compared with those who receive more liberal fluid therapy. Conservative fluid therapy involves infusing smaller amounts of IV fluid and using diuretics to maintain fluid balance, whereas liberal fluid therapy often results in an increasingly positive fluid balance and more edema.

### Nutrition Therapy.

The patient with ARDS is at risk for malnutrition, which further reduces respiratory muscle function and the immune response. The interprofessional team should include a registered dietitian, and enteral nutrition (tube feeding) or parenteral nutrition is started as soon as possible.

## Clinical Judgment Challenge 32-2

### Safety; Teamwork and Collaboration; Evidence-Based Practice QSEN

The patient is a 26-year-old who was admitted to the surgical floor 2 days ago after a motor vehicle crash. His injuries include a thoracic fracture, for which he must remain flat, and some chest bruising. He was started on enteral feeding yesterday. His IV fluid rate is 150 mL/hr, and he is receiving IV morphine every 2 hours for pain. At change of shift, your assessment findings include that the patient is dyspneic and slightly confused. Lung sounds are diminished in the right base, and he is febrile to 101.5° F (38.6° C). Pulse is 120 beats/min; respirations are 36 breaths/min and shallow. Blood pressure is 88/56 mm Hg, pulse oximetry shows an SpO<sub>2</sub> of 88%, and capnography shows an end-tidal CO<sub>2</sub> (ETCO<sub>2</sub>) of 48.

1. Is this patient experiencing ventilatory failure, oxygen failure, or a combination of ventilatory and oxygenation failure? Explain your answer.
2. What are some possible causes of the patient's distress?
3. Which interprofessional team members should you contact now and why?
4. Which diagnostic tests should you anticipate?

## The Patient Requiring Intubation and Ventilation

### ❖ Pathophysiology

With mechanical ventilation, the patient who has severe problems of GAS EXCHANGE may be supported until the underlying problem improves or resolves. Usually mechanical ventilation is a temporary life-support technique. The need for this support may be lifelong for those with severe restrictive lung disease or chronic progressive neuromuscular disease that reduces ventilation.

Mechanical ventilation is most often used for patients with hypoxemia and progressive alveolar hypoventilation with respiratory acidosis. The hypoxemia is usually caused by pulmonary shunting of blood when other methods of oxygen delivery do not provide a sufficiently high fraction of inspired oxygen ( $F_{iO_2}$ ). Mechanical ventilation may be used for patients who need temporary ventilatory support after surgery, those who expend too much energy with breathing and barely maintain adequate GAS EXCHANGE, or those who have general anesthesia or heavy sedation.

### ❖ Interprofessional Collaborative Care

Assess the patient to be intubated in the same way as for other breathing problems. Once mechanical ventilation has been started, assess the respiratory system on an ongoing basis. Monitor and assess for problems related to the artificial airway or ventilator.

### Endotracheal Intubation

The patient who needs mechanical ventilation must have an artificial airway. The most common type of airway for a short-term basis is the endotracheal (ET) tube. To reduce tracheal and vocal cord damage, a tracheostomy is considered if an artificial airway is needed for longer than 10 to 14 days (see Chapter 28). The expectations of intubation are to maintain a patent airway, provide a means to remove secretions, and provide ventilation and oxygen.

#### Endotracheal Tube.

An ET tube is a long polyvinyl chloride tube that is passed through the mouth or nose and into the trachea (Fig. 32-2). When properly positioned, the tip of the ET tube rests about 2 cm above the **carina** (the point at which the trachea divides into the right and left mainstem bronchi). Oral intubation is a fast and easy way to establish an airway and is often performed as an emergency procedure. The nasal route is used for oral surgeries and when oral intubation is not possible. This route is avoided with midface trauma or possible basilar skull fracture. This route is not used if the patient has a blood CLOTTING problem. An anesthesiologist, nurse anesthetist, or respiratory therapist usually performs the intubation.

**FIG. 32-2** A, Endotracheal tubes. B, Correct placement of an oral endotracheal tube. (A Courtesy Sims Porter, Inc.)

The shaft of the tube has a radiopaque line running the length of the tube. This line shows on x-

ray and is used to determine correct tube placement. Short horizontal lines (depth markings) are used to place the tube correctly at the naris or mouth (at the incisor tooth) and to identify how far the tube has been inserted.

The cuff at the distal end of the tube is inflated after placement and creates a seal between the trachea and the cuff. The seal ensures delivery of a set tidal volume when mechanical ventilation is used. The cuff is inflated using a minimal-leak technique: when the cuff is inflated to an adequate sealing volume, a minimal amount of air can pass around it to the vocal cords, nose, or mouth. The patient cannot talk when the cuff is inflated.

The pilot balloon with a one-way valve permits air to be inserted into the cuff and prevents air from escaping. This balloon is a guide for determining whether air is present in the cuff, but it does not show how much or how little air is present.

The adaptor connects the ET tube to ventilator tubing or an oxygen delivery system. The ET tube size is listed on the shaft of the tube. Adult tube sizes range from 7 to 9 mm. Tube size selected is based on the size of the patient.

### Preparing for Intubation.

Know the proper procedure for summoning intubation personnel in the facility to the bedside in an emergency situation. Explain the procedure to the patient as clearly as possible. *Basic life support measures, such as obtaining a patent airway and delivering 100% oxygen by a manual resuscitation bag with a facemask, are crucial to survival until help arrives.*

## Nursing Safety Priority QSEN

### Critical Rescue

Monitor patients at risk for airway obstruction and impaired ventilation. When you recognize the need for emergency intubation and ventilation, respond by bringing the code (or “crash”) cart, airway equipment box, and suction equipment (often already on the code cart) to the bedside. Maintain a patent airway through positioning (head-tilt, chin-lift) and the insertion of an oral or nasopharyngeal airway until the patient is intubated. Delivering manual breaths with a bag-valve-mask may also be required.

During intubation, the nurse coordinates the rescue response and continuously monitors the patient for changes in vital signs, signs of hypoxia or hypoxemia, dysrhythmias, and aspiration. Ensure that each intubation attempt lasts no longer than 30 seconds, preferably less than 15 seconds. After 30 seconds, provide oxygen by means of a mask and manual resuscitation bag to prevent hypoxia and cardiac arrest. Suction as necessary.

### Verifying Tube Placement.

Immediately after an ET tube is inserted, placement should be verified. The most accurate ways to verify placement are by checking end-tidal carbon dioxide levels and by chest x-ray. Assess for breath sounds bilaterally, sounds over the gastric area, symmetric chest movement, and air emerging from the ET tube. If breath sounds and chest wall movement are absent on the left side, the tube may be in the right mainstem bronchus. The person intubating the patient should be able to reposition the tube without repeating the entire intubation procedure.

If the tube is in the stomach, the abdomen may be distended and must be decompressed with a nasogastric (NG) tube after the ET tube is replaced. Monitor chest wall movement and breath sounds until tube placement is verified by chest x-ray.

### Stabilizing the Tube.

The nurse, respiratory therapist, or anesthesia provider stabilizes the ET tube at the mouth or nose. The tube is marked at the level where it touches the incisor tooth or naris. Two people working together use a head halter technique to secure the tube. An oral airway also may be inserted, or a commercial bite block placed to keep the patient from biting an oral ET tube. One person stabilizes the tube at the correct position and prevents head movement while a second person applies the tube holding device. Commercial tube holders are preferred over securing the tube with tape. After the procedure is completed, verify and document the presence of bilateral and equal breath sounds

and the level of the tube.

### Nursing Care.

The priority nursing action when caring for an intubated patient is maintaining a patent airway. Assess tube placement, cuff leak, breath sounds, indications of adequate GAS EXCHANGE and oxygenation, and chest wall movement regularly.

## Nursing Safety Priority QSEN

### Critical Rescue

Assess intubated patients to recognize indications of decreased GAS EXCHANGE. When these indications are present, respond by checking for DOPE: *displaced tube, obstructed tube* (most often with secretions), *pneumothorax*, and *equipment problems*.

Prevent the patient from pulling or tugging on the tube to avoid tube dislodgment and check the pilot balloon to ensure that the cuff is inflated. Monitor the pressure within the cuff to ensure that it is maintained between 20 to 30 cm H<sub>2</sub>O to stabilize the tube without causing tracheal injury.

Suctioning, coughing, and speaking can cause dislodgment. Neck flexion, neck extension, and rotation of the head also can cause the tube to move. In addition, cuff pressures may be affected by patient position changes and may require more frequent monitoring (Lizy et al., 2014). Tongue movement also can change the tube's position. When other measures fail, obtain a prescription for soft wrist restraints and apply these for the patient who is pulling on the tube. *Restraints are used as a last resort to prevent accidental extubation.* To remain in compliance with The Joint Commission's National Patient Safety Goals (NPSG), reassess the need for restraint use daily. If the need continues, a new prescription is needed daily. Adequate sedation (chemical restraint) may be needed to decrease agitation or prevent extubation. Obtain permission for restraints from the patient or family. More information on airway management is found in [Chapter 28](#).

Complications of an ET or nasotracheal tube can occur during placement, while in place, during extubation, or after extubation (either early or late). Common complications include tube obstruction, dislodgment, pneumothorax, tracheal tears, bleeding, and infection. Trauma and other problems can occur to the face; eye; nasal and paranasal areas; oral, pharyngeal, bronchial, tracheal, and pulmonary areas; esophageal and gastric areas; and cardiovascular, musculoskeletal, and neurologic systems.

## NCLEX Examination Challenge 32-2

### Safe and Effective Care Environment

The client from Clinical Judgment Challenge 32-2 continues to deteriorate clinically and is to be intubated. What are the **most important** actions for the nurse to implement? **Select all that apply.**

- A. Obtain a cervical x-ray.
- B. Discontinue the IV fluids.
- C. Immediately page anesthesia or the Rapid Response Team (depending on institution policy).
- D. Confirm that suction is at the bedside and functioning properly.
- E. Have the crash cart available.
- F. Place client on nasal cannula oxygen.
- G. Have manual resuscitation bag with facemask at bedside.
- H. Verify bilateral breath sounds postintubation.

## Mechanical Ventilation

Mechanical ventilation to support and maintain GAS EXCHANGE is used in many settings, not just in critical care units. The nurse plays a pivotal role in the coordination of care and prevention of problems. [Chart 32-9](#) lists best practices for patient care during mechanical ventilation.

### Chart 32-9

## Best Practice for Patient Safety & Quality Care QSEN

### Care of the Patient Receiving Mechanical Ventilation

- Assess the patient's respiratory status and GAS EXCHANGE at least every 4 hours for the first 24 hours and then as needed:
- Take vital signs at least every 4 hours.
- Assess the patient's color (especially lips and nail beds).
- Observe the patient's chest for bilateral expansion.
- Assess the placement of the nasotracheal or endotracheal tube.
- Obtain pulse oximetry reading.
- Evaluate ABGs as available.
- Maintain head of the bed more than 30 degrees when patient is supine to prevent aspiration and ventilator-associated pneumonia.
- Document pertinent observations in the patient's medical record.
- Check at least every 8 hours to be sure that the ventilator setting is as prescribed.
- Check to be sure that alarms are set (especially low-pressure and low-exhaled volume).
- If the patient is on PEEP, observe the peak airway pressure dial to determine the proper level of PEEP.
- Check the exhaled volume digital display to be sure that the patient is receiving the prescribed tidal volume.
- Empty ventilator tubings when moisture collects. Never empty fluid in the tubing back into the cascade.
- Ensure humidity by keeping delivered air temperature maintained at body temperature.
- Be sure the tracheostomy cuff (or endotracheal cuff) is adequately inflated to ensure tidal volume.
- Auscultate the lungs for crackles, wheezes, equal breath sounds, and decreased or absent breath sounds.
- Check the patient's need for tracheal, oral, or nasal suctioning every 2 hours and suction as needed.

- Assess the patient's mouth around the ET tube for pressure injuries.
- Perform mouth care every 2 hours.
- Change tracheostomy tube holder or tape or ET tube holder or tape as needed:
- Carefully move the oral ET tube to the opposite side of the mouth once daily to prevent ulcers.
- Provide tracheostomy care every 8 hours.
- Assess ventilated patients for GI distress (diarrhea, constipation, tarry stools).
- Maintain accurate intake and output records to monitor fluid balance.
- Turn the patient at least every 2 hours and get the patient out of bed as prescribed to promote pulmonary hygiene and prevent complications of immobility.
- Schedule treatments and nursing care at intervals for rest.
- Monitor the patient's progress on current ventilator settings and make appropriate changes as indicated.
- Monitor the patient for the effectiveness of mechanical ventilation in terms of his or her physiologic and psychological status.
- Monitor for adverse effects of mechanical ventilation: infection, barotrauma, reduced cardiac output.
- Position the patient to facilitate ventilation-perfusion (V/Q) matching ("good lung down"), as appropriate.
- Monitor the effects of ventilator changes on GAS EXCHANGE and the patient's subjective response.
- Monitor readiness to wean.
- Explain all procedures and treatments; provide access to a call light; visit the patient frequently.
- Provide a method of communication. Request consultation with a speech-language pathologist for assistance, if necessary.
- Initiate relaxation techniques, as appropriate.
- Administer muscle-paralyzing agents, sedatives, and narcotic analgesics, as prescribed.
- Include the patient and family whenever possible (especially during suctioning and tracheostomy care).

*ABGs*, Arterial blood gases; *ET*, endotracheal; *PEEP*, positive end-expiratory pressure.

The purposes of mechanical ventilation are to improve GAS EXCHANGE and decrease the work needed for effective breathing. It is used to support the patient until lung function is adequate or until the acute episode has passed. *A ventilator does not cure diseased lungs; it provides ventilation until the patient can resume the process of breathing on his or her own.* Remember *why* the patient is using the ventilator so your management efforts also can focus on correcting the causes of the respiratory failure. If normal gas exchange with oxygenation, ventilation, and respiratory muscle strength is achieved, mechanical ventilation can be discontinued.

## Types of Ventilators.

Many types of ventilators are available. The ventilator selected depends on the severity of the breathing problem and the length of time ventilator support is needed. Most ventilators are positive-pressure ventilators. During inspiration, pressure is generated that pushes air into the lungs and expands the chest. Usually an endotracheal (ET) tube or tracheostomy is needed. Positive-pressure ventilators are classified by the mechanism that ends inspiration and starts expiration. Inspiration is cycled in three major ways: pressure-cycled, time-cycled, or volume-cycled.

*Pressure-cycled ventilators* push air into the lungs until a preset airway pressure is reached. Tidal volumes and inspiratory time vary. These ventilators are used for short periods, such as just after surgery and for respiratory therapy. Bi-level positive airway pressure (Bi-PAP) ventilators are a newer form of pressure-cycled ventilators in which the ventilator provides a preset inspiratory pressure and an expiratory pressure similar to positive end-expiratory pressure (PEEP).

*Time-cycled ventilators* push air into the lungs until a preset time has elapsed. Tidal volume and pressure vary, depending on the needs of the patient and the type of ventilator.

*Volume-cycled ventilators* push air into the lungs until a preset volume is delivered. A constant tidal volume is delivered, regardless of the pressure needed to deliver the tidal volume. However, a set pressure limit prevents excessive pressure from being exerted on the lungs. The advantage of this type of ventilator is that a constant tidal volume is delivered, regardless of changes in lung or chest wall compliance or airway resistance.

*Microprocessor ventilators* are computer-managed positive-pressure ventilators. A computer is built into the ventilator to allow ongoing monitoring of ventilatory functions, alarms, and patient conditions. It often has components of volume-, time-, and pressure-cycled ventilators. This type of ventilator is more responsive to patients who have severe lung disease and those who need prolonged weaning trials. Examples include the Dräger Evita XL (Fig. 32-3) and Puritan-Bennett 840.

**FIG. 32-3** Display signals, alarms, and control panel of a typical volume-cycled ventilator. (© Dräger Medical AG & Co. KG, Lübeck, Germany. All rights reserved. No portion hereof may be reproduced, saved or stored in a data processing system, electronically or mechanically copied or otherwise recorded by any other means without express prior written permission.)

## Modes of Ventilation.

The mode of ventilation is the way in which the patient receives breaths from the ventilator. The most common modes are assist-control ventilation, synchronized intermittent mandatory ventilation, and bi-level positive airway pressure (BiPAP) ventilation.

*Assist-control (AC) ventilation* is the mode used most often as a resting mode. The ventilator takes over the work of breathing for the patient. The tidal volume and ventilatory rate are preset. If the patient does not trigger spontaneous breaths, a ventilatory pattern is established by the ventilator. It is programmed to respond to the patient's inspiratory effort if he or she begins a breath. In this case,

the ventilator delivers the preset tidal volume while allowing the patient to control the rate of breathing.

A disadvantage of the AC mode is that the ventilator continues to deliver a preset tidal volume even when the patient's spontaneous breathing rate increases. This can cause hyperventilation and respiratory alkalosis. Investigate and correct causes of hyperventilation, such as pain, anxiety, or acid-base imbalances.

*Synchronized intermittent mandatory ventilation (SIMV)* is similar to AC ventilation in that tidal volume and ventilatory rate are preset. If the patient does not breathe, a ventilatory pattern is established by the ventilator. Unlike the AC mode, SIMV allows spontaneous breathing at the patient's own rate and tidal volume between the ventilator breaths. It can be used as a main ventilatory mode or as a weaning mode. When used for weaning, the number of mechanical breaths (SIMV breaths) is gradually decreased (e.g., from 12 to 2) as the patient resumes spontaneous breathing. The mandatory ventilator breaths are delivered when the patient is ready to inspire. This action coordinates breathing between the ventilator and the patient.

*Bi-level positive airway pressure (BiPAP)* provides noninvasive pressure support ventilation by nasal mask or facemask. It is most often used for patients with sleep apnea but also may be used for patients with respiratory muscle fatigue or impending respiratory failure to avoid more invasive ventilation methods.

*Other modes of ventilation*, such as pressure support and continuous flow (flow-by), are part of most microprocessor ventilators. Both types decrease the work of breathing and are used for weaning patients from mechanical ventilation. Other modes are maximum mandatory ventilation (MMV), inverse inspiration-expiration (I/E) ratio, permissive hypercarbia, airway pressure-release ventilation (APRV), proportional assist ventilation, and high-frequency oscillation. Most modes use special ventilators, tubing, or airways.

### Ventilator Controls and Settings.

The volume-cycled ventilator is the most widely used type in the acute care setting. Regardless of the type of volume-cycled ventilator used, the controls and types of settings are universal (see [Fig. 32-3](#)). The pulmonologist or primary health care provider prescribes the ventilator settings, and usually the ventilator is readied or set up by the respiratory therapy department. The nurse assists in connecting the patient to the ventilator and monitors the ventilator settings in conjunction with respiratory therapy.

*Tidal volume ( $V_T$ )* is the volume of air the patient receives with each breath, as measured on either inspiration or expiration. The average prescribed  $V_T$  ranges between 6 and 8 mL/kg of body weight. Adding a zero to a patient's weight in kilograms gives an estimate of tidal volume.

*Rate, or breaths/min*, is the number of ventilator breaths delivered per minute. The rate is usually set between 10 and 14 breaths/min.

*Fraction of inspired oxygen ( $FiO_2$ )* is the oxygen level delivered to the patient. The prescribed  $FiO_2$  is based on the ABG values and the patient's condition. The range is 21% to 100% oxygen.

The oxygen delivered to the patient is warmed to body temperature (98.6° F [37° C]) and humidified to 100%. This is needed because upper air passages of the respiratory tree, which normally warm and humidify air, are bypassed. Humidifying and warming prevent mucosal damage.

*Peak airway (inspiratory) pressure (PIP)* is the pressure used by the ventilator to deliver a set tidal volume at a given lung compliance. The PIP value appears on the display of the ventilator. It is the highest pressure reached during inspiration. Trends in PIP reflect changes in resistance of the lungs and resistance in the ventilator. An increased PIP reading means increased airway resistance in the patient or the ventilator tubing (bronchospasm or pinched tubing, patient biting the ET tube), increased secretions, pulmonary edema, or decreased pulmonary compliance (the lungs or chest wall is "stiffer" and harder to inflate) ([Covert & Niu, 2014](#)). An upper pressure limit is set to prevent barotrauma. When the limit is reached, the high-pressure alarm sounds, and the remaining volume is not given.

*Continuous positive airway pressure (CPAP)* applies positive airway pressure throughout the entire respiratory cycle for spontaneously breathing patients. Sedating drugs are given lightly or not at all when the patient is receiving CPAP so respiratory effort is not suppressed. CPAP keeps the alveoli open during inspiration and prevents alveolar collapse during expiration. This process increases functional residual capacity (FRC) and improves GAS EXCHANGE and oxygenation.

CPAP is commonly used to help in the weaning process. During CPAP, no ventilator breaths are delivered. The ventilator just delivers oxygen and provides monitoring and an alarm system. The respiratory pattern is determined by the patient's efforts. Normal levels of CPAP are 5 to 15 cm H<sub>2</sub>O to promote adequate GAS EXCHANGE and oxygenation. If no pressure is set, the patient receives no positive pressure. The patient is then using the ventilator as a T-piece with alarms. Modifications of CPAP include nasal CPAP and BiPAP, which are used on a temporary basis for select problems.

*Positive end-expiratory pressure (PEEP) is positive pressure exerted during expiration. PEEP improves oxygenation by enhancing GAS EXCHANGE and preventing atelectasis. It is used to treat persistent hypoxemia that does not improve with an acceptable oxygen delivery level. It may be added when the arterial oxygen pressure (PaO<sub>2</sub>) remains low with an FiO<sub>2</sub> of 50% to 70% or greater.*

The need for PEEP indicates a severe GAS EXCHANGE problem. *It is important to lower the FiO<sub>2</sub> delivered whenever possible because prolonged use of a high FiO<sub>2</sub> can damage lungs from the toxic effects of oxygen.* PEEP prevents alveoli from collapsing because the lungs are kept partially inflated so alveolar-capillary gas exchange is promoted throughout the ventilatory cycle. The effect should be an increase in arterial blood oxygenation so the FiO<sub>2</sub> can be decreased.

PEEP is “dialed in” on the control panel. The amount of PEEP is usually 5 to 15 cm H<sub>2</sub>O (although higher PEEP can be used) and is monitored on the peak airway pressure dial, the same dial used to read the PIP. When PEEP is added, the dial does not return to zero at the end of exhalation; rather, it returns to a baseline that is increased from zero by the amount of PEEP applied.

*Flow rate is how fast each breath is delivered and is usually set at 40 L/min. If a patient is agitated or restless, has a widely fluctuating inspiratory pressure reading, or has other signs of air hunger, the flow may be set too low. Increasing the flow should be tried before using chemical restraints.*

*Other settings may be used, depending on the type of ventilator and mode of ventilation. Examples include inspiratory and expiratory cycle, waveform, expiratory resistance, and plateau.*

### Nursing Management.

The use of mechanical ventilation involves a collaborative and complex decision-making process for the patient, family, and interprofessional care team. Address the physical and psychological concerns of the patient and family because the mechanical ventilator often causes them anxiety. Explain the purpose of the ventilator and acknowledge the patient's and family's feelings. Encourage the patient and family to express their concerns. Act as the coach to help and support them through this experience. Patients undergoing mechanical ventilation in ICUs often experience delirium, or “ICU psychosis.” These patients need frequent, repeated explanations and reassurance.

*When caring for a ventilated patient, be concerned with the patient first and the ventilator second.* If the ventilator alarm sounds, examine the patient for breathing, color, and oxygen saturation before assessing the ventilator. It is vital to understand *why* mechanical ventilation is needed. Some problems requiring ventilation, such as excessive secretions, sepsis, and trauma, require different interventions to successfully wean from the ventilator. Chronic health problems (e.g., chronic obstructive pulmonary disease, left-sided heart failure, anemia, malnutrition) may slow weaning from mechanical ventilation and require close monitoring and intervention.

## Nursing Safety Priority QSEN

### Action Alert

The nursing priorities in caring for the patient during mechanical ventilation are monitoring and evaluating patient responses, managing the ventilator system safely, and preventing complications.

### Monitoring the Patient's Response.

Monitor, evaluate, and document the patient's response to the ventilator. Assess vital signs and listen to breath sounds every 30 to 60 minutes at first. Monitor respiratory parameters (e.g., capnography, pulse oximetry) and check ABG values (Carlisle, 2014). Monitoring provides information to guide the patient's activities, such as weaning, physical or occupational therapy, and self-care. Pace activities to ensure effective ventilation with adequate GAS EXCHANGE and oxygenation. Interpret ABG values to evaluate the effectiveness of ventilation and determine

whether ventilator settings need to be changed.

Assess the breathing pattern in relation to the ventilatory cycle to determine whether the patient is tolerating or fighting the ventilator. Patient asynchrony with mechanical ventilation has many causes and reduces the effectiveness of GAS EXCHANGE (Mellott et al., 2014). Assess and record breath sounds, including bilateral equal breath sounds, to ensure proper endotracheal (ET) tube placement. Determine the need for suctioning by observing secretions for type, color, and amount. The most common indicator of the need for suctioning is the presence of coarse crackles over the trachea (Sole et al., 2015). Assess the area around the ET tube or tracheostomy site at least every 4 hours for color, tenderness, skin irritation, and drainage, and document the findings.

The nurse spends the most time with the patient and is most likely to be the first person to recognize changes in vital signs or ABG values, fatigue, or distress. If the patient's condition does not respond to current intervention, promptly coordinate with the pulmonary health care provider and respiratory therapist. The pulmonary health care provider may change the prescribed management plan to prevent the patient's condition from deteriorating. The respiratory therapist can most accurately assess the function of the ventilation equipment and make appropriate adjustments or replacements.

## Nursing Safety Priority QSEN

### Critical Rescue

Always assess patients being mechanically ventilated for indications of respiratory distress and poor GAS EXCHANGE. When symptoms of respiratory distress develop during mechanical ventilation, respond by immediately removing the ventilator and providing ventilation with a bag-valve-mask device. This action allows quick determination of whether the problem is with the ventilator or the patient.

Serve as a resource for the psychological needs of the patient and family. Anxiety can reduce tolerance for mechanical ventilation. Skilled and sensitive nursing care promotes emotional well-being and synchrony with the ventilator. The patient cannot speak, and communication can be frustrating and anxiety-producing. The patient and family may panic because they believe that the voice has been lost. Reassure them that the ET tube prevents speech only temporarily.

Plan methods of communication to meet the patient's needs, such as a picture board, pen and paper, alphabet board, electronic tablet computer, or programmable speech-generating device. Finding a successful means for communication is important because the patient often feels isolated by the inability to speak (see Chart 29-1). Anticipate his or her needs and provide easy access to frequently used belongings. The observation of facial expressions in noncommunicative patients may indicate pain, especially during suctioning (Darwish et al., 2016; Rahu et al., 2015). Visits from family, friends, and pets and keeping a call light within reach are some ways of giving patients a sense of control over the environment. Urge them to participate in self-care.

### Managing the Ventilator System.

Ventilator settings are prescribed by the pulmonary health care provider in conjunction with the respiratory therapist. Settings include tidal volume, respiratory rate, fraction of inspired oxygen (FiO<sub>2</sub>), and mode of ventilation (assist-control [AC] ventilation, synchronized intermittent mandatory ventilation [SIMV], and adjunctive modes such as positive end-expiratory pressure [PEEP], pressure support, or continuous flow).

Perform and document ventilator checks according to the standards of the unit or facility (in many facilities this function is performed by respiratory therapists). Respond promptly to alarms. During a ventilator check, compare the prescribed ventilator settings with the actual settings and confirm these findings with the respiratory therapist. Check the level of water in the humidifier and the temperature of the humidifying system to ensure that they are not too high. Temperature extremes damage the airway mucosa. Remove any condensation in the ventilator tubing by draining water into drainage collection receptacles and empty them every shift.

## Nursing Safety Priority QSEN

## Action Alert

To prevent bacterial contamination, do not allow moisture and water in the ventilator tubing to enter the humidifier.

Mechanical ventilators have alarm systems that warn of a problem with either the patient or the ventilator. *As required by The Joint Commission's NPSGs, alarm systems must be activated and functional at all times. If the cause of the alarm cannot be determined, ventilate the patient manually with a resuscitation bag until the problem is corrected by another health care professional.* Alarms should never be turned off or ignored during mechanical ventilation (Lukasewicz & Mattox, 2015). The major alarms on a ventilator indicate either a high pressure or a low exhaled volume. Table 32-5 lists interventions for causes of ventilator alarms.

**TABLE 32-5**  
**Nursing Interventions for Various Causes of Ventilator Alarms**

CAUSE	NURSING INTERVENTIONS
<b>High-Pressure Alarm (sounds when peak inspiratory pressure reaches the set alarm limit [usually set 10-20 mm Hg above the patient's baseline PIP])</b>	
An increased amount of secretions or a mucus plug is in the airways.	Suction as needed.
The patient coughs, gags, or bites on the oral ET tube.	Insert oral airway to prevent biting on the ET tube.
The patient is anxious or fights the ventilator.	Provide emotional support to decrease anxiety. Increase the flow rate. Explain all procedures to the patient. Provide sedation or paralyzing agent as prescribed.
Airway size decreases related to wheezing or bronchospasm.	Auscultate breath sounds. Collaborate with respiratory therapy to provide prescribed bronchodilators.
Pneumothorax occurs.	Alert the pulmonary health care provider or Rapid Response Team about a new onset of decreased breath sounds or unequal chest excursion, which may be caused by pneumothorax. Auscultate breath sounds.
The artificial airway is displaced; the ET tube may have slipped into the right mainstem bronchus.	Assess the chest for unequal breath sounds and chest excursion. Obtain a chest x-ray as prescribed to evaluate the position of the ET tube. After the proper position is verified, secure the tube in place.
Obstruction in tubing occurs because the patient is lying on the tubing or there is water or a kink in the tubing.	Assess the system, beginning with the artificial airway and moving toward the ventilator.
There is increased PIP associated with deliverance of a sigh.	Empty water from the ventilator tubing and remove any kinks. Coordinate with respiratory therapist or pulmonary health care provider to adjust the pressure alarm.
Decreased compliance of the lungs is noted; a trend of gradually increasing PIP is noted over several hours or a day.	Evaluate the reasons for the decreased compliance of the lungs. Increased PIP occurs in ARDS, pneumonia, or any worsening of pulmonary disease.
<b>Low-Exhaled Volume (or Low-Pressure) Alarm (sounds when there is a disconnection or leak in the ventilator circuit or a leak in the patient's artificial airway cuff)</b>	
A leak in the ventilator circuit prevents breath from being delivered.	Assess all connections and all ventilator tubing for disconnection.
The patient stops spontaneous breathing in the SIMV or CPAP mode or on pressure support ventilation.	Evaluate the patient's tolerance of the mode.
A cuff leak occurs in the ET or tracheostomy tube.	Evaluate the patient for a cuff leak. A cuff leak is suspected when the patient can talk (air escapes from the mouth) or when the pilot balloon on the artificial airway is flat (see Tracheostomy Tubes section in Chapter 28).

ARDS, Acute respiratory distress syndrome; CPAP, continuous positive airway pressure; ET, endotracheal; PIP, peak inspiratory pressure; SIMV, synchronized intermittent mandatory ventilation.

Assess and care for the ET or tracheostomy tube. Maintain a patent airway by suctioning when any of these conditions are present:

- Secretions
- Increased peak airway (inspiratory) pressure (PIP)
- Rhonchi
- Decreased breath sounds

Proper care of the ET or tracheostomy tube also ensures a patent airway. *Assess tube position at least every 2 hours, especially when the airway is attached to heavy ventilator tubing that may pull on the tube. Position the ventilator tubing so the patient can move without pulling on the ET or tracheostomy tube, possibly dislodging it.* To detect changes in tube position, mark it where the tube touches the patient's teeth or nose. Give oral care per facility policy. Standardized oral care has been shown to reduce ventilator-associated pneumonia (VAP), specifically using chlorhexidine oral rinses twice daily (Kiyoshi-Teo et al., 2014).

Special attention is needed for the patient being transported while receiving mechanical ventilation. Monitor SpO<sub>2</sub> during transport to assess adequacy of GAS EXCHANGE. Assess lung sounds each time the patient is moved, transferred, or turned.

## NCLEX Examination Challenge 32-3

### Safe and Effective Care Environment

The nurse is trouble-shooting multiple ventilator alarms sounding for a client who is intubated and being mechanically ventilated. The alarms persist despite suctioning, repositioning the client, and ensuring that the ventilator tubing is unobstructed. Which actions will the nurse perform next?  
**Select all that apply.**

- A. Turn off all ventilator alarms until a cause is found to prevent scaring the client.
- B. Page the primary health care provider to request additional sedation.
- C. Ensure that the endotracheal tube marking is at the client's incisor.
- D. Increase the PEEP to improve GAS EXCHANGE.
- E. Disconnect the client from the ventilator and use the manual resuscitation bag.
- F. Change all ventilator tubing.
- G. Stat page the respiratory therapist.
- H. Determine when the client received the last dose of the paralytic agent.

### Preventing Complications.

A wide variety of complications, now known as **ventilator-associated events (VAEs)**, are defined as “conditions that result in a significant and sustained deterioration in oxygenation (greater than 20% increase in the daily minimum fraction of inspired oxygen or an increase of at least 3 cm H<sub>2</sub>O in the daily minimum positive end-expiratory pressure [PEEP] to maintain oxygenation)” (Raouf & Baumann, 2014). Table 32-6 lists the tiers of VAEs. Other complications affecting many body systems are related to positive pressure from the ventilator.

**TABLE 32-6**  
**Tiers of Ventilator-Associated Events**

TIER	CHARACTERISTICS
1. Ventilator-Associated Condition (VAC)	Patient develops hypoxemia for a sustained period of more than 2 days, regardless of its etiology.
2. Infection-Related Ventilator-Associated Complication (IVAC)	Hypoxemia develops in the setting of generalized infection or inflammation, and antibiotics are instituted for a minimum of 4 days.
3. Ventilator-Associated Pneumonia (VAP)	There is additional laboratory evidence of white blood cells or Gram stain of material from a respiratory secretion specimen of acceptable quality and/or presence of respiratory pathogens on quantitative cultures from patients with IVAC.

Adapted from Raouf, S., & Baumann, M. (2014). Ventilator-associated events: The new definition. *American Journal of Critical Care*, 23(1), 7-9.

*Cardiac problems* from mechanical ventilation include hypotension and fluid retention. Hypotension is caused by positive pressure that increases chest pressure and inhibits blood return to the heart. The decreased blood return reduces cardiac output, causing hypotension, especially in patients who are dehydrated or need high PIP for ventilation. Teach the patient to avoid a **Valsalva maneuver** (bearing down while holding the breath).

Fluid is retained because of decreased cardiac output. The kidneys receive less blood flow, which stimulates the renin-angiotensin-aldosterone system to retain fluid. Humidified air in the ventilator system contributes to fluid retention. Monitor the patient's fluid intake and output, weight, hydration status, and indications of hypovolemia.

*Lung problems* from mechanical ventilation include:

- **Barotrauma** (damage to the lungs by positive pressure)
- **Volutrauma** (damage to the lung by excess volume delivered to one lung over the other)
- **Atelectrauma** (shear injury to alveoli from opening and closing)
- **Biotrauma** (inflammatory response-mediated damage to alveoli)
- **Ventilator-associated lung injury/ventilator-induced lung injury (VALI/VILI)** (damage from prolonged ventilation causing loss of surfactant, increased inflammation, fluid leakage, and noncardiac pulmonary edema)
- Acid-base imbalance

Barotrauma includes pneumothorax, subcutaneous emphysema, and pneumomediastinum. Patients at highest risk for barotrauma have chronic airflow limitation (CAL), have blebs or bullae, are on PEEP, have dynamic hyperinflation, or require high pressures to ventilate the lungs (because of “stiff” lungs, as seen in acute respiratory distress syndrome [ARDS]). Ventilator-induced lung injury can be prevented by using low tidal volumes combined with moderate levels of PEEP, especially in patients with acute lung injury (ALI) or ARDS. Blood gas problems can be corrected by ventilator changes and adjustment of fluid and electrolyte imbalances.

*GI and nutrition problems* result from the stress of mechanical ventilation. Stress ulcers occur in many patients receiving mechanical ventilation. These ulcers complicate the nutrition status and, because the mucosa is not intact, increase the risk for systemic infection. Antacids, sucralfate (Carafate, Sulcrate 🍀), and histamine blockers such as ranitidine (Zantac) or proton-pump inhibitors such as esomeprazole (Nexium) may be prescribed as soon as the patient is intubated. Because many other acute or life-threatening events occur at the same time, nutrition is often neglected. Malnutrition is an extreme problem for these patients and is a cause of failing to wean from the ventilator. In malnutrition, the respiratory muscles lose mass and strength. The diaphragm, the major muscle of inspiration, is affected early. When it and other respiratory muscles are weak, ineffective breathing results, fatigue occurs, and the patient cannot be weaned.

Balanced nutrition, whether by diet, enteral feedings, or parenteral feeding, is essential during ventilation and is often started within 48 hours of intubation. In addition, nutrition for the patient with chronic obstructive pulmonary disease (COPD) requires a reduction of dietary carbohydrates. During metabolism, carbohydrates are broken down to glucose, which then produces energy, carbon dioxide, and water. Excessive carbohydrate loads increase carbon dioxide production, which the patient with COPD may be unable to exhale. Hypercarbic respiratory failure results. Nutrition formulas with a higher fat content (e.g., Pulmocare, Nutri-Vent, Intralipid) are calorie sources to combat this problem.

Electrolyte replacement is also important because electrolytes influence muscle function. Monitor potassium, calcium, magnesium, and phosphate levels and replace them as prescribed.

*Infections* are part of two tiers of ventilator-associated events (VAEs) and are a threat for the patient using a ventilator, especially ventilator-associated pneumonia (VAP). The ET or tracheostomy tube bypasses the body's filtering process and provides a direct access for bacteria to enter the lower respiratory system. The artificial airway is colonized with bacteria within 48 hours, which promotes pneumonia development and increases morbidity. Aspiration of colonized fluid from the mouth or stomach can be a source of infection. *Infection prevention through strict adherence to infection control, especially handwashing during suctioning and care of the tracheostomy or ET tube, is essential (Kiyoshi-Teo et al., 2014).*

To prevent VAP, implement “ventilator bundle” sets, which typically include these actions (Munro & Ruggiero, 2014):

- Keeping the head of the bed elevated at least 30 degrees
- Performing oral care per agency policy (usually brushing teeth every 8 hours and antimicrobial rinse [chlorhexidine] every 2 hours)
- Ulcer prophylaxis
- Preventing aspiration
- Pulmonary hygiene, including chest physiotherapy, postural drainage, and turning and positioning

Using the ventilator bundle has greatly reduced the overall incidence of VAP. Vigilant oral care is a key component of the VAP prevention strategy, although actual practice varies regarding timing, products used, and specific application methods (Kiyoshi-Teo et al., 2014; Wong et al., 2016). Additional information on pneumonia can be found in [Chapter 31](#).

*Muscle deconditioning* and weakness can occur because of immobility. Getting the patient out of bed and having him or her ambulate with help and perform exercises not only improve muscle strength but also boost morale, enhance GAS EXCHANGE, and promote oxygen delivery to all muscles. Early progressive mobility decreases ventilator days and ICU stays. Early passive exercise also may be beneficial (Amidei & Sole, 2013).

*Ventilator dependence* is the inability to wean off the ventilator and can have both a physiologic and a psychological basis. The longer a patient uses a ventilator, the more difficult the weaning process is because the respiratory muscles fatigue and cannot assume breathing. The health care

team uses every method of weaning before a patient is declared “unweanable.”

Collaborate with the pulmonologist, social worker or psychologist, and a member of the clergy to discuss with the patient and family the patient's quality of life, goals, and values. As a result of this discussion, arrange for home ventilation, nursing home placement, or withdrawal of life support (in terminal cases). Special units and facilities can maximize the rehabilitation and weaning of ventilator-dependent patients.

### Weaning.

**Weaning** is the process of going from ventilatory dependence to spontaneous breathing. The process is prolonged by complications. Many problems can be avoided with appropriate nursing care. For example, turning and positioning the patient not only promote comfort and prevent skin breakdown but also improve GAS EXCHANGE and prevent pneumonia and atelectasis. Table 32-7 lists various weaning techniques.

**TABLE 32-7**  
**Weaning Methods**

<p><b>Synchronous Intermittent Mandatory Ventilation</b></p> <ul style="list-style-type: none"> <li>• The patient breathes between the machine's preset breaths/min rate.</li> <li>• The machine is initially set on an SIMV rate of 12, meaning that the patient receives a minimum of 12 breaths/min by the ventilator.</li> <li>• The patient's respiratory rate will be a combination of ventilator breaths and spontaneous breaths.</li> <li>• As the weaning process ensues, the pulmonary health care provider prescribes gradual decreases in the SIMV rate, usually at a decrease of 1 to 2 breaths/min.</li> </ul>
<p><b>T-Piece Technique</b></p> <ul style="list-style-type: none"> <li>• The patient is taken off the ventilator for short periods (initially 5 to 10 minutes) and allowed to breathe spontaneously.</li> <li>• The ventilator is replaced with a T-piece (see Chapter 28) or CPAP, which delivers humidified oxygen.</li> <li>• The prescribed FiO<sub>2</sub> may be higher for the patient on the T-piece than on the ventilator.</li> <li>• Weaning progresses as the patient can tolerate progressively longer periods off the ventilator.</li> <li>• Nighttime weaning is not usually attempted until the patient can maintain spontaneous respirations most of the day.</li> </ul>
<p><b>Pressure Support Ventilation</b></p> <ul style="list-style-type: none"> <li>• PSV allows the patient's respiratory effort to be augmented by a predetermined pressure assist from the ventilator.</li> <li>• As the weaning process ensues, the amount of pressure applied to inspiration is gradually decreased.</li> <li>• Another method of weaning with PSV is to maintain the pressure but gradually decrease the ventilator's preset breaths/min rate.</li> </ul>

CPAP, Continuous positive airway pressure; FiO<sub>2</sub>, fraction of inspired oxygen; PSV, pressure support ventilation; SIMV, synchronized intermittent mandatory ventilation.

## Considerations for Older Adults

### Patient-Centered Care QSEN

The older patient, especially one who has smoked or who has a chronic lung problem such as COPD, is at risk for ventilator dependence and failure to wean. Age-related changes, such as chest wall stiffness, reduced ventilatory muscle strength, and decreased lung elasticity, reduce the likelihood of weaning. The usual symptoms of ventilatory failure—hypoxemia and hypercarbia—may be less obvious in the older adult. Use other clinical measures of GAS EXCHANGE and oxygenation, such as a change in mental status, to determine breathing effectiveness (Touhy & Jett, 2016).

### Extubation.

**Extubation** is the removal of the endotracheal (ET) tube. The tube is removed when the need for intubation has been resolved. Before removal, explain the procedure. Set up the prescribed oxygen delivery system at the bedside and bring in the equipment for emergency reintubation. Hyperoxygenate the patient and thoroughly suction both the ET tube and the oral cavity. Then rapidly deflate the cuff of the ET tube and remove the tube at peak inspiration. Immediately instruct the patient to cough. It is normal for large amounts of oral secretions to collect. Give oxygen by facemask or nasal cannula. The fraction of inspired oxygen (FiO<sub>2</sub>) is usually prescribed at 10% higher than the level used while the ET tube was in place.

*Monitor vital signs after extubation every 5 minutes at first and assess the ventilatory pattern for signs of respiratory distress.* It is common for patients to be hoarse and have a sore throat for a few days after extubation. Teach the patient to sit in a semi-Fowler's position, take deep breaths every half-hour, use an incentive spirometer every 2 hours, and limit speaking. These measures help improve GAS EXCHANGE, decrease laryngeal edema, and reduce vocal cord irritation. Observe closely for respiratory fatigue and airway obstruction.

Early symptoms of obstruction are mild dyspnea, coughing, and the inability to expectorate secretions. **Stridor** is a high-pitched, crowing noise during inspiration caused by laryngospasm or edema around the glottis. It is a late sign of a narrowed airway and requires prompt attention. Racemic epinephrine, a topical aerosol vasoconstrictor, is given, and reintubation may be needed.

## Nursing Safety Priority QSEN

### Critical Rescue

Monitor the patient frequently to recognize symptoms of obstruction. When stridor or other symptoms of obstruction occur after extubation, respond by immediately calling the Rapid Response Team *before* the airway becomes completely obstructed.

## Chest Trauma

Chest injuries are responsible for or contribute to many traumatic deaths in the United States each year. Many of the injured die before arriving at the hospital. Few types of chest injury require thoracotomy. Most can be treated with basic resuscitation, intubation, or chest tube placement. *The first emergency approach to all chest injuries is ABC (airway, breathing, circulation), a rapid assessment and treatment of life-threatening conditions.* See [Chapter 8](#) for more information on care of the trauma patient.

### Pulmonary Contusion

Pulmonary contusion, a potentially lethal injury, is a common chest injury and occurs most often by rapid deceleration during car crashes. After a contusion, respiratory failure can develop immediately or over time. Hemorrhage and edema occur in and between the alveoli, reducing both lung movement and the area available for GAS EXCHANGE. Localized inflammation can cause further damage. The patient becomes hypoxemic and dyspneic.

Patients may be asymptomatic at first and can later develop various degrees of respiratory failure and possibly pneumonia ([Landeem & Smith, 2014](#)). These patients often have decreased breath sounds or crackles and wheezes over the affected area. Other symptoms include bruising over the injury, dry cough, tachycardia, tachypnea, and dullness to percussion. At first the chest x-ray may show no abnormalities. A hazy opacity in the lobes or parenchyma may develop over several days. If there is no disruption of the parenchyma, bruise resorption often occurs without treatment.

Management includes maintenance of ventilation and GAS EXCHANGE. Provide oxygen, give IV fluids as prescribed, and place the patient in a moderate-Fowler's position. If a high  $\text{FiO}_2$  is needed, oxygen may be administered using a high-flow nasal cannula (HFNC). When side-lying, the “good lung down” position may be helpful. The patient in obvious respiratory distress may need noninvasive positive-pressure ventilation (NPPV) or mechanical ventilation with positive end-expiratory pressure (PEEP) to inflate the lungs.

A vicious cycle occurs in which more muscle effort is needed for ventilating a lung with a contusion and the patient becomes progressively hypoxemic. This situation causes him or her to tire easily, have reduced GAS EXCHANGE, and become more fatigued and hypoxemic. This condition often leads to acute respiratory distress syndrome (ARDS).

### Rib Fracture

Rib fractures are a common injury to the chest wall, often resulting from direct blunt trauma to the chest. The force applied to the ribs fractures them and drives the bone ends into the chest. Thus there is a risk for deep chest injury such as pulmonary contusion, pneumothorax, and hemothorax.

The patient has pain on movement and splints the chest defensively. Splinting reduces breathing depth and clearance of secretions. If the patient has pre-existing lung disease, the risk for atelectasis and pneumonia increases. Those with injuries to the first or second ribs, flail chest, seven or more fractured ribs, or expired volumes of less than 15 mL/kg often have a deep chest injury and a poor prognosis.

Management of uncomplicated rib fractures is simple because the fractured ribs reunite spontaneously. The chest is usually not splinted by tape or other materials. The main focus is to decrease pain so adequate GAS EXCHANGE is maintained. An intercostal nerve block may be used if pain is severe. Analgesics that cause respiratory depression are avoided.

### Flail Chest

**Flail chest** is the result of fractures of at least two neighboring ribs in two or more places causing **paradoxical chest wall movement** (inward movement of the thorax during inspiration, with outward movement during expiration) ([Fig. 32-4](#)). It usually involves one side of the chest and results from blunt chest trauma—often high-speed car crashes. Because the force required to produce a flail chest is great, it is important to assess for other possible underlying injuries ([Poirier & Vacca, 2013](#)).

**FIG. 32-4** Flail chest. Normal respiration: **A**, Inspiration; **B**, Expiration. Paradoxical motion; **C**, Inspiration—area of the lung underlying unstable chest wall sucks in on inspiration; **D**, Expiration—unstable area balloons out. Note movement of mediastinum toward opposite lung during inspiration. (From McCance, K. L., Huether S. E., Brashers, V. L., & Rote, N. S. (2014). *Pathophysiology: The biologic basis for disease in adults and children* (7th ed.). St. Louis: Mosby.)

Flail chest can also occur from bilateral separations of the ribs from their cartilage connections to each other anteriorly, without an actual rib fracture. This condition can occur as a complication of cardiopulmonary resuscitation. Other injuries to the lung tissue under the flail segment may be present. GAS EXCHANGE, coughing, and clearance of secretions are impaired. Splinting further reduces the patient's ability to exert the extra effort to breathe and may contribute later to failure to wean.

Assess the patient with a flail chest for paradoxical chest movement, dyspnea, cyanosis, tachycardia, and hypotension. The patient is often anxious, short of breath, and in pain. Work of breathing is increased from the paradoxical movement of the involved segment of the chest wall.

Interventions include humidified oxygen, pain management, promotion of lung expansion through deep breathing and positioning, and secretion clearance by coughing and tracheal suction.

The patient with a flail chest may be managed with vigilant respiratory care. Mechanical ventilation is needed if respiratory failure or shock occurs. Monitor ABG values and vital capacity closely. With severe hypoxemia and hypercarbia, the patient is intubated and mechanically ventilated with PEEP. With lung contusion or an underlying pulmonary disease, the risk for respiratory failure increases. Usually flail chest is stabilized by positive-pressure ventilation. Surgical stabilization is used only in extreme cases of flail chest (Messing et al., 2014).

Monitor the patient's vital signs and fluid and electrolyte balance closely so hypovolemia or shock can be managed immediately. If he or she has a lung contusion, provide oxygen as needed and give IV fluids as prescribed. Assess for and relieve pain with prescribed analgesic drugs by IV, epidural, or nerve block route. Give psychosocial support to the anxious patient by explaining all procedures, talking slowly, and allowing time for expression of feelings and concerns.

## Pneumothorax and Hemothorax

### ❖ Pathophysiology

A **pneumothorax** is air in the pleural space causing a loss of negative pressure in chest cavity, a rise in chest pressure, and a reduction in vital capacity, which can lead to a lung collapse (Arsbad et al., 2016). It is often caused by blunt chest trauma and may occur with some degree of **hemothorax**, which is bleeding into the chest cavity. It can also occur as a complication of medical procedures. (A *simple* hemothorax is a blood loss of less than 1000 mL into the chest cavity; a *massive* hemothorax is a blood loss of more than 1000 mL.) The pneumothorax can be *open* (pleural cavity is exposed to outside air, as through an open wound in the chest wall) or *closed* (such as when a patient with chronic obstructive pulmonary disease has a spontaneous pneumothorax).

A **tension pneumothorax** is a life-threatening complication of pneumothorax in which air continues to enter the pleural space during inspiration and does not exit during expiration (Loftus, 2014). As a result, air collects under pressure, completely collapsing the lung and compressing blood vessels, which limits blood return. This process leads to decreased filling of the heart and reduced cardiac output. *If not promptly detected and treated, tension pneumothorax is quickly fatal.*

### ❖ **Interprofessional Collaborative Care**

#### ◆ **Assessment: Noticing**

Assessment findings for any type of pneumothorax commonly include:

- Reduced (or absent) breath sounds of the affected side on auscultation
- Hyperresonance on percussion
- Prominence of the involved side of the chest, which moves poorly with respirations
- When severe, deviation of the trachea *away* from the midline and side of injury toward the *unaffected* side (indicating pushing of tissues to the unaffected side [a *mediastinal shift*] from increasing pressure within the injured side)

For tension pneumothorax, additional assessment findings also may include:

- Extreme respiratory distress and cyanosis
- Distended neck veins
- Hemodynamic instability

With a hemothorax, percussion on the involved side produces a dull sound.

In addition to symptoms, chest x-rays, CT scans, or ultrasonography may be used for diagnosis of any type of pneumothorax or hemothorax.

#### ◆ **Interventions: Responding**

For a stable patient with a small pneumothorax who has mild symptoms and no continuing air leak, no treatment may be needed. For more severe pneumothorax, tension pneumothorax, and hemothorax, chest tube therapy is essential. Chest tube management is discussed in detail in [Chapter 30](#).

Initial management of a tension pneumothorax is an immediate **needle thoracostomy**, with a large-bore needle inserted by the primary health care provider into the second intercostal space in the midclavicular line of the affected side. A chest tube then is placed into the fourth intercostal space, and the other end is attached to a water-seal drainage system until the lung re-inflates. Interventions for hemothorax include chest tube placement to remove the blood in the pleural space to normalize breathing and prevent infection.

Closely monitor the chest tube drainage. Serial chest x-rays are used to determine treatment effectiveness. Other care includes pain control, pulmonary hygiene, and continued assessment for respiratory failure.

An open thoracotomy is needed when there is initial blood loss of 1000 mL from the chest or persistent bleeding at the rate of 150 to 200 mL/hr over 3 to 4 hours. Monitor the vital signs, blood loss, and intake and output. Assess the patient's response to the chest tubes and infuse IV fluids and blood as prescribed. The blood lost through chest drainage can be infused back into the patient after processing if needed.

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Use aseptic technique when caring for a patient requiring pulmonary suctioning. **QSEN: Safety**
- Identify patients in your setting who are at risk for developing a pulmonary embolism. **QSEN: Safety**
- Use Bleeding Precautions for patients receiving anti-clotting therapy (see [Chart 32-6](#)). **QSEN: Safety**
- Keep antidotes available when patients are receiving heparin (antidote is protamine) or warfarin (antidote is phytonadione). **QSEN: Safety**
- Inspect the mouth and perform oral care every 2 hours for anyone who has an endotracheal tube or is being mechanically ventilated. **QSEN: Safety**
- Check and document ventilator settings hourly. **QSEN: Safety**
- Ensure that alarm systems on mechanical ventilators are activated and functional at all times. **QSEN: Safety**
- Ensure that bag-valve-mask device and suction equipment are at the bedside at all times. **QSEN: Safety**
- Evaluate the need for chemical restraint or soft wrist restraints. **QSEN: Patient-Centered Care**

### Health Promotion and Maintenance

- Teach patients ways to promote venous return and avoid venous thromboembolism (VTE), especially when traveling long distances (see [Chart 32-1](#)). **QSEN: Patient-Centered Care**
- Teach patients ways to prevent injury when taking drugs that reduce CLOTTING (see [Chart 32-7](#)). **QSEN: Patient-Centered Care**

### Psychosocial Integrity

- Allow the patient and family members the opportunity to express feelings and concerns about a change in breathing status or the possibility of intubation and mechanical ventilation. **QSEN: Patient-Centered Care**
- Use alternate ways to communicate with a patient who is intubated or being mechanically ventilated. **QSEN: Patient-Centered Care**
- Reassure intubated patients that speech loss is temporary. **QSEN: Patient-Centered Care**
- Remember that patients who are receiving mechanical ventilation and are being chemically paralyzed usually can hear and can feel pain. **QSEN: Patient-Centered Care**
- Provide appropriate pain management. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Use Aspiration Precautions for any patient with an altered level of consciousness, poor gag reflex, or neurologic impairment or who has an endotracheal tube. **QSEN: Evidence-Based Practice**
- Check the patient with ARDS hourly for oxygen saturation, vital sign changes, or any indication of increased work of breathing such as cyanosis, pallor, and retractions. **QSEN: Patient-Centered Care**
- Assess all patients with blunt chest trauma for tracheal position and bilateral breath sounds. **QSEN: Patient-Centered Care**

- Notify the pulmonary health care provider immediately for any patient who develops sudden-onset respiratory difficulty. **QSEN: Safety**
- Check GAS EXCHANGE by pulse oximetry for any patient who has trouble breathing or who develops acute confusion. **QSEN: Patient-Centered Care**
- Evaluate ABG values to assess the severity of hypoxia and the patient's response to therapy. **QSEN: Patient-Centered Care**
- Apply oxygen to anyone who is hypoxemic. **QSEN: Evidence-Based Practice**
- Ensure that oxygen therapy delivered to the patient is humidified. **QSEN: Evidence-Based Practice**
- Assess lung sounds bilaterally each hour for patients who are receiving PEEP. **QSEN: Patient-Centered Care**
- Check all ventilator settings against the prescription at least once per shift. **QSEN: Safety**
- Administer drugs for pain to patients who have rib fractures and encourage deep breaths. **QSEN: Patient-Centered Care**
- Evaluate nutrition status and collaborate with the dietitian to meet the patient's nutrition needs. **QSEN: Teamwork and Collaboration**
- If a patient experiences respiratory distress during mechanical ventilation, remove him or her from the ventilator and provide ventilation by bag-valve-mask device. **QSEN: Safety**

## UNIT VIII

# Interprofessional Collaboration for Patients With Problems of the Cardiovascular System

### OUTLINE

---

Chapter 33 Assessment of the Cardiovascular System

Chapter 34 Care of Patients With Dysrhythmias

Chapter 35 Care of Patients With Cardiac Problems

Chapter 36 Care of Patients With Vascular Problems

Chapter 37 Care of Patients With Shock

Chapter 38 Care of Patients With Acute Coronary Syndromes

## CHAPTER 33

# Assessment of the Cardiovascular System

Laura M. Dechant

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is PERFUSION.**

**The interrelated concept for this chapter is FLUID AND ELECTROLYTE BALANCE.**

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to perform a complete cardiovascular (CV) assessment, including PERFUSION status and FLUID AND ELECTROLYTE BALANCE.
2. Prioritize evidence-based care for patients having invasive CV diagnostic testing affecting PERFUSION.

### Health Promotion and Maintenance

3. Teach evidence-based ways for adults to decrease their risk for CV health problems.
4. Explain how physiologic aging changes of the CV system affect PERFUSION and associated care of older adults.

### Psychosocial Integrity

5. Implement nursing interventions to decrease the psychosocial impact caused by a CV health problem.

### Physiological Integrity

6. Apply knowledge of anatomy and physiology to perform a patient-centered assessment for the patient with a CV health problem, including cultural and spiritual considerations.
7. Use clinical judgment to document the cardiovascular assessment in the electronic health record.
8. Interpret assessment findings for patients with a suspected or actual CV health problem.
9. Identify the CV assessment components that contribute to disparities in certain populations.

The cardiovascular (CV) system is responsible for supplying oxygen to body organs and other tissues (PERFUSION). It is made up of the heart and blood vessels (both arteries and veins).

The heart muscle, called the **myocardium**, must receive sufficient oxygen to pump blood to other parts of the body. The arteries must be patent so the pumped blood can reach the rest of the body. Oxygen in the blood is required for cells to live and function properly. When diseases or other problems of the CV systems occur, gas exchange and PERFUSION decrease, often resulting in life-threatening events or a risk for these events.

The CV system works with the respiratory and hematologic systems to meet the human need for gas exchange and tissue PERFUSION. Any problem in these systems requires the CV system to work harder to meet gas exchange and tissue perfusion needs.

Cardiovascular disease (CVD) continues to be the number-one cause of death in the United States. An average of one death in the United States occurs every 40 seconds from CVD (Mozaffarian et al., 2016). The disease kills more people than the next four causes of death combined, including cancer, chronic lower respiratory diseases, accidents, and diabetes. Of particular concern is that CVD is the leading cause of death for women. In addition, the American Heart Association (AHA) estimates that more than one in three adults are living with some form of the disease. About 20% of people who experience a myocardial infarction will die within 1 year

from the initial cardiac event ([Mozaffarian et al., 2016](#)).

# Anatomy and Physiology Review

## Heart

### Structure

The human heart is a fist-sized, muscular organ located in the mediastinum between the lungs (Fig. 33-1). Each beat of the heart pumps about 60 mL of blood, or 5 L/min. During strenuous physical activity, the amount of blood pumped can double to meet the body's increased gas exchange needs. A covering called the *pericardium* protects the heart. A muscular wall (septum) separates the heart into two halves: right and left. Each half has an atrium and a ventricle (Fig. 33-2).

**FIG. 33-2** Blood flow through the heart.

The *right atrium (RA)* receives *deoxygenated* venous blood, which is returned from the body through the superior and inferior vena cava. It also receives blood from the heart muscle through the coronary sinus. Most of this venous return flows passively from the RA, through the opened tricuspid valve, and to the right ventricle during ventricular diastole, or filling. The RA actively propels the remaining venous return into the right ventricle during atrial systole, or contraction.

The *right ventricle (RV)* is a muscular pump located behind the sternum. It generates enough pressure to close the tricuspid valve, open the pulmonic valve, and propel blood into the pulmonary artery and the lungs.

After blood is *reoxygenated* in the lungs, it flows freely from the four pulmonary veins into the left atrium. Blood then flows through an opened mitral valve into the left ventricle during ventricular diastole. When the left ventricle is almost full, the *left atrium (LA)* contracts, pumping the remaining blood volume into the left ventricle. With systolic contraction, the *left ventricle (LV)* generates enough pressure to close the mitral valve and open the aortic valve. Blood is propelled into the aorta and the systemic arterial circulation. Blood flow through the heart is shown in [Fig. 33-2](#).

Blood moves from the aorta throughout the systemic circulation to the various tissues of the body. The pressure of blood in the aorta of a young adult averages about 100 to 120 mm Hg, whereas the pressure of blood in the RA averages about 0 to 5 mm Hg. These differences in pressure produce a pressure gradient, with blood flowing from an area of higher pressure to an area of lower pressure. The heart and vascular structures are responsible for maintaining these pressures.

The four *cardiac valves* are responsible for maintaining the forward flow of blood through the chambers of the heart (see [Fig. 33-2](#)). These valves open and close when pressure and volume change within the heart's chambers. The cardiac valves are classified into two types: atrioventricular (AV) valves and semilunar valves.

The *AV valves* separate the atria from the ventricles. The *tricuspid valve* separates the RA from the RV. The *mitral (bicuspid) valve* separates the LA from the LV. During ventricular diastole, these

valves act as funnels and help move the flow of blood from the atria to the ventricles. During systole, the valves close to prevent the backflow (valvular regurgitation) of blood into the atria.

The *semilunar valves* are the pulmonic valve and the aortic valve, which prevent blood from flowing back into the ventricles during diastole. The *pulmonic valve* separates the right ventricle from the pulmonary artery. The *aortic valve* separates the left ventricle from the aorta.

The heart muscle receives blood to meet its metabolic needs through the coronary arterial system (Fig. 33-3). The coronary arteries originate from an area on the aorta just beyond the aortic valve. All of the coronary arteries feeding the left heart originate from the left main coronary artery (LMCA). The right coronary artery (RCA) branches from the aorta to perfuse the right side of the heart and inferior wall of the left side of the heart.

FIG. 33-3 Coronary arterial system.

Coronary artery blood flow to the myocardium occurs primarily during diastole, when coronary vascular resistance is minimized. To maintain adequate blood flow through the coronary arteries, **mean arterial pressure (MAP)** must be *at least 60 mm Hg*. A MAP between 60 and 70 mm Hg is necessary to maintain **PERFUSION** of major body organs, such as the kidneys and brain.

The *left main artery* divides into two branches: the left anterior descending (LAD) branch and the left circumflex (LCX) branch. The LAD branch descends toward the anterior wall and the apex of the left ventricle. It supplies blood to portions of the left ventricle, ventricular septum, chordae tendineae, papillary muscle, and, to a lesser extent, the right ventricle.

The LCX branch descends toward the lateral wall of the left ventricle and apex. It supplies blood to the left atrium, the lateral and posterior surfaces of the left ventricle, and sometimes portions of the interventricular septum. In about half of people, the LCX branch supplies the sinoatrial (SA) node. In a very small number of people, it supplies the AV node. Peripheral branches arise from the LAD and LCX branches and form an abundant network of vessels throughout the entire myocardium.

The *right coronary artery (RCA)* originates from the right sinus of Valsalva, encircles the heart, and descends toward the apex of the right ventricle. The RCA supplies the RA, RV, and inferior portion of the LV. In about half of the people, the RCA supplies the SA node; and in almost everyone, it supplies the AV node.

## Function

The electrophysiologic properties of heart muscle are responsible for regulating heart rate (HR) and rhythm. Cardiac muscle cells possess the characteristics of automaticity, excitability, conductivity, contractility, and refractoriness. [Chapter 34](#) describes these properties and cardiac conduction in detail.

## Sequence of Events During the Cardiac Cycle.

The phases of the cardiac cycle are generally described in relation to changes in pressure and volume in the left ventricle during filling (diastole) and ventricular contraction (systole) (Fig. 33-4). **Diastole** consists of relaxation and filling of the atria and ventricles and comprises about two thirds of the cardiac cycle. **Systole** consists of the contraction and emptying of the atria and ventricles.

**FIG. 33-4** Events of the cardiac cycle. AV, Atrioventricular.

Myocardial contraction results from the release of large numbers of calcium ions from the sarcoplasmic reticulum and the blood. These ions diffuse into the myofibril sarcomere (the basic contractile unit of the myocardial cell). Calcium ions promote the interaction of actin and myosin protein filaments, causing these filaments to link and overlap. Cross-bridges, or linkages, are formed as the protein filaments slide over or overlap each other. These cross-bridges act as force-generating sites. The sliding of these protein filaments shortens the sarcomeres, producing myocardial contraction.

Cardiac muscle relaxes when calcium ions are pumped back into the sarcoplasmic reticulum, causing a decrease in the number of calcium ions around the myofibrils. This reduced number of ions causes the protein filaments to disengage, the sarcomere to lengthen, and the muscle to relax.

### Mechanical Properties of the Heart.

The electrical and mechanical properties of cardiac muscle determine the function of the cardiovascular system. The healthy heart can adapt to various pathophysiologic conditions (e.g., stress, infections, hemorrhage) to maintain PERFUSION to the various body tissues. Blood flow from the heart into the systemic arterial circulation is measured clinically as **cardiac output (CO)**, the amount of blood pumped from the left ventricle each minute. CO depends on the relationship between heart rate (HR) and stroke volume (SV); it is the product of these two variables:

$$\text{Cardiac output} = \text{Heart rate} \times \text{Stroke volume}$$

In adults the CO ranges from 4 to 7 L/min. Because CO requirements vary according to body size, the cardiac index is calculated to adjust for differences in body size. The **cardiac index** can be determined by dividing the CO by the body surface area. The normal range is 2.8 to 4.2 L/min/m<sup>2</sup> (Pagana et al., 2017).

**Heart rate (HR)** refers to the number of times the ventricles contract each minute. The normal resting HR for an adult is between 60 and 100 beats/min. Increases in rate increase myocardial oxygen demand. The HR is extrinsically controlled by the autonomic nervous system (ANS), which adjusts rapidly when necessary to regulate cardiac output. The parasympathetic (vagus nerve) system *slows* the HR, whereas sympathetic stimulation *increases* the heart rate. An increase in circulating catecholamines (e.g., epinephrine and norepinephrine) usually causes an increase in HR and contractility. Many cardiovascular drugs, particularly beta blockers, block this sympathetic (fight or flight) pattern by decreasing the HR.

**Stroke volume (SV)** is the amount of blood ejected by the left ventricle during each contraction. Several variables influence SV and, ultimately, CO. These variables include HR, preload, afterload, and contractility.

**Preload** refers to the degree of myocardial fiber stretch at the end of diastole and just before contraction. The stretch imposed on the muscle fibers results from the volume contained within the ventricle at the end of diastole. Preload is determined by the amount of blood returning to the heart from both the venous system (right heart) and the pulmonary system (left heart) (left ventricular end-diastolic [LVED] volume).

An increase in ventricular volume increases muscle-fiber length and tension, thereby enhancing contraction and improving stroke volume. This statement is derived from Starling's law of the heart: The more the heart is filled during diastole (within limits), the more forcefully it contracts. However, excessive filling of the ventricles results in excessive LVED volume and pressure and may result in decreased cardiac output.

Another factor affecting stroke volume, **afterload**, is the pressure or resistance that the ventricles must overcome to eject blood through the semilunar valves and into the peripheral blood vessels. The amount of resistance is directly related to arterial blood pressure and the diameter of the blood vessels.

Impedance, the peripheral component of afterload, is the pressure that the heart must overcome to open the aortic valve. The amount of impedance depends on aortic compliance and total systemic vascular resistance, a combination of blood viscosity (thickness) and arteriolar constriction. A decrease in stroke volume can result from an increase in afterload without the benefit of compensatory mechanisms, thus leading to a decrease in cardiac output.

Myocardial contractility affects stroke volume and CO and is the force of cardiac contraction independent of preload. Contractility is increased by factors such as sympathetic stimulation, calcium release, and positive inotropic drugs. It is decreased by factors such as hypoxia and acidemia.

## Vascular System

The vascular system serves several purposes:

- Provides a route for blood to travel from the heart to nourish the various tissues of the body
- Carries cellular wastes to the excretory organs
- Allows lymphatic flow to drain tissue fluid back into the circulation
- Returns blood to the heart for recirculation

The vascular system is divided into the arterial system and the venous system. In the arterial system, blood moves from the larger arteries to a network of smaller blood vessels, called *arterioles*, which meet the capillary bed. In the venous system, blood travels from the capillaries to the venules and to the larger system of veins, eventually returning in the vena cava to the heart for recirculation.

### Arterial System

The primary function of the arterial system is to deliver oxygen and nutrients to various tissues in the body. Nutrients are carried through arteries to arterioles, then branch into smaller terminal

arterioles, and finally join with capillaries and venules to form a capillary network. Within this network, nutrients are exchanged across capillary membranes by three primary processes: osmosis, filtration, and diffusion. (See [Chapter 11](#) for detailed discussions of these processes.)

The arterial system delivers blood to various tissues for oxygen and nourishment. At the tissue level, nutrients, chemicals, and body defense substances are distributed and exchanged for cellular waste products, depending on the needs of the particular tissue. The arteries transport the cellular wastes to the excretory organs (e.g., kidneys and lungs) to be reprocessed or removed. These vessels also contribute to temperature regulation in the tissues. Blood can be either directed toward the skin to promote heat loss or diverted away from it to conserve heat.

**Blood pressure (BP)** is the *force* of blood exerted against the vessel walls. Pressure in the larger arterial blood vessels is greater (about 80 to 100 mm Hg) and decreases as blood flow reaches the capillaries (about 25 mm Hg). By the time blood enters the right atrium, the BP is about 0 to 5 mm Hg. Volume, ventricular contraction, and vascular tone are necessary to maintain blood pressure.

BP is determined primarily by the quantity of blood flow or cardiac output (CO) and by the resistance in the arterioles.

Any factor that increases CO or total peripheral vascular resistance increases the BP. In general, BP is maintained at a relatively constant level. Therefore an increase or decrease in total peripheral vascular resistance is associated with a decrease or an increase in CO, respectively. Three mechanisms mediate and regulate BP:

- The autonomic nervous system (ANS), which excites or inhibits sympathetic nervous system activity in response to impulses from chemoreceptors and baroreceptors
- The kidneys, which sense a change in blood flow and activate the renin-angiotensin-aldosterone mechanism
- The endocrine system, which releases various hormones (e.g., catecholamine, kinins, serotonin, histamine) to stimulate the sympathetic nervous system at the tissue level

**Systolic BP** is the amount of pressure/force generated by the left ventricle to distribute blood into the aorta with each contraction of the heart. It is a measure of how effectively the heart pumps and is an indicator of vascular tone. **Diastolic BP** is the amount of pressure/force against the arterial walls during the relaxation phase of the heart.

BP is regulated by balancing the sympathetic and parasympathetic nervous systems of the autonomic nervous system. Changes in autonomic activity are responses to messages sent by the sensory receptors in the various tissues of the body. These receptors, including the baroreceptors, chemoreceptors, and stretch receptors, respond differently to the biochemical and physiologic changes of the body.

**Baroreceptors** in the arch of the aorta and at the origin of the internal carotid arteries are stimulated when the arterial walls are stretched by an increased BP. Impulses from these baroreceptors inhibit the vasomotor center, which is located in the pons and the medulla. Inhibition of this center results in a drop in BP.

Several 1- to 2-mm collections of tissue have been identified in the carotid arteries and along the aortic arch known as **peripheral chemoreceptors**. These receptors are sensitive primarily to hypoxemia (a decrease in the partial pressure of arterial oxygen [ $PaO_2$ ]). When stimulated, these chemoreceptors send impulses along the vagus nerves to activate a vasoconstrictor response and raise BP.

The central chemoreceptors in the respiratory center of the brain are also stimulated by **hypercapnia** (an increase in partial pressure of arterial carbon dioxide [ $PaCO_2$ ]) and acidosis. However, the direct effect of carbon dioxide on the central nervous system (CNS) is 10 times stronger than the effect of hypoxia on the peripheral chemoreceptors.

Stretch receptors in the vena cava and the right atrium are sensitive to pressure or volume changes. When a patient is hypovolemic, stretch receptors in the blood vessels sense a reduced volume or pressure and send fewer impulses to the CNS. This reaction stimulates the sympathetic nervous system to increase the heart rate (HR) and constrict the peripheral blood vessels.

The kidneys also help regulate cardiovascular activity. When renal blood flow or pressure decreases, the kidneys retain sodium and water. BP tends to rise because of fluid retention and activation of the renin-angiotensin-aldosterone mechanism (see [Fig. 11-6](#)). This mechanism results in vasoconstriction and sodium retention (and thus fluid retention). Vascular volume is also regulated by the release of antidiuretic hormone (vasopressin) from the posterior pituitary gland

(see Chapter 11).

Other factors can also influence the activity of the cardiovascular system. Emotional behaviors (e.g., excitement, pain, anger) stimulate the sympathetic nervous system to increase BP and HR. Increased physical activity such as exercise also increases BP and HR during the activity. Body temperature can affect the metabolic needs of the tissues, thereby influencing the delivery of blood. In hypothermia, tissues require fewer nutrients, and BP falls. In hyperthermia, the metabolic requirement of the tissues is greater, and BP and HR rise.

## Venous System

The primary function of the venous system is to complete the circulation of blood by returning blood from the capillaries to the right side of the heart. It is composed of a series of veins that are located next to the arterial system. A second superficial venous circulation runs parallel to the subcutaneous tissue of the extremity. These two venous systems are connected by communicating veins that provide a means for blood to travel from the superficial veins to the deep veins. Blood flow is directed toward the deep venous circulation.

Veins have the ability to accommodate large shifts in volume with minimal changes in venous pressure. This flexibility allows the venous system to accommodate the administration of IV fluids and blood transfusions and to maintain pressure during blood loss and dehydration. Veins in the superficial and deep venous systems (except the smallest and the largest veins) have valves that direct blood flow back to the heart and prevent backflow. Skeletal muscles in the extremities provide a force that helps push the venous blood forward. The superior vena cava and inferior vena cava are valveless and large enough to allow blood flow to return easily to the heart.

Gravity exerts an increase in **hydrostatic pressure** in the capillaries when the patient is in an upright position, delaying venous return. Hydrostatic pressure is decreased in dependent areas such as the legs when the patient is lying down; thus there is less hindrance of venous return to the heart.

## Cardiovascular Changes Associated With Aging

A number of physiologic changes in the cardiovascular system occur with advancing age (Chart 33-1). Many of these changes result in a loss of cardiac reserve. These changes are usually not evident when the older adult is resting. They become apparent only when the person is physically or emotionally stressed and the heart cannot meet the increased metabolic demands of the body.

### Chart 33-1

## Nursing Focus on the Older Adult

### Changes in the Cardiovascular System Related to Aging

CHANGE	NURSING INTERVENTIONS	RATIONALES
<b>Cardiac Valves</b> Calcification and mucoid degeneration occur, especially in mitral and aortic valves.	Assess heart rate and rhythm and heart sounds for murmurs. Question patients about dyspnea.	Murmurs may be detected before other symptoms. Valvular abnormalities may result in rhythm changes.
<b>Conduction System</b> Pacemaker cells decrease in number. Fibrous tissue and fat in the sinoatrial node increase. Few muscle fibers remain in the atrial myocardium and bundle of His. Conduction time increases.	Assess the electrocardiogram (ECG) and heart rhythm for dysrhythmias or a heart rate less than 60 beats/min.	The sinoatrial (SA) node may lose its inherent rhythm. Atrial dysrhythmias occur in many older adults; 80% of older adults experience premature ventricular contractions (PVCs).
<b>Left Ventricle</b> The size of the left ventricle increases. The left ventricle becomes stiff and less distensible. Fibrotic changes in the left ventricle decrease the speed of early diastolic filling by about 50%.	Assess the ECG for a widening QRS complex and a longer QT interval. Assess the heart rate at rest and with activity. Assess for activity intolerance.	Ventricular changes result in decreased stroke volume, ejection fraction, and cardiac output during exercise; the heart is less able to meet increased oxygen demands. Maximum heart rate with exercise is decreased. The heart is less able to meet increased oxygen demands.
<b>Aorta and Other Large Arteries</b> The aorta and other large arteries thicken and become stiffer and less distensible. Systolic blood pressure increases to compensate for the stiff arteries. Systemic vascular resistance increases as a result of less distensible arteries; therefore the left ventricle pumps against greater resistance, contributing to left ventricular hypertrophy.	Assess blood pressure. Note increases in systolic, diastolic, and pulse pressures. Assess for activity intolerance and shortness of breath. Assess the peripheral pulses.	Hypertension may occur and must be treated to avoid target organ damage.
<b>Baroreceptors</b> Baroreceptors become less sensitive.	Assess the patient's blood pressure with the patient lying and then sitting or standing. Assess for dizziness when the patient changes from a lying to a sitting or standing position. Teach the patient to change positions slowly.	Orthostatic (postural) and postprandial changes occur because of ineffective baroreceptors. Changes may include blood pressure decreases of 10 mm Hg or more, dizziness, and fainting.

## Assessment: Noticing and Interpreting

### Patient History

The focus of the patient history is on obtaining information about risk factors and symptoms of cardiovascular disease. Assess *nonmodifiable* (uncontrollable) risk factors, including the patient's age, gender, ethnic origin and a family history of cardiovascular disease. Ask about any chronic disease or illness that the patient may have. The incidence of conditions such as coronary artery disease (CAD) and valvular disease increases with age. The incidence of CAD also varies with the patient's gender. Men have a higher risk for CAD than women of all ages except in the oldest age-group of 75 years and older (Mozaffarian et al., 2016).

### Gender Health Considerations

#### Patient-Centered Care QSEN

Postmenopausal women are two to three times more likely than premenopausal women to have CAD. The incidence for the disease in women is about 10 years later than in men and 20 years later for myocardial infarction (MI) and death to occur. After an acute MI, women tend to have a higher mortality rate and suffer more complications when compared with men (Mozaffarian et al., 2016).

Women with waist and abdominal obesity (greater waist-hip ratio) are more likely to experience cardiovascular disease (CVD) than are women with excess fat in their buttocks, hips, and thighs.

Heart disease is the leading cause of diabetes-related death for both men and women. Adults with diabetes have heart disease death rates two to four times higher than those without diabetes. The risk for stroke is also two to four times higher among people with diabetes.

Modifiable (controllable) risk factors should also be assessed. *Modifiable* risk factors are personal lifestyle habits, including cigarette use, physical inactivity, obesity, and psychological variables. Ask the patient about each of these common risk factors.

*Cigarette smoking* is a major risk factor for CVD, specifically coronary artery disease (CAD) and peripheral vascular disease (PVD). Three compounds in cigarette smoke have been implicated in the development of CAD: tar, nicotine, and carbon monoxide. The smoking history should include the number of cigarettes smoked daily, the duration of the smoking habit, and the age of the patient when smoking started. Record the smoking history in **pack-years**, which is the number of packs per day multiplied by the number of years the patient has smoked.

Ask about the patient's desire to quit, past attempts to quit, and the methods used. Determine nicotine dependence by asking questions such as:

- How soon after you wake up in the morning do you smoke?
- Do you wake up in the middle of your sleep time to smoke?
- Do you find it difficult not to smoke in places where smoking is prohibited?
- Do you smoke when you're ill?

Three to four years after a patient has stopped smoking, his or her CVD risk appears to be similar to that of a person who has never smoked. Be sure to ask those who do not currently smoke whether they have ever smoked and when they quit. Passive smoke significantly reduces blood flow in healthy young adults' coronary arteries, and the risk for dying increases among those who are exposed to secondhand smoke (American Heart Association [AHA], 2015b).

A *sedentary lifestyle* is also a major risk factor for heart disease. Regular physical activity promotes cardiovascular fitness and produces beneficial changes in blood pressure and levels of blood lipids and clotting factors. Unfortunately, few people in the United States follow the recommended exercise guidelines: 150 minutes of moderate exercise or 75 minutes of vigorous exercise per week (or a combination of the two) plus completing muscle-strengthening exercises at least 2 days per week (Mozaffarian et al., 2016). According to the AHA (2015b), only 20.9% of people in the United States meet the guidelines for physical activity. Encourage increased physical exercise as part of a lifestyle change to reduce the risk for CAD. Ask patients about the type of exercise they perform, how long a period they have participated in the exercise, and the frequency and intensity of the

exercise.

About two thirds of American adults are **overweight** as defined by a body mass index (BMI) of 25 to 30. **Obesity**, defined as a BMI greater than 30, is particularly a problem for African-American women and Mexican Americans; however, the exact cause of this cultural difference is unknown (Mozaffarian et al., 2016). Asian Americans, with the exception of Filipino adults, have the lowest prevalence of obesity. Obesity is also associated with hypertension, hyperlipidemia, and diabetes; all are known contributors to CVD.

The American Heart Association provides guidelines to combat obesity and improve cardiac health, including ingesting more nutrient-rich foods that have vitamins, minerals, fiber, and other nutrients but are low in calories. To get the necessary nutrients, teach patients to choose foods such as vegetables, fruits, unrefined whole-grain products, and fat-free dairy products most often. Also teach patients to not eat more calories than they can burn every day (AHA, 2015a).

A variety of *psychological factors* make people more vulnerable to the development of heart disease. Those who are highly competitive, overly concerned about meeting deadlines, and often hostile or angry are at higher risk for heart disease. Psychological stress, anger, depression, and hostility are all closely associated with risk for developing heart disease.

You might ask the patient, "How do you respond when you have to wait for an appointment?" Chronic anger and hostility appear to be closely associated with CVD. The constant arousal of the sympathetic nervous system as a result of anger may influence BP, serum fatty acids and lipids, and clotting mechanisms. Observe the patient and assess his or her response to stressful situations.

Review the patient's medical history, noting any major illnesses such as diabetes mellitus, renal disease, anemia, high BP, stroke, bleeding disorders, connective tissue diseases, chronic pulmonary diseases, heart disease, and thrombophlebitis. These conditions can influence the patient's cardiovascular status.

Ask about previous treatment for CVD, identify previous diagnostic procedures (e.g., ECG, cardiac catheterization), and request information about any medical or invasive treatment of CVD. Ask specifically about recurrent tonsillitis, streptococcal infections, and rheumatic fever, because these conditions may lead to valvular abnormalities of the heart. In addition, inquire about any known congenital heart defects. Many patients with congenital heart problems live into adulthood because of improved treatment and surgeries.

Ask patients about their drug history, beginning with any current or recent use of prescription or over-the-counter (OTC) medications or herbal/natural products. Inquire about known sensitivities to any drug and the nature of the reaction (e.g., nausea, rash). Patients should be asked whether they have recently used cocaine or any IV "street" drugs, because these substances are often associated with heart disease.

## NCLEX Examination Challenge 33-1

### Health Promotion and Maintenance

While performing an admission assessment on a client, the nurse assesses which of the following as risk factors for cardiovascular disease? **Select all that apply.**

- A. BMI of 22
- B. Well-controlled diabetes mellitus
- C. Exposure to secondhand cigarette smoke
- D. BP of 128/54
- E. History of repeated streptococcal tonsillitis
- F. Family history of cardiovascular disease
- G. Total cholesterol level of 140 mg/dL

## Gender Health Considerations

### Patient-Centered Care QSEN

Research is clear that women frequently present with CAD differently than men. Assess women for nonspecific cardiovascular symptoms, such as fatigue, malaise, anxiety, and shortness of breath. Although knowledge of presentation in women is increasing, educational needs remain, because heart disease remains the leading cause of death in women (Froedge, 2015).

The *social history* includes information about the patient's living situation, including having a domestic partner, other household members, environment, and occupation. Identification of support systems is especially important in exploring the possibility that the patient might have difficulty paying for medications or treatment. Ask about occupation, including the type of work performed and the requirements of the specific job. For instance, does the job involve physical exertion such as lifting heavy objects? Is the job emotionally stressful? What does a day's work entail? Does the patient's job require him or her to be outside in extreme weather conditions?

## Veterans' Health Considerations

### Patient-Centered Care QSEN

The risk of heart disease in the veteran population has been assumed as increased as a result of increased incidence of poor physical and mental health. This assumption was based on the number of veterans facing mental health issues such as depression and post-traumatic stress disorder (PTSD) and the increased incidence of health-compromising behaviors such as smoking. However, recent research suggests that veterans are at a higher risk of having new-onset heart disease, and this link may be independent of health behaviors and chronic medical conditions (Assari, 2014). Research suggests that targeted teaching interventions should be considered in veterans before the development of heart disease to decrease their risk for heart disease (Assari, 2014).

### Nutrition History

A nutrition history includes the patient's recall of food and fluid intake during a 24-hour period, self-imposed or medically prescribed dietary restrictions or supplementations, and the amount and type of alcohol consumption. If needed, the dietitian may review the type of foods selected by the patient for the amount of sodium, sugar, cholesterol, fiber, and fat. Cultural beliefs and economic status can influence the choice of food items and therefore are seriously considered. Family members or significant others who are responsible for shopping and cooking should be included in this screening.

## NCLEX Examination Challenge 33-2

### Health Promotion and Maintenance

The nurse is teaching a client with a newly diagnosed cardiovascular disorder. Which statement made by the client demonstrates health promotion?

- A. "My heart disease will go away when I cut down to one cigarette a day."
- B. "I'm glad I don't have to change my diet and can continue to eat whatever I want."
- C. "I need to get at least 150 minutes of moderate exercise a week."
- D. "I finally have my blood pressure to a normal level of 150/85."

### Family History and Genetic Risk

Review the family history and obtain information about the age, health status, and cause of death of immediate family members. A positive family history for CAD in a first-degree relative (parent, sibling, or child) is a major risk factor. It is *more* important than other factors such as hypertension, obesity, diabetes, or sudden cardiac death.

## Genetic/Genomic Considerations

### Patient-Centered Care QSEN

Cardiovascular disease has many contributory factors, including a genetic tendency. A significant association between familial cardiac history and CVD is consistently demonstrated in the evidence of multiple large-scale prospective epidemiology studies (Mozaffarian et al., 2016). Although several genes have been reported to be associated with heart disease, stroke, and hypertension, the impact of each individual gene is not fully understood. Genetic association studies are under way to determine more specific genetic variants that may underlie the family history (Roberts, 2014). Additional discussions about genetic factors related to specific CVDs are found in other chapters in this unit.

### Current Health Problems

Ask the patient to describe his or her health concerns. Expand on the description of these concerns by obtaining information about their onset, duration, sequence, frequency, location, quality, intensity, associated symptoms, and precipitating, aggravating, and relieving factors. Major symptoms usually identified by patients with CVD include chest pain or discomfort, dyspnea, fatigue, palpitations, weight gain, syncope, and extremity pain.

*Pain or discomfort*, considered a traditional symptom of heart disease, can result from ischemic heart disease, pericarditis, and aortic dissection. Chest pain can also be caused by noncardiac conditions such as pleurisy, pulmonary embolus, hiatal hernia, gastroesophageal reflux disease, neuromuscular abnormalities, and anxiety.

## Nursing Safety Priority QSEN

### Action Alert

Thoroughly evaluate the nature and characteristics of the chest pain. Because pain resulting from myocardial ischemia is life threatening and can lead to serious complications, its cause should be considered ischemic (reduced or obstructed blood flow to the myocardium) until proven otherwise. When assessing for symptoms, ask the patient if he or she has “discomfort,” “heaviness,” “pressure,” and/or “indigestion.” It is important to note that chest pain can occur in any setting. Proper assessment of the pain can decrease the potential for serious complications.

## Gender Health Considerations

### Patient-Centered Care QSEN

Some patients, especially women, do not experience pain in the chest but, instead, feel discomfort or indigestion. Women often present with a “triad” of symptoms. In addition to indigestion or a feeling of abdominal fullness, chronic fatigue despite adequate rest and feelings of an “inability to catch my breath” (dyspnea) are also common in heart disease. The patient may also describe the sensation as aching, choking, strangling, tingling, squeezing, constricting, or viselike. Others with severe neuropathy may experience few or no traditional symptoms except shortness of breath, despite major ischemia. Be aware that CVD affects younger people as well. According to the American Heart Association (2015b), 31% to 48% of women over the age of 20 have cardiovascular disease.

Ask the patient to identify when the symptoms were first noticed (onset):

- Did the symptoms begin suddenly or develop gradually (manner of onset)?
- How long did the symptoms last (duration)?

If he or she has repeated painful episodes, assess how often the symptoms occur (frequency). If pain is present, ask whether it is different from any other episodes of pain. Ask the patient to describe which activities he or she was doing when it first occurred, such as sleeping, arguing, or running (precipitating factors). If possible, the patient should point to the area where the chest pain occurred (location) and describe if and how the pain radiated (spread).

In addition, ask how the pain feels and whether it is sharp, dull, or crushing (quality of pain). To understand the severity of the pain, ask the patient to grade it from 0 to 10, with 10 indicating severe pain (intensity). He or she may also report other signs and symptoms that occur at the same time (associated symptoms), such as dyspnea, diaphoresis (excessive sweating), nausea, and vomiting. Other factors that need to be addressed are those that may have made the chest pain worse (aggravating factors) or less intense (relieving factors). Chest pain can arise from a variety of sources (Table 33-1). By obtaining the appropriate information, you can help identify the source of the discomfort.

**TABLE 33-1**  
**Assessment of Chest Discomfort: How Various Types of Chest Pain Differ**

ONSET	QUALITY AND SEVERITY	LOCATION AND RADIATION	DURATION AND RELIEVING FACTORS
<b>Angina</b>			
Sudden, usually in response to exertion, emotion, or extremes in temperature	Squeezing, viselike pain	Usually the left side of chest without radiation Substernal; may spread across the chest and the back and/or down the arms	Usually lasts less than 15 min; relieved with rest, nitrate administration, or oxygen therapy
<b>Myocardial Infarction</b>			
Sudden, without precipitating factors, often in early morning	Intense stabbing, viselike pain or pressure, severe	Substernal; may spread throughout the anterior chest and to the arms, jaw, back, or neck	Continuous or no chest discomfort; relieved with morphine, cardiac drugs, and oxygen therapy
<b>Pericarditis</b>			
Sudden	Sharp, stabbing, moderate to severe	Substernal; usually spreads to the left side or the back	Intermittent; relieved with sitting upright, analgesia, or administration of anti-inflammatory agents
<b>Pleuropulmonary</b>			
Variable	Moderate ache, worse on inspiration	Lung fields	Continuous until the underlying condition is treated or the patient has rested
<b>Esophageal-Gastric</b>			
Variable	Squeezing, heartburn, variable severity	Substernal; may spread to the shoulders or the abdomen	Variable; may be relieved with antacid administration, food intake, or taking a sitting position
<b>Anxiety</b>			
Variable, may be in response to stress or fatigue	Dull ache to sharp stabbing; may be associated with numbness in fingers	Not well located and usually does not radiate to other parts of the body as pain	Usually lasts a few minutes

*Dyspnea* (difficult or labored breathing) can occur as a result of both cardiac and pulmonary disease. It is experienced by the patient as uncomfortable breathing or shortness of breath. When obtaining the history, ask which factors precipitate and relieve dyspnea, what level of activity produces dyspnea, and what the patient's body position was when dyspnea occurred.

Dyspnea that is associated with activity, such as climbing stairs, is referred to as **dyspnea on exertion (DOE)**. This is usually an early symptom of heart failure and may be the *only* symptom experienced by women.

The patient with advanced heart disease may experience **orthopnea** (dyspnea that appears when he or she lies flat). Several pillows may be needed to elevate the head and chest, or a recliner to prevent breathlessness may be used. The number of pillows or the amount of head elevation needed to provide restful sleep often measures the severity of orthopnea. This symptom is usually relieved within a matter of minutes by sitting up or standing.

**Paroxysmal nocturnal dyspnea (PND)** develops after the patient has been lying down for several hours. In this position, blood from the lower extremities is redistributed to the venous system, which increases venous return to the heart. A diseased heart cannot compensate for the increased volume and is ineffective in pumping the additional fluid into the circulatory system. Pulmonary congestion results, and the patient awakens abruptly, often with a feeling of suffocation and panic. He or she sits upright and dangles the legs over the side of the bed to relieve the dyspnea. This sensation may last for 20 minutes.

*Fatigue* may be described as a feeling of tiredness or weariness resulting from activity. The patient may report that an activity takes longer to complete or that he or she tires easily after activity. Although fatigue in itself is not diagnostic of heart disease, many people with heart failure are limited by leg fatigue during exercise. Fatigue that occurs after mild activity and exertion usually indicates inadequate cardiac output (due to low stroke volume) and anaerobic metabolism in skeletal muscle. It can also accompany other symptoms or may be an early indication of heart disease in women.

Ask about the time of day the patient experiences fatigue and the activities that he or she can perform. Fatigue resulting from decreased cardiac output is often worse in the evening. Ask whether the patient can perform the same activities as he or she could perform a year ago or the same activities as others of the same age. Often he or she limits activities in response to fatigue and, unless questioned, is unaware how much less active he or she has become.

A feeling of fluttering or an unpleasant feeling in the chest caused by an irregular heartbeat is referred to as **palpitations**. They may result from a change in heart rate or rhythm or from an increase in the force of heart contractions. Rhythm disturbances that may cause palpitations include paroxysmal supraventricular tachycardia, premature contractions, and sinus tachycardia. Those that occur during or after strenuous physical activity, such as running and swimming, may indicate overexertion or possibly heart disease. Noncardiac factors that may precipitate palpitations include anxiety; stress; fatigue; insomnia; hyperthyroidism; and the ingestion of caffeine, nicotine, or alcohol. Ask the patient about specific factors that cause his or her palpitations.

A sudden weight increase of 2.2 lb (1 kg) can result from excess fluid (1 L) in the interstitial spaces. The *best indicator* of fluid balance is weight. Excess fluid accumulation is commonly known as **edema**. It is possible for weight gains of up to 10 to 15 lb (4.5 to 6.8 kg, or 4 to 7 L of fluid) to occur before edema is apparent. Ask whether the patient has noticed a tightness of shoes, indentations from socks, or tightness of rings.

**Syncope** refers to a brief loss of consciousness. The most common cause is decreased perfusion to the brain. Any condition that suddenly reduces cardiac output, resulting in decreased cerebral blood flow, can lead to a syncopal episode. Conditions such as cardiac rhythm disturbances, especially ventricular dysrhythmias, and valvular disorders such as aortic stenosis may trigger this symptom. **Near-syncope** refers to dizziness with an inability to remain in an upright position. Explore the circumstances that lead to dizziness or syncope.

## Considerations for Older Adults

### Patient-Centered Care QSEN

Syncope in the aging person may result from hypersensitivity of the carotid sinus bodies in the carotid arteries. Pressure applied to these arteries while turning the head, shrugging the shoulders, or performing a Valsalva maneuver (bearing down during defecation) may stimulate a vagal response. A decrease in blood pressure and heart rate can result, which can produce syncope. This type of syncopal episode may also result from postural (orthostatic) or postprandial (after eating) hypotension.

*Extremity pain* may be caused by two conditions: ischemia from atherosclerosis and venous insufficiency of the peripheral blood vessels. Patients who report a moderate-to-severe cramping sensation in their legs or buttocks associated with an activity such as walking have **intermittent claudication** related to decreased arterial tissue PERFUSION. Resting or lowering the affected extremity to decrease tissue demands or to enhance arterial blood flow usually relieves claudication pain. Leg pain that results from prolonged standing or sitting is related to venous insufficiency from either incompetent valves or venous obstruction. Elevating the extremity may relieve this pain.

### Functional History

After the history of the patient's cardiovascular status is obtained, he or she may be classified according to the New York Heart Association Functional Classification (Table 33-2) or other system. The four classifications (I, II, III, and IV) depend on the degree to which ordinary physical activities (routine ADLs) are affected by heart disease. The Killip Classification provides a more objective description of the hemodynamics of heart failure and is described in Chapter 38.

**TABLE 33-2**

**New York Heart Association Functional Classification of Cardiovascular Disability**

Class I
• Patients with cardiac disease but without resulting limitations of physical activity

• Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or anginal pain
<b>Class II</b>
• Patients with cardiac disease resulting in slight limitation of physical activity
• Comfortable at rest
• Ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain
<b>Class III</b>
• Patients with cardiac disease resulting in marked limitation of physical activity
• Comfortable at rest
• Less than ordinary physical activity causes fatigue, palpitation, dyspnea, or anginal pain
<b>Class IV</b>
• Patients with cardiac disease resulting in inability to carry on any physical activity without discomfort
• Symptoms of cardiac insufficiency or of the anginal syndrome may be present, even at rest
• If any physical activity is undertaken, discomfort is increased

Excerpted from The New York Heart Association. (1964). *Diseases of the heart and blood vessels: Nomenclature and criteria for diagnosis* (6th ed.). Boston: Little, Brown.

## Physical Assessment

A thorough physical assessment is the foundation for the nursing database and the patient's priority problems. Any changes noted during the course of illness can be compared with this initial database. Evaluate the patient's vital signs on admission to the hospital or during the initial visit to the clinic or primary care provider's office.

### General Appearance

Physical assessment begins with the patient's general appearance. Assess general build and appearance, skin color, distress level, level of consciousness, shortness of breath, position, and verbal responses.

Patients can have left- or right-sided heart failure, or both. They can also be diagnosed with systolic and/or diastolic heart failure. As a result, poor cardiac output and decreased cerebral PERFUSION may cause confusion, memory loss, and slowed verbal responses, especially in older adults. Patients with chronic heart failure may also appear malnourished, thin, and cachectic. Late signs of severe right-sided heart failure are ascites, jaundice, and **anasarca** (generalized edema) as a result of prolonged congestion of the liver. Heart failure may also cause fluid retention and may be manifested by obvious generalized dependent edema. [Chapter 35](#) differentiates right and left failure and systolic from diastolic heart failure in detail.

### Skin

Skin assessment includes color and temperature. The best areas in which to assess circulation include the nail beds, mucous membranes, and conjunctival mucosa, because small blood vessels are located near the surface of the skin in those areas.

If there is normal blood flow or adequate perfusion to a given area in light-colored skin, it appears pink, perhaps rosy, and is warm. Decreased PERFUSION is manifested as cool, pale, and moist skin. Pallor is characteristic of anemia and can be seen in areas such as the nail beds, palms, and conjunctival mucous membranes in any patient.

A bluish or darkened discoloration of the skin and mucous membranes in *light-skinned* adults is referred to as **cyanosis**. This condition results from an increased amount of deoxygenated hemoglobin. It is not an early sign of decreased perfusion but occurs later with other symptoms. *Dark-skinned* adults may experience cyanosis as a graying of the same tissues.

*Central* cyanosis involves decreased oxygenation of the arterial blood in the lungs and appears as a bluish tinge of the conjunctivae and the mucous membranes of the mouth and tongue. Central cyanosis may indicate impaired lung function or a right-to-left shunt found in congenital heart conditions. Because of impaired circulation, there is marked desaturation of hemoglobin in the peripheral tissues, which produces a bluish or darkened discoloration of the nail beds, earlobes, lips, and toes.

*Peripheral* cyanosis occurs when blood flow to the peripheral vessels is decreased by peripheral vasoconstriction. Constriction results from a low cardiac output or an increased extraction of oxygen from the peripheral tissues. Peripheral cyanosis localized in an extremity is usually a result of arterial or venous insufficiency. **Rubor** (dusky redness) that replaces pallor in a dependent foot suggests arterial insufficiency.

Skin *temperature* can be assessed for symmetry by touching different areas of the body with the dorsal (back) surface of the hand or fingers. Decreased blood flow results in decreased skin temperature. It is lowered in several clinical conditions, including heart failure, peripheral vascular disease, and shock.

## Extremities

Assess the patient's hands, arms, feet, and legs for skin changes, vascular changes, clubbing, and edema. Skin mobility and turgor are affected by fluid status. Dehydration and aging reduce skin turgor, and edema decreases skin elasticity. Vascular changes in an affected extremity may include paresthesia, muscle fatigue and discomfort, numbness, pain, coolness, and loss of hair distribution from a reduced blood supply.

Clubbing of the fingers and toes is caused by *chronic* oxygen deprivation in body tissues. It is common in patients with advanced chronic pulmonary disease, congenital heart defects, and cor pulmonale (right-sided heart failure). The angle of the normal nail bed is 160 degrees. With **clubbing**, the nail straightens out to an angle of 180 degrees and the base of the nail becomes spongy. [Fig. 30-10](#) shows late clubbing.

Peripheral edema (fluid accumulation in the legs and feet) is a common finding in patients with cardiovascular problems. The location of edema helps determine its potential cause. Bilateral edema of the legs may be seen in those with heart failure or chronic venous insufficiency. Abdominal and leg edema can be seen in patients with heart disease and cirrhosis of the liver. Localized edema in one extremity may be the result of venous obstruction (thrombosis) or lymphatic blockage of the extremity (lymphedema). Edema may also be noted in dependent areas, such as the sacrum, when a patient is confined to bed. In other patients, edema results from third spacing when plasma proteins decrease. Dependent foot and ankle edema is also a common side effect of certain antihypertensive drugs, such as amlodipine (Norvasc).

Document the location of edema as precisely as possible (e.g., midthibial or sacral) and the number of centimeters from an anatomic landmark. The extent of edema can be assessed as mild, moderate, or severe (or 1+, 2+, 3+, or 4+). However, these values are not precise and are very unreliable. Determine whether the edema is **pitting** (the skin can be indented) ([Fig. 33-5](#)) or nonpitting.

**FIG. 33-5** Peripheral pitting edema. (From Sahrman, S. (2011). *Movement system impairment syndromes of the extremities, cervical and thoracic spines*. St. Louis: Mosby.)

The finger is typically used for pulse oximetry as a noninvasive method for assessing oxygenation and PERFUSION of many medical-surgical nursing patients. Correct placement of the pulse oximetry sensor is essential for accurate readings. Oxygen saturation levels of above 90% are considered normal, depending on the patient's age. Detailed information about this assessment method can be found in [Chapter 27](#).

## Blood Pressure

Arterial blood pressure is measured *indirectly* by sphygmomanometry. This technique of measurement is described in detail in nursing skills textbooks.

The Eighth National High Blood Pressure Education Program National Committee (JNC) on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure ([James et al., 2014](#)) defines **hypertension** as a systolic pressure of 140 mm Hg or higher or a diastolic pressure of 90 mm Hg or higher or taking drugs to control blood pressure. Specific treatment goals were outlined for patients based on age and comorbidities. [Chapter 36](#) describes hypertension in detail.

A BP less than 90/60 mm Hg (hypotension) may not be adequate for providing enough oxygen and sufficient nutrition to body cells. In certain circumstances such as shock, the Korotkoff sounds are less audible or are absent. In these cases palpate the BP, use an ultrasonic device (Doppler

device), or obtain a direct measurement by arterial catheter in the critical care setting. When BP is palpated, only the systolic pressure can be determined. Patients may report dizziness or light-headedness when they move from a flat, supine position to a sitting or a standing position at the edge of the bed. Normally these symptoms are transient and pass quickly; pronounced symptoms may be due to postural hypotension. **Postural (orthostatic) hypotension** occurs when the BP is not adequately maintained while moving from a lying to a sitting or standing position. It is defined as a decrease of more than 20 mm Hg of the systolic pressure or more than 10 mm Hg of the diastolic pressure and a 10% to 20% increase in heart rate. The causes of postural hypotension include cardiovascular drugs, blood volume decrease, prolonged bedrest, age-related changes, or disorders of the nervous system.

To detect orthostatic changes in BP, first measure the BP when the patient is supine. After remaining supine for at least 3 minutes, the patient changes position to sitting or standing. Normally systolic pressure drops slightly or remains unchanged as the patient rises, whereas diastolic pressure rises slightly. After the position change, wait for at least 1 minute before auscultating BP and counting the radial pulse. The cuff should remain in the proper position on the patient's arm. Observe and record any signs or symptoms of dizziness. If the patient cannot tolerate the position change, return him or her to the previous position of comfort.

**Paradoxical blood pressure** is an exaggerated decrease in systolic pressure by more than 10 mm Hg during the inspiratory phase of the respiratory cycle (normal is 3 to 10 mm Hg). Certain clinical conditions that potentially alter the filling pressures in the right and left ventricles may produce a paradoxical BP. Such conditions include pericardial tamponade, constrictive pericarditis, and pulmonary hypertension. During inspiration, the filling pressures normally decrease slightly. However, decreased fluid volume in the ventricles resulting from these pathologic conditions produces a marked reduction in cardiac output. The difference between the systolic and diastolic values is referred to as **pulse pressure**. This value can be used as an indirect measure of cardiac output. Narrowed pulse pressure is rarely normal and results from increased peripheral vascular resistance or decreased stroke volume in patients with heart failure, hypovolemia, or shock. It can also be seen in those with mitral stenosis or regurgitation. An increased pulse pressure may occur in patients with slow heart rates, aortic regurgitation, atherosclerosis, hypertension, and aging.

The **ankle-brachial index (ABI)** can be used to assess the vascular status of the lower extremities. A BP cuff is applied to the lower extremity just above the malleolus. The systolic pressure is measured by Doppler ultrasound at both the dorsalis pedis and posterior tibial pulses. The higher of these two pressures is then divided by the higher of the two brachial pulses to obtain the ABI.

Normal values for the ABI are 1.00 or higher because BP in the legs is usually higher than BP in the arms. ABI values less than 0.90 usually indicate moderate vascular disease, whereas values less than 0.50 indicate severe vascular compromise. Although used primarily to help identify peripheral vascular disease, the ABI may be effective as a risk factor in predicting other CVD. An ABI of  $\leq 0.90$  and  $\geq 1.40$  suggests an increased risk of CVD and mortality; a result between 0.91 and 1.0 indicates moderate risk (Aboyans et al., 2012).

A **toe brachial pressure index (TBPI)** may be performed instead of or in addition to the ABI to determine arterial perfusion in the feet and toes. TBPI is the toe systolic pressure divided by the brachial (arm) systolic pressure.

## Venous and Arterial Pulses

Observe the venous pulsations in the neck to assess the adequacy of blood volume and central venous pressure (CVP). Specially educated or critical care nurses can assess jugular venous pressure (JVP) to estimate the filling volume and pressure on the right side of the heart. An increase in JVP causes **jugular venous distention (JVD)**.

Normally the JVP is 3 to 10 cm H<sub>2</sub>O. Increases are usually caused by right ventricular failure. Other causes include tricuspid regurgitation or stenosis, pulmonary hypertension, cardiac tamponade, constrictive pericarditis, hypervolemia, and superior vena cava obstruction.

Assessment of *arterial pulses* provides information about vascular integrity and circulation. For patients with suspected or actual vascular disease, major peripheral pulses should be assessed for presence or absence, amplitude, contour, rhythm, rate, and equality. Palpate the peripheral arteries in a head-to-toe approach with a side-to-side comparison (Fig. 33-6).

**FIG. 33-6** Pulse points for assessment of arterial pulses.

A *hypokinetic* pulse is a weak pulse indicative of a narrow pulse pressure. It is seen in patients with hypovolemia, aortic stenosis, and decreased cardiac output. A *hyperkinetic* pulse is a large, “bounding” pulse caused by an increased ejection of blood. It occurs in patients with a high cardiac output (with exercise, sepsis, or thyrotoxicosis) and in those with increased sympathetic system activity (with pain, fever, or anxiety).

Auscultation of the major arteries (e.g., carotid and aorta) is necessary to assess for bruits. **Bruits** are swishing sounds that may occur from turbulent blood flow in narrowed or atherosclerotic arteries. Assess for the absence or presence of bruits by placing the bell of the stethoscope on the neck over the carotid artery while the patient holds his or her breath. Normally there are no sounds if the artery has uninterrupted blood flow. A bruit may develop when the internal diameter of the vessel is narrowed by 50% or more, but this does not indicate the severity of disease in the arteries. Once the vessel is blocked 90% or greater, the bruit often cannot be heard.

## Precordium

Assessment of the precordium (the area over the heart) involves inspection, palpation, percussion, and auscultation. In most settings, the medical-surgical nurse seldom performs precordial palpation and percussion. Critical care nurses and advanced practice nurses are qualified to perform the complete assessment. Therefore only inspection and auscultation are described here. Begin by placing the patient in a supine position, with the head of the bed slightly elevated for comfort. Some patients may require elevation of the head of the bed to 45 degrees for ease and comfort in breathing.

## Inspection

A cardiac examination is usually performed in a systematic order, beginning with inspection. Inspect the chest from the side, at a right angle, and downward over areas of the precordium where vibrations are visible. Cardiac motion is of low amplitude, and sometimes the inward movements are more easily detected by the naked eye.

Examine the entire precordium (Fig. 33-7) and note any prominent pulses. Movement over the aortic, pulmonic, and tricuspid areas is abnormal. Pulses in the mitral area (the apex of the heart)

are considered normal and are referred to as the **apical impulse**, or the **point of maximal impulse (PMI)**. The PMI should be located at the left fifth intercostal space (ICS) in the midclavicular line. If it appears in more than one ICS and has shifted lateral to the midclavicular line, the patient may have left ventricular hypertrophy.

**FIG. 33-7** Areas for myocardial inspection and auscultation.

## Auscultation

Auscultation evaluates heart rate and rhythm, cardiac cycle (systole and diastole), and valvular function. The technique of auscultation requires a good-quality stethoscope and extensive clinical practice. Identifying specific abnormal heart sounds is most important in critical care and telemetry.

Listen to heart sounds in a systematic order. Examination usually begins at the aortic area and progresses slowly to the apex of the heart. The diaphragm of the stethoscope is pressed tightly against the chest to listen for high-frequency sounds and is useful in listening to the first and second heart sounds and high-frequency murmurs. Repeat the progression from the base to the apex of the heart using the bell of the stethoscope, which is held lightly against the chest. The bell can screen out high-frequency sounds and is useful in listening for low-frequency gallops (diastolic filling sounds) and murmurs.

## Normal Heart Sounds.

The **first heart sound (S<sub>1</sub>)** is created by the closure of the mitral and tricuspid valves (atrioventricular valves) (see Fig. 33-4). When auscultated, S<sub>1</sub> is softer and longer; it is of a low pitch and is best heard at the lower left sternal border or the apex of the heart. Palpating the carotid pulse while listening may help to identify S<sub>1</sub>. S<sub>1</sub> marks the beginning of ventricular systole and occurs right after the QRS complex on the ECG.

S<sub>1</sub> can be accentuated or intensified in conditions such as exercise, hyperthyroidism, and mitral stenosis. A decrease in sound intensity occurs in patients with mitral regurgitation and heart failure. If you have difficulty hearing heart sounds, have the patient lean forward or roll to his or her left side.

The **second heart sound (S<sub>2</sub>)** is created by the closing of the aortic and pulmonic valves (semilunar valves) (see Fig. 33-4). S<sub>2</sub> is characteristically shorter. It is higher pitched and is heard best at the base of the heart at the end of ventricular systole.

The splitting of heart sounds is often difficult to differentiate from diastolic filling sounds (gallops). A splitting of S<sub>1</sub> (closure of the mitral valve followed by closure of the tricuspid valve) occurs physiologically because left ventricular contraction occurs slightly before right ventricular contraction. However, closure of the mitral valve is louder than closure of the tricuspid valve, so splitting is often not heard. Normal splitting of S<sub>2</sub> occurs because of the longer systolic phase of the right ventricle. Splitting of S<sub>1</sub> and S<sub>2</sub> can be accentuated by inspiration (due to increased venous return), and it narrows during expiration.

## Abnormal Heart Sounds.

Abnormal splitting of  $S_2$  is referred to as **paradoxical splitting** and has a wider split heard on expiration. Paradoxical splitting of  $S_2$  is heard in patients with severe myocardial depression that causes early closure of the pulmonic valve or a delay in aortic valve closure. Such conditions include myocardial infarction (MI), left bundle-branch block, aortic stenosis, aortic regurgitation, and right ventricular pacing.

Gallops and murmurs are common abnormal heart sounds that may occur with heart disease, but they can occur in some healthy people. Diastolic filling sounds ( $S_3$  and  $S_4$ ) are produced when blood enters a noncompliant chamber during rapid ventricular filling. The third heart sound ( $S_3$ ) is produced during the rapid passive filling phase of ventricular diastole when blood flows from the atrium to a noncompliant ventricle. The sound arises from vibrations of the valves and supporting structures. The fourth heart sound ( $S_4$ ) occurs as blood enters the ventricles during the active filling phase at the end of ventricular diastole.

$S_3$  is called a **ventricular gallop**, and  $S_4$  is referred to as **atrial gallop**. These sounds can be caused by decreased compliance of either or both ventricles. Left ventricular diastolic filling sounds are best heard with the patient on his or her left side. The bell of the stethoscope is placed at the apex and at the left lower sternal border during expiration.

An  $S_3$  heart sound is most likely to be a normal finding in those younger than 35 years. An  $S_3$  gallop in patients older than 35 years is considered abnormal and represents a decrease in left ventricular compliance. It can be detected as an early sign of heart failure or as a ventricular septal defect.

An atrial gallop ( $S_4$ ) may be heard in patients with hypertension, anemia, ventricular hypertrophy, MI, aortic or pulmonic stenosis, and pulmonary emboli. It may also be heard with advancing age because of a stiffened ventricle.

**Murmurs** reflect turbulent blood flow through normal or abnormal valves. They are classified according to their timing in the cardiac cycle: *systolic* murmurs (e.g., aortic stenosis and mitral regurgitation) occur between  $S_1$  and  $S_2$ , whereas *diastolic* murmurs (e.g., mitral stenosis and aortic regurgitation) occur between  $S_2$  and  $S_1$ . Murmurs can occur during presystole, midsystole, or late systole or diastole or can last throughout both phases of the cardiac cycle. They are also graded by the primary care provider according to their intensity, depending on their level of loudness (Table 33-3).

**TABLE 33-3**  
**Grading of Heart Murmurs**

Grade I	Very faint
Grade II	Faint but recognizable
Grade III	Loud but moderate in intensity
Grade IV	Loud; accompanied by a palpable thrill
Grade V	Very loud; accompanied by a palpable thrill; audible with the stethoscope partially off the patient's chest
Grade VI	Extremely loud; may be heard with the stethoscope slightly above the patient's chest; accompanied by a palpable thrill

Although you are not expected to grade murmurs as a medical-surgical nurse, describe their location based on where they are best heard. Some murmurs transmit or radiate from their loudest point to other areas, including the neck, the back, and the axilla. The configuration is described as *crescendo* (increases in intensity) or *decrescendo* (decreases in intensity). The quality of murmurs can be further characterized as harsh, blowing, whistling, rumbling, or squeaking. They are also described by pitch—usually *high* or *low*.

A **pericardial friction rub** originates from the pericardial sac and occurs with the movements of the heart during the cardiac cycle. Rubs are usually transient and are a sign of inflammation, infection, or infiltration. They may be heard in patients with pericarditis resulting from MI, cardiac tamponade, or post-thoracotomy.

## Psychosocial Assessment

To most people, the heart is a symbol of their ability to exist, survive, and love. A patient with a heart-related illness, whether acute or chronic, usually perceives it as a major life crisis. The patient and family confront not only the possibility of death but also fears about pain, disability, lack of self-esteem, physical dependence, and changes in family dynamics. Assess the meaning of the

illness to the patient and family by asking, “What do you understand about what happened to you (or the patient)?” and “What does that mean to you?” When they perceive the stressor as overwhelming, formerly adequate support systems may no longer be effective. In these circumstances, the patient and family members attempt to cope to regain a sense or feeling of control.

Coping behaviors vary among patients and their families. Those who feel helpless to meet the demands of the situation may exhibit behaviors such as disorganization, fear, and anxiety. Ask them, “Have you ever encountered such a situation before?” “How did you manage that situation?” and “To whom can you turn for help?” The answers to these questions often reassure the patient and family that they have encountered difficult situations in the past and have the ability and resources to cope with them.

A common and normal response is *denial*, which is a defense mechanism that enables the patient to cope with threatening circumstances. He or she may deny the current cardiovascular condition, may state that it was present but is now absent, or may be excessively cheerful. Denial becomes maladaptive when the patient is noncompliant or does not adhere to the interdisciplinary plan of care.

Family members and significant others may be more anxious than the patient. Often they recall all events of the illness, are unprotected by denial, and are afraid of recurrence. Disagreements may occur between the patient and family members over adherence to appropriate follow-up care.

## Clinical Judgment Challenge 33-1

### Safety; Teamwork and Collaboration QSEN

A middle-age man presents to the emergency department (ED) with reports of chest pain and indigestion. He reports some minor discomfort in his jaw. The patient is alert and oriented; BP 90/50; HR/80. You are the RN assigned to his care. There is an unlicensed assistive personnel (UAP) working with you.

1. Which assessment data will you perform on his arrival to the ED? Why?
2. The provider orders labs, 12-lead ECG, IV fluids, blood pressure checks, medication for chest pain, and oxygen at 2 L per nasal cannula. What part of the patient's care will you delegate to the UAP? Which information will you communicate on delegation?
3. Which interventions will you implement to ensure this patient's safety?
4. Which priority information will you document in the patient's electronic health record?
5. The patient's wife is very concerned about her husband returning to work as owner of a roofing company. What education will you provide the patient and his wife at this time? With which health care team members will you collaborate to ensure positive patient outcomes?

## Diagnostic Assessment

### Laboratory Assessment

Assessment of the patient with cardiovascular dysfunction includes examination of the blood for abnormalities. The examination is performed to help establish a diagnosis, detect concurrent disease, assess risk factors, and monitor response to treatment. Normal values for serum cardiac enzymes and serum lipids are listed in [Chart 33-2](#).

### Chart 33-2

## Laboratory Profile

### Cardiovascular Assessment

NORMAL RANGE	SIGNIFICANCE OF ABNORMAL FINDINGS
--------------	-----------------------------------

Serum Lipids	
Total lipids 400-1000 mg/dL	Elevation indicates increased risk for coronary artery disease (CAD).
Cholesterol Less than 200 mg/dL	Elevation indicates increased risk for CAD.
Triglycerides Females: 35-135 mg/dL Males: 40-160 mg/dL	Elevation indicates increased risk for CAD.
Plasma high-density lipoproteins (HDLs) Females: >55 mg/dL Males: >45 mg/dL Older adults: range increases with age	Elevations protect against CAD.
Plasma low-density lipoproteins (LDLs) <130 mg/dL	Elevation indicates increased risk for CAD.
HDL:LDL ratio 3 : 1	Elevated ratios may protect against CAD.
VLDL 7-32 ng/dL	Elevated level indicates risk for CAD.
C-reactive protein (CRP) <1.0 mg/dL	Elevation may indicate tissue infarction or damage.
Serum Markers	
Troponins Cardiac troponin T <0.10 ng/mL Cardiac troponin I <0.03 ng/mL	Elevations indicate myocardial injury or infarction.

VLDL, Very-low-density lipoproteins.

## Serum Markers of Myocardial Damage.

Events leading to cellular injury cause a release of enzymes from intracellular storage, and circulating levels of these enzymes are dramatically elevated. Acute myocardial infarction (MI), also known as **acute coronary syndrome**, can be confirmed by abnormally high levels of certain proteins or isoenzymes.

**Troponin** is a myocardial muscle protein released into the bloodstream with injury to myocardial muscle. Troponins T and I are not found in healthy patients, so any rise in values indicates cardiac necrosis or acute MI. Specific markers of myocardial injury, troponins T and I, have a wide diagnostic time frame, making them useful for patients who present several hours after the onset of chest pain. Even low levels of troponin T are treated aggressively because of increased risk for death from cardiovascular disease (CVD). Obtaining cardiac markers at the bedside in the emergency department can be done as “point-of-care” (POC) testing for patients experiencing or at risk for acute MI, with results available within 15 to 20 minutes. These markers are evaluated in addition to clinical signs and symptoms and electrocardiogram (ECG) changes when identifying at-risk patients. Following initial troponin assessment, levels should be assessed again in 3 to 6 hours. Before the development of highly sensitive troponin levels, providers relied on creatinine kinase (CK), its isoenzyme (CK-MB), and myoglobin to assist with diagnosis of acute myocardial infarction. Use of these cardiac markers is no longer recommended (Amsterdam et al., 2014; Jaffe & Morrow, 2015).

## Serum Lipids.

Elevated lipid levels are considered a risk factor for coronary artery disease (CAD). **Cholesterol**, **triglycerides**, and the protein components of **high-density lipoproteins (HDLs)** and **low-density lipoproteins (LDLs)** are evaluated to assess the risk for CAD. The desired ranges for lipids are (Pagana et al., 2017):

- Total cholesterol less than 200 mg/dL
- Triglycerides between 40 and 160 mg/dL for men and between 35 and 135 mg/dL for women
- HDL more than 45 mg/dL for men; more than 55 mg/dL for women (“good” cholesterol)
- LDL less than 130 mg/dL

Each of the lipoproteins contains varying proportions of cholesterol, triglyceride, protein, and phospholipid. HDL contains mainly protein and 20% cholesterol, whereas LDL is mainly cholesterol. Elevated LDL levels are positively correlated with CAD, whereas elevated HDL levels are negatively correlated and appear to be protective for heart disease. LDL pattern size is of significant importance in determining risk for CVD. LDL pattern A is associated with non-insulin resistance; normal glucose, insulin, and HDL levels; and normal blood pressure. LDL pattern B is associated with insulin resistance; increased glucose, insulin, and triglyceride levels; and hypertension.

A fasting blood sample for the measurement of serum cholesterol levels is preferable to a nonfasting sample. If triglycerides are to be evaluated with cholesterol, the health care provider requests the specimen after a 12-hour fast.

*Lipoprotein-a*, or *Lp(a)*, is a modified form of LDL, the most common familial lipoprotein disorder

in patients with premature coronary artery disease. Lp(a) is atherogenic (increases atherosclerotic plaques) and prothrombotic (increases clots). Therefore the desired outcome is a value less than 30 mg/dL. The patient should be fasting and avoid smoking before the test (Pagana et al., 2017).

### Other Laboratory Tests.

**Homocysteine** is an amino acid that is produced when proteins break down. A certain amount of homocysteine is present in the blood, but elevated values may be an independent risk factor for the development of CVD. Although the relationship between homocysteine and CVD remains controversial, elevated levels of homocysteine may increase the risk for disease as much as smoking and hyperlipemia, especially in women. High-risk patients who have a personal or family history of premature heart disease should be screened. A level less than 14 mmol/dL is considered optimal, but this level increases as one ages (Pagana et al., 2017).

Inflammation is a common and critical component to the development of atherothrombosis.

**Highly sensitive C-reactive protein (hsCRP)** has been the most studied marker of inflammation. Any inflammatory process can produce CRP in the blood. Elevations also are seen with hypertension, infection, and smoking. A level less than 1 mg/dL is considered low risk; a level over 3 mg/dL places the patient at high risk for heart disease. The CRP is very helpful in determining treatment outcomes in patients at risk for coronary disease and in managing statin therapy after an acute myocardial infarction. The most useful time to measure CRP appears to be for risk assessment in middle-age or older persons.

**Microalbuminuria**, or small amounts of protein in the urine, has been shown to be a clear marker of widespread endothelial dysfunction in cardiovascular disease (along with elevated CRP). It should be screened annually in all patients with hypertension, metabolic syndrome, or diabetes mellitus. Microalbuminuria has also been used as a marker for renal disease, particularly in patients with hypertension and diabetes.

Blood coagulation studies evaluate the ability of the blood to clot. They are important in patients with a greater tendency to form thrombi (e.g., those with atrial fibrillation, prosthetic valves, or infective endocarditis). These tests are also essential for monitoring patients receiving anticoagulant therapy (e.g., during cardiac surgery, during treatment of an established thrombus).

*Prothrombin time (PT)* and *international normalized ratio (INR)* are used when initiating and maintaining therapy with oral anticoagulants, such as sodium warfarin (Coumadin, Warfilone). They measure the activity of prothrombin, fibrinogen, and factors V, VII, and X. INR is the most reliable way to monitor anticoagulant status in warfarin therapy. The therapeutic ranges vary significantly based on the reason for the anticoagulation and the patient's history. The normal INR is 1.

*Partial thromboplastin time (PTT)* is assessed in patients who are receiving heparin (Hepalean). It measures deficiencies in all coagulation factors except VII and XIII.

*Arterial blood gas (ABG)* determinations are often obtained in patients with CVD. Determination of tissue oxygenation, carbon dioxide removal, and acid-base status is essential to appropriate treatment. (See [Chapter 12](#) for a complete discussion of ABGs.)

FLUID AND ELECTROLYTE BALANCE is essential for normal cardiovascular performance. Cardiac manifestations often occur when there is an imbalance in either fluids or electrolytes in the body. For example, the cardiac effects of hypokalemia (low serum potassium level) include increased electrical instability, ventricular dysrhythmias, and an increased risk for digitalis toxicity. The effects of hyperkalemia on the myocardium include slowed ventricular conduction, peaked T waves on the ECG, and contraction followed by asystole (cardiac standstill).

Cardiac manifestations of hypocalcemia are ventricular dysrhythmias, a prolonged QT interval, and cardiac arrest. Hypercalcemia shortens the QT interval and causes atrioventricular block, digitalis hypersensitivity, and cardiac arrest. Serum sodium values reflect fluid balance and may be decreased, indicating fluid excess in patients with heart failure (dilutional hyponatremia).

Because magnesium regulates some aspects of myocardial electrical activity, hypomagnesemia has been implicated in some forms of ventricular dysrhythmias known as *torsades de pointes*. Hypomagnesemia prolongs the QT interval, causing this specific type of ventricular tachycardia. [Chapter 11](#) describes these electrolytes in more detail.

The *erythrocyte (red blood cell [RBC]) count* is usually decreased in rheumatic fever and infective endocarditis. It is increased in heart diseases as needed to compensate for decreased available oxygen.

Decreased *hematocrit and hemoglobin* levels (e.g., caused by hemorrhage or hemolysis from prosthetic valves) indicate anemia and can lead to angina or aggravate heart failure. Vascular volume depletion with hemoconcentration (e.g., hypovolemic shock and excessive diuresis) results in an elevated hematocrit.

The *leukocyte (white blood cell [WBC]) count* typically is elevated after an MI and in various infectious and inflammatory diseases of the heart (e.g., infective endocarditis and pericarditis).

### Other Diagnostic Assessment

Posteroanterior (PA) and left lateral *x-ray* views of the chest are routinely obtained to determine the size, silhouette, and position of the heart. In acutely ill patients, a simple anteroposterior (AP) view may be obtained at the bedside. Cardiac enlargement, pulmonary congestion, cardiac calcifications, and placement of central venous catheters, endotracheal tubes, and hemodynamic monitoring devices are assessed by x-ray.

*Angiography* of the arterial vessels, or **arteriography**, is an invasive diagnostic procedure that involves fluoroscopy and the use of contrast media. This procedure is performed when an arterial obstruction, narrowing, or aneurysm is suspected. The interventional radiologist performs selective arteriography to evaluate specific areas of the arterial system. For example, a coronary arteriography, which is performed during left-sided cardiac catheterization, assesses arterial circulation within the heart. It can also be performed on arteries in the extremities, mesentery, and cerebrum. Angiography is discussed under the appropriate associated diseases elsewhere in this text.

### Cardiac Catheterization.

The most definitive but most invasive test in the diagnosis of heart disease is cardiac catheterization. **Cardiac catheterization** may include studies of the right or left side of the heart and the coronary arteries. Some of the most common indications for cardiac catheterization are listed in [Table 33-4](#).

**TABLE 33-4**  
**Indications for Cardiac Catheterization**

<ul style="list-style-type: none"> <li>• To confirm suspected heart disorders, including congenital abnormalities, coronary artery disease, myocardial disease, valvular disease, and valvular dysfunction</li> <li>• To determine the location and extent of the disease process</li> <li>• To assess:             <ul style="list-style-type: none"> <li>• Stable, severe angina unresponsive to medical management</li> <li>• Unstable angina pectoris</li> <li>• Uncontrolled heart failure, ventricular dysrhythmias, or cardiogenic shock associated with acute myocardial infarction, papillary muscle dysfunction, ventricular aneurysm, or septal perforation</li> </ul> </li> <li>• To determine best therapeutic option (percutaneous transluminal coronary angioplasty, stents, coronary artery bypass graft, valvulotomy versus valve replacement)</li> <li>• To evaluate effects of medical or invasive treatment on cardiovascular function, percutaneous transluminal coronary angioplasty, or coronary artery bypass graft patency</li> </ul>
--

### Patient Preparation.

Assess the patient's physical and psychosocial readiness and knowledge level about the procedure because many patients have anxiety and fear about cardiac catheterization. Review the purpose of the procedure, inform the patient about the length of the procedure, state who will be present, and describe the appearance of the catheterization laboratory. Tell the patient about the sensations that he or she may experience during the procedure, such as palpitations (as the catheter is passed up to the left ventricle), a feeling of heat or a hot flash (as the medium is injected into either side of the heart), and a desire to cough (as the medium is injected into the right side of the heart). Written, electronic, or illustrated materials or DVDs may be used to assist in understanding.

The cardiologist explains the risks of cardiac catheterization. The risks vary with the procedures to be performed and the patient's physical status ([Table 33-5](#)). Although not common, several serious complications may follow coronary arteriography, such as:

**TABLE 33-5**  
**Complications of Cardiac Catheterization**

<b>Right-Sided Heart Catheterization</b>
<ul style="list-style-type: none"> <li>• Thrombophlebitis</li> <li>• Pulmonary embolism</li> <li>• Vagal response</li> </ul>
<b>Left-Sided Heart Catheterization and Coronary Arteriography</b>

<ul style="list-style-type: none"> <li>• Myocardial infarction</li> <li>• Stroke</li> <li>• Arterial bleeding or thromboembolism</li> <li>• Dysrhythmias</li> </ul>
<b>Right-Sided or Left-Sided Heart Catheterization*</b>
<ul style="list-style-type: none"> <li>• Cardiac tamponade</li> <li>• Hypovolemia</li> <li>• Pulmonary edema</li> <li>• Hematoma or blood loss at insertion site</li> <li>• Reaction to contrast medium</li> </ul>

\*In addition to those cited for each procedure.

- Myocardial infarction (MI)
- Stroke
- Arterial bleeding
- Thromboembolism
- Lethal dysrhythmias
- Arterial dissection
- Death

The cardiologist or interventional radiologist obtains a written informed consent from the patient or responsible party before the procedure.

The patient is admitted to the hospital on the day of the catheterization procedure. He or she may be admitted earlier if there is renal dysfunction. Fluids may be given 12 to 24 hours before the procedure for renal protection. Contrast-induced renal dysfunction can result from vasoconstriction and the direct toxic effect of the contrast agent on the renal tubules. Hydration pre- and post-study helps eliminate or minimize contrast-induced renal toxicity.

Standard preoperative tests are performed, which usually include a chest x-ray, complete blood count, coagulation studies, and 12-lead ECG. Patients may ingest clear liquids up to 2 hours prior; solids and other liquids are held 6 hours before the procedure. The catheterization site is antiseptically prepared with hairs clipped according to agency policy.

Before the procedure, take the patient's vital signs, auscultate the heart and the lungs, and assess the peripheral pulses. Question him or her about any history of allergy to iodine-based contrast agents. An antihistamine or steroid may be given to a patient with a positive history or to prevent a reaction. **Be sure that the signed informed consent is completed, as required by The Joint Commission's National Patient Safety Goals (NPSGs).** A mild sedative is usually administered before the procedure. Certain medications, such as diuretics, may be held before the procedure. In addition, warfarin and other oral anticoagulants are held if it is anticipated that the femoral artery will be used for access. Analysis of electrolytes, blood urea nitrogen (BUN), creatinine, coagulation profile, and complete blood count (CBC) is essential before and after the procedure; and abnormalities are discussed with the health care provider.

### Procedure.

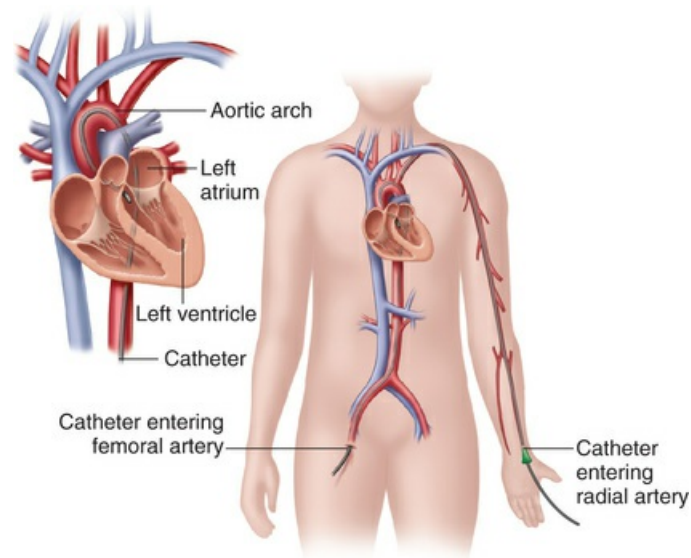

The patient is taken to the cardiac catheterization laboratory (sometimes referred to as the *cath lab*), placed in the supine position on the x-ray table, and securely strapped to the table. The physician injects a local anesthetic at the insertion site. During the procedure, the patient is instructed to report any chest pain, pressure, or other symptoms to the staff.

The *right side of the heart* is catheterized first and may be the only side examined. The cardiologist inserts a catheter through the femoral vein to the inferior vena cava or through the basilic vein to the superior vena cava. The catheter is advanced through either the inferior or the superior vena cava and, guided by fluoroscopy, is advanced through the right atrium, through the right ventricle, and, at times, into the pulmonary artery. Intracardiac pressures (right atrial, right ventricular, pulmonary artery, and pulmonary artery wedge pressures) and blood samples are obtained. A contrast medium is usually injected to detect any cardiac shunts or regurgitation from the pulmonic or tricuspid valves.

In a *left-sided heart catheterization*, the cardiologist advances the catheter against the blood flow from the femoral, brachial, or radial artery up the aorta, across the aortic valve, and into the left ventricle (Fig. 33-8). Radial artery access has recently become the most common access site for diagnostic heart catheterization examinations. Because of the size of stent delivery catheters, radial artery access is not possible for all patients. Alternatively, the catheter may be passed from the right side of the heart through the atrial septum, using a special needle to puncture the septum. Intracardiac pressures and blood samples are obtained. The pressures of the left atrium, left

ventricle, and aorta and mitral and aortic valve status are evaluated. The cardiologist injects contrast dye into the ventricle; digital subtraction angiography evaluates left ventricular motion. Calculations are made regarding end-systolic volume, end-diastolic volume, stroke volume, and ejection fraction.

**FIG. 33-8** Left-sided cardiac catheterization.

The technique for *coronary arteriography* is the same as for left-sided heart catheterization. The catheter is advanced into the aortic arch and positioned selectively in the right or left coronary artery. Injection of a contrast medium permits viewing the coronary arteries. By assessing the flow of the medium through the coronary arteries, information about the site and severity of coronary lesions is obtained.

An alternative to injecting a medium into the coronary arteries is **intravascular ultrasonography (IVUS)**, which introduces a flexible catheter with a miniature transducer at the distal tip to view the coronary arteries. The transducer emits sound waves, which reflect off the plaque and the arterial wall to create an image of the blood vessel. IVUS can be used in vessels as small as 2 mm to assess the nature of plaques or vessel condition following an intervention.

Fractional flow reserve (FFR) can also be assessed to determine if a blockage needs to be revascularized. FFR is an objective method to measure the flow across the stenosis in the coronary artery. A special pressure wire is passed through the area of stenosis, and measurements are taken proximal and distal to the area of stenosis. These two measurements are used to calculate the FFR. A measure of 0.8 or less indicates that the stenosis is clinically significant and the artery should be revascularized.

### Follow-Up Care.

The patient recovers in a specialty area equipped with monitored beds. After cardiac catheterization, restrict him or her to bedrest and keep the insertion site extremity straight. A soft knee brace can be applied to prevent bending of the affected extremity. Some cardiologists allow the head of the bed to be elevated up to 30 degrees during the period of bedrest, whereas others prefer that the patient remain supine. Current practice is for patients to remain in bed for 2 to 6 hours depending on the type of vascular closure device used. Various types of vascular closure devices are used to eliminate the need for manual compression after the catheterization. Examples include arteriotomy sutures and collagen plugs to seal the insertion site. Radial artery access is growing in popularity because it allows for a faster discharge (when compared with femoral access) and has fewer post-discharge restrictions on the patient than femoral or brachial artery access.

Monitor the patient's vital signs every 15 minutes for 1 hour, then every 30 minutes for 2 hours or until vital signs are stable, and then every 4 hours or according to agency policy. Assess the insertion site for bloody drainage or hematoma formation. Complications with vascular closure devices are not common but can be very serious. Assess peripheral pulses in the affected extremity

and skin temperature and color with every vital sign check. Observe for complications of cardiac catheterization (see [Table 33-5](#)).

## Nursing Safety Priority QSEN

### Critical Rescue

If the patient experiences symptoms of cardiac ischemia such as chest pain, dysrhythmias, bleeding, hematoma formation, or a dramatic change in peripheral pulses in the affected extremity, contact the Rapid Response Team or provider immediately to provide prompt intervention! Remain with the patient and obtain a 12-lead ECG for patients experiencing chest pain or dysrhythmias. For bleeding or hematoma formation, hold steady, firm pressure to the access site until the Rapid Response Team arrives. Neurologic changes indicating a possible stroke, such as visual disturbances, slurred speech, swallowing difficulties, and extremity weakness, should also be reported immediately.

Because the contrast medium acts as an osmotic diuretic, monitor urine output and ensure that the patient receives sufficient oral and IV fluids for adequate excretion of the medium. Pain medication for insertion site or back discomfort may be given as prescribed.

Review home instructions and risk factor modification with the patient before discharge. Remind the patient to:

- Limit activity for several days, including avoiding lifting and exercise
- Leave the dressing in place for at least the first day at home
- Observe the insertion site over the next few weeks for increased swelling, redness, warmth, and pain. (Bruising or a small hematoma is expected.)

## NCLEX Examination Challenge 33-3

### Physiological Integrity

Which statement made by the client on the way to the catheterization laboratory requires an **immediate** action by the nurse?

- A. "My allergies are bothering me, so I took some Benadryl last night before bed."
- B. "I was nervous last night, but I still remembered to take my warfarin."
- C. "I sure am hungry. I haven't had anything to eat since I went to bed last night."
- D. "I don't know what I will do if they find a blockage in my heart."

### Electrocardiography.

The electrocardiogram (ECG) is a routine part of every cardiovascular evaluation and is one of the most valuable diagnostic tests. Various forms are available: resting ECG, continuous ambulatory ECG (Holter monitoring), exercise ECG (stress test), signal-averaged ECG, and 30-day event monitoring. The resting ECG provides information about cardiac dysrhythmias, myocardial ischemia, the site and extent of MI, cardiac hypertrophy, electrolyte imbalances, and the effectiveness of cardiac drugs. The normal ECG pattern and a detailed discussion of the interpretation of abnormal patterns are discussed in [Chapter 34](#).

### Electrophysiologic Studies.

An **electrophysiologic study (EPS)** is an invasive procedure during which programmed electrical stimulation of the heart is used to cause and evaluate lethal dysrhythmias and conduction abnormalities. Patients who have survived cardiac arrest, have recurrent tachydysrhythmias, or experience unexplained syncopal episodes may be referred for EPS. Induction of the dysrhythmia

during EPS helps find an accurate diagnosis and aids in effective treatment. These procedures have risks similar to those for cardiac catheterization and are performed in a special catheterization laboratory, where conditions are strictly controlled and immediate treatment is available for any adverse effects.

### **Exercise Electrocardiography (Stress Test).**

The **exercise electrocardiography** test (also known as **exercise tolerance**, or **stress test**) assesses cardiovascular response to an increased workload. The stress test helps determine the functional capacity of the heart and screens for asymptomatic coronary artery disease. Dysrhythmias that develop during exercise may be identified, and the effectiveness of antidysrhythmic drugs can be evaluated.

#### **Patient Preparation.**

Because risks are associated with exercising, the patient must be adequately informed about the purpose of the test, the procedure, and the risks involved. Written consent must be obtained. Anxiety and fear are common before stress testing. Therefore assure the patient that the procedure is performed in a controlled environment in which prompt nursing and medical attention are available.

Instruct the patient to get plenty of rest the night before the procedure. He or she may have a light meal 2 hours before the test but should avoid smoking or drinking alcohol or caffeine-containing beverages on the day of the test. The cardiologist decides whether the patient should stop taking any cardiac medications. Usually cardiovascular drugs such as beta blockers or calcium channel blockers are withheld on the day of the test to allow the heart rate to increase during the stress portion of the test. Patients are advised to wear comfortable, loose clothing and rubber-soled, supportive shoes. Remind them to tell the provider if symptoms such as chest pain, dizziness, shortness of breath, and an irregular heartbeat are experienced during the test.

Before the stress test, a resting 12-lead ECG, cardiovascular history, and physical examination are performed to check for any ECG abnormalities or medical factors that might interfere with the test. Check to see that all emergency supplies such as cardiac drugs, a defibrillator, and other necessary resuscitation equipment are available in the room in which the stress test is performed. It is important to be proficient in the use of resuscitation equipment when assisting the provider because chest pain, dysrhythmias, and other ECG changes may occur.

#### **Procedure.**

The technician places electrodes on the patient's chest and attaches them to a multilead monitoring system. Note baseline blood pressure (BP), heart rate (HR), and respiratory rate. The two major modes of exercise available for stress testing are pedaling a bicycle ergometer and walking on a treadmill. A bicycle ergometer has a wheel operated by pedals that can be adjusted to increase the resistance to pedaling. The treadmill is a motorized device with an adjustable conveyor belt. It can reach speeds of 1 to 10 miles/hr and can also be adjusted from a flat position to a 22-degree incline.

After the patient is shown how to use the bicycle or walk on the treadmill, he or she begins to exercise. During the test, the BP and ECG are closely monitored as the resistance to cycling or the speed and incline of the treadmill are increased (Fig. 33-9). The patient exercises until one of these findings occurs:

**FIG. 33-9** Patient using a treadmill for a stress test. (From Baker, T., Nikolic, G., & O'Connor, S. (2008). *Practical cardiology*, (2nd ed.). Sydney: Churchill Livingstone Australia.)

- A predetermined HR is reached and maintained.
- Signs and symptoms such as chest pain, fatigue, extreme dyspnea, vertigo, hypotension, and ventricular dysrhythmias appear.
- Significant ST-segment depression or T-wave inversion occurs.
- The 20-minute protocol is completed.

#### Follow-Up Care.

After the test, the nurse or other qualified health care team member monitors the ECG and BP until the patient has completely recovered. After recovery, he or she can return home if the test was performed on an ambulatory basis. Advise him or her to avoid a hot shower for 1 to 2 hours after the test because this may cause hypotension. If he or she does not recover but continues to have pain or ventricular dysrhythmias or appears medically unstable, admission to a telemetry unit for observation is needed.

For patients who cannot exercise because of conditions such as peripheral vascular disease or arthritis, pharmacologic stress testing with inotropes such as dobutamine and a vasodilator such as adenosine, dipyridamole, or regadenoson may be indicated. The nursing considerations are similar to those for the patient who has undergone an exercise ECG.

#### Echocardiography.

As a noninvasive, risk-free test, echocardiography is easily performed at the bedside or on an ambulatory care basis. **Echocardiography** uses ultrasound waves to assess cardiac structure and mobility, particularly of the valves. It helps assess and diagnose cardiomyopathy, valvular disorders, pericardial effusion, left ventricular function, ventricular aneurysms, and cardiac tumors.

There is no special *preparation* for echocardiography. Inform the patient that the test is painless and takes 30 to 60 minutes to complete. The patient is instructed to lie quietly during the test and on his or her left side with the head elevated 15 to 20 degrees.

*During* an echocardiogram, a small transducer lubricated with gel to facilitate movement and conduction is placed on the patient's chest at the level of the third or fourth intercostal space near the left sternal border. The transducer transmits high-frequency sound waves and receives them as they are reflected from different structures. These echoes are usually videotaped simultaneously with the echocardiogram and can be recorded on graph paper for a permanent record.

After the images are taped, cardiac measurements that require several images can be obtained. Routine measurements include chamber size, ejection fraction, and flow gradient across the valves. There is no specific *follow-up care* for a patient who has undergone an echocardiogram.

A slightly more aggressive form of echocardiogram is a **pharmacologic stress echocardiogram** using either dobutamine or dipyridamole. This test is usually used when patients cannot tolerate exercise. Dobutamine (Dobutrex) increases the heart's contractility; dipyridamole (Persantine, Apo-Dipyridamole) is a coronary artery dilator. Patients are required to be NPO for 3 to 6 hours before the test, except for sips of water with medications. The technician ensures that IV access is present

before the procedure and monitors BP and pulse continuously throughout the procedure. After the procedure, vital signs are monitored until BP returns to baseline and the pulse rate slows to less than 100 beats/min.

### Transesophageal Echocardiography.

Echocardiograms may also be performed transesophageally (through the esophagus).

**Transesophageal echocardiography (TEE)** examines cardiac structure and function with an ultrasound transducer placed immediately behind the heart in the esophagus or stomach. The transducer provides especially detailed views of posterior cardiac structures such as the left atrium, mitral valve, and aortic arch. Preparation and follow-up are similar to that for an upper GI endoscopic examination (see [Chapter 52](#)).

### Myocardial Nuclear Perfusion Imaging.

The use of radionuclide techniques in cardiovascular assessment is called **myocardial nuclear perfusion imaging (MNPI)**. Cardiovascular abnormalities can be viewed, recorded, and evaluated using radioactive tracer substances. These studies are useful for detecting myocardial infarction (MI) and decreased myocardial blood flow and for evaluating left ventricular ejection. Conducting myocardial nuclear imaging tests, in conjunction with exercise or the administration of vasodilating agents, allows clearer identification of how the heart responds to stress.

Inform the patient that these tests are noninvasive. Because the amount of radioisotope is small, radiation exposure risks are minimal. If a dilating agent is to be used, advise the patient to avoid cigarettes and caffeinated food or drinks for 4 hours before administration of the vasodilator.

Common tests in nuclear cardiology include technetium ( $^{99m}\text{Tc}$ ) pyrophosphate scanning, thallium imaging, and multigated cardiac blood pool imaging. Each test requires the injection of different types of radioactive isotopes into the antecubital vein. After the cells and tissues have time to take up the radioactive substances, usually 10 minutes to 2 hours, nuclear imaging can detect the difference between healthy and unhealthy tissue.

During the *technetium scan*, radioisotopes ( $^{99m}\text{Tc}$  pyrophosphate) accumulate in damaged myocardial tissue, which appears as a “hot spot” during the scan. This test helps detect the location and size of acute myocardial infarctions.

Alternatively, during the *thallium imaging scan*, necrotic or ischemic tissue does not absorb the radioisotope (thallium-201) and appears as “cold spots” on the scan. Thallium imaging is used to assess myocardial scarring and perfusion, to detect the location and extent of an acute or chronic myocardial infarction, to evaluate graft patency after coronary bypass surgery, and to evaluate antianginal therapy, thrombolytic therapy, or balloon angioplasty.

Thallium imaging may be performed during an exercise test or with the patient at rest. Thallium imaging performed during an exercise test may demonstrate perfusion deficits not apparent at rest. First the stress test procedure is performed. After the patient reaches maximum activity level, a small dose of thallium-201 is injected IV. The patient continues to exercise for about 1 to 2 minutes, after which the scanning is performed. Nuclear cardiologists often compare the resting and stress images to differentiate between fixed and reversible defects in the myocardium.

If a patient cannot exercise on a bike or treadmill, dipyridamole (Persantine, Apo-Dipyridamole) or dobutamine hydrochloride (Dobutrex) is administered to simulate the effects of exercise. Tell the patient that these vasodilators may cause flushing, headache, dyspnea, and chest tightness for a few moments after injection.

*Cardiac blood pool imaging* is a noninvasive test for evaluating cardiac motion and calculating ejection fraction. It uses a computer to synchronize the patient's ECG with pictures taken by a special camera. The technician attaches the patient to an ECG and injects a small amount of  $^{99m}\text{Tc}$  IV. The radioisotope is not taken up by tissue but remains “tagged” to red blood cells in the circulation. The camera may take pictures of the radioactive material as it makes its first pass through the heart.

During **multigated blood pool scanning**, the computer breaks the time between R waves on the ECG into fractions of a second, called *gates*. The camera records blood flow through the heart during each of these gates. By analyzing the information from multiple gates, the computer can evaluate the ventricular wall motion and calculate ejection fraction (percentage of the left ventricular volume that is ejected with each contraction) and ejection velocity. Areas of decreased, absent, or paradoxical movement of the left ventricle may also be identified.

*Positron emission tomography (PET)* scans are used to compare cardiac perfusion and metabolic

function and differentiate normal from diseased myocardium. The technician administers the first radioisotope (nitrogen-13-ammonia) and then begins a 20-minute scan to detect myocardial perfusion. Next the technician administers a second radioisotope (fluoro-18-deoxyglucose). After a pause, a second scan is performed to detect the metabolically active myocardium, which is using glucose.

The two scans are compared. In a normal heart, performance and metabolic function will match. In an ischemic heart, there will be a mismatch (i.e., a reduction in perfusion and increased glucose uptake by the ischemic myocardium). The scanning procedure takes 2 to 3 hours, and the patient may be asked to use a treadmill or exercise bicycle in conjunction with the scan.

Depending on which test is performed, the patient may report fatigue or discomfort at the antecubital injection site. If a stress test was paired with the study, he or she will need follow-up care for the stress test.

### **Computed Tomography Imaging.**

Cardiac computed tomography (CT) imaging is a noninvasive option to evaluate calcium formation in the coronary arteries. This modality requires a low resting heart rate as images are taken during end systole and mid-diastole. Beta blockers or calcium channel blockers may be given to assist with slowing the heart rate. Coronary artery calcium (CAC) calculation is often performed during the CT and may help identify patients at risk for coronary artery disease. To identify areas of stenosis, ionated contrast may be administered IV to visualize the coronary arteries. This is referred to as *CT angiography (CTA)*. Presence of coronary stents can make this test less reliable. Use of IV ionated contrast puts the patient at risk for contrast-induced nephropathy (CIN) or renal damage. Assess renal function before and after the test and ensure adequate hydration by administering IV fluids as ordered. Encourage oral fluids after testing.

### **Magnetic Resonance Imaging.**

Magnetic resonance imaging (MRI) is a noninvasive diagnostic option. An image of the heart or great vessels is produced through the interaction of magnetic fields, radio waves, and atomic nuclei showing hydrogen density. Simply put, the radio waves “bounce off” the body tissue being examined. Because each tissue has its own density, the computer image clearly differentiates between various types of tissues. MRI permits determination of cardiac wall thickness, chamber dilation, valve and ventricular function, and blood movement in the great vessels. Improved MRI techniques allow coronary artery blood flow to be mapped with nearly the accuracy of a cardiac catheterization.

Before an MRI, ensure that the patient has removed all metallic objects, including watches, jewelry, clothing with metal fasteners, and hair clips. Patients with pacemakers or implanted defibrillators may not be able to have an MRI because the magnetic fields can deactivate them. However, some newer MRI machines have eliminated this complication. A few patients may experience claustrophobia during the 15 to 60 minutes required to complete the scan.

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Assess patients for allergy to iodine-based contrast media before having invasive diagnostic tests requiring an iodine-based contrast agent. **QSEN: Safety**
- After invasive cardiovascular diagnostic testing, such as angiography and cardiac catheterization, monitor the insertion site for bleeding and hematoma formation. **QSEN: Safety**
- Assess vital signs carefully in patients having invasive cardiovascular testing; report and document any new dysrhythmias after testing. **QSEN: Informatics**

### Health Promotion and Maintenance

- Identify patients at risk for cardiovascular disease, especially those with hyperlipidemia, hypertension, excess weight, physical inactivity, smoking, psychological stress, a positive family history, and diabetes. **QSEN: Evidence-Based Practice**
- Teach patients how to reduce the risk for heart disease through modifiable factors such as exercise, diet modification, smoking cessation, and medications, as needed. **QSEN: Patient-Centered Care**
- Inform patients that genetics and other nonmodifiable risk factors, such as family history and gender, contribute to the development of coronary artery disease (CAD). **QSEN: Evidence-Based Practice**
- Assess the older adult for cardiovascular changes associated with aging as described in [Chart 33-1](#). **QSEN: Safety**

### Psychosocial Integrity

- Discuss with the patient any feelings or concerns that he or she might have about the stress of cardiac illness, diagnostic testing, or other issues and use therapeutic measures to decrease anxiety. **QSEN: Patient-Centered Care**
- Recognize that denial is a common and normal response to help patients cope with threatening circumstances. **QSEN: Patient-Centered Care**
- Be aware that coping behaviors of those who have cardiovascular problems vary from patient to patient. **QSEN: Patient-Centered Care**
- Allow the patient to express feelings about an actual or perceived loss of health or social status related to cardiovascular disease. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Be aware of the importance of recalling the anatomy and physiology of the cardiovascular (CV) system to best understand how to care for patients with CV health problems. **Clinical Judgment**
- Assess the patient's report of pain to differentiate the pain of angina and myocardial infarction (MI) from other noncardiac causes; *discomfort, indigestion, squeezing, heaviness, and viselike* are common terms used to describe chest pain of cardiac origin. **Clinical Judgment**
- Be aware that gender differences in CVD exist; with women often experiencing more vague symptoms such as fatigue, indigestion, and shortness of breath. **Health Care Disparities**
- Recall that syncope is a transient loss of consciousness and is common in older adults.
- Be aware that the veteran population has increased risk for development of cardiovascular disease. **Health Care Disparities**

- Assess for bruits, which are swishing sounds that develop in narrowed arteries. **QSEN: Patient-Centered Care**
- Auscultate the heart for normal first and second sounds and for abnormalities such as an  $S_3$ ,  $S_4$  murmur, or gallop. **QSEN: Patient-Centered Care**
- Monitor serum markers of myocardial damage and other cardiac-related laboratory tests as listed in [Chart 33-2](#). **QSEN: Patient-Centered Care**
- Prepare patients having a cardiac catheterization for expectations of the procedure and postprocedure care. **QSEN: Patient-Centered Care**
- Assess patients having cardiac catheterizations for potential complications as listed in [Table 33-5](#). **QSEN: Safety**
- Include all relevant findings of the patient's CV assessment in the electronic health record. **QSEN: Informatics**

## CHAPTER 34

# Care of Patients With Dysrhythmias

Laura M. Dechant, Nicole M. Heimgartner

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is PERFUSION.**

✚ The PERFUSION concept exemplar for this chapter is Atrial Fibrillation, p. 678.

**The interrelated concepts for this chapter are:**

- FLUID AND ELECTROLYTE BALANCE
- CLOTTING

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to coordinate high-quality care to promote PERFUSION in patients with dysrhythmias.
2. Provide a safe environment for patients and staff when using a cardiac defibrillator.

### Health Promotion and Maintenance

3. Teach the patient and caregiver(s) about drug therapy used for common dysrhythmias.
4. Teach the patient with a pacemaker or implantable cardioverter/defibrillator about self-management when in the community.

### Psychosocial Integrity

5. Implement patient and family-centered nursing interventions to decrease the psychosocial impact caused by life-threatening dysrhythmias and emergency care procedures.

### Physiological Integrity

6. Apply knowledge of pathophysiology to assess patients with common dysrhythmias.
7. Analyze an ECG rhythm strip to identify normal sinus rhythm and common or life-threatening dysrhythmias.
8. Use clinical judgment to plan care coordination and transition management for patients experiencing common dysrhythmias.
9. Plan evidence-based nursing care to promote PERFUSION to prevent complications in patients experiencing dysrhythmias.
0. Explain the need to perform evidence-based emergency care procedures, such as cardiopulmonary resuscitation (CPR) and automated external defibrillation.

The heart is an intricate pump that works to perfuse the body. When the heart does not work effectively as a pump, PERFUSION to vital organs and peripheral tissues can be impaired, resulting in organ dysfunction or failure. Cardiac dysrhythmias are abnormal rhythms of the heart's electrical system that can affect its ability to effectively pump *oxygenated* blood throughout the body. Some dysrhythmias are life threatening, and others are not. They are the result of disturbances in cardiac electrical impulse formation, conduction, or both.

Many health problems, especially coronary artery disease (CAD), electrolyte imbalances,

impaired gas exchange, and drug toxicity (both legal and illicit drugs), can cause abnormal heart rhythms. Dysrhythmias can occur in people of any age but occur most often in older adults. To provide collaborative patient-centered care using best practices, a *basic* understanding of cardiac electrophysiology, the conduction system of the heart, and the principles of electrocardiography is needed as a medical-surgical nurse. Specialty nurses and advanced practice nurses have a more in-depth knowledge because they manage patients with these cardiac problems in critical care and ambulatory care settings.

## Review of Cardiac Conduction System

Conduction begins with the **sinoatrial (SA) node** (also called the *sinus node*), located close to the surface of the right atrium near its junction with the superior vena cava. *The SA node is the heart's primary pacemaker.* It can spontaneously and rhythmically generate electrical impulses at a rate of 60 to 100 beats/min and therefore has the greatest degree of automaticity (pacing function). The SA node is richly supplied by the sympathetic and parasympathetic nervous systems, which increase and decrease the rate of discharge of the sinus node, respectively. This process results in changes in the heart rate.

Impulses from the sinus node move directly through atrial muscle and lead to atrial depolarization, which is *reflected in a P wave on the electrocardiogram (ECG).* Atrial muscle contraction should follow. Within the atrial muscle are slow and fast conduction pathways leading to the atrioventricular (AV) node.

The **atrioventricular (AV) junctional** area consists of a transitional cell zone, the AV node itself, and the bundle of His. The AV node lies just beneath the right atrial endocardium, between the tricuspid valve and the ostium of the coronary sinus. Here T-cells (transitional cells) cause impulses to slow down or be delayed in the AV node before proceeding to the ventricles. This delay is reflected in the *PR segment* on the ECG. This slow conduction provides a short delay, allowing the atria to contract and the ventricles to fill. The contraction is known as *atrial kick* and contributes additional blood volume for a greater cardiac output. The AV node is also controlled by both the sympathetic and the parasympathetic nervous systems. The bundle of His connects with the distal portion of the AV node and continues through the interventricular septum.

The *bundle of His* extends as a right bundle branch down the right side of the interventricular septum to the apex of the right ventricle. On the left side, it extends as a left bundle branch, which further divides.

At the ends of both the right and the left bundle branch systems are the Purkinje fibers. These fibers are an interweaving network located on the endocardial surface of both ventricles, from apex to base. The fibers then partially penetrate into the myocardium. **Purkinje cells** make up the bundle of His, bundle branches, and terminal Purkinje fibers. These cells are responsible for the rapid conduction of electrical impulses throughout the ventricles, leading to ventricular depolarization and the subsequent ventricular muscle contraction. A few nodal cells in the ventricles also occasionally demonstrate automaticity, giving rise to ventricular beats or rhythms.

The cardiac conduction system consists of specialized myocardial cells ([Fig. 34-1](#)). The electrophysiologic properties of these cells regulate heart rate and rhythm and possess unique properties: automaticity, excitability, conductivity, and contractility.

**FIG. 34-1** The cardiac conduction system.

**Automaticity** (pacing function) is the ability of cardiac cells to generate an electrical impulse spontaneously and repetitively. Normally only the sinoatrial (SA) node can generate an electrical impulse. However, under certain conditions, such as myocardial ischemia (decreased blood flow), electrolyte imbalance, hypoxia, drug toxicity, and infarction (cell death), any cardiac cell may produce electrical impulses independently and create dysrhythmias. Disturbances in automaticity may involve either an increase or a decrease in pacing function.

**Excitability** is the ability of nonpacemaker heart cells to respond to an electrical impulse that begins in pacemaker cells. **Depolarization** occurs when the normally negatively charged cells within the heart muscle develop a positive charge.

**Conductivity** is the ability to send an electrical stimulus from cell membrane to cell membrane. As a result, excitable cells depolarize in rapid succession from cell to cell until all cells have depolarized. The wave of depolarization causes the deflections in the ECG waveforms that are recognized as the P wave and the QRS complex. Disturbances in conduction result when conduction is too rapid or too slow, when the pathway is totally blocked, or when the electrical impulse travels an abnormal pathway.

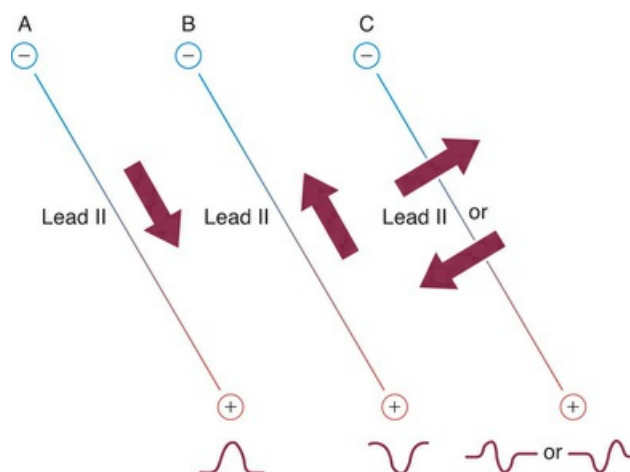

**Contractility** is the ability of atrial and ventricular muscle cells to shorten their fiber length in response to electrical stimulation, causing sufficient pressure to push blood forward through the heart. In other words, *contractility is the mechanical activity of the heart.*

## Electrocardiography

The **electrocardiogram (ECG)** provides a graphic representation, or picture, of cardiac electrical activity. The cardiac electrical currents are transmitted to the body surface. Electrodes, consisting of a conductive gel on an adhesive pad, are placed on specific sites on the body and attached to cables connected to an ECG machine or to a monitor. The cardiac electrical current is transmitted via the electrodes and through the lead wires to the machine or monitor, which displays the cardiac electrical activity. A **lead** provides one view of the heart's electrical activity. Multiple leads, or views, can be obtained. Electrode placement is the same for male and female patients.

Lead systems are made up of a positive pole and a negative pole. An imaginary line joining these two poles is called the **lead axis**. The direction of electrical current flow in the heart is the **cardiac axis**. The relationship between the cardiac axis and the lead axis is responsible for the deflections seen on the ECG pattern:

- The baseline is the **isoelectric** line. It occurs when there is no current flow in the heart after complete depolarization and also after complete repolarization. Positive deflections occur above this line, and negative deflections occur below it. Deflections represent depolarization and repolarization of cells.
- If the direction of electrical current flow in the heart (cardiac axis) is toward the positive pole, a **positive deflection** (above the baseline) is viewed (Fig. 34-2A).

**FIG. 34-2** A, The cardiac axis (*bold arrow*) is parallel to the lead axis (*the line between the negative and the positive electrodes*), going toward the positive electrode; a positive deflection is inscribed. B, The cardiac axis is parallel to the lead axis, going toward the negative electrode; a negative deflection is inscribed. C, The cardiac axis is perpendicular to the lead axis, going neither toward the positive electrode nor toward the negative electrode; a biphasic deflection is inscribed.

- If the direction of electrical current flow in the heart (cardiac axis) is moving away from the positive pole toward the negative pole, a **negative deflection** (below the baseline) is viewed (Fig. 34-2B).
- If the cardiac axis is moving neither toward nor away from the positive pole, a biphasic complex (both above and below baseline) will result (Fig. 34-2C).

### Lead Systems

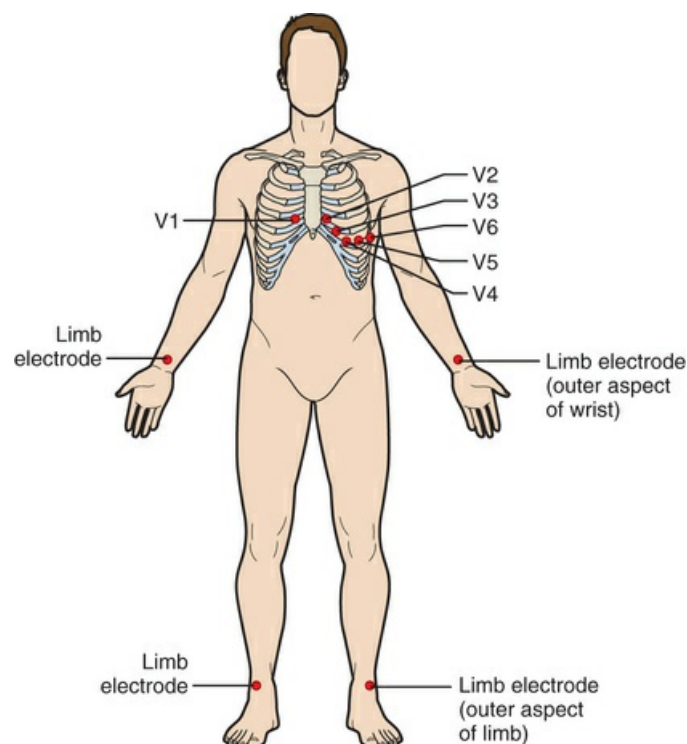

The standard 12-lead ECG consists of 12 leads (or views) of the heart's electrical activity. Six of the leads are called *limb leads* because the electrodes are placed on the four extremities in the frontal plane. The remaining six leads are called *chest (precordial) leads* because the electrodes are placed on the chest in the horizontal plane.

Standard bipolar *limb leads* consist of three leads (I, II, and III) that each measure the electrical activity between two points and a fourth lead (right leg) that acts as a ground electrode. Of the three measuring leads, the right arm is always negative, the left leg is always positive, and the left arm

can be either positive or negative.

Other lead systems include the 18-lead ECG, which adds six leads placed on the horizontal plane on the right side of the chest to view the right side of the heart. This is sometimes referred to as a *right-sided ECG*. The extra leads are sometimes placed on the back. Unipolar limb leads consist of a positive electrode only. The unipolar limb leads are aVR, aVL, and aVF, with *a* meaning augmented; *V* is a designation for a unipolar lead. The third letter denotes the positive electrode placement: *R* for right arm, *L* for left arm, and *F* for foot (left leg). The positive electrode is at one end of the lead axis. The other end is the center of the electrical field, at about the center of the heart.

There are six unipolar (or *V*) *chest leads*, determined by the placement of the chest electrode. The four limb electrodes are placed on the extremities, as designated on each electrode (right arm, left arm, right leg, and left leg). The fifth (chest) electrode on a monitor system is the positive, or exploring, electrode and is placed in one of six designated positions to obtain the desired chest lead. With a 12-lead ECG, four leads are placed on the limbs, and six are placed on the chest, eliminating the need to move any electrodes about the chest (Fig. 34-3).

**FIG. 34-3** Electrode positions for 12-lead ECG.

Positioning of the electrodes is crucial in obtaining an accurate ECG. Comparisons of ECGs taken at different times will be valid only when electrode placement is accurate and identical at each test. Positioning is particularly important when working with patients with chest deformities or large breasts. Patients may be asked to move the breasts to ensure proper electrode placement. For serial ECGs, a surgical marker may be used to mark the electrode placement site to allow for accurate placement. It is important to remove the electrodes following the ECG because skin breakdown can occur.

While obtaining a 12-lead ECG, remind the patient to be as still as possible in a semi-reclined position, breathing normally. Any repetitive movement will cause artifact and could lead to inaccurate interpretation of the ECG.

Nurses are sometimes responsible for obtaining 12-lead ECGs; but more commonly, technicians are trained to perform this skill. Remind the technician to notify the nurse or physician of any suspected abnormality. A nurse may direct a technician to take a 12-lead ECG on a patient experiencing chest pain to observe for diagnostic changes, but it is ultimately the primary health care provider's responsibility to definitively interpret the ECG.

## Continuous Electrocardiographic Monitoring

For continuous ECG monitoring, the electrodes are not placed on the limbs because movement of the extremities causes “noise,” or motion artifact, on the ECG signal. Place the electrodes on the trunk, a more stable area, to minimize such artifacts and to obtain a clearer signal. If the monitoring system provides five electrode cables, place the electrodes as follows:

- Right arm electrode just below the right clavicle
- Left arm electrode just below the left clavicle
- Right leg electrode on the lowest palpable rib, on the right midclavicular line
- Left leg electrode on the lowest palpable rib, on the left midclavicular line
- Fifth electrode placed to obtain one of the six chest leads

With this placement, the monitor lead-select control may be changed to provide lead I, II, III, aVR, aVL, aVF, or one chest lead. The monitor automatically alters the polarity of the electrodes to provide the lead selected.

The clarity of continuous ECG monitor recordings is affected by skin preparation and electrode quality. To ensure the best signal transmission and decrease skin impedance, clean the skin and clip hairs if needed. Make sure that the area for electrode placement is dry. The gel on each electrode must be moist and fresh. Attach the electrode to the lead cable and then to the contact site. The contact site should be free of any lotion, tincture, or other substance that increases skin impedance. Electrodes cannot be placed on irritated skin or over scar tissue. Electrodes may be applied by unlicensed assistive personnel (UAP), but the nurse determines which lead to select and checks for correct electrode placement. Assess the quality of the ECG rhythm transmission to the monitoring system.

The ECG cables can be attached directly to a wall-mounted monitor (a hard-wired system) if the patient's activity is restricted to bedrest and sitting in a chair, as in a critical care unit. For an ambulatory patient, the ECG cable is attached to a battery-operated transmitter (a **telemetry** system) held in a pouch. The ECG is transmitted to a remote monitor via antennae located in strategic places, usually in the ceiling. Telemetry allows freedom of movement within a certain area without losing transmission of the ECG.

Most acute care facilities have monitor technicians (monitor “techs”) who are educated in ECG rhythm interpretation and are responsible for:

- Watching a bank of monitors on a unit
- Printing ECG rhythm strips routinely and as needed
- Interpreting rhythms
- Reporting the patient's rhythm and significant changes to the nurse

The technical support is particularly helpful on a telemetry unit that does not have monitors at the bedside. The nurse is responsible for accurate patient assessment and management.

Some units have full-disclosure monitors, which continuously store ECG rhythms in memory up to a certain amount of time. This system allows nurses and health care providers to access and print rhythm strips for more thorough patient assessment. Routine strips and any changes in rhythm are printed and documented in the patient's record.

The health care provider is responsible for determining when monitoring can be suspended, such as during showering. He or she also determines whether monitoring is needed during off-unit testing procedures and for transportation to other facilities. Clinical alarms, such as those associated with continuous ECG monitoring, have been identified as one of the top ten technology hazards. The Joint Commission has responded to this hazard with a National Patient Safety Goal to improve the safety of clinical alarms. As part of implementation, hospitals are asked to implement specific policy and procedure regarding clinical alarm safety. Lukasewicz & Mattox (2015) suggest that the best method for reduction of alarm hazards is through proactive alarm management. *Think carefully before suspending an alarm or adjusting alarm parameters* and be informed regarding organizational policy regarding alarm management. (See the Quality Improvement box for proactive alarm management.)

## Proper Skin Preparation and Electrode Placement to Decrease Clinical Alarms

Walsh-Irwin, C., & Jurgens, C. (2015). Proper skin preparation and electrode placement decreases alarms on a telemetry unit. *Dimensions of Critical Care Nursing*. 34(3). doi: 10.1097.

For patients who have cardiovascular disease, electrocardiogram (ECG) monitoring is common practice and an integral part of safe care within the hospital setting. However, with ECG monitoring comes the responsibility of alarm management. Walsh-Irwin & Jurgens (2015) estimate that 85% to 99% of ECG alarms are false. Repeated response leads to alarm fatigue, which is the desensitization of nurses to clinical alarms as a result of an overload of alarms. Alarm fatigue has resulted in sentinel events creating national concern. Current studies indicate that nurses do not properly prepare the skin for electrode placement before monitoring.

As a result of existing research, a quality improvement project was initiated at Veterans' Hospital to test the effect of proper skin preparation and ECG electrode placement on the number of alarms on a telemetry unit. This study was an application of current evidence on a standard of care. Telemetry alarms were measured for 24 hours. Following the baseline assessment, electrodes were replaced using proper skin preparation. The following steps were used: (1) clip hair; (2) wash skin with soap and water; (3) dry skin with washcloth; (4) attach electrodes to leads; and (5) place electrodes in correct anatomical position. Following the change in electrodes, alarms were monitored again for a 24-hour period with mean results showing a 44% decrease in alarms.

### Commentary: Implications for Practice and Research

The Joint Commission's (TJC's) National Patient Safety Goal specific to alarm management requires alarm management strategies. These strategies include educating staff about alarms and developing policy and procedure for alarm management. This quality improvement study provides additional evidence that proper skin preparation and correct electrode placement will decrease clinical alarms. In addition, this project clearly demonstrates implementation of TJC's National Patient Safety Goal. Although these steps may take additional time, the safety benefits are clear. Additional research to address parameters for alarms is needed to determine best practice.

Prehospital personnel, such as paramedics and emergency medical technicians (EMTs) with advanced training, frequently monitor ECG rhythms at the scene and on the way to a health care facility. They function under medical direction and protocols but may also be communicating with a nurse in the emergency department.

The ECG strip is printed on graph paper (Fig. 34-4), with each small block measuring 1 mm in height and width. ECG recorders and monitors are standardized at a speed of 25 mm/sec. Time is measured on the horizontal axis. At this speed, each small block represents 0.04 second. Five small blocks make up one large block, defined by darker bold lines and representing 0.20 second. Five large blocks represent 1 second, and 30 large blocks represent 6 seconds. Vertical lines in the top margin of the graph paper are usually 15 large blocks apart, representing 3-second segments (Fig. 34-5).

**FIG. 34-4** Electrocardiographic waveforms are measured in amplitude (voltage) and duration (time).

**FIG. 34-5** Each segment between the dark lines (*above the monitor strip*) represents 3 seconds when the monitor is set at a speed of 25 mm per second. To estimate the ventricular rate, count the QRS complexes in a 6-second strip and multiply that number by 10 to estimate the rate for 1 minute. In this example, there are 9 QRS complexes in 6 seconds. Therefore the heart rate can be estimated to be 90 beats/min.

### Electrocardiographic Complexes, Segments, and Intervals

Complexes that make up a normal ECG consist of a P wave, a QRS complex, a T wave, and possibly a U wave. Segments include the PR segment, the ST segment, and the TP segment. Intervals include the PR interval, the QRS duration, and the QT interval (Fig. 34-6).

- P wave:** Represents atrial depolarization.
- PR segment:** Represents the time required for the impulse to travel through the AV node, where it is delayed, and through the bundle of His, bundle branches, and Purkinje fiber network, just before ventricular depolarization.
- PR interval:** Represents the time required for atrial depolarization as well as impulse travel through the conduction system and Purkinje fiber network, inclusive of the P wave and PR segment. It is measured from the beginning of the P wave to the end of the PR segment.
- QRS complex:** Represents ventricular depolarization and is measured from the beginning of the Q (or R) wave to the end of the S wave.
- J point:** Represents the junction where the QRS complex ends and the ST segment begins.
- ST segment:** Represents early ventricular repolarization.
- T wave:** Represents ventricular repolarization.
- U wave:** Represents late ventricular repolarization.
- QT interval:** Represents the total time required for ventricular depolarization and repolarization and is measured from the beginning of the QRS complex to the end of the T wave.

**FIG. 34-6** The components of a normal electrocardiogram.

The **P wave** is a deflection representing atrial depolarization. The shape of the P wave may be a positive, negative, or biphasic (both positive and negative) deflection, depending on the lead selected. When the electrical impulse is consistently generated from the sinoatrial (SA) node, the P waves have a consistent shape in a given lead. If an impulse is then generated from a different (ectopic) focus, such as atrial tissue, the shape of the P wave changes in that lead, indicating that an ectopic focus has fired.

The **PR segment** is the isoelectric line from the end of the P wave to the beginning of the QRS complex, when the electrical impulse is traveling through the atrioventricular (AV) node, where it is delayed. It then travels through the ventricular conduction system to the Purkinje fibers.

The **PR interval** is measured from the beginning of the P wave to the end of the PR segment. It represents the time required for atrial depolarization, the impulse delay in the AV node, and the travel time to the Purkinje fibers. It normally measures from 0.12 to 0.20 second (five small blocks).

The **QRS complex** represents ventricular depolarization. The shape of the QRS complex depends on the lead selected. The Q wave is the first negative deflection and is not present in all leads. When present, it is small and represents initial ventricular septal depolarization. When the Q wave is abnormally present in a lead, it represents myocardial necrosis (cell death). The R wave is the first positive deflection. It may be small, large, or absent, depending on the lead. The S wave is a negative deflection following the R wave and is not present in all leads.

The **QRS duration** represents the time required for depolarization of both ventricles. It is

measured from the beginning of the QRS complex to the **J** point (the junction where the QRS complex ends and the ST segment begins). It normally measures from 0.04 to 0.12 second (up to three small blocks).

The **ST segment** is normally an isoelectric line and represents early ventricular repolarization. It occurs from the **J** point to the beginning of the T wave. Its length varies with changes in the heart rate, the administration of medications, and electrolyte disturbances.

The **T wave** follows the ST segment and represents ventricular repolarization. It is usually positive, rounded, and slightly asymmetric. T waves may become tall and peaked; inverted (negative); or flat as a result of myocardial ischemia, potassium or calcium imbalances, medications, or autonomic nervous system effects.

The **U wave**, when present, follows the T wave and may result from slow repolarization of ventricular Purkinje fibers. It is of the same polarity as the T wave, although generally it is smaller. It is not normally seen in all leads and is more common in lead V<sub>3</sub>. An abnormal U wave may suggest an electrolyte abnormality (particularly hypokalemia) or other disturbance. Correct identification is important so it is not mistaken for a P wave. If in doubt, notify the primary health care provider and request that a potassium level be obtained.

The **QT interval** represents the total time required for ventricular depolarization and repolarization. The QT interval is measured from the beginning of the Q wave to the end of the T wave. This interval varies with the patient's age and gender and changes with the heart rate, lengthening with slower heart rates and shortening with faster rates. It may be prolonged by certain medications, electrolyte disturbances, or subarachnoid hemorrhage. A prolonged QT interval may lead to a unique type of ventricular tachycardia called *torsades de pointes*.

**Artifact** is interference seen on the monitor or rhythm strip, which may look like a wandering or fuzzy baseline. It can be caused by patient movement, loose or defective electrodes, improper grounding, or faulty ECG equipment such as broken wires or cables. Some artifact can mimic lethal dysrhythmias such as ventricular tachycardia (with toothbrushing) or ventricular fibrillation (with tapping on the electrode). *Assess the patient to differentiate artifact from actual lethal rhythms! Do not rely only on the ECG monitor.*

## Electrocardiographic Rhythm Analysis

Analysis of an ECG rhythm strip requires a systematic approach using an eight-step method facilitated by use of a measurement tool called an **ECG caliper** (Palmer, 2011):

1. **Determine the heart rate.** The most common method is to count the number of QRS complexes in 6 seconds and multiply that number by 10 to calculate the rate for a full minute. This is called the *6-second strip method* and is a quick method to determine the mean or *average* heart rate. Normal heart rates fall between 60 and 100 beats/min. A rate less than 60 beats/min is called **bradycardia**. A rate greater than 100 beats/min is called **tachycardia**. Current monitoring systems will display a continuous heart rate and print it on the ECG strip. *Use caution and confirm that the rate is correct by assessing the patient's heart rate directly.* Many factors can incorrectly alter the rate displayed by the monitor.

2. **Determine the heart rhythm.** Assess for atrial and/or ventricular regularity. Heart rhythms can be either regular or irregular. Irregular rhythms can be regularly irregular, occasionally irregular, or irregularly irregular. Check the regularity of the atrial rhythm by assessing the PP intervals, placing one caliper point on a P wave and the other point on the precise spot on the next P wave. Then move the caliper from P wave to P wave along the entire strip ("walking out" the P waves) to determine the regularity of the rhythm. P waves of a different shape (ectopic waves), if present, create an irregularity and do not walk out with the other P waves. A slight irregularity in the PP intervals, varying no more than three small blocks, is considered essentially regular if the P waves are all of the same shape. This alteration is caused by changes in intrathoracic pressure during the respiratory cycle.

Check the regularity of the ventricular rhythm by assessing the RR intervals, placing one caliper point on a portion of the QRS complex (usually the most prominent portion of the deflection) and the other point on the precise spot of the next QRS complex. Move the caliper from QRS complex to QRS complex along the entire strip (walking out the QRS complexes) to determine the regularity of the rhythm. QRS complexes of a different shape (ectopic QRS complexes), if present, create an

irregularity and do not walk out with the other QRS complexes. A slight irregularity of no more than three small blocks between intervals is considered essentially regular if the QRS complexes are all of the same shape.

**3. Analyze the P waves.** Check that the P-wave shape is consistent throughout the strip, indicating that atrial depolarization is occurring from impulses originating from one focus, normally the SA node. Determine whether there is one P wave occurring before each QRS complex, establishing that a relationship exists between the P wave and the QRS complex. This relationship indicates that an impulse from one focus is responsible for both atrial and ventricular depolarization. The nurse may observe more than one P-wave shape, more P waves than QRS complexes, absent P waves, or P waves coming after the QRS, each indicating that a dysrhythmia exists. Ask these five questions when analyzing P waves:

- Are P waves present?
- Are the P waves occurring regularly?
- Is there one P wave for each QRS complex?
- Are the P waves smooth, rounded, and upright in appearance; or are they inverted?
- Do all P waves look similar?

**4. Measure the PR interval.** Place one caliper point at the beginning of the P wave and the other point at the end of the PR segment. The PR interval normally measures between 0.12 and 0.20 second. The measurement should be constant throughout the strip. The PR interval cannot be determined if there are no P waves or if P waves occur after the QRS complex. Ask these three questions about the PR interval:

- Are PR intervals greater than 0.20 second?
- Are PR intervals less than 0.12 second?
- Are PR intervals constant across the ECG strip?

**5. Measure the QRS duration.** Place one caliper point at the beginning of the QRS complex and the other at the J point, where the QRS complex ends and the ST segment begins. The QRS duration normally measures between 0.04 and 0.10 second. The measurement should be constant throughout the entire strip. Check that the QRS complexes are consistent throughout the strip. When the QRS is narrow (0.10 second or less), it indicates that the impulse was not formed in the ventricles and is referred to as *supraventricular* or *above the ventricles*. When the QRS complex is wide (greater than 0.10 second), it indicates that the impulse is either of ventricular origin or of supraventricular origin with aberrant conduction, meaning deviating from the normal course or pattern. More than one QRS complex pattern or occasionally missing QRS complexes may be observed, indicating a dysrhythmia. Ask these questions to evaluate QRS intervals:

- Are QRS intervals less than or greater than 0.12 second?
- Are the QRS complexes similar in appearance across the ECG paper?

**6. Examine the ST segment.** The normal ST segment begins at the isoelectric line. ST elevation or depression is significant if displacement is 1 mm (one small box) or more above or below the line and is seen in two or more leads. ST *elevation* may indicate problems such as myocardial infarction, pericarditis, and hyperkalemia. ST *depression* is associated with hypokalemia, myocardial infarction, or ventricular hypertrophy.

**7. Assess the T wave.** Note the shape and height of the T wave for peaking or inversion. Abnormal T waves may indicate problems such as myocardial infarction and ventricular hypertrophy.

**8. Measure the QT interval.** A normal QT interval should be equal to or less than one-half the distance of the RR interval.

Using steps 1 through 8, you can interpret the cardiac rhythm and differentiate normal and abnormal cardiac rhythms (dysrhythmias).

## Overview of Normal Cardiac Rhythms

**Normal sinus rhythm (NSR)** is the rhythm originating from the sinoatrial (SA) node (dominant pacemaker) that meets these ECG criteria (Fig. 34-7):

**FIG. 34-7** Normal sinus rhythm. Both atrial and ventricular rhythms are essentially regular (a slight variation in rhythm is normal). Atrial and ventricular rates are both 87 beats/min. There is one P wave before each QRS complex, and all the P waves are of a consistent morphology, or shape. The PR interval measures 0.18 second and is constant; the QRS complex measures 0.06 second and is constant.

- *Rate*: Atrial and ventricular rates of 60 to 100 beats/min
- *Rhythm*: Atrial and ventricular rhythms regular
- *P waves*: Present, consistent configuration, one P wave before each QRS complex
- *PR interval*: 0.12 to 0.20 second and constant
- *QRS duration*: 0.04 to 0.10 second and constant

**Sinus arrhythmia** is a variant of NSR. It results from changes in intrathoracic pressure during breathing. In this context, the term *arrhythmia* does not mean an absence of rhythm, as the term suggests. Instead, the heart rate increases slightly during inspiration and decreases slightly during exhalation. This irregular rhythm is frequently observed in healthy adults.

Sinus arrhythmia has all the characteristics of NSR except for its irregularity. The PP and RR intervals vary, with the difference between the shortest and the longest intervals being greater than 0.12 second (three small blocks):

- *Rate*: Atrial and ventricular rates between 60 and 100 beats/min
- *Rhythm*: Atrial and ventricular rhythms irregular, with the shortest PP or RR interval varying at least 0.12 second from the longest PP or RR interval
- *P waves*: One P wave before each QRS complex; consistent configuration
- *PR interval*: Normal, constant
- *QRS duration*: Normal, constant

Sinus arrhythmias occasionally are due to nonrespiratory causes such as digitalis or morphine. These drugs enhance vagal tone and cause decreased heart rate and irregularity unrelated to the respiratory cycle.

## Common Dysrhythmias

Any disorder of the heartbeat is called a **dysrhythmia**. Historically the term *arrhythmia* has been used in the literature. Although the terms often are used interchangeably, *dysrhythmia* is more accurate. Although many dysrhythmias have no signs and symptoms, many others have serious consequences if not treated.

### ❖ Pathophysiology

Dysrhythmias are classified in several ways. As broad categories, they include premature complexes, bradydysrhythmias (bradycardias), and tachydysrhythmias (tachycardias).

### Premature Complexes

**Premature complexes** are early rhythm complexes. They occur when a cardiac cell or cell group, other than the sinoatrial (SA) node, becomes irritable and fires an impulse before the next sinus impulse is produced. The abnormal focus is called an *ectopic focus* and may be generated by atrial, junctional, or ventricular tissue. After the premature complex, there is a pause before the next normal complex, creating an irregularity in the rhythm. The patient with premature complexes may be unaware of them or may feel **palpitations** or a “skipping” of the heartbeat. If premature complexes, especially those that are ventricular, become more frequent, the patient may experience symptoms of decreased cardiac output.

Premature complexes may occur *repetitively in a rhythmic fashion*:

- **Bigeminy** exists when normal complexes and premature complexes occur alternately in a repetitive two-beat pattern, with a pause occurring after each premature complex so complexes occur in pairs.
- **Trigeminy** is a repeated three-beat pattern, usually occurring as two sequential normal complexes followed by a premature complex and a pause, with the same pattern repeating itself in triplets.
- **Quadrigeminy** is a repeated four-beat pattern, usually occurring as three sequential normal complexes followed by a premature complex and a pause, with the same pattern repeating itself in a four-beat pattern.

### Bradydysrhythmias

**Bradydysrhythmias** occur when the heart rate is less than 60 beats/min. These rhythms can also be significant because:

- Myocardial oxygen demand is reduced from the slow heart rate, which can be beneficial.
- Coronary PERFUSION time may be adequate because of a prolonged diastole, which is desirable.
- Coronary perfusion pressure may decrease if the heart rate is too slow to provide adequate cardiac output and blood pressure; this is a serious consequence.

Therefore the patient may tolerate the bradydysrhythmia well if the blood pressure is adequate. If the blood pressure is not adequate, symptomatic bradydysrhythmias may lead to myocardial ischemia or infarction, dysrhythmias, hypotension, and heart failure.

### Tachydysrhythmias

**Tachydysrhythmias** are heart rates greater than 100 beats/min. They are a major concern in the adult patient with coronary artery disease (CAD). Coronary artery blood flow occurs mostly during diastole when the aortic valve is closed and is determined by diastolic time and blood pressure in the root of the aorta. Tachydysrhythmias are serious because they:

- Shorten the diastolic time and therefore the coronary PERFUSION time (the amount of time available for blood to flow through the coronary arteries to the myocardium)
- Initially increase cardiac output and blood pressure (However, a continued rise in heart rate decreases the ventricular filling time because of a shortened diastole, decreasing the stroke volume. Consequently, cardiac output and blood pressure will begin to decrease, reducing aortic pressure and therefore coronary PERFUSION pressure.)
- Increase the work of the heart, increasing myocardial oxygen demand

The patient with a tachydysrhythmia may have:

- Palpitations
- Chest discomfort (pressure or pain from myocardial ischemia or infarction)
- Restlessness and anxiety
- Pale, cool skin
- Syncope (“blackout”) from hypotension

Tachydysrhythmias may also lead to heart failure. Presenting symptoms of heart failure may include dyspnea, lung crackles, distended neck veins, fatigue, and weakness (see [Chapter 35](#)). [Chart 34-1](#) summarizes key features of sustained bradydysrhythmias and tachydysrhythmias.

### **Chart 34-1**

## **Key Features**

### **Sustained Tachydysrhythmias and Bradydysrhythmias**

- Chest discomfort, pressure, or pain, which may radiate to the jaw, the back, or the arm
- Restlessness, anxiety, nervousness, confusion
- Dizziness, syncope
- Palpitations (in tachydysrhythmias)
- Change in pulse strength, rate, and rhythm
- Pulse deficit
- Shortness of breath, dyspnea
- Tachypnea
- Pulmonary crackles
- Orthopnea
- S<sub>3</sub> or S<sub>4</sub> heart sounds
- Jugular venous distention
- Weakness, fatigue
- Pale, cool, skin; diaphoresis
- Nausea, vomiting
- Decreased urine output
- Delayed capillary refill
- Hypotension

### **Etiology**

Dysrhythmias occur for many reasons, including myocardial infarction (MI), electrolyte imbalances (especially potassium and magnesium), hypoxia, drug toxicity, and hypovolemia (decreased blood volume). People who use cocaine and illicit inhalants are particularly at risk for potentially fatal dysrhythmias. Stress, fear, anxiety, and caffeine can cause an increased heart rate (tachycardia or premature ventricular contractions). Nicotine and alcohol excess can lead to abnormal heart rates

such as atrial fibrillation. Specific etiologies are described for each common dysrhythmia discussed in this chapter.

### ❖ **Interprofessional Collaborative Care**

Dysrhythmias may also be classified by their site of origin in the heart. These include common sinus, atrial, and ventricular dysrhythmias. Although many specific dysrhythmias can occur, general assessment and interventions for patient care may be similar ([Chart 34-2](#)). Assess the patient's apical and radial pulses for a full minute for any irregularity, which may occur with premature beats or atrial fibrillation. If the apical pulse differs from the radial pulse rate, a **pulse deficit** exists and indicates that the heart is not pumping adequately to achieve optimal PERFUSION to the body.

#### 📊 **Chart 34-2**

### **Best Practice for Patient Safety & Quality Care** QSEN

#### **Care of the Patient With Dysrhythmias**

- Assess vital signs at least every 4 hours and as needed.
- Monitor patient for cardiac dysrhythmias.
- Evaluate and document the patient's response to dysrhythmias.
- Encourage the patient to notify the nurse when chest pain occurs.
- Assess chest pain (e.g., location, intensity, duration, radiation, and precipitating and alleviating factors).
- Assess peripheral circulation (e.g., palpate for presence of peripheral pulses, edema, capillary refill, color, and temperature of extremity).
- Provide antidysrhythmic therapy according to unit policy (e.g., antidysrhythmic medication, cardioversion, or defibrillation), as appropriate.
- Monitor and document patient's response to antidysrhythmic medications or interventions.
- Monitor appropriate laboratory values (e.g., cardiac enzymes, electrolyte levels).
- Monitor the patient's activity tolerance and schedule exercise/rest periods to avoid fatigue.
- Observe for respiratory difficulty (e.g., shortness of breath, rapid breathing, labored respirations).
- Promote stress reduction.
- Offer spiritual support to the patient and/or family (e.g., contact clergy), as appropriate.

Dysrhythmias are often managed with antidysrhythmic drug therapy. Specific drugs and other treatments for common dysrhythmias are discussed later in this chapter.

## Sinus Dysrhythmias

The sinoatrial (SA) node in the right atrium is the pacemaker in all sinus dysrhythmias. Innervation from sympathetic and parasympathetic nerves is normally in balance to ensure a normal sinus rhythm (NSR). An imbalance increases or decreases the rate of SA node discharge either as a normal response to activity or physiologic changes or as a pathologic response to disease. Sinus tachycardia and sinus bradycardia are the two most common types of sinus dysrhythmias.

### Sinus Tachycardia

#### ❖ Pathophysiology

Sympathetic nervous system stimulation or vagal (parasympathetic) inhibition results in an increased rate of SA node discharge, which increases the heart rate. When the rate of SA node discharge is more than 100 beats/min, the rhythm is called **sinus tachycardia** (Fig. 34-8A). From age 10 years to adulthood, the heart rate normally does not exceed 100 beats/min except in response to activity and then usually does not exceed 160 beats/min. Rarely does the heart rate reach 180 beats/min.

**FIG. 34-8** Sinus rhythms. **A**, Sinus tachycardia (heart rate, 115 beats/min; PR interval, 0.12 second; QRS complex, 0.08 second). **B**, Sinus bradycardia (heart rate, 52 beats/min; PR interval, 0.18 second; QRS complex, 0.08 second).

Sinus tachycardia initially increases cardiac output and blood pressure. However, continued increases in heart rate decrease coronary PERFUSION time, diastolic filling time, and coronary PERFUSION pressure while increasing myocardial oxygen demand.

Increased sympathetic stimulation is a normal response to physical activity but may also be caused by anxiety, pain, stress, fever, anemia, hypoxemia, and hyperthyroidism. Drugs such as epinephrine, atropine, caffeine, alcohol, nicotine, cocaine, aminophylline, and thyroid medications may also increase the heart rate. In some cases, sinus tachycardia is a compensatory response to decreased cardiac output or blood pressure, as occurs in dehydration, hypovolemic shock, myocardial infarction (MI), infection, and heart failure. Assess patients for signs and symptoms of hypovolemia and dehydration, including increased pulse rate, decreased urinary output, decreased blood pressure, and dry skin and mucous membranes.

### ❖ Interprofessional Collaborative Care

The patient may be asymptomatic except for an increased pulse rate. However, if the rhythm is not well tolerated, he or she may have symptoms of instability.

## 📌 Nursing Safety Priority QSEN

### Action Alert

For patients with sinus tachycardia, assess for fatigue, weakness, shortness of breath, orthopnea, decreased oxygen saturation, increased pulse rate, and decreased blood pressure. Also assess for restlessness and anxiety from decreased cerebral perfusion and for decreased urine output from impaired renal perfusion. The patient may also have anginal pain and palpitations. The ECG pattern may show T-wave inversion or ST-segment elevation or depression in response to myocardial ischemia.

The desired outcome is to decrease the heart rate to normal levels by treating the underlying cause. Remind the patient to remain on bedrest if the tachycardia is causing hypotension or weakness. Teach the patient to avoid substances that increase cardiac rate, including caffeine, alcohol, and nicotine. Help patients develop stress-management strategies or refer the patient to a mental health professional.

## Sinus Bradycardia

### ❖ Pathophysiology

Excessive vagal (parasympathetic) stimulation to the heart causes a decreased rate of sinus node discharge. It may result from carotid sinus massage, vomiting, suctioning, Valsalva maneuvers (e.g., bearing down for a bowel movement or gagging), ocular pressure, or pain. Increased parasympathetic stimuli may also result from hypoxia, inferior wall MI, and the administration of drugs such as beta-adrenergic blocking agents, calcium channel blockers, and digitalis. Lyme disease, ELECTROLYTE disturbances, neurologic disorders, and hypothyroidism may also cause bradycardia.

The stimuli slow the heart rate and decrease the speed of conduction through the heart. When the sinus node discharge rate is less than 60 beats/min, the rhythm is called **sinus bradycardia** (Fig. 34-8B). Sinus bradycardia increases coronary PERFUSION time, but it may decrease coronary perfusion pressure. However, myocardial oxygen demand is *decreased*. Well-conditioned athletes with bradycardia have a hypereffective heart in which the strong heart muscle provides an adequate stroke volume and a low heart rate to achieve a normal cardiac output.

### ❖ Interprofessional Collaborative Care

#### ◆ Assessment: Noticing

The patient with sinus bradycardia may be asymptomatic except for the decreased pulse rate. In many cases, the cause of sinus bradycardia is unknown. Assess the medication administration record (MAR) to determine if the patient is receiving medications that slow the conduction through the SA or AV node. Assess the patient for:

- Syncope (“blackouts” or fainting)
- Dizziness and weakness
- Confusion
- Hypotension
- Diaphoresis (excessive sweating)
- Shortness of breath
- Chest pain

## 📌 NCLEX Examination Challenge 34-1

## Physiological Integrity

During routine suctioning of a client with a tracheostomy, the client becomes diaphoretic and nauseous, and the heart rate decreases to 39 beats/min. What is the nurse's **best** action at this time?

- A. Continue to clear the airway.
- B. Stop suctioning the patient.
- C. Administer atropine.
- D. Call the health care provider immediately.

### ◆Interventions: Responding

If the patient is stable, treatment includes identification and treatment of the underlying cause. If the patient has any of these symptoms and the underlying cause cannot be determined, the treatment is to administer drug therapy with atropine 0.5 mg IV, increase intravascular volume via IV fluids, and apply oxygen. Drugs suspected of causing the bradycardia are discontinued. If beta-blocker overdose is suspected, administration of glucagon may help by increasing the heart rate and blood pressure. If the heart rate does not increase sufficiently, prepare for transcutaneous or transvenous pacing to increase the heart rate. If treatment of the underlying cause does not restore normal sinus rhythm, the patient will require permanent pacemaker implantation.

### Temporary Pacing.

**Temporary pacing** is a nonsurgical intervention that provides a timed electrical stimulus to the heart when either the impulse initiation or the conduction system of the heart is defective. The electrical stimulus then spreads throughout the heart to depolarize the cells, which should be followed by contraction and cardiac output. Electrical stimuli may be delivered to the right atrium or right ventricle (single-chamber pacemakers) or to both (dual-chamber pacemakers).

Temporary pacing is used for patients with symptomatic bradydysrhythmias who do not respond to atropine or for patients with asystole. There are two types of temporary pacing: transcutaneous and transvenous.

**Transcutaneous pacing** is accomplished through the application of two large external electrodes. The electrodes are attached to an external pulse generator. The generator emits electrical pulses, which are transmitted through the electrodes and then transcutaneously to stimulate ventricular depolarization when the patient's heart rate is slower than the rate set on the pacemaker.

Transcutaneous pacing is used as an *emergency* measure to provide demand ventricular pacing in a profoundly bradycardic or asystolic patient until invasive pacing can be used or the patient's heart rate returns to normal. This method of pacing is painful and may require administration of pain and sedative medications for the patient to tolerate the therapy. Transcutaneous pacing is used only as a temporary measure to maintain heart rate and PERFUSION until a more permanent method of pacing is used.

A temporary transvenous system can be inserted in an emergency as a bridge until a permanent pacemaker can be inserted. This system consists of an external battery-operated pulse generator and pacing electrodes, or lead wire. The wire attaches to the generator on one end and is threaded to the right ventricle via the subclavian or femoral vein (Fig. 34-9).

**FIG. 34-9** Placement of pacemaker in chest and heart leads.

In pacemaker systems, electrical pulses, or stimuli, are emitted from the negative terminal of the generator, flow through a lead wire, and stimulate the cardiac cells to depolarize. The current seeks ground by returning through the other lead wire to the positive terminal of the generator, thus completing a circuit. The intensity of electrical current is set by selecting the appropriate current output, measured in milliamperes.

The two major modes of pacing are synchronous (demand) pacing and asynchronous (fixed-rate) pacing. Temporary pacing is *usually* done in the synchronous (demand) pacing mode. The pacemaker's sensitivity is set to sense the patient's own beats. When the patient's heart rate is above the rate set on the pulse generator, the pacemaker does not fire (inhibits itself). When the patient's heart rate is less than the generator setting, the pacemaker provides electrical impulses (paces).

When a pacing stimulus is delivered to the heart, a spike (or pacemaker artifact) is seen on the monitor or ECG strip. The spike should be followed by evidence of depolarization (i.e., a P wave, indicating atrial depolarization, or a QRS complex, indicating ventricular depolarization). This pattern is referred to as *capture*, indicating that the pacemaker has successfully depolarized, or captured, the chamber.

### Permanent Pacemaker.

Permanent pacemaker insertion is performed to treat conduction disorders that are not temporary, including complete heart block. These pacemakers are usually powered by a lithium battery and have an average life span of 10 years. After the battery power is depleted, the generator must be replaced by a procedure done with the patient under local anesthesia. Some pacemakers are nuclear powered and have a life span of 20 years or longer. Other pacemakers can be recharged externally. Combination pacemaker/defibrillator devices are also available.

A biventricular pacemaker may be used to coordinate contractions between the right and left ventricles. In addition to pacing used in the right side of the heart, an additional lead is placed in the left lateral wall of the left ventricle through the coronary sinus. This procedure allows synchronized depolarization of the ventricles and is used in patients with moderate-to-severe heart failure to improve functional ability.

The electrophysiologist implants the pulse generator in a surgically made subcutaneous pocket at the shoulder in the right or left subclavicular area, which may create a visible bulge (see Fig. 34-9). The leads are introduced transvenously via the cephalic or the subclavian vein to the endocardium on the right side of the heart. After the procedure, monitor the ECG rhythm to check that the pacemaker is working correctly. Assess the implantation site for bleeding, swelling, redness, tenderness, and infection. The dressing over the site should remain clean and dry. The patient should be afebrile and have stable vital signs. The health care provider prescribes initial activity restrictions, which are then gradually increased. Complications of permanent pacemakers are similar to those of temporary invasive pacing and include development of pericardial effusion, pericardial tamponade, and diaphragmatic pacing. In diaphragmatic pacing, the patient may report

pain at the level of the diaphragm. Observe for muscle contractions over the diaphragm that are synchronous with the heart rate.

Pacemaker checks are done on an ambulatory-care basis at regular intervals. Reprogramming may be needed if pacemaker problems develop. The pulse generator is interrogated using an electronic device to determine the pacemaker settings and battery life (Fig. 34-10). In addition, most pacemaker manufacturers offer wireless home transmitter devices. Data are then sent via landline telephone to a database, which is then accessed by the device clinic or primary health care provider. Stress the need to keep follow-up appointments for more detailed pacemaker checks and reprogramming, if necessary, and for assessment.

**FIG. 34-10** Permanent pacemaker (A) and programmer (B). (From Fischell, T. A., et al. [2010]. Initial clinical results using intracardiac electrogram monitoring to detect and alert patients during coronary plaque rupture and ischemia, *Journal of the American College of Cardiology*, 56(14), 1089-1098.)

Give written and verbal information to patients who have a *permanent pacemaker* about the type and settings of their pacemaker. Teach the patient to report any pulse rate lower than that set on the pacemaker. Review the proper care of the pacemaker insertion site and the importance of reporting any fever or any redness, swelling, or drainage at the pacemaker insertion site. If the surgical incision is near either shoulder, advise the patient to avoid lifting the arm over the head or lifting more than 10 lb for the next 4 weeks because this could dislodge the pacemaker wire. Encourage the patient that usual arm movement is encouraged to prevent shoulder stiffness.

## **Nursing Safety Priority** QSEN

### **Action Alert**

Teach patients who have permanent pacemakers to:

- Keep handheld cellular phones at least 6 inches away from the generator, with the handset on the ear opposite the side of the generator
- Avoid sources of strong electromagnetic fields, such as magnets and telecommunications transmitters (These may cause interference and could change the pacemaker settings, causing a malfunction. Magnetic resonance imaging (MRI) is usually contraindicated, depending on the machine's technology.)
- Carry a pacemaker identification card provided by the manufacturer and wear a medical alert bracelet at all times

[Chart 34-3](#) outlines the major points for patient and family teaching after the insertion of a permanent pacemaker.

### **Chart 34-3**

## **Patient and Family Education: Preparing for Self-Management**

## Permanent Pacemakers

- Follow the instructions for pacemaker site skin care that have been specifically prepared for you. Report any fever or redness, swelling, or drainage from the incision site to your physician.
- Do not manipulate the pacemaker generator site.
- Keep your pacemaker identification card in your wallet and wear a medical alert bracelet.
- Take your pulse for 1 full minute at the same time each day and record the rate in your pacemaker diary. Take your pulse any time you feel symptoms of a possible pacemaker failure and report your heart rate and symptoms to your primary health care provider.
- Know the rate at which your pacemaker is set and the basic functioning of your pacemaker. Know which rate changes to report to your primary health care provider.
- Do not apply pressure over your generator. Avoid tight clothing or belts.
- You may take baths or showers without concern for your pacemaker.
- Inform all health care providers that you have a pacemaker. Certain tests that they may wish to perform (e.g., magnetic resonance imaging) could affect or damage it.
- Know the indications of battery failure for your pacemaker as you were instructed and report these findings to your primary health care provider if they occur.
- Do not operate electrical appliances directly over your pacemaker site because this may cause your pacemaker to malfunction.
- Do not lean over electrical or gasoline engines or motors. Be sure that electrical appliances or motors are properly grounded.
- Avoid all transmitter towers for radio, television, and radar. Radio, television, other home appliances, and antennas do not pose a hazard.
- Be aware that antitheft devices in stores may cause temporary pacemaker malfunction. If symptoms develop, move away from the device.
- Inform airport personnel of your pacemaker before passing through a metal detector and show them your pacemaker identification card. The metal in your pacemaker will trigger the alarm in the metal detector device.
- Stay away from any arc welding equipment.
- Be aware that it is safe to operate a microwave oven unless it does not have proper shielding (old microwave ovens) or is defective.
- Report any of these symptoms to your primary health care provider if you experience them: difficulty breathing, dizziness, fainting, chest pain, weight gain, and prolonged hiccupping. If you have any of these symptoms, check your pulse rate and call your primary health care provider.
- If you feel symptoms when near any device, move 5 to 10 feet away from it and check your pulse. Your pulse rate should return to normal.
- Keep all of your health care provider and pacemaker clinic appointments.
- Take all medications prescribed for you as instructed.
- Follow your prescribed diet.

- Follow instructions about restrictions on physical activity, such as no sudden, jerky movement, for 8 weeks to allow the pacemaker to settle in place.

# Atrial Dysrhythmias

In patients with atrial dysrhythmias, the focus of impulse generation shifts away from the sinus node to the atrial tissues. The shift changes the axis (direction) of atrial depolarization, resulting in a P-wave shape that differs from normal P waves. The most common atrial dysrhythmias are:

- Premature atrial complexes
- Supraventricular tachycardia
- Atrial fibrillation

## Premature Atrial Complexes

A **premature atrial complex (contraction) (PAC)** occurs when atrial tissue becomes irritable. This ectopic focus fires an impulse before the next sinus impulse is due. The premature P wave may not always be clearly visible because it can be hidden in the preceding T wave. Examine the T wave closely for any change in shape and compare with other T waves. A PAC is usually followed by a pause.

- The causes of atrial irritability include:
  - Stress
  - Fatigue
  - Anxiety
  - Inflammation
  - Infection
  - Caffeine, nicotine, or alcohol
- Drugs such as epinephrine, sympathomimetics, amphetamines, digitalis, or anesthetic agents

PACs may also result from myocardial ischemia, hypermetabolic states, electrolyte imbalance, or atrial stretch. Atrial stretch can result from congestive heart failure, valvular disease, and pulmonary hypertension with cor pulmonale.

The patient usually has no symptoms except for possible heart palpitations. No intervention is needed except to treat causes such as heart failure. If PACs occur frequently, they may lead to more serious atrial tachydysrhythmias and therefore may need treatment. Administration of prescribed antidysrhythmic drugs may be necessary (Chart 34-4). Teach the patient measures to manage stress and substances to avoid, such as caffeine and alcohol, that are known to increase atrial irritability.

**Chart 34-4**

## Common Examples of Drug Therapy

### Antidysrhythmic Medication

DRUG CATEGORY	SELECTED NURSING IMPLICATIONS
<b>Class I: Sodium Channel Blockers</b> —There are three subgroups of Class I drugs.	
Common examples of sodium channel blockers: <b>Type IA</b> <ul style="list-style-type: none"> <li>• Disopyramide phosphate (Norpace)</li> </ul> <b>Type IB</b> <ul style="list-style-type: none"> <li>• Lidocaine (Xylocaine, Xylocard)</li> <li>• Mexiletine hydrochloride (Mexitil)</li> <li>• Tocainide hydrochloride (Tonocard)</li> </ul> <b>Type IC</b> <ul style="list-style-type: none"> <li>• Flecainide acetate (Tambacor)</li> <li>• Propafenone hydrochloride (Rythmol)</li> </ul>	Monitor BP and HR; <i>hypotension and bradycardia can occur.</i> Monitor for arrhythmias; <i>these agents affect conduction patterns, sometimes increasing the frequency or severity of dysrhythmias.</i> Monitor for CNS side effects such as dizziness, anxiety, ataxia, insomnia, confusion, seizures, and GI distress; <i>these side effects may require dose reduction or discontinuation of the drug.</i> Monitor for signs of heart failure; <i>many Class I agents can also cause HF.</i>
<b>Class II: Beta Blockers</b> —Only four beta blockers are approved for the treatment of dysrhythmias.	
Common examples of beta blockers: <ul style="list-style-type: none"> <li>• Propranolol (Inderal, Apo-Propranolol)</li> <li>• Acebutolol (Sectral)</li> <li>• Esmolol (Brevibloc)</li> <li>• Sotalol (Betapace)</li> </ul> • Sotalol is a Class II dysrhythmic and a Class III drug because of effect on the QT interval and delay of repolarization • Assess ventricular arrhythmias because this drug can have proarrhythmic effects.	Monitor HR and BP; <i>bradycardia and decreased BP are expected effects.</i> Assess for wheezing or shortness of breath; <i>beta<sub>2</sub>-blocking effects on the lungs can cause bronchospasm.</i> Assess for insomnia, fatigue, and dizziness; <i>side effects may require a decrease in dosage or discontinuation of the drug.</i>
<b>Class III: Calcium Channel Blockers</b> —There are currently five Class III agents. Each drug works to delay repolarization and prolongs the QT interval. Although their effects are similar, the side effects and mechanism of action vary greatly. <b>Selected examples of drug-specific side effects with associated rationales are listed.</b>	
<ul style="list-style-type: none"> <li>• Sotalol (Betapace)</li> <li>• Used for atrial and ventricular dysrhythmias.</li> </ul>	For all Class III calcium channel blockers: <ul style="list-style-type: none"> <li>• Monitor BP and HR; <i>hypotension and bradycardia can occur.</i></li> <li>• Monitor for arrhythmias; <i>these agents affect conduction patterns, sometimes increasing the frequency or severity of dysrhythmias.</i></li> </ul>

<ul style="list-style-type: none"> <li>• Amiodarone (Cordarone)</li> <li>• Used for atrial and ventricular dysrhythmias.</li> <li>• Continually monitor ECG rhythm during infusion; <i>bradycardia and AV block can occur.</i></li> <li>• This drug can cause serious toxicities (lung damage, visual impairment). As a result, <i>approval is limited to use for life-threatening dysrhythmias. However, because of efficacy, use remains very common</i> (Burcham &amp; Rosenthal, 2016).</li> <li>• Corneal pigmentation occurs in most patients, but it generally does not interfere with vision.</li> <li>• Dronedarone (Multaq)</li> <li>• Used for AF and atrial flutter.</li> <li>• Teach patient to take with meals and to avoid grapefruit juice; this drug is better absorbed with food and <i>grapefruit juice alters the effect of the drug.</i></li> <li>• Teach patient to notify provider with signs of HF; <i>this drug is contraindicated for patient with HF.</i></li> <li>• Ibutilide (Corvert)</li> <li>• Used for AF and atrial flutter.</li> <li>• Stop infusion as soon as the dysrhythmia is terminated or in the event of VT; <i>this drug may cause potentially fatal dysrhythmias.</i></li> <li>• Assess potassium and magnesium levels before infusion.</li> <li>• Dofetilide (Tikosyn)</li> <li>• Used for AF and atrial flutter.</li> <li>• Teach patient to change positions slowly; <i>orthostatic hypotension is a common side effect.</i></li> </ul>	
<b>Class IV: Calcium Channel Blockers</b> —Only two calcium channel blockers are approved for use in the treatment of dysrhythmias.	
<ul style="list-style-type: none"> <li>• Verapamil (Calan, Isoptin)</li> <li>• Diltiazem (Cardizem, Tiazac XC 🍀)</li> </ul>	For all Class IV calcium channel blockers: <ul style="list-style-type: none"> <li>• Monitor HR and BP; <i>bradycardia and hypotension are common side effects.</i></li> <li>• Teach patients to change position slowly when receiving oral therapy; <i>orthostatic hypotension can occur until tolerance develops.</i></li> <li>• Used for AF and atrial flutter.</li> <li>• Teach patients to report dyspnea, orthopnea, distended neck veins, or swelling of the extremities; <i>HF can occur, necessitating a decrease in dosage or discontinuation of drug.</i></li> </ul>
<b>Class: Other</b> —Other drugs used in the treatment of dysrhythmias fall outside of the previous categories. They are unclassified drugs for dysrhythmia treatment.	
Common examples of other dysrhythmia medications: <ul style="list-style-type: none"> <li>• Digoxin (Lanoxin, Toloxin 🍀)</li> <li>• Used for AF and atrial flutter.</li> <li>• Assess apical HR before administration; <i>decreased HR is an expected response.</i></li> <li>• Teach patient to report nausea, vomiting, diarrhea, paresthesias, confusion, or visual disturbance; <i>these can indicate digoxin toxicity.</i></li> <li>• Atropine sulfate</li> <li>• Used for bradycardia.</li> <li>• Monitor HR and rhythm after administration; <i>increased heart rate is expected.</i></li> <li>• Adenosine (Adenocard)</li> <li>• Used for paroxysmal SVT.</li> <li>• Have emergency equipment available <i>because a short period of asystole is common after administration; bradycardia and hypotension may occur.</i></li> <li>• Facial flushing, shortness of breath, and chest pain are common side effects.</li> </ul>	

AF, Atrial fibrillation; AV, atrioventricular; BP, blood pressure; BUN, blood urea nitrogen; CAD, coronary artery disease; CHF, congestive heart failure; CNS, central nervous system; ECG, electrocardiogram; HF, heart failure; HR, heart rate; SVT, supraventricular tachycardia.

## Supraventricular Tachycardia

### ❖ Pathophysiology

**Supraventricular tachycardia (SVT)** involves the rapid stimulation of atrial tissue at a rate of 100 to 280 beats/min in adults. During SVT, P waves may not be visible, especially if there is a 1 : 1 conduction with rapid rates, because the P waves are embedded in the preceding T wave. *SVT may occur in healthy young people, especially women.*

SVT is usually caused by a re-entry mechanism in which one impulse circulates repeatedly throughout the atrial pathway, re-stimulating the atrial tissue at a rapid rate. The term **paroxysmal supraventricular tachycardia (PSVT)** is used when the rhythm is intermittent. It is initiated suddenly by a premature complex such as a PAC and terminated suddenly with or without intervention.

### ❖ Interprofessional Collaborative Care

Signs and symptoms depend on the duration of the SVT and the rate of the ventricular response. In patients with a *sustained* rapid ventricular response, assess for palpitations, chest pain, weakness, fatigue, shortness of breath, nervousness, anxiety, hypotension, and syncope. Cardiovascular deterioration may occur if the rate does not sustain adequate blood pressure. In that case, SVT can result in angina, heart failure, and cardiogenic shock. With a *nonsustained* or slower ventricular response, the patient may be asymptomatic except for occasional palpitations.

If SVT occurs in a healthy person and stops on its own, no intervention may be needed other than eliminating identified causes. If it continues, the patient should be studied in the electrophysiology study (EPS) laboratory. The preferred treatment for recurrent SVT is radiofrequency catheter ablation, described later in this chapter with treatment of atrial fibrillation. In sustained SVT with a rapid ventricular response, the desired outcomes of treatment are to decrease the ventricular response, convert the dysrhythmia to a sinus rhythm, and treat the cause.

**Vagal maneuvers** induce vagal stimulation of the cardiac conduction system, specifically the SA and AV nodes. Although not as common today, vagal maneuvers may be attempted to treat supraventricular tachydysrhythmias and include carotid sinus massage and Valsalva maneuvers. However, the results of these interventions are often temporary and may cause “rebound” tachycardia or severe bradycardia. Further therapy must be initiated.

In *carotid sinus massage*, the health care provider massages over one carotid artery for a few seconds, observing for a change in cardiac rhythm. This intervention causes vagal stimulation,

slowing SA and AV nodal conduction. Prepare the patient for the procedure. Instruct him or her to turn the head slightly away from the side to be massaged and observe the cardiac monitor for a change in rhythm. An ECG rhythm strip is recorded before, during, and after the procedure. After the procedure, assess vital signs and the level of consciousness. Complications include bradycardias, asystole, ventricular fibrillation (VF), and cerebral damage. Because of these risks, carotid massage is not commonly performed. *A defibrillator and resuscitative equipment must be immediately available during the procedure.*

To stimulate a *vagal reflex*, the health care provider instructs the patient to bear down as if straining to have a bowel movement. Assess the patient's heart rate, heart rhythm, and blood pressure. Observe the cardiac monitor and record an ECG rhythm strip before, during, and after the procedure to determine the effect of therapy.

Drug therapy is prescribed for some patients to convert SVT to a normal sinus rhythm (NSR). Adenosine (Adenocard) is used to terminate the acute episode and given rapidly (over several seconds) followed by a normal saline bolus.

## Nursing Safety Priority QSEN

### Drug Alert

Side effects of adenosine include significant bradycardia with pauses, nausea, and vomiting. When administering adenosine, be sure to have emergency equipment readily available!

AV nodal blocking agents, such as beta and calcium channel blockers, are also given to treat SVT. [Chart 34-4](#) lists medications that may be used for SVT.

If symptoms of poor PERFUSION are severe and persistent, the patient may require synchronized cardioversion to immediately terminate the SVT. For long-term treatment, patients are referred to an electrophysiologist for radiofrequency catheter ablation. Synchronized cardioversion and catheter ablation are discussed later in this chapter with treatment of atrial fibrillation.

## Perfusion Concept Exemplar Atrial Fibrillation

**Atrial fibrillation (AF)** is the most common dysrhythmia seen in clinical practice. AF can be encountered and treated in the ambulatory and acute care settings. It can impair quality of life and cause considerable morbidity and mortality, largely related to CLOTTING concerns such as embolic stroke, deep venous thrombosis (DVT) or pulmonary embolism (PE).

### ❖ Pathophysiology

In patients with AF, multiple rapid impulses from many atrial foci depolarize the atria in a totally disorganized manner at a rate of 350 to 600 times per minute; ventricular response is usually 120 to 200 beats/min. The result is a chaotic rhythm with no clear P waves, no atrial contractions, loss of atrial kick, and an irregular ventricular response (Fig. 34-11). The atria merely quiver in fibrillation (commonly called *A fib*). Often the ventricles beat with a rapid rate in response to the numerous atrial impulses. The rapid and irregular ventricular rate decreases ventricular filling and reduces cardiac output. This alteration in cardiac function allows for blood to pool, placing the patient at risk for CLOTTING concerns such as DVT or PE. AF is frequently associated with underlying cardiovascular disease (Urden et al., 2016).

**FIG. 34-11** Atrial fibrillation. Note wavy baseline with atrial electrical activity and irregular ventricular rhythm.

### Etiology and Genetic Risk

AF is associated with atrial fibrosis and loss of muscle mass. These structural changes are common in heart diseases such as hypertension, heart failure, and coronary artery disease. For those without an underlying disorder leading to the development of AF, as many as 30 genetic mutations have been identified as the potential cause (Palatinus & Das, 2015). Investigation continues in the development of genetic testing to identify patients at risk and targeted treatment (Palatinus & Das, 2015). As AF progresses, cardiac output decreases by as much as 20% to 30%.

### Incidence and Prevalence

Currently, about 2.7 to 6.1 million people in the United States are diagnosed with AF; it occurs more often in those of European ancestry and African Americans (January et al., 2014). The incidence of AF increases with age; it causes serious problems in older people, leading to stroke and/or heart failure. Risk factors include hypertension (HTN), previous ischemic stroke, transient ischemic attack (TIA) or other thromboembolic event, coronary heart disease, diabetes mellitus, heart failure, obesity, hyperthyroidism, chronic kidney disease, excessive alcohol use, and mitral valve disease.

### ❖ Interprofessional Collaborative Care

#### ◆ Assessment: Noticing

##### History.

When obtaining a history, assess for prior history of AF or other dysrhythmias. Recurrence of AF is common, and assessment of previous conduction issues can be helpful in developing the plan of care. Assess for history of cardiovascular disease. The risk of AF is much higher in patients with a

history of hypertension, heart failure, obesity, or acute coronary syndrome (Urden, Stacy & Lough, 2016).

### Physical Assessment/Signs and Symptoms.

On physical examination, the apical pulse may be irregular. Symptoms depend on the ventricular rate. Because of the loss of atrial kick, the patient in uncontrolled AF is at greater risk for inadequate cardiac output. Signs of poor PERFUSION may be seen. Assess the patient for fatigue, weakness, shortness of breath, dizziness, anxiety, syncope, palpitations, chest discomfort or pain, and hypotension. Some patients may be asymptomatic.

### Psychosocial Assessment.

Patients with AF, especially those with a high ventricular rate, can feel very anxious. With increased heart rate, cardiac output decreases, which can create dyspnea, contributing to feelings of anxiety. Assess patients who have chronic atrial fibrillation for methods of coping with a long-term conduction issue. Patients with chronic AF may have anxiety related to anticoagulation medications and the potential for emboli development.

### Other Diagnostic Assessment.

Definitive diagnosis occurs by obtaining a 12-lead ECG. AF is classified into five categories based on length of time in the rhythm: paroxysmal, persistent, long-standing persistent, permanent, and nonvalvular. AF is termed *paroxysmal* when the patient experiences an episode within 7 days that converts back to sinus rhythm. Episode lengths vary but do not continue beyond a week. *Persistent AF* is experienced as episodes that occur for longer than 7 days. AF sustained for more than 12 months is categorized as *long-standing persistent*. *Permanent AF* is defined as patients who remain in AF, and a decision is made not to restore or maintain sinus rhythm by either medical or surgical intervention. *Nonvalvular AF* occurs in the absence of mitral valve disease or repair.

### ◆Analysis: Interpreting

The priority collaborative problems for most patients with atrial fibrillation are:

1. Potential for embolus formation due to irregular cardiac rhythm
2. Potential for heart failure due to altered conduction pattern

### ◆Planning and Implementation: Responding

Interventions for AF depend on the severity of the problem and the patient's response. Be sure to individualize care based on the patient's values and preferences, your clinical expertise, and best current evidence. Drug therapy is often effective for treating AF.

### Preventing Embolus Formation

#### Planning: Expected Outcomes.

The expected outcome is that the patient will remain free of embolus formation by restoring regular cardiac conduction.

#### Interventions.

The purpose of collaborative care is to restore regular blood flow through the atrium when possible. Correcting the rhythm and controlling the rate of the rhythm restore blood flow, which helps prevent embolus formation and increases cardiac output. Drug therapy is often effective for treating AF.

## 🚨Nursing Safety Priority QSEN

### Action Alert

The loss of coordinated atrial contractions in AF can lead to pooling of blood, resulting in CLOTTING. *The patient is at high risk for pulmonary embolism!* Thrombi may form within the right atrium and

then move through the right ventricle to the lungs. If pulmonary embolism is suspected, remain with the patient and monitor for shortness of breath, chest pain, and/or hypotension. Initiate the Rapid Response Team and notify the provider.

In addition, the patient is at risk for systemic emboli, particularly an embolic stroke, which may cause severe neurologic impairment or death. Monitor patients carefully for signs of stroke. Initiate Rapid Response Team if stroke is suspected to facilitate timely diagnosis.

Patients with AF who have valvular disease are particularly at risk for venous thromboembolism (VTE). In VTE, the patient may complain of lower extremity pain and swelling. Anticipate ultrasound of vasculature and initiation of systemic anticoagulation.

Traditional interventions for AF include antidysrhythmic drugs to slow the ventricular conduction or to convert the AF to normal sinus rhythm (NSR). Examples of drugs to slow conduction are calcium channel blockers such as diltiazem (Cardizem, Tiazac XC ) or, for more difficult-to-control AF, amiodarone (Cordarone). Dronedarone (Multaq) is a medication similar to amiodarone, yet better tolerated by patients, for maintenance of sinus rhythm after cardioversion. However, dronedarone should not be used in patients with heart failure because it can cause an exacerbation of cardiac symptoms or with permanent AF because it increases the risk of stroke, myocardial infarction, or cardiovascular death.

Beta blockers, such as metoprolol (Toprol, Betaloc ) and esmolol (Brevibloc), may also be used to slow ventricular response. Digoxin (Lanoxin, Toloxin ) is given for patients with heart failure and AF. It is useful in controlling the rate of ventricular response. However, it does not convert AF to sinus rhythm. Carefully monitor the pulse rate of patients taking these drugs.

Medications used for rhythm control of AF include flecainide (Tambocor), dofetilide (Tikosyn), propafenone (Rythmol), and ibutilide (Corvert). These medications are usually started within the acute care setting because of the risk of developing prolonged QT intervals and bradycardia. Continuous cardiac monitoring and frequent 12-lead ECGs are needed. Amiodarone is also used but does not require an acute care stay. If permanent AF is present, rhythm control antiarrhythmic medications should not be used. The medications used for rate and rhythm control are further discussed in [Chart 34-4](#).

The primary health care provider weighs the benefit of anticoagulant use versus risk of bleeding to determine the treatment path. The patient should be made aware of the risk of stroke development versus the risk of bleeding, and his or her preferences should also be a part of the decision-making process.

Because of the unpredictable drug response and many food-drug interactions, laboratory test monitoring (e.g., international normalized ratio [INR]) is required when a patient is taking warfarin. Teach patients the importance of avoiding foods high in vitamin K and to avoid herbs such as ginger, ginseng, goldenseal, *Ginkgo biloba*, and St. John's wort, which could interfere with the drug's action. [Chapter 36](#) describes care of patients receiving anticoagulant therapy.

Because of the problems associated with warfarin, novel oral anticoagulants (NOACs) such as dabigatran (Pradaxa), rivaroxaban (Xarelto), apixaban (Eliquis), or edoxaban (Savaysa) may be given on a long-term basis to prevent strokes associated with nonvalvular AF. Because these drugs achieve a steady state, there is no need for laboratory test monitoring. Prothrombin time (PT) and INR are not accurate predictors of bleeding time when NOACs are used. However, if the patient does experience severe bleeding, the only NOAC with a reversal agent is dabigatran (Pradaxa).

For those taking dabigatran (Pradaxa), a reversal agent has been approved by the U.S. Food and Drug Administration (FDA). Idarucizumab (Praxbind), an intravenous monoclonal antibody, binds to dabigatran, thereby preventing dabigatran from inhibiting thrombin. Side effects of idarucizumab (Praxbind) include hypokalemia, confusion, constipation, fever, and pneumonia. Use of idarucizumab (Praxbind) increases the risk of CLOTTING and stroke and should only be used in the event of life-threatening bleeding.

## Nursing Safety Priority QSEN

### Drug Alert

Teach patients taking any type of anticoagulant drug to report bruising, bleeding nose or gums, and other signs of bleeding to their primary health care provider immediately.

## NCLEX Examination Challenge 34-2

### Physiological Integrity

The primary health care provider prescribes warfarin (Coumadin) for a client with atrial fibrillation. Which statement made by the client indicates that additional education is needed?

- A. "I need to go to the clinic once a week to have my blood level checked."
- B. "If my stools turn black, I will be sure to call my primary health care provider"
- C. "I'm glad I don't need to change my diet. Salads are my favorite food."
- D. "I need to stop taking my herbal supplement."

### Preventing Heart Failure

#### Planning: Expected Outcomes.

The expected outcome is that the patient will remain free of heart failure by restoration of normal conduction with a controlled ventricular rate.

#### Interventions.

Collaborative care to prevent heart failure and improve cardiac output generally begins with drug therapy; however, the patient may require other nonsurgical or surgical interventions if medication is not successful in meeting optimal outcomes.

#### Nonsurgical Interventions.

Nonsurgical interventions most commonly include electrical cardioversion, left atrial appendage closure, radiofrequency catheter ablation, and pacing.

#### Electrical Cardioversion.

Electrical cardioversion is a *synchronized* countershock that may be performed to restore normal conduction in a hospitalized patient with *new-onset* AF. A cardioversion can also be scheduled electively for stable AF that is resistant to medical therapy. When the onset of AF is greater than 48 hours, the patient must take anticoagulants for 4 to 6 weeks before the procedure to prevent clots from moving from the heart to the brain or lungs. If the onset of AF is uncertain, a transesophageal echocardiogram (TEE) may be performed to assess for clot formation in the left atrium.

The shock depolarizes a large amount of myocardium during the cardiac depolarization. It is intended to stop the re-entry circuit and allow the sinus node to regain control of the heart. Emergency equipment must be available during the procedure. The physician, advanced practice nurse, or other qualified nurse explains the procedure to the patient and family. Help the patient sign a consent form unless the procedure is an emergency for a life-threatening dysrhythmia. Because he or she is usually conscious, a short-acting anesthetic agent is administered for sedation.

One electrode is placed to the left of the precordium, and the other is placed on the right next to the sternum and below the clavicle. The defibrillator should be set in the synchronized mode. A dot or line will be indicated over each QRS complex, confirming the synchronized mode. This avoids discharging the shock during the T wave, which may increase ventricular irritability, causing ventricular fibrillation (VF). Charge the defibrillator to the energy level requested, usually starting at a low rate of 120 to 200 joules for biphasic machines.

## Nursing Safety Priority QSEN

### Critical Rescue

For safety before cardioversion, turn oxygen off and away from patient; fire could result. Shout "CLEAR" before shock delivery for electrical safety!

After cardioversion, assess the patient's response and heart rhythm. Therapy is repeated, if necessary, until the desired result is obtained or alternative therapies are considered. If the patient's condition deteriorates into VF after cardioversion, check to see that the synchronizer is turned off so immediate defibrillation can be administered.

Nursing care after cardioversion includes:

- Maintaining a patent airway
- Administering oxygen
- Assessing vital signs and the level of consciousness
- Administering antidysrhythmic drug therapy, as prescribed
- Monitoring for dysrhythmias
- Assessing for chest burns from electrodes
- Providing emotional support
- Documenting the results of cardioversion

### **Left Atrial Appendage Closure.**

For patients who are high risk for stroke and who are not candidates for anticoagulation, the left atrial appendage (LAA) occlusion device may be an option (Cheng & Hijazi, 2015). The LAA is a small sac in the wall of the left atrium. For those with nonvalvular AF, the LAA is the most common site of blood clot development leading to the risk of stroke. Inserted percutaneously via the femoral vein, a device to occlude the LAA is delivered via a transseptal puncture. In the United States, the Watchman, (nitinol frame with fenestrated fabric) is the only device approved for use in atrial fibrillation patients. After insertion, anticoagulation with aspirin and warfarin is required. A repeat TEE is performed approximately 45 days after insertion to assess for leaks around the device. If no leak is detected, the warfarin is stopped, and antiplatelet therapy is continued. Complications are similar to those for undergoing cardiac ablation procedure.

### **Radiofrequency Catheter Ablation.**

Radiofrequency catheter ablation (RCA) is an invasive procedure that may be used to destroy an irritable focus in atrial or ventricular conduction. The patient must first undergo electrophysiologic studies and mapping procedures to locate the focus. Then radiofrequency waves are delivered to abolish the irritable focus. When ablation is performed in the AV nodal or His bundle area, damage may also occur to the normal conduction system, causing heart blocks and requiring implantation of a permanent pacemaker.

In AF, pulmonary vein isolation and ablation create scar tissue that blocks impulses and disconnects the pathway of the abnormal rhythm. Patients with AF with a rapid ventricular rate not responsive to drug therapy may have AV nodal ablation performed to totally disconnect the conduction from the atria to the ventricles, which requires implantation of a permanent pacemaker. AF ablation should not be performed if long-term anticoagulation is contraindicated.

### **Biventricular Pacing.**

This type of pacing may be another alternative for patients with heart failure and conduction disorders. Biventricular pacing, anti-tachycardia pacing, and implantable atrial defibrillators are other methods used to suppress or resolve AF. (See full pacing discussion earlier in this chapter.)

### **Surgical Interventions.**

Patients in AF with heart failure (discussed in Chapter 35) may benefit from the *surgical maze procedure*, an open-chest surgical technique often performed with coronary artery bypass grafting (CABG). Before this procedure, electrophysiologic mapping studies are done to confirm the diagnosis of AF. The surgeon places a maze of sutures in strategic places in the atrial myocardium, pulmonary artery, and possibly the superior vena cava to prevent electrical circuits from developing and continuing AF. Sinus impulses can then depolarize the atria before reaching the AV node and preserve the atrial kick. Postoperative care is similar to that after other open-heart surgical procedures (see Chapter 38).

The surgical MAZE procedure is being replaced by catheter procedures using a minimally invasive form. The *catheter maze procedure* is done by inserting a catheter through a leg vein into the atria and dragging a heated ablating catheter along the atria to create lines (scars) of conduction

block. Patients having this minimally invasive form of the procedure have fewer complications, less pain, and a quicker recovery than those with the open, surgical maze procedure.

### Chart 34-5

## Nursing Focus on the Older Adult

### Dysrhythmias

Special nursing considerations for the older patient with dysrhythmias are:

- Evaluate the patient with dysrhythmias immediately for the presence of a life-threatening dysrhythmia or hemodynamic deterioration.
- Assess the patient with a dysrhythmia for angina, hypotension, heart failure, and decreased cerebral and renal perfusion.
- Consider these causes of dysrhythmias when taking the patient's history: hypoxia, drug toxicity, electrolyte imbalances, heart failure, and myocardial ischemia or infarction.
- Assess the patient's level of education, hearing, learning style, and ability to understand and recall instructions to determine the best approaches for teaching.
- Assess the patient's ability to read written instructions.
- Teach the patient the generic and trade names of prescribed antidysrhythmic drugs and their purposes, dosage, side effects, and special instructions for use.
- Provide clear written instructions in basic language and easy-to-read print.
- Provide a written drug dosage schedule for the patient, considering all the drugs the patient is taking and possible drug interactions.
- Assess the patient for possible side effects or adverse reactions to drugs, considering age and health status.
- Teach the patient to take his or her pulse and to report significant changes in heart rate or rhythm to the primary health care provider.
- Inform the patient of available resources for blood pressure and pulse checks, such as blood pressure clinics, home health agencies, and cardiac rehabilitation programs.
- Instruct the patient about the importance of keeping follow-up appointments with the primary health care provider and reporting symptoms promptly.
- Include the patient's family members or significant other in all teaching whenever possible.
- Teach the patient to avoid drinking caffeinated beverages, stop smoking, drink alcohol only in moderation, and follow his or her prescribed diet.

## Considerations for Older Adults

### Patient-Centered Care QSEN

Older adults are at increased risk for dysrhythmias because of normal physiologic changes in their cardiac conduction system. The sinoatrial node has fewer pacemaker cells. There is a loss of fibers in the bundle branch system. Therefore older adults are at risk for sinus node dysfunction and may require pacemaker therapy. The most common dysrhythmias are premature atrial contractions, premature ventricular contractions, and atrial fibrillation. Dysrhythmias tend to be more serious in

older patients because of underlying heart disease, causing cardiac decompensation. Consequently, blood flow to organs that may already be decreased because of the aging process may be further compromised, leading to multisystem organ dysfunction. Chart 34-5 highlights special considerations for older adults receiving antidysrhythmic therapy.

## Care Coordination and Transition Management

### Home Care.

Patients discharged from the hospital may have considerable needs, often more related to their underlying chronic diseases than to their dysrhythmia. A case manager or care coordinator can assess the need for health care resources and coordinate access to services.

The focus of the home care nurse's interventions is assessment and health teaching. The community-based nurse provides the patient and family members with an opportunity to verbalize their concerns and fears. Provide emotional support and referrals for ongoing care in the community. Assess the patient for possible side effects of antidysrhythmic agents or anticoagulation therapy.

### Self-Management Education.

Patients and their families must have a thorough understanding of the prescribed *medication therapy*, including antidysrhythmic and anticoagulant agents. Pharmacies provide written instructions with filled prescriptions. Teach patients and families the generic and trade names of their drugs and the drugs' purposes, using basic terms that are easily understood. Clear instructions regarding dosage schedules and common side effects are important (see [Chart 34-4](#)). Emphasize the importance of reporting these side effects and any dizziness, nausea, vomiting, chest discomfort, or shortness of breath to the primary care provider. Be sure to include education that medication should not be stopped abruptly unless instructed by the primary health care provider. Teach the patient the signs and symptoms of bleeding. Advise patients to call the provider if any signs of bleeding are identified.

Teach all patients and their family members how to take a pulse and blood pressure. Some patients may want to use technology to calculate and record their pulse rate. Several applications (apps) for handheld mobile devices (such as the iPhone) are available, but their accuracy varies. "Instant Health Rate" and "Quick Heart Rate" are examples of apps used to calculate pulse rate.

Remind patients to report any signs of a change in heart rhythm, such as a significant decrease in pulse rate, a rate more than 100 beats/min, or increased rhythm irregularity. Smart Blood Pressure (SmartBP) is a blood pressure and pulse-management system that records, tracks, and analyzes data to share via an iPhone or iPad. The patient can send these readings to his or her primary health care provider as needed to maintain frequent vital sign monitoring ([Chart 34-6](#)).

### Chart 34-6

## Patient and Family Education: Preparing for Self-Management

### How to Prevent or Decrease Dysrhythmias

#### For Patients at Risk for Vasovagal Attacks Causing Bradydysrhythmias

- Avoid doing things that stimulate the vagus nerve, such as raising your arms above your head, applying pressure over your carotid artery, applying pressure on your eyes, bearing down or straining during a bowel movement, and stimulating a gag reflex when brushing your teeth or putting objects in your mouth.

#### For Patients With Premature Beats and Ectopic Rhythms

- Take the medications that have been prescribed for you and report any adverse effects to your physician.

- Stop smoking, avoid caffeinated beverages and energy drinks as much as possible, and drink alcohol only in moderation.
- Learn ways to manage stress and avoid getting too tired.

### For Patients With Ischemic Heart Disease

- If you have an angina attack, treat it promptly with rest and nitroglycerin administration as prescribed by your physician. This decreases your chances of experiencing a dysrhythmia.
- If chest pain is not relieved after taking the amount of nitroglycerin that has been prescribed for you, seek medical attention promptly. Also seek prompt medical attention if the pain becomes more severe or you experience other symptoms, such as sweating, nausea, weakness, and palpitations.

### For Patients at Risk for Potassium Imbalance

- Know the symptoms of decreased potassium levels, such as muscle weakness and cardiac irregularity.
- Eat foods high in potassium, such as tomatoes, beans, prunes, avocados, bananas, strawberries, and lettuce.
- Take the potassium supplements that have been prescribed for you.

### Health Care Resources.

The cardiac rehabilitation nurse typically provides written and oral information about dysrhythmias, antidysrhythmic drugs, and anticoagulant drugs. In addition, information about cardiac exercise programs, educational programs, and support groups is provided. The office or ambulatory care nurse may also provide information about resources. Teach the patient how to contact the local chapter of the American Heart Association ([www.americanheart.org](http://www.americanheart.org)) or the provincial chapter of the Heart and Stroke Foundation in Canada ([www.heartandstroke.ca](http://www.heartandstroke.ca)) for information about dysrhythmias, pacemakers, and CPR training.

### ◆Evaluation: Reflecting

Evaluate the care of the patient with AF on the basis of the identified patient problems. The expected outcomes include that the patient will:

- Remain free of embolus formation associated with AF
- Remain free of heart failure with regular heart rate and rhythm

## Ventricular Dysrhythmias

Ventricular dysrhythmias are potentially more life threatening than atrial dysrhythmias because the left ventricle pumps oxygenated blood throughout the body to perfuse vital organs and other tissues. The most common or life-threatening ventricular dysrhythmias include:

- Premature ventricular complexes
- Ventricular tachycardia
- Ventricular fibrillation
- Ventricular asystole

### Premature Ventricular Complexes

#### ❖ Pathophysiology

**Premature ventricular complexes (PVCs)**, also called *premature ventricular contractions*, result from increased irritability of ventricular cells and are seen as early ventricular complexes followed by a pause. When multiple PVCs are present, the QRS complexes may be unifocal or uniform, meaning that they are of the same shape (Fig. 34-12A), or multifocal or multiform, meaning that they are of different shapes (Fig. 34-12B). PVCs frequently occur in repetitive rhythms, such as bigeminy (two), trigeminy (three), and quadrigeminy (four). Two sequential PVCs are a pair, or couplet. Three or more successive PVCs are usually called **nonsustained ventricular tachycardia (NSVT)**.

**FIG. 34-12** Premature ventricular contractions. **A**, Normal sinus rhythm with unifocal premature ventricular complexes (PVCs). **B**, Normal sinus rhythm with multifocal PVCs (one negative and the other positive).

*Premature ventricular contractions are common, and their frequency increases with age. They may be insignificant or may occur with problems such as myocardial infarction, chronic heart failure, chronic obstructive pulmonary disease (COPD), and anemia. PVCs may also be present in patients with hypokalemia or hypomagnesemia. Sympathomimetic agents, anesthesia drugs, stress, nicotine, caffeine, alcohol, infection, or surgery can also cause PVCs, especially in older adults. Postmenopausal women often find that caffeine causes palpitations and PVCs.*

#### ❖ Interprofessional Collaborative Care

The patient may be asymptomatic or experience palpitations or chest discomfort caused by increased stroke volume of the normal beat after the pause. Peripheral pulses may be diminished or absent with the PVCs themselves because the decreased stroke volume of the premature beats may decrease peripheral PERFUSION.

## Nursing Safety Priority QSEN

### Action Alert

Because other dysrhythmias can cause widened QRS complexes, assess whether the premature complexes perfuse to the extremities. Palpate the carotid, brachial, or femoral arteries while observing the monitor for widened complexes or auscultating apical heart sounds. With acute MI, PVCs may be considered as a warning, possibly triggering life-threatening ventricular tachycardia (VT) or ventricular fibrillation (VF).

If there is no underlying heart disease, PVCs are not usually treated other than by eliminating or managing any contributing cause (e.g., caffeine, stress). Potassium or magnesium is given for replacement therapy if hypokalemia or hypomagnesemia is the cause. If the number of PVCs in a 24-hour period is excessive, the patient may be placed on beta-adrenergic blocking agents (beta blockers) (see [Chart 34-4](#)).

## Ventricular Tachycardia

### ❖ Pathophysiology

**Ventricular tachycardia (VT)**, sometimes referred to as *V tach*, occurs with repetitive firing of an irritable ventricular ectopic focus, usually at a rate of 140 to 180 beats/min or more ([Fig. 34-13](#)). VT may result from increased automaticity or a re-entry mechanism. It may be intermittent (nonsustained VT) or sustained, lasting longer than 15 to 30 seconds. The sinus node may continue to discharge independently, depolarizing the atria but not the ventricles, although P waves are seldom seen in sustained VT.

**FIG. 34-13** Sustained ventricular tachycardia at a rate of 166 beats/min.

### ❖ Interprofessional Collaborative Care

Ventricular tachycardia may occur in patients with ischemic heart disease, MI, cardiomyopathy, hypokalemia, hypomagnesemia, valvular heart disease, heart failure, drug toxicity (e.g., steroids), or hypotension. Patients who use cocaine or illicit inhalants are at a high risk for VT. *In patients who go into cardiac arrest, VT is commonly the initial rhythm before deterioration into ventricular fibrillation (VF) as the terminal rhythm!*

Signs and symptoms of sustained VT partially depend on the ventricular rate. Slower rates are better tolerated.

## Nursing Safety Priority QSEN

### Critical Rescue

In some patients, VT causes cardiac arrest. Assess the patient's circulation and airway, breathing, level of consciousness, and oxygenation level. For the *stable* patient with sustained VT, administer oxygen and confirm the rhythm via a 12-lead ECG. Amiodarone (Cordarone), lidocaine, or magnesium sulfate may be given.

Current Advanced Cardiac Life Support (ACLS) guidelines state that elective cardioversion is highly recommended for stable VT. The primary health care provider may prescribe an oral antidysrhythmic agent, such as mexiletine (Mexitil) or sotalol (Betapace, Rylosol ) , to prevent further occurrences. If the patient has been taking digoxin, the drug is withheld for up to 48 hours before an elective cardioversion. Digoxin increases ventricular irritability and puts the patient at risk for VF after the countershock. Patients who persist with episodes of stable VT may require radiofrequency catheter ablation. *Unstable* VT without a pulse is treated the same way as ventricular fibrillation as described in the following paragraphs.

## Ventricular Fibrillation

### ❖Pathophysiology

**Ventricular fibrillation (VF)**, sometimes called *V fib*, is the result of electrical chaos in the ventricles and is *life threatening!* Impulses from many irritable foci fire in a totally disorganized manner so ventricular contraction cannot occur. There are no recognizable ECG deflections (Fig. 34-14A). The ventricles merely quiver, consuming a tremendous amount of oxygen. *There is no cardiac output or pulse and therefore no cerebral, myocardial, or systemic perfusion. This rhythm is rapidly fatal if not successfully ended within 3 to 5 minutes.*

**FIG. 34-14** Ventricular dysrhythmias. **A**, Coarse ventricular fibrillation. **B**, Ventricular asystole with one idioventricular complex.

VF may be the first manifestation of coronary artery disease (CAD). Patients with myocardial infarction (MI) are at great risk for VF. It may also occur in those with hypokalemia, hypomagnesemia, hemorrhage, drug therapy, rapid supraventricular tachycardia (SVT), or shock. Surgery or trauma may also cause VF.

## ❖ Interprofessional Collaborative Care

*Emergency care for ventricular fibrillation* is critical for survival. When VF begins, the patient becomes faint, immediately loses consciousness, and becomes pulseless and apneic (no breathing). There is no blood pressure, and heart sounds are absent. Respiratory and metabolic acidosis develop. Seizures may occur. Within minutes, the pupils become fixed and dilated, and the skin becomes cold and mottled. *Death results without prompt intervention.*

The desired outcomes of collaborative care are to resolve VF promptly and convert it to an organized rhythm. *Therefore the priority is to defibrillate the patient immediately according to ACLS protocol.* If a defibrillator is not readily available, high-quality CPR must be initiated and continued until the defibrillator arrives. An automated external defibrillator (AED) is frequently used because it is simple for both medical and lay personnel. Defibrillation is discussed with cardiopulmonary resuscitation later in this chapter.

*Drug therapy* is used when dysrhythmias are sustained and/or life threatening. Drug therapy from one or more classes of antidysrhythmic agents is often used (see [Chart 34-4](#)). The **Vaughn-Williams classification** is commonly used to categorize drugs according to their effects on the action potential of cardiac cells (Classes I through IV). Other drugs also have antidysrhythmic effects but do not fit the Vaughn-Williams classification.

*Class I antidysrhythmics* are membrane-stabilizing agents used to decrease automaticity. The three subclassifications in this group include type IA drugs, which moderately slow conduction and prolong repolarization, prolonging the QT interval. These drugs are used to treat or prevent supraventricular and ventricular premature beats and tachydysrhythmias, but they are not as commonly used as other drugs. An example is procainamide hydrochloride (Pronestyl). Type IB drugs shorten repolarization. These drugs are used to treat or prevent ventricular premature beats, ventricular tachycardia (VT), and ventricular fibrillation (VF). Examples include lidocaine and mexiletine hydrochloride (Mexitil). Type IC drugs markedly slow conduction and widen the QRS complex. These agents are used primarily to treat or to prevent recurrent, life-threatening ventricular premature beats, VT, and VF. Examples include flecainide acetate (Tambocor) and propafenone hydrochloride (Rythmol).

*Class II antidysrhythmics* control dysrhythmias associated with excessive beta-adrenergic stimulation by competing for receptor sites, thereby decreasing heart rate and conduction velocity. Beta-adrenergic blocking agents, such as propranolol (Inderal) and esmolol hydrochloride (Brevibloc), are Class II drugs. They are used to treat or prevent supraventricular and ventricular premature beats and tachydysrhythmias. Sotalol hydrochloride (Betapace, Sotacor) is an antidysrhythmic agent with both noncardioselective beta-adrenergic blocking effects (Class II) and action potential duration prolongation properties (Class III). It is an oral agent that may be used for the treatment of documented ventricular dysrhythmias such as VT that are life threatening.

*Class III antidysrhythmics* lengthen the absolute refractory period and prolong repolarization and the action potential duration of ischemic cells. Class III drugs include amiodarone (Cordarone) and ibutilide (Corvert) and are used to treat or prevent ventricular premature beats, VT, and VF.

*Class IV antidysrhythmics* slow the flow of calcium into the cell during depolarization, thereby depressing the automaticity of the sinoatrial (SA) and atrioventricular (AV) nodes, decreasing the heart rate, and prolonging the AV nodal refractory period and conduction. Calcium channel blockers, such as verapamil hydrochloride (Calan, Isoptin, and diltiazem hydrochloride [Cardizem]), are Class IV drugs. They are used to treat supraventricular tachycardia (SVT) and atrial fibrillation (AF) to slow the ventricular response.

Magnesium sulfate is an electrolyte administered to treat refractory VT or VF because these patients may be hypomagnesemic, with increased ventricular irritability. The drug is also used for a life-threatening VT called **torsades de pointes** that can result from certain antidysrhythmics such as amiodarone.

## Ventricular Asystole

### ❖ Pathophysiology

**Ventricular asystole**, sometimes called *ventricular standstill*, is the complete absence of any ventricular rhythm ([Fig. 34-14B](#)). There are no electrical impulses in the ventricles and therefore *no* ventricular depolarization, no QRS complex, no contraction, no cardiac output, and no PERFUSION to the rest of the body.

## ❖ Interprofessional Collaborative Care

### ◆ Assessment: Noticing

The patient in ventricular asystole has no pulse, respirations, or blood pressure. *The patient is in full cardiac arrest.* In some cases, the sinoatrial (SA) node may continue to fire and depolarize the atria, with only P waves seen on the ECG. However, the sinus impulses do not conduct to the ventricles, and QRS complexes remain absent. In most cases, the entire conduction system is electrically silent, with no P waves seen on the ECG.

Ventricular asystole usually results from myocardial hypoxia, which may be a consequence of advanced heart failure. It may also be caused by severe hyperkalemia and acidosis. If P waves are seen, asystole is likely because of severe ventricular conduction blocks.

### ◆ Interventions: Responding

*When cardiac arrest occurs, cardiac output stops.* The underlying rhythm is usually ventricular tachycardia (VT), ventricular fibrillation (VF), or asystole. Without cardiac output, the patient is pulseless and becomes unconscious because of inadequate cerebral PERFUSION and gas exchange. Shortly after cardiac arrest, respiratory arrest occurs. Therefore cardiopulmonary resuscitation is essential to prevent brain damage and death.

#### Cardiopulmonary Resuscitation and Defibrillation.

Cardiopulmonary resuscitation (CPR), also known as **Basic Cardiac Life Support (BCLS)**, must be initiated immediately when asystole occurs. When finding an unresponsive patient, confirm unresponsiveness and call 911 (in community or long-term care setting) or the emergency response team (in the hospital). Gather the AED or defibrillator *before initiating CPR*. Guidelines for CPR have changed from an ABC (airway-breathing-compressions) approach to the initial priorities of CAB (compressions-airway-breathing) (AHA, 2015).

- Check for a carotid pulse for 5 to 10 seconds.
  - *If carotid pulse is absent*, start chest compressions of 100 to 120 compressions per minute and a compression depth of at least 2 inches with no more than 2.4 inches. Push hard and fast! Avoid leaning into the chest after each compression to allow for full chest wall recoil.
  - Maintain a patent airway.
  - Ventilate (breathing) with a mouth-to-mask device. Give rescue breaths at a rate of 10 to 12 breaths/min. If an advanced airway is in place, one breath should be given every 6 to 8 seconds (8 to 10 breaths/min).
  - Ventilation-to-compression ratio should be maintained at 30 compressions to 2 breaths if advanced airway is not in place.
- 
- Limit interruptions to compressions to less than 10 seconds.
  - When possible, compressors should be rotated every 2 minutes to maintain effective compressions.

Be sure to use Standard Precautions when administering CPR. Be aware that complications of CPR include:

- Rib fractures
- Fracture of the sternum
- Costochondral separation
- Lacerations of the liver and spleen
- Pneumothorax
- Hemothorax
- Cardiac tamponade
- Lung contusions

- Fat emboli

As soon as help arrives, place a board under the patient who is not on a firm surface. To make room for the resuscitation team and the crash cart, ask that the area be cleared of movable items and unnecessary personnel. When the AED or defibrillator arrives, *do not stop chest compressions while the defibrillator is being set up*. If trained to use the AED or defibrillator, apply hands-off defibrillator pads to the patient's chest and turn on the monitor. If the patient is in VF or pulseless VT, the immediate priority is to defibrillate! **Defibrillation**, an *asynchronous* countershock, depolarizes a critical mass of myocardium simultaneously to stop the re-entry circuit, allowing the sinus node to regain control of the heart. After defibrillation, CPR is resumed. CPR must continue at all times except during defibrillation.

## Nursing Safety Priority QSEN

### Critical Rescue

Early defibrillation is critical in resolving pulseless ventricular tachycardia (VT) or ventricular fibrillation (VF). It must not be delayed for any reason after the equipment and skilled personnel are present. The earlier defibrillation is performed, the greater the chance of survival! *Do not defibrillate ventricular asystole*. The purpose of defibrillation is disruption of the chaotic rhythm, allowing the SA node signals to restart. In ventricular asystole, no electrical impulses are present to disrupt.

Before defibrillation, loudly and clearly command all personnel to clear contact with the patient and the bed and check to see they are clear before the shock is delivered. Deliver shock and immediately resume CPR for 5 cycles or about 2 minutes. Reassess the rhythm every 2 minutes and if indicated. Charge the defibrillator to deliver an additional shock at the same energy level previously used. During the 2-minute intervals while high-quality CPR is being delivered, the Advanced Cardiac Life Support (ACLS) team administers medications and performs interventions to try and restore an organized cardiac rhythm. *Discussion of ACLS protocol is beyond the scope of this text.*

After the ACLS team initiates interventions, the role of the medical-surgical nurse is to provide information about the patient. Specific nursing responsibilities include providing a brief summary of the patient's medical condition and the events that occurred up until the time of cardiac arrest. Report the patient's initial cardiac rhythm. Remain in the room to answer questions, document the event, and assist with compressions. If family is present, provide emotional support and explanation of events in the room.

An emerging clinical practice is allowing or encouraging family presence at resuscitation attempts. This can be a positive experience for family members and significant others because it promotes closure after the death of a loved one. Although there may be staff resistance and some limits to family presence, overall it is a beneficial practice that should be considered in all resuscitation attempts.

When spontaneous circulation resumes, the patient is transported to the intensive care unit. Be ready to give hand-off report to the ICU nurse using SBAR communication or other agency system and assist with patient transport.

## NCLEX Examination Challenge 34-3

### Safe and Effective Care Environment

A client in the telemetry unit is on a cardiac monitor. The monitor technician notices that there are no ECG complexes, and the alarm sounds. What is the **first** action by the nurse?

- A. Suspend the alarm.
- B. Call the emergency response team.
- C. Press the record button to get an ECG strip.

D. Assess the client and check lead placement.

## Clinical Judgment Challenge 34-1

### Teamwork and Collaboration; Evidence-Based Practice; Safety QSEN

A 48-year-old male was found unresponsive in the stands at a basketball game. An AED was used on site and delivered a shock to the patient. He was admitted to the hospital following the event. Currently the patient is in sinus rhythm with frequent PVCs and reports intermittent chest pain. HR is 112, BP 92/48, and the patient is dyspneic.

1. What is the initial treatment for this patient at this time?
2. What drugs should you anticipate administering to this patient? Why are they indicated?
3. What evidence-based precautions must be taken to promote safety?
4. If this rhythm deteriorates to ventricular fibrillation or VT without a pulse, what steps should you take? Why?

#### Automated External Defibrillation.

The American Heart Association promotes the use of automated external defibrillators (AEDs) for use by laypersons and health care professionals responding to cardiac arrest emergencies (Fig. 34-15). These devices are found in many public places such as malls, airports, and commercial jets. The patient in cardiac arrest must be on a firm, dry surface. The rescuer places two large adhesive-patch electrodes on the patient's chest in the same positions as for defibrillator electrodes. The rescuer stops CPR and commands anyone present to move away, ensuring that no one is touching the patient. This measure eliminates motion artifact when the machine analyzes the rhythm. The rescuer presses the "analyze" button on the machine. After rhythm analysis, which may take up to 30 seconds, the machine advises either that a shock is necessary or that a shock is not indicated. *Shocks are recommended for VF or pulseless VT only.*

**FIG. 34-15** Automated external defibrillator. (Courtesy Defibtech LLC, Guilford, CT).

If a shock is indicated, issue a command to clear all contact with the patient and press the charge button. Once the AED is charged, press the shock button, and the shock will be delivered. The shock is delivered through the patches; so it is hands-off defibrillation, which is safer for the

rescuer. The rescuer then resumes CPR until the AED instructs to “stop CPR” to analyze the rhythm. If the rhythm is VF or VT and another shock is indicated, the AED will instruct the rescuer to charge and deliver another shock. Newer AEDs perform rhythm analysis and defibrillation without the need for a rescuer to press a button to analyze or shock the victim. It is essential that Advanced Cardiac Life Support (ACLS) be provided as soon as possible. Use of AEDs allows for earlier defibrillation. Therefore there is a greater chance of successful rhythm conversion and patient survival.

### **Implantable Cardioverter/Defibrillator.**

The implantable cardioverter/defibrillator (ICD) is indicated for patients who have experienced one or more episodes of spontaneous sustained ventricular tachycardia (VT) or ventricular fibrillation (VF) not caused by a myocardial infarction (MI). Collaborate with the physician and the electrophysiology nurse to prepare the patient for this procedure. A psychological profile is done to determine whether the patient can cope with the discomfort and fear associated with internal defibrillation from the ICD. Many patients report anxiety, depression, and decreased quality of life, which improves for the majority of patients after 12 months.

Two types of lead systems are available: transvenous and subcutaneous. In the traditional transvenous system, the leads are introduced via the subclavian vein, and the generator is implanted in the left pectoral area, similar to a permanent pacemaker insertion. In the subcutaneous ICD, the leads are tunneled underneath the skin and placed to the left of the sternum to form a right angle just below the xiphoid, where they attach to the generator. The generator is implanted in the left midaxillary chest wall. The subcutaneous ICD is recommended for younger patients (<40 years), patients without venous access, and patients who do not require concomitant pacemaker therapy. This procedure is performed in the electrophysiology laboratory. If the patient experiences a VT or VF episode after ICD placement and the ICD therapies are not successful, the qualified nurse or health care provider promptly externally defibrillates and initiates high-quality CPR.

The generator may be activated or deactivated by the provider placing a magnet over the implantation site for a few moments. The patient requires close monitoring in the postoperative period for dysrhythmias and complications such as bleeding and cardiac tamponade. The nurse must know whether the ICD is activated or deactivated. Care of the patient is similar to that after implantation of a permanent pacemaker, discussed earlier in this chapter. [Chart 34-7](#) highlights the important points for health teaching.

### **Chart 34-7**

## **Patient and Family Education: Preparing for Self-Management**

### **Implantable Cardioverter/Defibrillator**

- Follow the instructions for implantable cardioverter/defibrillator (ICD) site skin care that have been specifically prepared for you.
- Report to your primary health care provider any fever or redness, swelling, soreness, or drainage from your incision site.
- Do not wear tight clothing or belts that could cause irritation over the ICD generator.
- Do not manipulate your generator site.
- Avoid activities that involve rough contact with the ICD implantation site.
- Keep your ICD identification card in your wallet and consider wearing a medical alert bracelet.
- Know the basic functioning of your ICD device, its rate cutoff, and the number of consecutive shocks it can deliver.
- Avoid magnets directly over your ICD because they can inactivate the device. If beeping tones are

coming from the ICD, move away from the electromagnetic field immediately (within 30 seconds) before the inactivation sequence is completed and notify your primary health care provider.

- Inform all health care providers caring for you that you have an ICD implanted, because certain diagnostic tests and procedures must be avoided to prevent ICD malfunction. These include diathermy, electrocautery, and nuclear magnetic resonance tests.
- Avoid other sources of electromagnetic interference, such as devices emitting microwaves (not microwave ovens); transformers; radio, television, and radar transmitters; large electrical generators; metal detectors, including handheld security devices at airports; antitheft devices; arc welding equipment; and sources of 60-cycle (Hz) interference. Also avoid leaning directly over the alternator of a running motor of a car or boat.
- Report to your primary health care provider symptoms such as fainting, nausea, weakness, blackout, and rapid pulse rates.
- Take all medications prescribed for you as instructed.
- Follow instructions on restrictions on physical activity, such as not swimming, driving motor vehicles, or operating dangerous equipment.
- Keep all health care provider and ICD clinic appointments.
- Sit or lie down immediately if you feel dizzy or faint to avoid falling if the ICD discharges.
- Know how to contact the local emergency medical services (EMS) systems in your community. Inform them in advance that you have an ICD so they can be prepared if they need to respond to an emergency call for you.
- Encourage family members to learn how to perform CPR. Family members should know that, if they are touching you when the device discharges, they may feel a slight shock but this is not harmful to them.
- Follow instructions on what to do if the ICD successfully discharges, after which you feel well. This may include maintaining a diary of the date, the time, activity preceding the shock, symptoms, the number of shocks delivered, and how you feel after the shock. The physician may wish to be notified each time the device discharges.
- Avoid strenuous activities that may cause your heart rate to meet or exceed the rate cutoff of your ICD because this causes the device to discharge inappropriately.
- Notify your primary health care provider for information regarding access to health care if you are leaving town or relocating.

Some patients use a lightweight, automated wearable cardioverter/defibrillator (WCD). This external vestlike device is worn 24 hours a day except when the patient showers or bathes. One popular brand is the Zoll Lifecore LifeVest, which is programmed to monitor for VT and VF. A family member must be present to call 911 and initiate CPR if the patient experiences pulseless VT or VF while in the shower. If the patient is conscious while experiencing VT, he or she can press a button to prevent a shock. This precaution is an advantage over implantable devices because ICDs are programmed to always deliver a shock when VT or VF occurs.

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Be very careful to protect patients and staff to prevent electrical injury when assisting with invasive pacemakers, cardioversion, and defibrillation. **QSEN: Safety**
- For safety during cardioversion, turn oxygen off and away from the patient to prevent a fire. Shout “CLEAR” before shock delivery for electrical safety. **QSEN: Safety**
- Teach patients who have permanent pacemakers to keep cell phones at least 6 inches away from the generator, avoid electromagnetic fields such as telecommunication transmitters, wear a medical alert bracelet at all times, and carry a pacemaker identification card. **QSEN: Safety**

### Health Promotion and Maintenance

- Teach patients with dysrhythmias the correct drug, dose, route, time, and side effects of prescribed drugs and teach them to notify their primary care provider if adverse effects occur (see [Chart 34-4](#)).
- Teach patients taking anticoagulant therapy to report any signs of bruising or unusual bleeding immediately to their primary health care provider.
- Teach family members where to learn cardiopulmonary resuscitation (CPR) to decrease their anxiety while living with a patient with dysrhythmias or ICD/pacemaker. **QSEN: Patient-Centered Care**
- Teach patients the importance of adhering to their prescribed cardiac regimen, such as checking their pulse to ascertain pacemaker function.

### Physiological Integrity

- Assess patients with dysrhythmias for a decrease in cardiac output resulting in inadequate gas exchange and perfusion to vital organs (see [Chart 34-2](#)); typical assessment findings include shortness of breath, dizziness or syncope, weakness and fatigue, and irregular pulse. **Clinical Judgment**
- Monitor patients with dysrhythmias, including conducting a physical assessment and health history and interpreting ECG rhythm strips. Report significant changes to the primary health care provider. **Clinical Judgment**
- Interpret common dysrhythmias, especially bradycardia, tachycardia, atrial fibrillation (AF) and ventricular fibrillation (VF), premature ventricular contractions (PVCs), and asystole, using the steps of ECG analysis.
- Use special considerations when caring for older adults with dysrhythmias, as described in [Chart 34-5](#). **QSEN: Patient-Centered Care**
- Recognize that noninvasive pacing is an emergency measure to provide demand ventricular pacing in patients with profound bradycardia or asystole. Teach patients to expect possible discomfort.
- Identify and intervene in life-threatening situations by providing cardiopulmonary resuscitation, electrical therapy, or drug administration. **QSEN: Evidence-Based Practice**
- Be aware that automated external defibrillators (AEDs) are used by medical and lay personnel as an essential intervention for VF.
- Do not perform CPR while the patient is being defibrillated. **QSEN: Safety**
- Educate patients who have permanent pacemakers or ICDs about self-management (see [Charts 34-3](#) and [34-7](#)).

## CHAPTER 35

# Care of Patients With Cardiac Problems

Laura M. Dechant

## PRIORITY AND INTERRELATED CONCEPTS

**The priority concept for this chapter is PERFUSION.**

✚ The PERFUSION concept exemplar for this chapter is Heart Failure, below.

*The interrelated concepts for this chapter are:*

- GAS EXCHANGE
- COMFORT
- IMMUNITY

## LEARNING OUTCOMES

### Safe and Effective Care Environment

1. Collaborate with the interprofessional team to provide high-quality care for patients with cardiac problems that impact PERFUSION and GAS EXCHANGE.
2. Teach the patient and caregiver(s) about home safety affected by cardiac problems.
3. Prioritize evidence-based care for patients with common cardiac problems affecting PERFUSION.

### Health Promotion and Maintenance

4. Plan care coordination and transition management for patients and caregiver(s) with cardiac problems.
5. Teach the patient and caregiver(s) about drug therapy used for cardiac problems.

### Psychosocial Integrity

6. Implement patient and family-centered nursing interventions to decrease the psychosocial impact of living with chronic cardiac problems.

### Physiological Integrity

7. Apply knowledge of anatomy and physiology to perform an evidence-based assessment for the patient with a cardiovascular problem.
8. Explain how common drug therapies improve cardiac output, enhance peripheral perfusion, and prevent worsening cardiovascular problems.
9. Plan nursing care to promote PERFUSION and prevent complications such as altered GAS EXCHANGE, altered COMFORT, and altered IMMUNITY in patients with cardiovascular problems.
0. Use clinical judgment to assess laboratory data and signs and symptoms to prioritize nursing care for patients with a cardiovascular problem.
  1. Plan postoperative care for patients requiring cardiovascular surgery.
  2. Provide emergency care for patients experiencing life-threatening complications, such as cardiac tamponade and pulmonary edema.

Heart failure is the most common reason for hospital stays in patients over 65 years of age in the United States. When the heart is diseased, it cannot effectively pump an adequate amount of arterial

blood to the rest of the body. Arterial blood carries *oxygen* and nutrients to vital organs, such as the kidneys and brain, and to peripheral tissues. When these organs and other body tissues are not adequately *perfused*, they may not function properly. This chapter focuses on heart failure and its common causes in the adult population; coronary artery disease is discussed in [Chapter 38](#).

## Perfusion Concept Exemplar Heart Failure

**Heart failure**, also called *pump failure*, is a general term for the inability of the heart to work effectively as a pump. It results from a number of acute and chronic cardiovascular problems that are discussed in this chapter and within the cardiovascular unit.

### ❖ Pathophysiology

Heart failure (HF) is a common *chronic* health problem, with acute episodes often causing hospitalization. Acute coronary disease and other structural or functional problems of the heart can lead to *acute* HF. Both acute and chronic HF can be life threatening if they are not adequately treated or if the patient does not respond to treatment.

### Types of Heart Failure

The major types of heart failure are:

- Left-sided heart failure
- Right-sided heart failure
- High-output failure

Because the two ventricles of the heart represent two separate pumping systems, it is possible for one to fail by itself for a short period. *Most heart failure begins with failure of the left ventricle and progresses to failure of both ventricles.* Typical causes of **left-sided heart (ventricular) failure** include hypertension, coronary artery disease, and valvular disease. Decreased tissue PERFUSION from poor cardiac output and pulmonary congestion from increased pressure in the pulmonary vessels indicate left ventricular failure (LVF).

Left-sided heart failure was formerly referred to as **congestive heart failure (CHF)**; however, not all cases of LVF involve fluid accumulation. In the clinical setting, though, the term *CHF* is still commonly used. Left-sided failure may be acute or chronic and mild to severe. It can be further divided into two subtypes: systolic heart failure and diastolic heart failure.

**Systolic heart failure** (heart failure with reduced ejection fraction [HFrEF]) results when the heart cannot contract forcefully enough during systole to eject adequate amounts of blood into the circulation. Preload increases with decreased contractility, and afterload increases as a result of increased peripheral resistance (e.g., hypertension) (McCance et al., 2014). The **ejection fraction** (the percentage of blood ejected from the heart during systole) drops from a normal of 50% to 70% to below 40% with ventricular dilation. As it decreases, tissue PERFUSION diminishes and blood accumulates in the pulmonary vessels. Manifestations of systolic dysfunction may include symptoms of inadequate tissue PERFUSION or pulmonary and systemic congestion. Systolic heart failure is often called *forward failure* because cardiac output is decreased and fluid backs up into the pulmonary system. Because these patients are at high risk for sudden cardiac death, patients with an ejection fraction of less than 30% are considered candidates for an implantable cardioverter/defibrillator (ICD) (see Chapter 34).

In contrast, **diastolic heart failure** (heart failure with preserved left ventricular function [HFpEF]) occurs when the left ventricle cannot relax adequately during diastole. Inadequate relaxation or “stiffening” prevents the ventricle from filling with sufficient blood to ensure an adequate cardiac output. Although ejection fraction is more than 40%, the ventricle becomes less compliant over time because more pressure is needed to move the same amount of volume compared with a healthy heart. Diastolic failure represents about 20% to 40% of all heart failure, primarily in older adults and in women who have chronic hypertension and undetected coronary artery disease. Signs and symptoms and management of diastolic failure are similar to those of systolic dysfunction (McCance et al., 2014).

**Right-sided heart (ventricular) failure** may be caused by left ventricular failure, right ventricular myocardial infarction (MI), or pulmonary hypertension. In this type of heart failure (HF), the right ventricle cannot empty completely. Increased volume and pressure develop in the venous system, and peripheral edema results.

**High-output heart failure** can occur when cardiac output remains normal or above normal, unlike left- and right-sided heart failure, which are typically low-output states. High-output failure is caused by increased metabolic needs or hyperkinetic conditions, such as septicemia, high fever,

anemia, and hyperthyroidism. This type of heart failure is not as common as other types.

### **Classification and Staging of Heart Failure**

The American College of Cardiology (ACC) and American Heart Association (AHA) have developed evidence-based guidelines for staging and managing heart failure as a chronic, progressive disease. These guidelines do not replace the New York Heart Association (NYHA) functional classification system, which is used to describe symptoms that a patient may exhibit (see [Table 33-2](#) in [Chapter 33](#)).

The ACC/AHA staging system when compared with the NYHA system categorizes patients as:

- A. Patients at high risk for developing heart failure (Class I NYHA)
- B. Patients with cardiac structural abnormalities or remodeling who have not developed HF symptoms (Class I NYHA)
- C. Patients with current or prior symptoms of heart failure (Class II or III NYHA)
- D. Patients with refractory end-stage heart failure (Class IV NYHA)

Another method for staging heart failure is the Killip classification system, which is based on the heart's hemodynamic ability. [Table 38-3](#) outlines this system.

### **Compensatory Mechanisms**

When cardiac output is insufficient to meet the demands of the body, compensatory mechanisms work to improve it ([Fig. 35-1](#)). Although these mechanisms may initially increase cardiac output, they eventually have a damaging effect on pump function. Major compensatory mechanisms include:

**FIG. 35-1** Compensatory mechanisms in heart failure. Myocardial dysfunction activates the renin-angiotensin-aldosterone and sympathetic nervous systems, releasing neurohormones (angiotensin II, aldosterone, catecholamines, and cytokines). (From McCance, K. L., Huether S. E., Brashers, V., & Rote, N. [2014]. *Pathophysiology: The biologic basis for disease in adults and children* [7th ed.]. St. Louis: Mosby. Redrawn from Carelock, J., Clark, A. P. [2001]. *The American Journal of Nursing* 101[12], 27.)

- Sympathetic nervous system stimulation
- Renin-angiotensin system (RAS) activation (also called *renin-angiotensin-aldosterone [RAAS] activation*)
- Other chemical responses
- Myocardial hypertrophy

In heart failure (HF), *stimulation of the sympathetic nervous system* (i.e., increasing catecholamines) as a result of tissue hypoxia represents the most immediate compensatory mechanism. Stimulation of the adrenergic receptors causes an increase in heart rate (beta adrenergic) and blood pressure from vasoconstriction (alpha adrenergic).

Because cardiac output (CO) is the product of heart rate (HR) and stroke volume (SV), an increase

in HR results in an immediate *increase in CO*. The HR is limited, though, in its ability to compensate for decreased CO. If it becomes too rapid, diastolic filling time is limited, and CO may start to decline. An increase in HR also significantly increases oxygen demand by the myocardium. If the heart is poorly perfused because of arteriosclerosis, HF may worsen.

*Stroke volume (SV)* is also *improved* by sympathetic stimulation. Sympathetic stimulation increases venous return to the heart, which further stretches the myocardial fibers causing dilation. According to Starling's law, increased myocardial stretch results in more forceful contraction. More forceful contractions increase SV and CO. After a critical point is reached within the cardiac muscle, further volume and stretch reduce the force of contraction and cardiac output.

Sympathetic stimulation also results in *arterial vasoconstriction*. Vasoconstriction has the benefit of maintaining blood pressure and improving tissue PERFUSION in low-output states. However, constriction of the arteries increases **afterload**, the resistance against which the heart must pump. Afterload is the major determinant of myocardial oxygen requirements. As it increases, the left ventricle requires more energy to eject its contents, and SV may decline.

Reduced blood flow to the kidneys, a common occurrence in low-output states, results in *activation of the renin-angiotensin system (RAS)*. Vasoconstriction becomes more pronounced in response to angiotensin II, and aldosterone secretion causes sodium and water retention. Preload and afterload increase. Angiotensin II contributes to *ventricular remodeling*, resulting in progressive myocyte (myocardial cell) contractile dysfunction over time (McCance et al., 2014).

In addition to the sympathetic nervous system and RAS responses, other mechanisms are activated when a patient experiences heart failure (HF). Most of these actions contribute to worsening of the condition.

For example, in those who have had an MI, heart muscle cell injury causes an *immune response*. Pro-inflammatory cytokines, such as tumor necrosis factor (TNF) and interleukins (IL-1 and IL-6), are released, especially with left-sided HF. These substances contribute to ventricular remodeling.

*Natriuretic peptides* are neurohormones that work to promote vasodilation and diuresis through sodium loss in the renal tubules. The **B-type natriuretic peptide (BNP)** is produced and released by the ventricles when the patient has fluid overload as a result of HF. It increases with age and as renal function worsens (Hill et al., 2014). People who are obese have lower BNP levels compared with those who are not (Madamanchi et al., 2014).

Low cardiac output (CO) causes decreased cerebral perfusion. As a result, the posterior pituitary gland secretes *vasopressin* (antidiuretic hormone [ADH]). The hormone causes vasoconstriction and fluid retention, which worsen HF.

**Endothelin** is secreted by endothelial cells when they are stretched. As the myocardial fibers are stretched in patients with HF, this potent vasoconstrictor is released, which increases peripheral resistance and hypertension. HF worsens as a result of these actions.

**Myocardial hypertrophy** (enlargement of the myocardium), with or without chamber dilation, is another compensatory mechanism. The walls of the heart thicken to provide more muscle mass, which results in more forceful contractions, further increasing CO. However, cardiac muscle may hypertrophy more rapidly than collateral circulation can provide adequate blood supply to the muscle. Often a hypertrophied heart is slightly oxygen deprived.

All the compensatory mechanisms contribute to an increase in the consumption of myocardial oxygen. When the demand for oxygen increases and the myocardial reserve has been exhausted, signs and symptoms of HF develop.

## Etiology

Heart failure (HF) is caused by systemic hypertension in most cases. Some patients experiencing myocardial infarction (MI, "heart attack") also develop HF. The next most common cause is structural heart changes, such as valvular dysfunction, particularly pulmonic or aortic stenosis, which leads to pressure or volume overload on the heart. Common direct causes and risk factors for HF are listed in [Table 35-1](#).

**TABLE 35-1**

### Common Causes and Risk Factors for Heart Failure

<ul style="list-style-type: none"> <li>• Hypertension</li> <li>• Coronary artery disease</li> <li>• Cardiomyopathy</li> <li>• Substance abuse (alcohol and illicit/prescribed drugs)</li> </ul>	<ul style="list-style-type: none"> <li>• Dysrhythmias</li> <li>• Diabetes mellitus</li> <li>• Smoking/tobacco use</li> <li>• Family history</li> </ul>
---	--

- Valvular disease
- Congenital defects
- Cardiac infections and inflammations

- Obesity
- Severe lung disease
- Sleep apnea
- Hyperkinetic conditions (e.g., hyperthyroidism)

## Considerations for Older Adults

### Patient-Centered Care QSEN

Heart failure is a common problem among older adults. The use of certain drugs can contribute to the development or exacerbation of the problem in this population. For example, long-term use of NSAIDs for arthritis and other chronic pain can cause fluid and sodium retention. NSAIDs may cause peripheral vasoconstriction and increase the toxicity of diuretics and angiotensin-converting enzyme inhibitors (ACEIs). Thiazolidinediones (TZDs) (e.g., pioglitazone [Actos]) used for patients with diabetes also cause fluid and sodium retention. Rosiglitazone (Avandia), another TZD drug, has recently been found to cause acute myocardial infarction (AMI) in patients with type 2 diabetes. These drugs should be used with caution and restrictions in the older-adult population.

Right-sided HF in the absence of left-sided HF is usually the result of pulmonary problems such as chronic obstructive pulmonary disease (COPD) or pulmonary hypertension. Acute respiratory distress syndrome (ARDS) may also cause right-sided HF. These problems are discussed elsewhere in this text.

### Incidence and Prevalence

Over five million people in the United States have HF, causing about 875,000 hospitalizations each year. HF is the most common reason for hospital admission for people older than 65 years. African Americans are affected more often than Euro-Americans, probably because they have more risk factors that can lead to HF (Mozaffarian et al., 2015). The disease is a major cause of disability and death after MI, often because of nonadherence to the treatment plan and recommended lifestyle changes.

## Considerations for Older Adults

### Patient-Centered Care QSEN

Heart failure has been referred to as a U.S. epidemic, although it is a major problem worldwide. One of the U.S. *Healthy People 2020* objectives is to reduce the number of hospitalizations of older adults with HF as the principal diagnosis. Patient and family education can help meet this objective (Table 35-2). As the “baby boomer” population reaches 65 years of age, the numbers of hospital stays and deaths from HF are likely to increase dramatically.

**TABLE 35-2**

### Meeting *Healthy People 2020* Objectives

Cardiac Disease
<p>To reduce hospitalizations of older adults with heart failure as the principal diagnosis:</p> <ul style="list-style-type: none"> <li>• For patients hospitalized for heart failure, collaborate with the case manager for discharge planning, including adequate support in the community.</li> <li>• Provide a continuing plan of care for patients and their families or other caregivers when the patient is discharged from the hospital.</li> <li>• If the patient is discharged to home, call to check that he or she has no impending signs and symptoms of heart failure (the case manager may make calls).</li> <li>• Teach the patient and family or other caregiver about when to call the health care provider for health changes so the patient can be treated at home.</li> <li>• Ensure that the interprofessional team provides the patient with follow-up care in the home or nursing home.</li> </ul>

## ❖ Interprofessional Collaborative Care

### ◆ Assessment: Noticing

#### History.

When obtaining a history, keep in mind the many conditions that can lead to HF. Carefully question the patient about his or her medical history, including hypertension, angina (cardiac pain), MI,

rheumatic heart disease, valvular disorders, endocarditis, and pericarditis. Ask about the patient's perception of his or her activity tolerance, breathing pattern, sleeping pattern, urinary pattern, and fluid volume status and his or her knowledge about HF.

### Left-Sided Heart Failure.

With left ventricular systolic dysfunction, cardiac output (CO) is diminished, leading to impaired tissue PERFUSION, anaerobic metabolism, and unusual fatigue. Assess activity tolerance by asking whether the patient can perform normal ADLs or climb flights of stairs without fatigue or dyspnea. Many patients with heart failure (HF) experience weakness or fatigue with activity or have a feeling of heaviness in their arms or legs. Ask about their ability to perform simultaneous arm and leg work (e.g., walking while carrying a bag of groceries). Such activity may place an unacceptable demand on the failing heart. Ask the patient to identify his or her most strenuous activity in the past week. Many people unconsciously limit their activities in response to fatigue or dyspnea and may not realize how limited they have become.

Perfusion to the myocardium is often impaired as a result of left ventricular failure, especially with cardiac hypertrophy. The patient may report *chest discomfort* or may describe palpitations, skipped beats, or a fast heartbeat.

As the amount of blood ejected from the left ventricle diminishes, hydrostatic pressure builds in the pulmonary venous system and results in fluid-filled alveoli and pulmonary congestion, which results in a *cough*. The patient in early HF describes the cough as irritating, nocturnal (at night), and usually nonproductive. *As HF becomes very severe, he or she may begin expectorating frothy, pink-tinged sputum—a sign of life-threatening pulmonary edema.*

*Dyspnea* also results from increasing pulmonary venous pressure and pulmonary congestion. Carefully question about the presence of dyspnea and when and how it developed. The patient may refer to dyspnea as “trouble catching my breath,” “breathlessness,” or “difficulty breathing.”

As **exertional dyspnea** develops (also called *dyspnea upon* or *on exertion [DUE/DOE]*), the patient often stops previously tolerated levels of activity because of shortness of breath. Dyspnea at rest in the recumbent (lying flat) position is known as **orthopnea**. Ask how many pillows are used to sleep or whether the patient sleeps in an upright position in a bed, recliner, or other type of chair.

Patients who describe sudden awakening with a feeling of breathlessness 2 to 5 hours after falling asleep have **paroxysmal nocturnal dyspnea (PND)**. Sitting upright, dangling the feet, or walking usually relieves this condition.

### Right-Sided Heart Failure.

Signs of systemic congestion occur as the right ventricle fails, fluid is retained, and pressure builds in the venous system. Edema develops in the lower legs and may progress to the thighs and abdominal wall. Patients may notice that their shoes fit more tightly, or their shoes or socks may leave indentations on their swollen feet. They may have removed their rings because of swelling in their fingers and hands. Ask about weight gain. An adult may retain 4 to 7 liters of fluid (10 to 15 lb [4.5 to 6.8 kg]) before pitting edema occurs.

Reports of *nausea and anorexia* may be a direct consequence of liver engorgement (congestion) resulting from fluid retention. In *advanced* heart failure (HF), *ascites* and an increased abdominal girth may develop from severe liver congestion. Another common finding related to fluid retention is *diuresis at rest*. At rest, fluid in the peripheral tissue is mobilized and excreted, and the patient describes frequent awakening at night to urinate.

Obtain a careful nutritional history, questioning about the use of salt and the types of food consumed. Ask about daily fluid intake. Patients with HF may experience increased thirst and drink excessive fluid (4000 to 5000 mL/day) because of sodium retention.

### Physical Assessment/Signs and Symptoms.

Signs and symptoms of HF depend on the type of failure, the ventricle involved, and the underlying cause. Impaired tissue PERFUSION and pulmonary congestion are associated with *left* ventricular failure ([Chart 35-1](#)). Conversely, systemic venous congestion and peripheral edema are associated with *right* ventricular failure ([Chart 35-2](#)).

#### ▶ Chart 35-1

## Key Features

### Left Ventricular Failure

Decreased Cardiac Output	Pulmonary Congestion
<ul style="list-style-type: none"><li>• Fatigue</li><li>• Weakness</li><li>• Oliguria during the day (nocturia at night)</li><li>• Angina</li><li>• Confusion, restlessness</li><li>• Dizziness</li><li>• Tachycardia, palpitations</li><li>• Pallor</li><li>• Weak peripheral pulses</li><li>• Cool extremities</li></ul>	<ul style="list-style-type: none"><li>• Hacking cough, worse at night</li><li>• Dyspnea/breathlessness</li><li>• Crackles or wheezes in lungs</li><li>• Frothy, pink-tinged sputum</li><li>• Tachypnea</li><li>• S<sub>3</sub>/S<sub>4</sub> summation gallop</li></ul>

### Chart 35-2

## Key Features

### Right Ventricular Failure

#### Systemic Congestion

- Jugular (neck vein) distention
- Enlarged liver and spleen
- Anorexia and nausea
- Dependent edema (legs and sacrum)
- Distended abdomen
- Swollen hands and fingers
- Polyuria at night
- Weight gain
- Increased blood pressure (from excess volume) or decreased blood pressure (from failure)

#### Left-Sided Heart Failure.

Left ventricular failure is associated with decreased cardiac output and elevated pulmonary venous pressure. It may appear clinically as:

- Weakness
- Fatigue
- Dizziness
- Acute confusion
- Pulmonary congestion
- Breathlessness
- Oliguria (scant urine output)

Decreased blood flow to the major body organs can cause dysfunction, especially renal failure. Nocturia may occur when the patient is at rest.

The pulse may be tachycardic, or it may alternate in strength (**pulsus alternans**). Take the apical pulse for a full minute, noting any irregularity in heart rhythm. *An irregular heart rhythm resulting from premature atrial contractions (PACs), premature ventricular contractions (PVCs), or atrial fibrillation (AF) is common in HF (see Chapter 34).* The sudden development of an irregular rhythm may further compromise CO. Carefully monitor the patient's respiratory rate, rhythm, and character, as well as oxygen saturation. The respiratory rate typically exceeds 20 breaths/min.

Assess whether the patient is oriented to person, place, and time. A short mental status

examination may be used if there are concerns about orientation. Objective assessment is important because many people are skillful at covering up memory loss. Older adults are frequently disoriented or confused when the heart fails as a result of brain hypoxia (decreased oxygen).

Increased heart size is common with a displacement of the apical impulse to the left. A third heart sound, **S<sub>3</sub> gallop**, is an early diastolic filling sound indicating an increase in left ventricular pressure. This sound is often the first sign of HF. A fourth heart sound (S<sub>4</sub>) also can occur; it is not a sign of failure but is a reflection of decreased ventricular compliance.

Auscultate for crackles and wheezes of the lungs. Late inspiratory crackles and fine profuse crackles that repeat themselves from breath to breath and do not diminish with coughing indicate HF. *Crackles are produced by intra-alveolar fluid and are often noted first in the bases of the lungs and spread upward as the condition worsens.* Wheezes indicate a narrowing of the bronchial lumen caused by engorged pulmonary vessels. Identify the precise location of crackles and wheezes and whether the wheezes are heard on inspiration, expiration, or both.

### Right-Sided Heart Failure.

Right ventricular failure is associated with increased systemic venous pressures and congestion. On inspection, assess the neck veins for distention and measure abdominal girth. Hepatomegaly (liver engorgement), hepatojugular reflux, and ascites may also be assessed. Abdominal fluid can reach volumes of more than 10 liters. When the fluid accumulates in the abdomen, pressure is placed on the stomach and intestines. This pressure can lead to early satiety and malnutrition.

Assess for dependent edema. In ambulatory patients, edema commonly presents in the ankles and legs. When patients are restricted to bedrest, the sacrum is dependent, and fluid accumulates there.

## Nursing Safety Priority QSEN

### Action Alert

Edema is an extremely unreliable sign of HF. Be sure that accurate daily weights are taken to document fluid retention. Assessing weight at the same time of the morning using the same scale is important. *Weight is the most reliable indicator of fluid gain and loss!*

## NCLEX Examination Challenge 35-1

### Physiological Integrity

A client is diagnosed with right-sided heart failure. Which assessment findings will the nurse expect the client to have? **Select all that apply.**

- A. Peripheral edema
- B. Crackles in both lungs
- C. Increased abdominal girth
- D. Ascites
- E. Tachypnea

### Psychosocial Assessment.

Chronic heart failure (HF) typically is a slow, debilitating disease. Anxiety and frustration are common. Symptoms such as dyspnea increase the patient's anxiety level.

Patients with HF, especially those with advanced disease, are at high risk for depression. It is not certain whether the functional impairments contribute to the depression or depression affects functional ability. Older hospitalized patients may be depressed, particularly those who have been re-admitted for an acute episode of HF. Lifestyle changes and quality-of-life issues can also cause

depression many months after the initial diagnosis of HF.

Assess patients and their families for anxiety and depression. Ask them about their usual methods of coping and any history of depression. If anxiety or depression is present, notify the primary health care provider for further assessment. Social workers, certified clinical chaplains, or psychologists may administer specific assessment tools to determine the extent of the problem. Some patients need drug therapy and nonpharmacologic modalities, such as cognitive behavior therapy, biofeedback, or relaxation training.

Hope is a major indicator of well-being for patients with HF. Those who are hopeful tend to feel better and are more socially involved. Ask patients about their daily activities and how often they interact with the significant people in their life to help determine patient and family coping strategies.

### Laboratory Assessment.

Electrolyte imbalance may occur from complications of HF or as side effects of drug therapy, especially diuretic therapy. Regular evaluations of a patient's serum electrolytes, including sodium, potassium, magnesium, calcium, and chloride, are essential. Any impairment of renal function resulting from inadequate perfusion causes elevated blood urea nitrogen and serum creatinine and decreased creatinine clearance levels. Hemoglobin and hematocrit tests should be performed to identify HF resulting from anemia. If the patient has fluid volume excess, the hematocrit levels may be low as a result of hemodilution.

*B-type natriuretic peptide (BNP)* is used for diagnosing HF (in particular, diastolic HF) in patients with acute dyspnea. As discussed earlier, it is part of the body's response to decreased cardiac output (CO) from either left or right ventricular dysfunction. An absence of elevation in BNP, in conjunction with history and physical, rules out HF as the cause of acute dyspnea and points to a primary lung dysfunction (Hill et al., 2014). Patients with renal disease may have elevated BNP levels (Hill et al., 2014). In the ambulatory care setting, BNP trends may be used over time to guide ambulatory care treatment (Traughton et al., 2014). As therapy is optimized, BNP levels decrease. If BNP levels increase, alternate causes such as ischemia are considered before intensifying treatment.

Urinalysis may reveal proteinuria and high specific gravity. *Microalbuminuria* is an early indicator of decreased compliance of the heart and occurs before the BNP rises. It serves as an “early warning detector” that lets the primary health care provider know that the heart is experiencing early signs of decreased compliance long before symptoms occur.

## Considerations for Older Adults

### Patient-Centered Care QSEN

Thyroxine ( $T_4$ ) and thyroid-stimulating hormone (TSH) levels should be assessed in patients who are older than 65 years, have atrial fibrillation, or have evidence of thyroid disease. Heart failure (HF) may be caused or aggravated by hypothyroidism or hyperthyroidism.

*Arterial blood gas (ABG)* values often reveal hypoxemia (low blood oxygen level) because oxygen does not diffuse easily through fluid-filled alveoli. Respiratory alkalosis may occur because of hyperventilation; respiratory acidosis may occur because of carbon dioxide retention. Metabolic acidosis may indicate an accumulation of lactic acid.

### Imaging Assessment.

*Chest x-rays* can be helpful in diagnosing left ventricular failure. Typically the heart is enlarged (cardiomegaly), representing hypertrophy or dilation. Pleural effusions develop less often and generally reflect biventricular failure. *Echocardiography* is considered the best tool in diagnosing heart failure. Cardiac valvular changes, pericardial effusion, chamber enlargement, and ventricular hypertrophy can be diagnosed with this noninvasive technique. The test can also be used to determine ejection fraction.

*Radionuclide studies* (thallium imaging or technetium pyrophosphate scanning) can also indicate the presence and cause of HF. Multigated acquisition (MUGA) scans, also called *multigated blood pool scans*, provide information about left ventricular ejection fraction and velocity, which are typically low in patients with HF. These tests are discussed in Chapter 33.

### Other Diagnostic Assessment.

An *electrocardiogram* (ECG) is also performed. It may show ventricular hypertrophy; dysrhythmias; and any degree of myocardial ischemia, injury, or infarction. However, it is *not* helpful in determining the presence or extent of HF.

**Invasive hemodynamic monitoring** allows the direct assessment of cardiac function and volume status in acutely ill patients. Although medical-surgical nurses do not manage these systems on general hospital units, they should be familiar with the interpretation of some of the major hemodynamic pressures as they relate to patient assessment. These measurements can confirm the diagnosis and guide the management of HF. For example, right atrial pressure is either normal or elevated in left ventricular failure and elevated in right ventricular failure. Pulmonary artery pressure (PAP) and pulmonary artery wedge pressure (PAWP) are elevated in left-sided HF because volumes and pressures are increased in the left ventricle. Hemodynamic monitoring is described in [Chapter 38](#).

### ◆Analysis: Interpreting

The priority collaborative problems for most patients with heart failure (HF) include:

1. Decreased gas exchange due to ventilation/perfusion imbalance
2. Potential for decreased PERFUSION due to inadequate cardiac output
3. Fatigue due to hypoxemia
4. Potential for pulmonary edema due to left-sided HF

### ◆Planning and Implementation: Responding

The patient-centered collaborative care that patients with HF need depends on their disease stage and severity of signs and symptoms. Be sure to individualize care based on the patient's values and preferences, your clinical expertise, and best current evidence.

#### Increasing Gas Exchange

##### Planning: Expected Outcomes.

The expected outcome is that the patient will have an optimal spontaneous breathing pattern that increases GAS EXCHANGE and maintains a serum carbon dioxide level that is within normal limits.

##### Interventions.

The purpose of collaborative care is to help promote GAS EXCHANGE. *Ventilation assistance* may be needed because the oxygen content of the blood is often decreased in patients who have pulmonary congestion. Monitor the patient's respiratory rate, rhythm, and quality every 1 to 4 hours. Auscultate breath sounds every 4 to 8 hours.

## ■ Nursing Safety Priority QSEN

### Action Alert

Provide the necessary amount of supplemental oxygen within a range prescribed by the health care provider *to maintain oxygen saturation at 90% or greater*. If the patient has dyspnea, place in a high-Fowler's position with pillows under each arm to maximize chest expansion and improve gas exchange. Repositioning and performing coughing and deep-breathing exercises every 2 hours helps to improve gas exchange and prevents atelectasis. Interprofessional collaboration with the respiratory therapist is important to plan the most effective methods for assisting with ventilation.

#### Increasing Perfusion

##### Planning: Expected Outcomes.

The expected outcome is that the patient will have increased perfusion with adequate cardiac

output.

### Interventions.

Collaborative care begins with nonsurgical interventions, but the patient may need surgery if these are not successful in meeting optimal outcomes.

### Nonsurgical Management.

Nonsurgical management relies primarily on a variety of drugs (Table 35-3). If drug therapy is ineffective, other nonsurgical options are available. Drugs to improve stroke volume include those that reduce afterload, reduce preload, and improve cardiac muscle contractility. A major role of the nurse is to give medications as prescribed, monitor for their therapeutic and adverse effects, and teach the patient and family about drug therapy.

**TABLE 35-3**

**Commonly Used Drug Classifications for Patients With Systolic Heart Failure**

Angiotensin-converting enzyme (ACE) inhibitors or angiotensin-receptor blockers (ARBs)
Diuretics:
• High-ceiling
• Potassium-sparing
Human B-type natriuretic peptides
Nitrites
Inotropics:
• Beta-adrenergic agonists
• Phosphodiesterase inhibitors
• Calcium sensitizers
• Digoxin (Lanoxin)
Beta-adrenergic blockers
Angiotensin receptor neprilysin inhibitor (ARNI):
• Sacubitril/valsartan (Entresto)
Aldosterone antagonist
HCN Channel blocker
• Ivabradine (Corlanor)

HCN, Hyperpolarization-activated cyclic nucleotide-gated.

### Drugs That Reduce Afterload.

By relaxing the arterioles, arterial vasodilators can reduce the resistance to left ventricular ejection (afterload) and improve cardiac output (CO). These drugs do not cause excessive vasodilation but reverse some of the inappropriate or excessive vasoconstriction common in HF.

### Angiotensin-Converting Enzyme Inhibitors and Angiotensin-Receptor Blockers.

Patients with even mild heart failure (HF) resulting from left ventricular dysfunction are given a trial of angiotensin-converting enzyme (ACE) inhibitors or angiotensin-receptor blockers (ARBs). Both ACE inhibitors (e.g., enalapril [Vasotec] and fosinopril [Monopril]) and ARBs (e.g., valsartan [Diovan], irbesartan [Avapro], and losartan [Cozaar]) improve function and quality of life for patients with HF. ACE inhibitors are the first-line drug of choice, but some health care providers prefer to start the patient on an ARB because ACE inhibitors can cause a nagging, dry cough. For patients with *acute* HF, the health care provider may prescribe an IV-push ACE inhibitor such as Vasotec IV.

The ACE inhibitors and ARBs suppress the renin-angiotensin system (RAS), which is activated in response to decreased renal blood flow. ACE inhibitors prevent conversion of angiotensin I to angiotensin II, resulting in arterial dilation and increased stroke volume. ARBs block the effect of angiotensin II receptors and thus decrease arterial resistance and arterial dilation. In addition, these drugs block aldosterone, which prevents sodium and water retention, thus decreasing fluid overload. *Both ACEIs and ARBs work more effectively for Euro-Americans than for African-American populations.* Volume-depleted patients should receive a low starting dose, or the fluid volume should be restored before beginning the prescribed drug. Monitor for hyperkalemia, a potential adverse drug effect in patients who have renal dysfunction.

A new combination medication, sacubitril/valsartan (Entresto), has demonstrated a reduction in death and hospitalization in patients with Class II-IV HF with a decreased ejection fraction. Entresto is a first-in-class medication as an angiotensin receptor neprilysin inhibitor (ARNI). It is used in place of an ACE inhibitor or ARB and should not be given in patients with a history of angioedema. Other side effects are similar to those of ACE inhibitors and include hypotension, hyperkalemia, cough, dizziness, and renal failure. Monitor potassium and creatinine levels while on therapy.

## Nursing Safety Priority QSEN

### Drug Alert

ACEIs and ARBs are started slowly and cautiously. The first dose may be associated with a rapid drop in blood pressure (BP). Patients at risk for hypotension usually have an initial systolic BP less than 100 mm Hg, are older than 75 years, have a serum sodium level less than 135 mEq/L, or are volume depleted. Monitor BP every hour for several hours after the initial dose and each time the dose is increased. Immediately report to the health care provider and document a systolic blood pressure of less than 90 mm Hg (or designated protocol level). If this problem occurs, place the patient flat and elevate legs to increase cerebral perfusion and promote venous return.

Assess for orthostatic hypotension, acute confusion, poor peripheral perfusion, and reduced urine output in patients with low systolic blood pressure. Monitor serum potassium and creatinine levels to determine renal dysfunction.

### Human B-Type Natriuretic Peptides.

Human B-type natriuretic peptides (hBNPs) such as nesiritide (Natrekor) are often used to treat *acute* HF. Endogenous BNP is released in response to decreased CO and causes *natriuresis*, or loss of sodium in the renal tubules, and vasodilation. Natrekor lowers pulmonary capillary wedge pressure (PCWP) and improves renal glomerular filtration. It is given as an IV bolus over 60 seconds followed with a continuous infusion for up to 48 hours.

## Nursing Safety Priority QSEN

### Drug Alert

When giving Natrekor, monitor BP and pulse carefully because significant decreases in BP may occur. Although the patient's systolic BP may be between 90 and 100 mm Hg, he or she is usually asymptomatic. *Give Natrekor through a separate infusion line because it is incompatible with heparin and most other parenteral medications.* Expect an increase in the serum BNP after drug administration.

### Interventions That Reduce Preload.

Ventricular fibers contract less forcefully when they are overstretched, such as in a failing heart. Interventions aimed at reducing preload attempt to decrease volume and pressure in the left ventricle, increasing ventricular muscle stretch and contraction. Preload reduction is appropriate for HF accompanied by congestion with total body sodium and water overload.

### Nutrition Therapy.

In HF, nutrition therapy is aimed at reducing sodium and water retention to decrease the workload of the heart. The primary care provider may restrict sodium intake in an attempt to decrease fluid retention. Many patients need to omit table salt (no added salt) from their diet, thus reducing sodium intake to about 3 g daily.

If salt intake must be reduced further, the patient may need to eliminate high-sodium foods (e.g., ham, bacon, pickles) and all salt in cooking, thus reducing sodium intake to 2 g daily. If needed, collaborate with the dietitian to help the patient select foods that meet such a restricted therapeutic diet. There is no current evidence to suggest that less than 2 g of sodium daily is helpful; in fact, it may be harmful (Reilly et al., 2015)

Few patients are placed on severe fluid restrictions. However, patients with excessive aldosterone secretion may experience thirst and drink 3 to 5 liters of fluid each day. As a result, their fluid intake may be limited to a more normal 2 liters daily. *Supervise unlicensed assistive personnel (UAP) to ensure that they limit the prescribed intake and accurately record intake and output.*

Weigh the patient daily or delegate this activity to UAP and supervise that it is done. Keep in mind that *1 kg of weight gain or loss equals 1 liter of retained or lost fluid.* The same scale should be used every morning before breakfast for the most accurate assessment of weight. Monitor for an expected *decrease* in weight because excess fluid is excreted from the body.

## Drug Therapy.

Common drugs prescribed to reduce preload are diuretics and venous vasodilators. *Morphine sulfate* is also given for patients in *acute* HF to reduce anxiety, decrease preload and afterload, slow respirations, and reduce pain associated with a myocardial infarction (MI).

The primary health care provider adds *diuretics* to the regimen when diet and fluid restrictions have not been effective in managing the symptoms of HF. Diuretics are the first-line drug of choice in older adults with HF and fluid overload. These drugs enhance the renal excretion of sodium and water by reducing circulating blood volume, decreasing preload, and reducing systemic and pulmonary congestion.

The type and dosage of diuretic prescribed depend on the severity of HF and renal function. Loop diuretics such as furosemide (Lasix), torsemide (Demadex), and bumetanide (Burinex ♣) are most effective for treating fluid volume overload.

## Considerations for Older Adults

### Patient-Centered Care QSEN

Loop diuretics continue to work even after excess fluid is removed. As a result, some patients, especially older adults, can become dehydrated. Observe for signs of dehydration in the older adult, especially acute confusion, decreased urinary output, and dizziness. Provide evidence-based interventions to reduce the risk for falls, as discussed in Chapter 3.

For patients with *acute* HF, furosemide (Lasix) or bumetanide (Burinex ♣) can be administered by IV push (IVP). Lasix can be given in doses of 20 to 40 mg IVP and increased by 20 mg every 2 hours until the desired diuresis is obtained. The usual IVP initial dose for bumetanide is 1 to 2 mg once or twice daily, but it is more often given in a continuous infusion of 10 mg over 24 hours.

The health care provider may initially prescribe a thiazide diuretic, such as hydrochlorothiazide (HCTZ) (Microzide, Uroside ♣) and metolazone (Zaroxolyn), for *older adults* with *mild* volume overload. Zaroxolyn is a long-acting agent and therefore is often given every second, third, or fourth day, depending on patient need and tolerance.

Unlike loop diuretics, the action of thiazides is self-limiting (i.e., diuresis decreases after edema fluid is lost). Therefore the dehydration that may occur with loop diuretics is not common with these drugs. Patients also prefer thiazides because of the gradual onset of diuresis.

As HF progresses, many patients develop diuretic resistance with refractory edema. The health care provider may choose to manage this problem by prescribing both types of diuretics. Other strategies include IV continuous infusion of furosemide or bumetanide or rotating loop diuretics.

Monitor for and prevent potassium deficiency (hypokalemia) from diuretic therapy. The primary signs of hypokalemia are nonspecific neurologic and muscular symptoms, such as generalized weakness, depressed reflexes, and irregular heart rate. A potassium supplement may be prescribed for some patients. Other practitioners prescribe a potassium-sparing diuretic, such as spironolactone (Aldactone), for patients at risk for dysrhythmias from hypokalemia. Although not as effective as other diuretics, spironolactone helps retain potassium, which decreases the risk for ventricular dysrhythmias, and is usually used in stage III/IV heart failure. Monitor for hyperkalemia and renal failure and anticipate stopping the medication if potassium or creatinine levels rise.

Patients being managed with ACE inhibitors or ARBs and diuretics at the same time may not experience hypokalemia. However, if their kidneys are not functioning well, they may develop hyperkalemia (elevated serum potassium level). Review the patient's serum creatinine level. *If the creatinine is greater than 1.8 mg/dL, notify the health care provider before administering supplemental potassium.*

The health care provider may prescribe *venous vasodilators* (e.g., nitrates) for the patient with HF who has persistent dyspnea. Significant constriction of venous and arterial blood vessels occurs to compensate for reduced CO. Constriction reduces the volume of fluid that the vascular bed can hold and increases preload. Venous vasodilators may benefit by:

- Returning venous vasculature to a more normal capacity
- Decreasing the volume of blood returning to the heart

- Improving left ventricular function

Nitrates may be administered IV, orally, or topically. IV nitrates are used most often for *acute* HF. These drugs cause primarily venous vasodilation but also a significant amount of arteriolar vasodilation. Monitor the patient's blood pressure when starting nitrate therapy or increasing the dosage. Patients may initially report headache, but assure them that they will develop a tolerance to this effect and that the headache will cease or diminish. Acetaminophen (Tylenol, Exdol) can be given to help relieve discomfort.

Unfortunately, tolerance to the vasodilating effects develops when nitrates are given around-the-clock. To prevent this tolerance, the health care provider may prescribe at least one 12-hour nitrate-free period out of every 24 hours (usually overnight). Nitrates such as isosorbide (Imdur, ISMO) are prescribed to provide nitrate-free periods and reduce the problem of tolerance. [Chapter 38](#) discusses nitrates in more detail.

### Drugs That Enhance Contractility.

Contractility of the heart can also be enhanced with drug therapy. Positive inotropic drugs are most commonly used, but vasodilators and beta-adrenergic blockers may also be administered. For *chronic* HF, low-dose beta blockers are most commonly used. Digoxin (Lanoxin) may be prescribed to improve symptoms, thereby decreasing dyspnea and improving functional activity. This older and long-used drug is not expensive. In some settings, nesiritide (Natrecor) may be administered for end-stage HF, although this drug is very expensive (see discussion of nesiritide [Natrecor] for acute HF later in this chapter).

### Digoxin.

Although not as commonly used today, digoxin (Lanoxin, Novo-digoxin), a cardiac glycoside, has been demonstrated to provide symptomatic benefits for patients in *chronic* heart failure (HF) with sinus rhythm and atrial fibrillation. Digoxin (sometimes called *dig*) therapy reduces exacerbations of HF and hospitalizations when added to a regimen of ACE inhibitors or ARBs, beta blockers, and diuretics. However, it may increase mortality as a result of drug toxicity, especially in older adults.

The potential benefits of digoxin include:

- Increased contractility
- Reduced heart rate (HR)
- Slowing of conduction through the atrioventricular node
- Inhibition of sympathetic activity while enhancing parasympathetic activity

Digoxin is absorbed from the GI tract erratically. Many drugs, especially antacids, interfere with its absorption. It is eliminated primarily by renal excretion. Older patients should be maintained on lower doses of the drug than younger patients.

## NCLEX Examination Challenge 35-2

### Physiological Integrity

An 84-year-old client with heart failure presents to the emergency department (ED) with confusion, blurry vision, and an upset stomach. Which assessment data are **most** concerning to the nurse?

- A. Digoxin (Lanoxin) therapy daily
- B. Daily metoprolol (Lopressor)
- C. Furosemide (Lasix) twice daily
- D. Currently taking an antacid for upset stomach

## Nursing Safety Priority QSEN

### Drug Alert

Increased cardiac automaticity occurs with toxic digoxin levels or in the presence of hypokalemia, resulting in ectopic beats (e.g., premature ventricular contractions [PVCs]). Changes in potassium level, especially a decrease, cause patients to be more sensitive to the drug and cause toxicity.

The signs and symptoms of **digoxin toxicity** are often vague and nonspecific and include anorexia, fatigue, blurred vision, and changes in mental status, especially in older adults. Toxicity may cause nearly any dysrhythmia, but PVCs are most commonly noted. Assess for early signs of toxicity such as bradycardia and loss of the P wave on the ECG. Carefully monitor the apical pulse rate and heart rhythm of patients receiving digoxin.

The health care provider determines the desirable heart rate (HR) to achieve. Some health care providers prefer a rate between 50 and 60 beats/min. Report the development of either an irregular rhythm in a patient with a previously regular rhythm or a regular rhythm in a patient with a previously irregular one. Monitor serum digoxin and potassium levels (hypokalemia potentiates digoxin toxicity) to identify toxicity. Older adults are more likely than other patients to become toxic because of decreased renal excretion.

Any drug that increases the workload of the failing heart also increases its oxygen requirement. Be alert for the possibility that the patient may experience angina (chest pain) in response to digoxin.

### Other Inotropic Drugs.

Patients experiencing *acute* heart failure are candidates for IV drugs that increase contractility. For example, *beta-adrenergic agonists*, such as dobutamine (Dobutrex), are used for short-term treatment of *acute* episodes of HF. Dobutamine improves cardiac contractility and thus cardiac output and myocardial-systemic perfusion.

A more potent drug used for *acute* HF, milrinone (Primacor), functions as a vasodilator/inotropic agent with phosphodiesterase activity. Also known as a *phosphodiesterase inhibitor*, this drug increases cyclic adenosine monophosphate (cAMP), which enhances the entry of calcium into myocardial cells to increase contractile function. Like the beta-adrenergic agonists, Primacor is given IV.

Levosimendan (Simdax) is a calcium-sensitizing medication and a positive inotropic drug. It appears to bind to troponin C in the heart muscle and therefore increases the contraction of the heart. Simdax is used most often in patients who have had or are at high risk for myocardial infarction. [Chapter 38](#) discusses inotropic drugs in more detail.

### Beta-Adrenergic Blockers.

Beta-adrenergic blockers (commonly referred to as *beta blockers*) improve the condition of some patients in HF. Prolonged exposure to increased levels of sympathetic stimulation and catecholamines worsens cardiac function. Beta-adrenergic blockade reverses this effect, improving morbidity, mortality, and quality of life for patients in HF.

Beta blockers must be started slowly for HF. *Patients in acute HF should not be started on these drugs.* Carvedilol (Coreg), metoprolol succinate (Toprol XL, Betaloc ) and bisoprolol (Zebeta) are approved for treatment of *chronic* HF. **Do not confuse metoprolol tartrate with metoprolol succinate.** Current guidelines only recommend the sustained-release formulation of metoprolol for chronic HF treatment. The first dose is extremely low. Monitor the patient either in the hospital or in the primary health care provider's office to assess for bradycardia or hypotension after the first dose is given.

Instruct the patient to weigh daily and report any signs of worsening HF immediately. The primary health care provider gradually increases the drug dose if HF worsens. The patient is evaluated at least weekly for changes in BP, pulse, activity tolerance, and orthopnea. A modest drop in BP is acceptable if he or she remains asymptomatic and can stand without experiencing dizziness or a further drop in BP. The resting heart rate (HR) should remain between 55 and 60 and increase slightly with exercise. Activity tolerance improves, and less orthopnea is experienced. Most patients with mild and moderate HF demonstrate improved ejection fraction, decreased hospital admissions, and improvement in symptoms when beta blockers are added to their treatment regimens. The benefits of this therapy are seen over a long period rather than immediately.

### Aldosterone Antagonists.

Those with Class II-IV HF with EF <35% or history of diabetes should be prescribed aldosterone

antagonists (spironolactone [Aldactone] or eplerenone [Inspra]). As a potassium-sparing diuretic, aldosterone antagonists decrease the risk for dysrhythmias from hypokalemia. Aldosterone antagonists also block the effect of aldosterone, which decreases the amount of water and sodium retained. Monitor the patient for hyperkalemia and renal failure and anticipate stopping the medication if potassium or creatinine levels rise. Every-other-day dosing is an alternative for patients at risk of developing hyperkalemia.

### HCN Channel Blocker.

Ivabradine (Corlanor) is a new medication, approved by the Food and Drug Administration (FDA) in 2015, for the treatment of stabilized chronic heart failure. This medication is a first-in-class, hyperpolarization-activated cyclic nucleotide-gated (HCN) channel blocker, which slows the heart rate by inhibiting a specific channel in the sinus node. It has been shown to reduce the risk of hospitalization rate in HF patients. Ivabradine is used for HF patients who have an ejection fraction (EF) <35% who are in sinus rhythm with a resting heart rate  $\geq$ 70 beats/min. This medication is used for patients who are either on the maximally tolerated dose of beta-blocker therapy or have a contraindication to it.

Ivabradine is contraindicated with hypotension, sick sinus syndrome, third-degree heart block, pacemaker dependence, severe hepatic impairment, and use of cytochrome P4503A4 inhibitors. Side effects include bradycardia, hypertension, atrial fibrillation, and luminous phenomena (visual brightness).

Advise the patient to take this medication with meals but to avoid taking St. John's wort or drinking grapefruit juice while on it. Teach the patient how to check radial pulse and to report low heart rate or irregularity to provider. Advise him or her that visual changes associated with light may occur with initial treatment. These visual changes are usually transient and will disappear with time (Aschenbrenner, 2015). Patients should use caution when driving or using machines in situations where light intensity may change abruptly.

## NCLEX Examination Challenge 35-3

### Physiological Integrity

A client with chronic heart failure presents to the ED with a new onset of atrial fibrillation. Which of the following medications would the nurse question?

- A. Lasix (furosemide)
- B. Toprol XL (metoprolol succinate)
- C. Cardizem (diltiazem)
- D. Corlanor (ivabradine)

For patients with *diastolic* HF, drug therapy has not been as effective. Calcium channel blockers, ACE inhibitors, and beta blockers have been used with various degrees of success.

### Other Nonsurgical Options.

In addition to drug therapy, other nonsurgical options, both noninvasive and invasive, may be used and include:

- Continuous positive airway pressure (CPAP)
- Cardiac resynchronization therapy (CRT)
- CardioMEMS™ implantable monitoring system
- Investigative gene therapy

**Continuous positive airway pressure (CPAP)** is a respiratory treatment that improves obstructive sleep apnea in patients with HF. It also improves cardiac output (CO) and ejection fraction (EF) by decreasing afterload and preload, blood pressure (BP), and dysrhythmias. Sleep apnea is directly correlated with coronary artery disease as a result of diminished oxygen supply to

the heart during apneic episodes. This respiratory problem is discussed in detail in [Chapter 29](#).

**Cardiac resynchronization therapy (CRT)**, also called *biventricular pacing*, uses a permanent pacemaker alone or is combined with an implantable cardioverter/defibrillator. Electrical stimulation causes more synchronous ventricular contractions to improve EF, CO, and mean arterial pressure. This modality is indicated for patients with Class III or IV HF, an EF of less than 35%, and presence of a left bundle branch block. CRT improves the patient's ability to perform ADLs. [Chapter 34](#) discusses pacing in more detail.

**CardioMEMs™ implantable monitoring system** is inserted into the pulmonary artery and allows the patient to take a daily reading of the pulmonary artery pressure. These data are transmitted to the provider's office and allow for management and adjustment of medications. The device, about the size of the quarter, is implanted during a right heart catheterization and is permanent. The patient is provided a special pillow with an antenna and portable electronic unit. He or she turns the system on, places the pillow on the bed, and lies on top of the pillow. The device will advise if the position needs to be changed and when reading is complete. The CardioMEMS™ device can detect increases in pulmonary pressures, indicating fluid retention before the patient demonstrates symptoms. Therapy can be adjusted before symptoms, which may prevent readmission to the hospital and improve quality of life.

**Gene therapy** may be indicated for patients in end-stage HF who are not candidates for heart transplantation. This therapy replaces damaged genes with normal or modified genes by a series of injections of growth factor into the left ventricle. Although still investigative, this therapy may result in improved exercise tolerance and regrowth of cardiac cells.

### Surgical Management.

Heart transplantation is still the ultimate choice for end-stage HF (see the [Heart Transplantation](#) section). Several surgical procedures are available to improve CO in patients who are *not* candidates for a transplant or are awaiting transplant.

### Ventricular Assist Devices.

Patients with debilitating end-stage heart failure are often sent home on drug therapy and referred to hospice. However, ventricular assist devices (VADs) can dramatically improve the lives of many patients. In this procedure, a mechanical pump is implanted to work with the patient's own heart ([Fig. 35-2](#)). Both left and right VADs are available, depending on the type of HF the patient has. Those with end-stage kidney disease, severe chronic lung disease, clotting disorders, and infections that do not respond to antibiotics are not candidates for this surgery. Postoperative complications include bleeding, infective endocarditis, ventricular dysrhythmias, and stroke. Nursing care is similar to that described for cardiac surgery in [Chapter 38](#).

**FIG. 35-2** The AbioCor Implantable Replacement Heart has four main parts that are placed inside the body. *TET*, Transtelephonic electrocardiographic transmission device. (Courtesy Abiomed, Inc., Danvers, MA.)

VADs can be used short-term while awaiting heart transplantation (a “bridge-to-transplant” procedure) or long-term (destination therapy). Most patients survive with a VAD until a transplant

is available.

### Other Surgical Therapies.

HF causes ventricular remodeling, or dilation, which worsens as the disease progresses. Several new therapies are used to reshape the left ventricle in patients with HF. Perioperative care is similar to that for the patient having a coronary artery bypass graft (CABG) (see [Chapter 38](#)). The most common ventricular reconstructive procedures include:

- **Partial left ventriculectomy (PLV)**
- Endoventricular circular patch cardioplasty
- Acorn cardiac support device
- Myosplint

Also known as *heart reduction surgery*, PLV (sometimes referred to as the *Batista procedure*) involves removing a triangle-shaped section of the weakened heart in the left lateral ventricle to reduce the ventricle's diameter and decrease wall tension. In *endoventricular circular patch cardioplasty*, the surgeon removes portions of the cardiac septum and left ventricular wall and grafts a circular patch (synthetic or autologous) into the opening. This procedure provides a more normal shape to the left ventricle to improve the heart's ejection fraction (EF) and cardiac output (CO).

The **Acorn cardiac support device** is a polyester mesh jacket that is placed over the ventricles to provide support and avoid overstretching the myocardial muscle. The material for the jacket has been used for other procedures, such as vascular grafts. The jacket appears to reduce hypertrophy of the heart muscle and assists with improvement of the EF.

The **Myosplint** has recently been approved for use in the United States. Electrical stimulation of several tension pads (splints) on the outside of the ventricle changes it to a more normal shape to improve function.

### Decreasing Fatigue

#### Planning: Expected Outcomes.

The expected outcomes are that the patient will have decreased fatigue and gain energy as HF improves.

#### Interventions.

The patient in severe heart failure initially requires physical and emotional rest for *energy management*. On the first day of hospitalization, he or she may sit up in a chair for meals and perform basic leg exercises while out of bed. Organize nursing care to allow periods of rest. Collaborate with the interprofessional team, including the physician, nurse, respiratory therapist, and clergy, to observe and document the patient's physiologic and emotional response to activity.

As the patient's condition improves, it is important to consult cardiac rehabilitation specialists. The cardiac rehabilitation specialist will start ambulation, usually on hospital day 2. The cardiac rehabilitation specialist or nurse checks the BP, pulse, and oxygen saturation before and after the activity. A BP change of more than 20 mm Hg or a pulse increase of more than 20 beats/min may indicate that the activity is too stressful. Other indications of activity intolerance include dyspnea, fatigue, and chest pain. Ask a patient having any of these symptoms to rate exertion on a scale of 1 to 20, with 20 being the maximum perceived exertion. If the patient rates the exertion more than 12, remind him or her to slow down. If activity is tolerated, the cardiac rehabilitation specialist steadily increases the activity level until the patient is ambulating 200 to 400 feet several times per day.

If the patient is able, the cardiac rehabilitation specialist (or assistive nursing or physical therapy personnel) might time him or her for 6 minutes while walking at a comfortable pace. The distance the patient can walk can be used to determine his or her functional level and activity plan. At discharge, encourage the patient to continue with cardiac rehabilitation. In addition to exercise programs, cardiac rehabilitation provides education on risk factor modification, medication adherence, and diet and weight management.

### Preventing or Managing Pulmonary Edema

#### Planning: Expected Outcomes.

The most desirable outcome is that the patient will not develop pulmonary edema as a result of

heart failure (HF). However, if the patient progresses to pulmonary edema, the expected outcome is that he or she will recover from this complication without other problems.

### Interventions.

Monitor for signs of acute pulmonary edema, a life-threatening event that can result from severe HF (with fluid overload), acute myocardial infarction (MI), mitral valve disease, and possibly dysrhythmias. In pulmonary edema, the left ventricle fails to eject sufficient blood, and pressure increases in the lungs as a result. The increased pressure causes fluid to leak across the pulmonary capillaries and into the lung airways and tissues.

## Nursing Safety Priority QSEN

### Critical Rescue

Assess for and report early symptoms, such as crackles in the lung bases, dyspnea at rest, disorientation, and confusion, especially in older patients. Document the precise location of the crackles because the level of the fluid progresses from the bases to higher levels in the lungs as the condition worsens. The patient in acute pulmonary edema is typically extremely anxious, tachycardic, and struggling for air. As pulmonary edema becomes more severe, he or she may have a moist cough productive of frothy, blood-tinged sputum; and his or her skin may be cold, clammy, or cyanotic. Chart 35-3 lists the major signs and symptoms of this complication.

### Chart 35-3

## Key Features

### Pulmonary Edema

- Crackles
- Dyspnea at rest
- Disorientation or acute confusion (especially in older adults as early symptom)
- Tachycardia
- Hypertension or hypotension
- Reduced urinary output
- Cough with frothy, pink-tinged sputum
- Premature ventricular contractions and other dysrhythmias
- Anxiety
- Restlessness
- Lethargy

The patient diagnosed with pulmonary edema is admitted to the acute care hospital, often in a critical care unit. Reassure the patient and family that his or her distress will decrease with proper management.

## Nursing Safety Priority QSEN

### Critical Rescue

If the patient is not hypotensive, place in a sitting (high-Fowler's) position with the legs down to decrease venous return to the heart. The *priority nursing action* is to administer oxygen therapy at 5 to 12 L/min by simple facemask or at 6 to 10 L/min by nonrebreathing mask with reservoir (which may deliver up to 100% oxygen) to promote GAS EXCHANGE and PERFUSION (Urden et al., 2016). Apply a pulse oximeter and titrate the oxygen flow to keep the patient's oxygen saturation above 90%. If supplemental oxygen does not resolve the patient's respiratory distress, collaborate with the respiratory therapist, physician, advanced practice nurse, or physician assistant for more aggressive therapy, such as continuous positive airway pressure (CPAP) or bi-level positive airway pressure (BiPAP) ventilation. Intubation and mechanical ventilation may be needed for some patients.

If the patient's systolic blood pressure is above 100, give sublingual nitroglycerin (NTG) to decrease afterload and preload every 5 minutes for three doses while establishing IV access for additional drug therapy. The health care provider prescribes rapid-acting diuretics, such as furosemide (Lasix) or bumetanide (Bumex). Give furosemide (Lasix) IV push (IVP) over 1 to 2 minutes, usually at a starting dose of 20 to 40 mg for diuretic-naïve patients and another 40 mg if needed in 30 minutes. Patients already on oral diuretic therapy should be given an amount that is the same or doubled in milligrams as initial IV diuretic therapy. Administer each increment of 40 mg of Lasix over 1 to 2 minutes to avoid ototoxicity. Bumetanide (Bumex) may be administered 1 to 2 mg IVP or as a continuous infusion to provide consistent fluid removal over 24 hours. Monitor vital signs frequently, at least every 30 to 60 minutes.

If the patient's blood pressure is adequate, IV morphine sulfate may be prescribed, 1 to 2 mg at a time, to reduce venous return (preload), decrease anxiety, and reduce the work of breathing. Monitor respiratory rate and BP closely. Other drugs, such as IV NTG and drugs to treat HF, may be administered. Monitor the patient's vital signs closely (especially BP) while these drugs are being given.

In severe cases of fluid overload and renal dysfunction or diuretic resistance, ultrafiltration may be used. Ultrafiltration can remove up to 500 mL/hr and uses a blood flow rate of 10 to 40 mL/hr. Peripheral lines are used for IV access. See [Chapter 68](#) for a complete discussion of this procedure and nursing implications.

The benefits of ultrafiltration include:

- Decrease in cardiac filling pressures
- Decrease in pulmonary arterial pressure
- Increase in cardiac index
- Reduction in norepinephrine, rennin, and aldosterone

## Clinical Judgment Challenge 35-1

### Safety; Patient-Centered Care; Evidence-Based Practice; Informatics QSEN

A 73-year-old woman is admitted to the telemetry unit with right-sided heart failure, type 2 diabetes mellitus, hypertension, and chronic obstructive pulmonary disease (COPD). When the patient arrives to the unit, you observe that her color is pale, she is becoming increasingly dyspneic, and she reports a new onset of chest discomfort. The patient's husband is very concerned because he thinks his wife is slightly disoriented. Her oxygen saturation levels are 88% on oxygen 2 liters per nasal cannula.

1. Using clinical judgment, what should you assess first?
2. What evidence-based actions will you plan to implement at this time based on your assessment? What is the source of the evidence?
3. The patient's health care provider prescribes an initial dose of furosemide (Lasix) 40 mg IVP. What assessments will you perform to determine if the drug was effective?
4. The patient's husband remains very anxious and asks to stay at her bedside. What will you tell him about her condition at this time? Should the patient's husband be present during her

emergency treatment? Why or why not?

5. After two doses of furosemide, the patient's condition improves. What data will you document in the electronic medical record (EMR)?

### Care Coordination and Transition Management

Patients who are not adequately prepared for discharge or do not have adequate community support and follow-up for self-management are at high risk for repeated hospital admissions for heart failure (HF). Collaborate with the case manager or care coordinator to assess the patient's needs for health care resources.

The Heart Failure Core Measure Set must be determined for hospitals accredited by The Joint Commission. These measures include that the patient with HF has:

- Discharge instructions (including information on diet, activity, medications, weight monitoring, and planning for worsening symptoms)
- Evaluation of left ventricular systolic function
- An ACEI or ARB for left ventricular systolic dysfunction
- Adult smoking-cessation advice/counseling (if appropriate)
- Posthospitalization visit with the primary health care provider within 7 days of discharge

An inability to obtain help in activities such as food shopping and obtaining medications is a major contributor to hospital readmission. If home support is available, the patient may be discharged home in the care of a family member or other caregiver. Home care nurses may direct the care and assess for adherence to the discharge plan; home health aides may provide assistance with ADLs for a short time. If the patient has multiple health problems or has been severely compromised by heart disease, he or she may require admission to a skilled unit for either transitional or long-term care.

#### Home Care Management.

The home care nurse's interventions focus on assessment and health teaching, which are reimbursable by Medicare and other third-party payers. [Chart 35-4](#) lists the major areas of home health assessment.

#### Chart 35-4

### Home Care Assessment

#### The Patient With Heart Failure

Assess for signs of heart failure, including:

- Changes in vital signs (heart rate >100 beats/min at rest, new atrial fibrillation, blood pressure <90 or >150 systolic)
- Indications of poor tissue perfusion:
  - Fatigue
  - Angina
  - Activity intolerance
  - Changes in mental status

- Pallor or cyanosis
- Cool extremities
- Indications of congestion:
- Presence of cough or dyspnea
- Weight gain
- Jugular venous distention and peripheral edema

Assess functional ability, including:

- Performance of ADLs
- Mobility and ambulation (review frequency and duration of walking, development of symptoms, and pulse rate)
- Cognitive ability

Assess nutritional status, including:

- Food and fluid intake
- Intake of sodium-rich foods
- Alcohol consumption
- Skin turgor

Assess home environment, including:

- Safety hazards, especially related to oxygen therapy
- Structural barriers affecting functional ability
- Social support (family, home health services)

Assess the patient's adherence and understanding of illness and its treatment, including:

- Signs and symptoms to report to primary health care provider
- Dosages, effects, and side or toxic effects of medications

- When to report for laboratory and health care provider visits
- Ability to accurately weigh self on scale
- Presence of advance directive
- Use of home oxygen, if appropriate

Assess patient and caregiver coping skills.

Patients with chronic HF need to make many adjustments in their lifestyles. They must adhere to the collaborative plan of care that includes dietary restrictions, activity, prescriptions, and drug therapy. They need careful, concise explanations of the self-management plan. The community-based nurse in any setting encourages the patient to verbalize fears and concerns about his or her illness and helps to explore coping skills. Patient participation in self-management can help alleviate and control symptoms.

### Self-Management Education.

Health teaching is essential for promoting self-management (also called *self-care*). Many patients are re-admitted to hospitals because they do not maintain their prescribed treatment plan, including lifestyle changes. Because of the need for extensive discharge instructions, most hospitals are using teaching packets with videos, CDs, and easy-to-read information about the importance of adhering to specific self-management strategies at home. One standardized and commonly used self-management plan called MAWDS is outlined in Table 35-4. Medication reconciliation is also important to be sure that similar drugs are not being prescribed and that patients meet the Core Measure requirements for HF. It is important to perform a learning needs assessment and tailor education to the patient's particular need to see changes in behavior and improved outcomes.

**TABLE 35-4**  
**Heart Failure Self-Management Health Teaching (MAWDS)**

<p><b>Medications:</b></p> <ul style="list-style-type: none"> <li>• Take medications as prescribed and do not run out.</li> <li>• Know the purpose and side effects of each drug.</li> <li>• Avoid NSAIDs to prevent sodium and fluid retention.</li> </ul> <p><b>Activity:</b></p> <ul style="list-style-type: none"> <li>• Stay as active as possible but don't overdo it.</li> <li>• Know your limits.</li> <li>• Be able to carry on a conversation while exercising.</li> </ul> <p><b>Weight:</b></p> <ul style="list-style-type: none"> <li>• Weigh each day at the same time on the same scale to monitor for fluid retention.</li> </ul> <p><b>Diet:</b></p> <ul style="list-style-type: none"> <li>• Limit daily sodium intake to 2 to 3 grams as prescribed.</li> <li>• Limit daily fluid intake to 2 liters.</li> </ul> <p><b>Symptoms:</b></p> <ul style="list-style-type: none"> <li>• Note any new or worsening symptoms and notify the health care provider immediately.</li> </ul>
--

Ambulatory care clinics for HF patients are also becoming increasingly common. Their purpose is to offer assessments, drug therapy, and health teaching. Some nurses specialize in caring for patients with health failure.

### Activity Schedule.

Encourage patients with HF to stay as active as possible and to develop a regular exercise regimen (e.g., home walking program). However, teach the patient not to overdo it. Patients should be referred to cardiac rehabilitation programs. Medicare and third-party payers are now reimbursing for this service, but patients may need to wait 6 weeks to fully participate in the program.

Remind patients with persistent crackles and uncontrolled edema to begin exercise after their condition stabilizes. When exercise is indicated, teach the patient to begin walking 200 to 400 feet per day. At home the patient should try to walk at least 3 times a week and should slowly increase the amount of time walked over several months. If chest pain or severe dyspnea occurs while exercising or the patient has fatigue the next day, he or she is probably advancing the activity too quickly and should slow down. Encourage him or her to keep a diary that documents the time and

duration of each exercise session, heart rate, and any symptoms that occur with exercise.

### Indications of Worsening or Recurrent Heart Failure.

Many patients who are re-admitted to hospitals for treatment of HF fail to seek medical attention promptly when symptoms recur.

## Nursing Safety Priority QSEN

### Action Alert

Per the HF Core Measure for discharge instructions, teach the patient and caregiver to immediately report to the primary health care provider the occurrence of *any* of these symptoms, which could indicate worsening or recurrent heart failure:

- Rapid weight gain (3 lb in a week or 1 to 2 lb overnight)
- Decrease in exercise tolerance lasting 2 to 3 days
- Cold symptoms (cough) lasting more than 3 to 5 days
- Excessive awakening at night to urinate
- Development of dyspnea or angina at rest or worsening angina
- Increased swelling in the feet, ankles, or hands

### Drug Therapy.

Provide oral, written, and video instructions about the drug regimen. Teach the caregiver and patient how to count a pulse rate, especially if the patient is taking digoxin, beta blockers, or ivabradine (Corlanor). [Chart 35-5](#) lists instructions for the patient taking beta blockers and digoxin.

## Chart 35-5

# Patient and Family Education: Preparing for Self-Management

## Beta Blocker/Digoxin Therapy

- Establish same time of day to take this medication every day.
- Continue taking this medication unless your health care provider tells you to stop.
- Do not take digoxin at the same time as antacids or cathartics (laxatives).
- Take your pulse rate before taking each dose of digoxin. Notify your health care provider of a change in pulse rate (60 to 100 beats/min is typically normal, depending on your baseline pulse rate) or rhythm and increasing fatigue, muscle weakness, confusion, or loss of appetite (signs of digoxin toxicity).
- If you forget to take a dose, it may be delayed a few hours. However, if you do not remember it until the next day, you should take only your usual daily dose.
- Report for scheduled laboratory tests (e.g., potassium and digoxin levels).
- If potassium supplements are prescribed, continue the dose until told to stop by your health care provider.

Advise the patient taking diuretics to take them in the morning to avoid waking during the night

for voiding. After determining whether he or she has a weight scale and can use it, emphasize the importance of weighing each morning at the same time. Daily weights indicate whether the patient is losing or retaining fluid. Some patients are taught to use a sliding scale to adjust their daily diuretic dose, depending on their daily weight, similar to the way a patient with diabetes adjusts an insulin dose based on the capillary glucose level.

Teach patients taking ACEIs, ARBs, or sacubitril/valsartan (Entresto) to move slowly when changing positions, especially from a lying to a sitting position. Remind them to report dizziness, light-headedness, and cough to the health care provider.

Serum potassium level and renal function are monitored at least every few months for patients taking diuretics and ACE inhibitors, ARBs or sacubitril/valsartan (Entresto). Diuretics, especially loop diuretics such as furosemide (Lasix) and bumetanide (Burinex ) , deplete potassium and often cause hypokalemia. Conversely, ACE inhibitors, ARBs, sacubitril/valsartan (Entresto), or potassium-sparing diuretics may result in potassium retention. If serum potassium levels drop below 4 mEq/L, the health care provider may prescribe potassium supplements or add a potassium-sparing diuretic such as spironolactone (Aldactone) or eplerenone (Inspra). Provide information about potassium-rich foods to include in the diet for patients at risk for hypokalemia (see [Chapter 11](#)).

### Nutrition Therapy.

Remind patients with chronic HF to restrict their dietary sodium. In collaboration with the home care nurse or dietitian, provide written instructions on low- or restricted-sodium diets. A 3-g sodium diet is recommended for *mild-to-moderate* disease. Remind the patient to avoid salty foods and table salt. Patients usually find this diet acceptable and fairly easy to follow. Teach patients how to read food labels, specifically ingredients that include sodium.

A 2-g sodium diet may be needed for patients with *severe* HF. They should not add salt during or after meal preparation, avoid milk and milk products, use few canned or prepared foods, and read food labels to determine sodium content. This diet is not easily tolerated for many patients, and the cost of low-sodium foods can be a financial burden.

Commercial salt substitutes typically contain potassium. Teach patients that their renal status and serum potassium level must be evaluated while using these products. Suggest that patients try lemon, spices, and herbs to enhance the flavor of low-salt foods.

### Advance Directives.

HF is a chronic, progressive debilitating disease. The only potential cure is transplantation. Early in the diagnosis stage, patients and families should be made aware of the progressive nature of this disease process. About 50% of deaths from HF are sudden—many without any warning or worsening of symptoms. Assess whether the patient has written advance directives. If not, provide information about them during the hospital stay. Because most of these deaths occur at home, it is important for the primary health care provider or home care nurse to discuss advance directives with the patient and family. The family should be prepared to act in agreement with the patient's wishes in the event of cardiac arrest. If resuscitation is desired, be sure that the family knows how to activate the emergency medical system (EMS) and how to provide cardiopulmonary resuscitation (CPR) until an ambulance arrives. If CPR is not desired, the patient, family, and nurse plan how the family will respond. Palliative consultation can provide support to the patient and the family as condition progresses and the patient's conditions declines. Goals of palliative care are to improve the quality of life, manage symptoms, and provide support. As the patient approaches end of life, hospice consultation would be appropriate. [Chapter 7](#) discusses hospice and end-of-life care in detail.

### Health Care Resources.

A home care nurse, ambulatory care clinic, or nurse-led follow-up program may be needed to assess the patient's adherence to drug and nutrition therapy and to monitor for worsening or recurrent HF. Many large hospitals use follow-up telephone calls or teleconferencing/videoconferencing devices to monitor patients at home. Teleconferencing can also assess the patient's heart and lung sounds. These follow-up processes have been very successful in decreasing repeated hospital stays for chronic HF patients.

In addition to home care support, other resources are available for patient education and family

support. The American Heart Association is an excellent community resource for print and electronic pamphlets, books, newsletters, and videotapes or DVDs related to HF and heart disease. The organization also provides referrals to various local support groups for patients and their caregivers.

For equipment needs (e.g., home oxygen therapy, hospital bed), medical supply companies provide setup and maintenance services. [Chapter 28](#) provides a detailed description of home oxygen therapy.

### ◆ **Evaluation: Reflecting**

Evaluate the care of the patient with HF on the basis of the identified patient problems. The expected outcomes include that the patient will:

- Have adequate pulmonary tissue PERFUSION
- Have increased cardiac pump effectiveness
- Take actions to manage energy
- Be free of pulmonary edema

# Valvular Heart Disease

## ❖ Pathophysiology

Acquired valvular dysfunctions include mitral stenosis, mitral regurgitation, mitral valve prolapse, aortic stenosis, and aortic regurgitation (Chart 35-6). The tricuspid valve is not affected often and may occur following endocarditis in IV drug abusers.

Chart 35-6

## Key Features

### Valvular Heart Disease

MITRAL STENOSIS	MITRAL REGURGITATION	MITRAL VALVE PROLAPSE	AORTIC STENOSIS
Fatigue Dyspnea on exertion Orthopnea Paroxysmal nocturnal dyspnea Hemoptysis Hepatomegaly Neck vein distention Pitting edema Atrial fibrillation Rumbling, apical diastolic murmur	Fatigue Dyspnea on exertion Orthopnea Palpitations Atrial fibrillation Neck vein distention Pitting edema High-pitched holosystolic murmur	Atypical chest pain Dizziness, syncope Palpitations Atrial tachycardia Ventricular tachycardia Systolic click	Dyspnea on exertion Angina Syncope on exertion Fatigue Orthopnea Paroxysmal nocturnal dyspnea Harsh, systolic crescendo-decrescendo murmur

## Mitral Stenosis

**Mitral stenosis** usually results from rheumatic carditis, which can cause valve thickening by fibrosis and calcification. Rheumatic fever is the most common cause of the problem. In mitral stenosis, the valve leaflets fuse and become stiff, and the chordae tendineae contract and shorten. The valve opening narrows, preventing normal blood flow from the left atrium to the left ventricle. As a result of these changes, left atrial pressure rises, the left atrium dilates, pulmonary artery pressures increase, and the right ventricle hypertrophies.

Pulmonary congestion and right-sided heart failure occur first. Later, when the left ventricle receives insufficient blood volume, preload is decreased and cardiac output (CO) falls.

People with mild mitral stenosis are usually asymptomatic. As the valvular orifice narrows and pressure in the lungs increases, the patient experiences dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea (sudden dyspnea at night), palpitations, and dry cough. Hemoptysis (coughing up blood) and pulmonary edema occur as pulmonary hypertension and congestion progress. Right-sided HF can cause hepatomegaly (enlarged liver), neck vein distention, and pitting dependent edema late in the disorder.

On palpation, the pulse may be normal, rapid, or irregularly irregular (as in atrial fibrillation). Because the development of atrial fibrillation indicates that the patient may decompensate, the health care provider should be notified immediately of the development of an irregularly irregular rhythm. A rumbling, apical diastolic murmur is noted on auscultation.

## Mitral Regurgitation (Insufficiency)

The fibrotic and calcific changes occurring in **mitral regurgitation** (insufficiency) prevent the mitral valve from closing completely during *systole*. Incomplete closure of the valve allows the backflow of blood into the left atrium when the left ventricle contracts. During *diastole*, regurgitant output again flows from the left atrium to the left ventricle along with the normal blood flow. The increased volume must be ejected during the next systole. To compensate for the increased volume and pressure, the left atrium and ventricle dilate and hypertrophy.

The primary causes of mitral regurgitation are mitral valve prolapse and rheumatic heart disease (McCance et al., 2014). Other causes include infective endocarditis, papillary muscle dysfunction, or

rupture resulting from ischemic heart disease or congenital anomalies. Rheumatic heart disease is the number-one cause in developing nations. When it results from rheumatic heart disease, it usually coexists with some degree of mitral stenosis; it affects women more often than men.

Mitral regurgitation usually progresses slowly; patients may remain symptom-free for decades. Symptoms begin to occur when the left ventricle fails in response to chronic blood volume overload. They include fatigue and chronic weakness as a result of reduced CO. Dyspnea on exertion and orthopnea develop later. A significant number of patients report anxiety, atypical chest pains, and palpitations. Assessment may reveal normal BP, atrial fibrillation, or changes in respirations characteristic of left ventricular failure.

When right-sided HF develops, the neck veins become distended, the liver enlarges (hepatomegaly), and pitting edema develops. A high-pitched systolic murmur at the apex, with radiation to the left axilla, is heard on auscultation. Severe regurgitation often exhibits a third heart sound (S<sub>3</sub>).

### Mitral Valve Prolapse

**Mitral valve prolapse (MVP)** occurs because the valvular leaflets enlarge and prolapse into the left atrium during systole. This abnormality is usually benign but may progress to pronounced mitral regurgitation in some patients.

The etiology of MVP is variable and has been associated with conditions such as Marfan syndrome and other congenital cardiac defects. MVP also has a familial tendency. Usually, however, no other cardiac abnormality is found.

Most patients with MVP are asymptomatic. However, some may report chest pain, palpitations, or exercise intolerance. Chest pain is usually atypical, with patients describing a sharp pain localized to the left side of the chest. Dizziness, **syncope** (“blackouts”), and palpitations may be associated with atrial or ventricular dysrhythmias.

A normal heart rate and BP are usually found on physical examination. A midsystolic click and a late systolic murmur may be heard at the apex of the heart. The intensity of the murmur is not related to the severity of the prolapse.

### Aortic Stenosis

Aortic stenosis is the most common cardiac valve dysfunction in the United States and is often considered a disease of “wear and tear.” In **aortic stenosis**, the aortic valve orifice narrows and obstructs left ventricular outflow during systole. This increased resistance to ejection or afterload results in ventricular hypertrophy. As stenosis worsens, cardiac output becomes fixed and cannot increase to meet the demands of the body during exertion. Symptoms then develop. Eventually the left ventricle fails, blood backs up in the left atrium, and the pulmonary system becomes congested. Right-sided HF can occur late in the disease. *When the surface area of the valve becomes 1 cm or less, surgery is indicated on an urgent basis!*

Congenital bicuspid or unicuspid aortic valves are the primary causes for aortic stenosis in many patients. Rheumatic aortic stenosis occurs with rheumatic disease of the mitral valve and develops in young and middle-age adults. Atherosclerosis and degenerative calcification of the aortic valve are the major causative factors in older adults. *Aortic stenosis has become the most common valvular disorder in all countries with aging populations.*

The classic symptoms of aortic stenosis result from fixed cardiac output: dyspnea, angina, and syncope occurring on exertion. When cardiac output falls in the late stages of the disease, the patient experiences marked fatigue, debilitation, and peripheral cyanosis. A narrow pulse pressure is noted when the BP is measured. A diamond-shaped, systolic crescendo-decrescendo murmur is usually noted on auscultation.

### Aortic Regurgitation (Insufficiency)

In patients with **aortic regurgitation**, the aortic valve leaflets do not close properly during diastole; and the *annulus* (the valve ring that attaches to the leaflets) may be dilated, loose, or deformed. This allows flow of blood from the aorta back into the left ventricle during diastole. The left ventricle, in compensation, dilates to accommodate the greater blood volume and eventually hypertrophies.

Aortic insufficiency usually results from nonrheumatic conditions such as infective endocarditis, congenital anatomic aortic valvular abnormalities, hypertension, and Marfan syndrome (a rare, generalized, systemic disease of connective tissue).

Patients with aortic regurgitation remain asymptomatic for many years because of the compensatory mechanisms of the left ventricle. As the disease progresses and left ventricular failure occurs, the major symptoms are exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea. Palpitations may be noted with severe disease, especially when the patient lies on the left side. Nocturnal angina with diaphoresis often occurs.

On palpation, the nurse notes a “bounding” arterial pulse. The pulse pressure is usually widened, with an elevated systolic pressure and diminished diastolic pressure. The classic auscultatory finding is a high-pitched, blowing, decrescendo diastolic murmur.

## ❖ **Interprofessional Collaborative Care**

### ◆ **Assessment: Noticing**

A patient with valvular disease may suddenly become ill or slowly develop symptoms over many years. Collect information about the patient's family health history, including valvular or other forms of heart disease to which he or she may be genetically predisposed. Ask about attacks of rheumatic fever and infective endocarditis, the specific dates when these occurred, and the use of antibiotics to prevent recurrence of these diseases. Also ask the patient about a history of IV drug abuse, a common cause of infective endocarditis. Discuss his or her fatigue and tolerated activity levels, the presence of angina or dyspnea, and the occurrence of palpitations, if present.

As part of the physical assessment, obtain vital signs, inspect for signs of edema, palpate and auscultate the heart and lungs, and palpate the peripheral pulses. Assessment findings are summarized in [Chart 35-6](#).

*Echocardiography* is the noninvasive diagnostic procedure of choice to visualize the structure and movement of the heart. The more invasive transesophageal echocardiography (TEE) or transthoracic echocardiography (TTE) is also performed to assess most valve problems. Exercise tolerance testing (ETT) and stress echocardiography are sometimes done to evaluate symptomatic response and assess functional capacity. With either mitral or aortic stenosis, cardiac catheterization may be indicated to assess the severity of the stenosis and its other effects on the heart.

In patients with mitral stenosis, the chest x-ray shows left atrial enlargement, prominent pulmonary arteries, and an enlarged right ventricle. In those with mitral regurgitation (insufficiency), the chest x-ray reveals an increased cardiac shadow, indicating left ventricular and left atrial enlargement.

In the later stages of aortic stenosis, the chest x-ray may show left ventricular enlargement and pulmonary congestion. Left atrial and left ventricular dilation appear on the chest x-ray of patients with aortic regurgitation (insufficiency). If HF is present, pulmonary venous congestion is also evident.

The health care provider also requests an ECG to assess abnormalities such as left ventricular hypertrophy, as seen with mitral regurgitation and aortic regurgitation, or right ventricular hypertrophy, as seen in severe mitral stenosis. Atrial fibrillation is a common finding in both mitral stenosis and mitral regurgitation and may develop in aortic stenosis because of left atrial dilation.

### ◆ **Interventions: Responding**

Management of valvular heart disease depends on which valve is affected and the degree of valve impairment. Some patients can be managed with annual monitoring and drug therapy, whereas others require invasive procedures or heart surgery.

#### **Nonsurgical Management.**

Nonsurgical management focuses on drug therapy and rest. During the course of valvular disease, left ventricular failure with pulmonary or systemic congestion may develop.

#### **Drug Therapy.**

Diuretics, beta blockers, ACE inhibitors, digoxin, and oxygen are often administered to improve the symptoms of HF. Nitrates are administered cautiously to patients with aortic stenosis because of the potential for syncope associated with a reduction in left ventricular volume (preload). Vasodilators such as calcium channel blockers may be used to reduce the regurgitant flow for patients with aortic or mitral stenosis.

## Nursing Safety Priority QSEN

### Drug Alert

Teach patients with valve disease the importance of prophylactic antibiotic therapy before any invasive dental or oral procedure. This includes patients with a previous history of endocarditis and cardiac transplant or valve recipients. Have patients demonstrate appropriate oral hygiene because optimal oral health is the best intervention to prevent endocarditis.

Prophylactic antibiotics are *not* recommended before GI procedures such as upper GI endoscopy, colonoscopy, or procedures requiring genitourinary instrumentation.

A major concern in valvular heart disease is maintaining cardiac output (CO) if atrial fibrillation develops. With mitral valvular disease, left ventricular filling is especially dependent on atrial contraction. When atrial fibrillation develops, there is no longer a single coordinated atrial contraction. CO can decrease, and HF may occur. Ineffective atrial contraction may also lead to the stasis of blood and thrombi in the left atrium. Monitor the patient for the development of an irregular rhythm and notify the primary care provider if it develops. (See [Chapter 34](#) for a detailed explanation of atrial fibrillation.)

The primary care provider usually starts drug therapy first to control the heart rate (HR) and maintain CO (HR < 100 is considered a controlled ventricular response). After these outcomes are met, drugs are used in an attempt to restore normal sinus rhythm (NSR). In some cases, the provider elects to convert a patient from atrial fibrillation to sinus rhythm using IV diltiazem (Cardizem, Apo-Diltiaz) or amiodarone (Cordarone, Pacerone). Monitor the patient on a unit where both cardiac rhythm and BP can be watched closely. Synchronized countershock (cardioversion) may be attempted if atrial fibrillation is rapid, the patient's condition worsens, and the rhythm is unresponsive to medical treatment (see [Chapter 34](#)).

If the patient remains in atrial fibrillation, low-dose amiodarone (Cordarone) is often prescribed to slow ventricular rate. Procainamide hydrochloride (Procan ) may be added to the regimen. A beta-blocking agent (e.g., metoprolol) may also be considered to slow the ventricular response.

For valvular heart disease and chronic atrial fibrillation, anticoagulation with sodium warfarin (Coumadin, Warfilone) is usually a part of the plan of care to prevent thrombus formation. Thrombi (clots) may form in the atria or on defective valve segments, resulting in systemic emboli. If a portion breaks off and travels to the brain, one or more strokes may occur. Assess the patient's baseline neurologic status and monitor for changes. A transesophageal echocardiography (TEE) is often done before synchronized cardioversion to ensure that thrombi that could embolize when this therapy is administered are not present. The novel oral anticoagulants (NOACs) *rivaroxaban* (Xarelto), *dabigatran* (Pradaxa), *apixaban* (Eliquis), and *edoxaban* (Savaysa) are *not recommended* to anticoagulate patients with atrial fibrillation related to valvular disease.

Rest is often an important part of treatment. Activity may be limited because CO cannot meet increased metabolic demands and angina or HF can result. A balance of rest and exercise is needed to prevent skeletal muscle atrophy and fatigue.

### Noninvasive Heart Valve Reparative Procedures.

Reparative procedures are becoming more popular because of continuing problems with thrombi, endocarditis, and left ventricular dysfunction after valve replacement. Reparative procedures do not result in a normal valve, but they usually “turn back the clock,” resulting in a more functional valve and an improvement in CO. Turbulent blood flow through the valve may persist, and degeneration of the repaired valve is possible.

*Balloon valvuloplasty*, an invasive nonsurgical procedure, is possible for stenotic mitral and aortic valves; however, careful selection of patients is needed. It may be the initial treatment of choice for people with noncalcified, mobile mitral valves. Patients selected for *aortic* valvuloplasty are usually older and are at high risk for surgical complications or have refused operative treatment. The benefits of this procedure for aortic stenosis tend to be short lived, rarely lasting longer than 6 months.

When performing *mitral* valvuloplasty, the physician passes a balloon catheter from the femoral vein, through the atrial septum, and to the mitral valve. The balloon is inflated to enlarge the mitral orifice. For *aortic* valvuloplasty, the physician inserts the catheter through the femoral artery and

advances it to the aortic valve, where it is inflated to enlarge the orifice. The procedure usually offers immediate relief of symptoms because the balloon has dilated the orifice and improved leaflet mobility. The results are comparable with those of surgical commissurotomy for appropriately selected patients.

Minimally invasive techniques have expanded. For patients who are not surgical candidates, *transcatheter aortic valve replacement (TAVR)* is an alternate option for treatment of aortic stenosis (Fig. 35-3). A bioprosthetic valve is placed percutaneously via either the transfemoral or transapical route under general anesthesia in a hybrid operating room (a combination of a catheterization laboratory and cardiovascular operating room). After initial balloon aortic valvuloplasty, the new valve, which is wrapped around a balloon on a large catheter, is inserted via the femoral artery (see Fig. 35-3A-B). The patient is transvenously paced at a rate of about 200 beats/min to mimic ventricular standstill. The balloon is then inflated, and the valve deployed (see Fig. 35-3C-D). In the transapical approach, a small incision is made at the apex of the heart. The catheter is then threaded through the incision and the left ventricle to gain access to the aortic valve. As in the transvenous approach, the balloon and catheter are deployed during rapid transvenous pacing. This procedure is performed by a health care team consisting of interventional cardiologists and cardiovascular surgeons. The team must be prepared to convert to an open or traditional aortic valve replacement (AVR) if necessary. Care of the patient is similar to that of the patient undergoing coronary artery bypass graft (CABG) (see Chapter 38); however, this patient population only needs anticoagulation with aspirin and clopidogrel (Plavix) after the procedure.

**FIG. 35-3** Transcatheter aortic valve replacement (TAVR) procedure. **A**, Balloon aortic valvuloplasty. **B**, New valve placed around balloon. **C**, Balloon inflated, deploying valve. **D**, Catheter removed, valve in place.

The pulmonary valve can also be replaced percutaneously by a device using a similar procedure to the TAVR. The Mitraclip is used to repair the mitral valve in patients with mitral regurgitation. Under general anesthesia, access is gained percutaneously via the femoral vein, and the catheter and Mitraclip are advanced in the left atria and then the left ventricle. The Mitraclip is then retracted and deployed to hold the leaflets of the valve together. Care is similar to that of the patient undergoing CABG (see Chapter 38).

## **Nursing Safety Priority** QSEN

### **Action Alert**

After valvuloplasty, observe the patient closely for bleeding from the catheter insertion site and institute post-angiogram precautions. Bleeding is likely because of the large size of the catheter. Assess for signs of a regurgitant valve by closely monitoring heart sounds, CO, and heart rhythm. Because vegetations (thrombi) may have been dislodged from the valve, observe for any indication of systemic emboli (see the Infective Endocarditis section in this chapter).

### **Surgical Management.**

Surgeries for patients with valvular heart disease include invasive reparative procedures and

replacement. These procedures are performed after symptoms of left ventricular failure have developed but before irreversible dysfunction occurs. Surgical therapy is the *only* definitive treatment of *aortic stenosis* and is recommended when angina, syncope, or dyspnea on exertion develops.

### Invasive Heart Valve Reparative Procedures.

*Direct (open) commissurotomy* is accomplished with cardiopulmonary bypass during open-heart surgery. The surgeon visualizes the valve, removes thrombi from the atria, incises the fused commissures (leaflets), and débrides calcium from the leaflets, widening the orifice.

*Mitral valve annuloplasty* (reconstruction) is the reparative procedure of choice for most patients with acquired mitral insufficiency. To make the annulus (the valve ring that attaches to and supports the leaflets) smaller, the surgeon may suture the leaflets to an annuloplasty ring or take tucks in the patient's annulus. Leaflet repair is often performed at the same time. Elongated leaflets may be shortened, and shortened leaflets may be repaired by lengthening the chordae that bind them in place. Perforated leaflets may be patched with synthetic grafts.

Annuloplasty and leaflet repair result in an annulus of the appropriate size and leaflets that can close completely. Thus regurgitation is eliminated or markedly reduced.

### Heart Valve Replacement Procedures.

The development of a wide variety of *prosthetic* (synthetic) and *biologic* (tissue) valves has improved the surgical therapy and prognosis of valvular heart disease. Each type has advantages and disadvantages. An aortic valve can be replaced only with a prosthetic valve for symptomatic adults with aortic stenosis and aortic insufficiency. A biologic valve cannot be used because of the high pressure within the aorta.

Biologic valve replacements may be **xenograft** (from other species), such as a porcine valve (from a pig) (Fig. 35-4) or a bovine valve (from a cow). Because tissue valves are associated with little risk for clot formation, long-term anticoagulation is *not* indicated. Xenografts are not as durable as prosthetic valves and usually must be replaced every 7 to 10 years. The durability of the graft is related to the age of the recipient. Calcium in the blood, which is present in larger quantities in younger patients, breaks down the valves. The older the patient, the longer the xenograft will last. Valves donated from human cadavers and **pulmonary autographs** (relocation of the patient's own pulmonary valve to the aortic position [Ross procedure]) are also used for valve replacement.

**FIG. 35-4** Examples of biologic (tissue) heart valves. **A**, Freestyle, a stentless pig valve with no frame. **B**, Hancock II, a stented pig valve. **C**, Carpentier-Edwards pericardial bioprosthesis. (A and B courtesy Medtronic, Inc., Minneapolis, MN; C courtesy Baxter Healthcare Corporation, Edwards CVS Division, Santa Ana, CA.)

Patients having a valve replacement have open-heart surgery similar to the procedure for a CABG (see Chapter 38). Ideally surgery is an elective and planned procedure. Patients need to have a preoperative dental examination. If dental caries or periodontal disease is present, these problems must be resolved before valve replacement. Teach patients receiving oral anticoagulants to stop taking them before surgery, usually at least 72 hours before the procedure. Inform the patient and family about the management of postoperative pain, incision care, and strategies to prevent infection and respiratory complications. Postoperative nursing interventions for patients with valve replacement are similar to those for a CABG (see Chapter 38).

## Nursing Safety Priority QSEN

### Critical Rescue

Patients with mitral stenosis often have pulmonary hypertension and stiff lungs. Therefore monitor respiratory status closely during weaning from the ventilator. Be especially alert for bleeding in those with aortic valve replacements because of a higher risk for postoperative hemorrhage. If heart rate or blood pressure decreases, call the Rapid Response Team or other health care provider immediately!

Patients with valve replacements are also more likely to have significant reductions in cardiac output (CO) after surgery, especially those with aortic stenosis or left ventricular failure from mitral valve disease. Carefully monitor CO and assess for indications of heart failure. Report any indications of HF to the surgeon immediately, and prepare for collaborative management (see earlier discussion on HF in this chapter).

When a patient has a mechanical valve, lifelong anticoagulant therapy with warfarin (Coumadin) is required. Teach the patient that the international normalized ratio (INR) will need to be monitored frequently. The therapeutic goal for patients with mechanical heart valves is 3.0 to 4.0 (Pagana et al., 2017). However, therapy must be individualized to each patient. Low-dose aspirin (75 to 100 mg) is also recommended. Novel oral anticoagulants (NOACs) *are not recommended* in patients with valve replacement. Teach patient the signs and symptoms of bleeding and to report these symptoms to the primary health care provider.

### Care Coordination and Transition Management

The patient with valvular heart disease may be discharged home on medical therapy or after valve repair or replacement surgery. Because fatigue is a common problem, ensure that the home environment can provide rest while moving the patient toward increased activity levels. Some older adults with aortic stenosis live in long-term care settings.

#### Home Care Management.

A home care nurse may be needed to help the patient adhere to drug therapy and activity schedules and to detect any problems, particularly with anticoagulant therapy. Patients who have undergone surgery may require a nurse for help with incision care. A home care aide may assist with ADLs if the patient lives alone or is older.

#### Self-Management Education.

The teaching plan for the patient with valvular heart disease includes:

- The disease process and the possibility of HF
- Drug therapy, including diuretics, vasodilators, beta blockers, calcium channel blockers, antibiotics, and anticoagulants
- The prophylactic use of antibiotics
- A plan of activity and rest to conserve energy

Because patients with defective or repaired valves are at risk for infective endocarditis, teach them to adhere to the precautions described for endocarditis. Remind them to inform all health care providers of the valvular heart disease history. Tell providers that they require antibiotic administration before all invasive dental procedures. Health teaching for the patient is summarized in [Chart 35-7](#).

## Chart 35-7

### Patient and Family Education: Preparing for Self-Management

#### Valvular Heart Disease

- Notify all your health care providers that you have a defective heart valve.
- Remind the health care provider of your valvular problem when you have any invasive dental work (e.g., extraction).
- Request antibiotic prophylaxis before and after these procedures if the health care provider does not offer it.
- Clean all wounds and apply antibiotic ointment to prevent infection.
- Notify your primary health care provider immediately if you experience fever, petechiae (pinpoint red dots on your skin), or shortness of breath.

Patients who have had valve replacements with prosthetic valves require lifetime prophylactic anticoagulation therapy to prevent thrombus formation. Teach patients taking anticoagulants how to manage their drug therapy successfully, including nutritional considerations (if taking warfarin) and the prevention of bleeding. For example, the patient should be taught to avoid foods high in vitamin K, especially dark green leafy vegetables, and to use an electric razor to avoid skin cuts. In addition, teach him or her to report any bleeding or excessive bruising to the primary health care provider.

For patients who have surgery, reinforce how to care for the sternal incision and instruct them to watch for and report any fever, drainage, or redness at the site. Most patients can usually return to normal activity after 6 weeks but should avoid heavy physical activity involving their upper extremities for 3 to 6 months to allow the incision to heal. Those who have had valvular surgery should also avoid invasive dental procedures for 6 months because of the potential for endocarditis. Those with prosthetic valves need to avoid any procedure using magnetic resonance unless the newest technology is available. Remind patients to obtain a medical alert bracelet, card, or necklace to indicate that they have a valve replacement and are taking anticoagulants.

Patients with valvular heart disease may have complicated medication schedules that can potentially lead to inadequate self-management. Provide clear, concise instructions about drug therapy and discuss the risks associated with nonadherence. Patients with a failed valve or those who do not follow the treatment plan are at high risk for heart failure. Teach them to report any changes in cardiovascular status, such as dyspnea, syncope, dizziness, edema, and palpitations.

The psychological response to valve surgery is similar to that after coronary artery bypass surgery. Patients may experience an altered self-image as a result of the required lifestyle changes or the visible medial sternotomy incision. In addition, those with prosthetic valves may need to adjust to a soft but audible clicking sound of the valve. Encourage patients to verbalize their feelings about the prosthetic heart valve. They may display a variety of emotions after surgery, especially after hospital discharge.

## NCLEX Examination Challenge 35-4

### Physiological Integrity

A client who recently had a heart valve replacement is preparing for discharge. Which statement by the client indicates that the nurse will need to do additional health teaching?

- “I need to brush my teeth at least twice daily and rinse with water.”
- “I’ll eat foods that are low in vitamin K, such as potatoes and iceberg lettuce.”
- “I need to take a full course of antibiotics before my colonoscopy.”
- “I’ll take my blood pressure every day and call if it is too high or low.”

### Health Care Resources.

The American Heart Association's *Mended Hearts, Inc.* ([www.mendedhearts.org](http://www.mendedhearts.org)) is a community resource that provides information about valvular heart disease. A wallet-size card can be obtained

to identify the patient as needing prophylactic antibiotics. An identification bracelet or necklace that states the name of the drugs the patient is taking should also be worn.

# Inflammations and Infections

## Infective Endocarditis

### ❖ Pathophysiology

**Infective endocarditis** (previously called *bacterial endocarditis*) is a microbial infection (e.g., viruses, bacteria, fungi) of the endocardium. The most common infective organism is *Streptococcus viridans* or *Staphylococcus aureus*.

Infective endocarditis occurs primarily in patients who abuse IV drugs, have had valve replacements, have experienced systemic alterations in IMMUNITY, or have structural cardiac defects. With a cardiac defect, blood may flow rapidly from a high-pressure area to a low-pressure zone, eroding a section of endocardium. Platelets and fibrin adhere to the denuded endocardium, forming a vegetative lesion. During bacteremia, bacteria become trapped in the low-pressure “sinkhole” and are deposited in the vegetation. Additional platelets and fibrin are deposited, which cause the vegetative lesion to grow. The endocardium and valve are destroyed. Valvular insufficiency may result when the lesion interferes with normal alignment of the valve. If vegetations become so large that blood flow through the valve is obstructed, the valve appears stenotic and then is very likely to *embolize* (i.e., cause emboli to be released into the systemic circulation) (McCance et al., 2014).

Possible ports of entry for infecting organisms include:

- The oral cavity (especially if dental procedures have been performed)
- Skin rashes, lesions, or abscesses
- Infections (cutaneous, genitourinary, GI, systemic)
- Surgery or invasive procedures, including IV line placement

### ❖ Interprofessional Collaborative Care

#### ◆ Assessment: Noticing

Because the mortality rate remains high, early detection of infective endocarditis is essential. Unfortunately, many patients (especially older adults) are misdiagnosed. Signs and symptoms typically occur within 2 weeks of a bacteremia (Chart 35-8).

#### ▶ Chart 35-8

### Key Features

#### Infective Endocarditis

- Fever associated with chills, night sweats, malaise, and fatigue
- Anorexia and weight loss
- Cardiac murmur (newly developed or change in existing)
- Development of heart failure
- Evidence of systemic embolization
- Petechiae
- Splinter hemorrhages
- Osler's nodes (on palms of hands and soles of feet)
- Janeway's lesions (flat, reddened maculae on hands and feet)

- Positive blood cultures

Most patients have recurrent fevers from 99° to 103° F (37.2° to 39.4° C). However, as a result of physiologic changes associated with aging, older adults may be afebrile. The severity of symptoms may depend on the virulence of the infecting organism.

### Physical Assessment/Signs and Symptoms.

Assess the patient's *cardiovascular status*. Almost all patients with infective endocarditis develop murmurs. Carefully auscultate the precordium, noting and documenting any new murmurs (usually regurgitant in nature) or any changes in the intensity or quality of an old murmur. An S<sub>3</sub> or S<sub>4</sub> heart sound also may be heard.

*HF is the most common complication of infective endocarditis.* Assess for right-sided HF (as evidenced by peripheral edema, weight gain, and anorexia) and left-sided HF (as evidenced by fatigue, shortness of breath, and crackles on auscultation of breath sounds). See the discussion of HF earlier in this chapter.

*Arterial embolization is a major complication in up to half of patients with infective endocarditis.*

Fragments of vegetation (clots) break loose and travel randomly through the circulation. When the left side of the heart is involved, vegetation fragments are carried to the spleen, kidneys, GI tract, brain, and extremities. When the right side of the heart is involved, emboli enter the pulmonary circulation.

Splenic infarction with sudden abdominal pain and radiation to the left shoulder can also occur. When performing an *abdominal assessment*, note rebound tenderness on palpation. The classic alteration in COMFORT described with renal infarction is flank pain that radiates to the groin and is accompanied by hematuria (red blood cells in the urine) or pyuria (white blood cells in the urine). Mesenteric emboli cause diffuse abdominal pain, often after eating, and abdominal distention.

About a third of patients have *neurologic changes*; others have signs and symptoms of pulmonary problems. Emboli to the central nervous system cause either transient ischemic attacks (TIAs) or a stroke. Confusion, reduced concentration, and aphasia or dysphagia may occur. Pleuritic chest pain, dyspnea, and cough are symptoms of pulmonary infarction related to embolization.

**Petechiae** (pinpoint red spots) occur in many patients with endocarditis. Examine the mucous membranes, the palate, the conjunctivae, and the skin above the clavicles for small, red, flat lesions. Assess the distal third of the nail bed for **splinter hemorrhages**, which appear as black longitudinal lines or small red streaks.

### Diagnostic Assessment.

The most reliable criteria for diagnosing endocarditis include positive blood cultures, a new regurgitant murmur, and evidence of endocardial involvement by echocardiography.

A positive *blood culture* is a prime diagnostic test. Both aerobic and anaerobic specimens are obtained for culture. Some slow-growing organisms may take 3 weeks and require a specialized medium to isolate. Low hemoglobin and hematocrit levels may also be present.

*Echocardiography* has improved the ability to diagnose infective endocarditis accurately. Transesophageal echocardiography (TEE) allows visualization of cardiac structures that are difficult to see with transthoracic echocardiography (TTE) (see [Chapter 33](#)).

### ◆Interventions: Responding

Care of the patient with endocarditis usually includes antimicrobials, rest balanced with activity, and supportive therapy for HF. If these interventions are successful, surgery is usually not required.

### Nonsurgical Management.

The major component of treatment for endocarditis is drug therapy. Other interventions help prevent the life-threatening complications of the disease.

*Antimicrobials* are the main treatment, with the choice of drug depending on the specific organism involved. Because vegetations surround and protect the offending microorganism, an appropriate drug must be given in a sufficiently high dose to ensure its destruction. Antimicrobials are usually given IV, with the course of treatment lasting 4 to 6 weeks. For most bacterial cases, the ideal antibiotic is one of the penicillins or cephalosporins.

Patients may be hospitalized for several days to institute IV therapy and then are discharged for

continued IV therapy at home. After hospitalization, most patients who respond to therapy may continue it at home when they become afebrile, have negative blood cultures, and have no signs of HF or embolization.

Anticoagulants do not prevent embolization from vegetations. Because they may result in bleeding, these drugs are avoided unless they are required to prevent thrombus formation (clotting) on a prosthetic valve.

The patient's activities are balanced with *adequate rest*. Consistently use appropriate aseptic technique to protect the patient from contact with potentially infective organisms. Continue to assess for signs of HF (e.g., rapid pulse, fatigue, cough, dyspnea) throughout the antimicrobial regimen and report significant changes.

### **Surgical Management.**

The cardiac surgeon may be consulted if antibiotic therapy is ineffective in sterilizing a valve, if refractory HF develops secondary to a defective valve, if large valvular vegetations are present, or if multiple embolic events occur. Current surgical interventions for infective endocarditis include:

- Removing the infected valve (either biologic or prosthetic)
- Repairing or removing congenital shunts
- Repairing injured valves and chordae tendineae
- Draining abscesses in the heart

Preoperative and postoperative care of patients having surgery involving the valves is similar to that described earlier in this chapter for valve replacement.

### **Care Coordination and Transition Management**

Community-based care for patients with infective endocarditis is essential to resolve the problem, prevent relapse, and avoid complications. Patients and families need to be willing and have the knowledge, physical ability, and resources to administer IV antibiotics at home. Collaborate with the home care nurse to complete health teaching started in the hospital and to monitor patient adherence and health status as directed by The Joint Commission's National Patient Safety Goals.

In collaboration with the case manager, the home care nurse and pharmacist arrange for appropriate supplies to be available to the patient at home. Supplies include the prepared antibiotic, IV pump with tubing, alcohol wipes, IV access device, normal saline solution, and a saline flush solution drawn up in syringes. A saline lock, peripherally inserted central catheter (PICC) line, or central catheter is positioned at a venous site that is easily accessible to the patient or a family member.

Teach the patient and family how to administer the antibiotic and care for the infusion site while maintaining aseptic technique. The patient or family member should demonstrate this technique before the patient is discharged from the hospital. Emphasize the importance of maintaining a blood level of the antibiotic by administering the antibiotics as scheduled. After stabilization at home, the case manager or other nurse contacts the patient every week to determine whether he or she is adhering to the antibiotic therapy and whether any problems have been encountered.

Encourage proper oral hygiene. Advise patients to use a soft toothbrush, to brush their teeth at least twice per day, and to rinse the mouth with water after brushing. They should not use irrigation devices or floss the teeth because bacteremia may result. Teach them to clean any open skin areas well and apply an antibiotic ointment.

## **Nursing Safety Priority** QSEN

### **Action Alert**

Patients must remind health care providers (including their dentists) of their endocarditis. Guidelines for antibiotic prophylaxis have been revised and are recommended only if the patient with a prosthetic valve, a history of infective endocarditis, or an unrepaired cyanotic congenital heart disease undergoes an invasive dental or oral procedure.

Instruct patients to note any indications of recurring endocarditis such as fever. Remind them to monitor and record their temperature daily for up to 6 weeks. Teach them to report fever, chills, malaise, weight loss, increased fatigue, sudden weight gain, or dyspnea to their primary care

provider.

## Pericarditis

### ❖ Pathophysiology

**Acute pericarditis** is an inflammation or alteration of the pericardium (the membranous sac that encloses the heart). The problem may be fibrous, serous, hemorrhagic, purulent, or neoplastic. Acute pericarditis is most commonly associated with:

- Infective organisms (bacteria, viruses, or fungi) (usually respiratory)
- Post–myocardial infarction (MI) syndrome (Dressler's syndrome)
- Post-pericardiectomy syndrome
- Acute exacerbations of systemic connective tissue disease

**Chronic constrictive pericarditis** occurs when chronic pericardial inflammation causes a fibrous thickening of the pericardium. It is caused by tuberculosis, radiation therapy, trauma, renal failure, or metastatic cancer. In chronic constrictive pericarditis, the pericardium becomes rigid, preventing adequate filling of the ventricles and eventually resulting in cardiac failure.

### ❖ Interprofessional Collaborative Care

#### ◆ Assessment: Noticing

Assessment findings for patients with *acute pericarditis* include substernal precordial pain that radiates to the left side of the neck, the shoulder, or the back. The alteration in COMFORT is classically grating and oppressive and is aggravated by breathing (mainly on inspiration), coughing, and swallowing. The pain is worse when the patient is in the supine position and may be relieved by sitting up and leaning forward. Ask specific questions to evaluate chest discomfort to differentiate it from the pain associated with an acute MI (see [Chapter 38](#)).

A pericardial friction rub may be heard with the diaphragm of the stethoscope positioned at the left lower sternal border. This scratchy, high-pitched sound is produced when the inflamed, roughened pericardial layers create friction as their surfaces rub together.

Patients with acute pericarditis may have an elevated white blood cell count and usually have a fever. Therefore blood culture and sensitivity may be analyzed in the laboratory. The ECG usually shows ST elevation in all leads, which returns to baseline with treatment. Atrial fibrillation is also common. Echocardiograms may be used to determine a pericardial effusion.

The proposed diagnostic criteria for acute pericarditis are presence of two of the following:

- Pericardial chest pain
- Presence of pericardial rub
- New ST elevation in all ECG leads or PR-segment depression
- New or worsening pericardial effusion

Patients with *chronic constrictive pericarditis* (lasting longer than 3 months) have signs of right-sided HF, elevated systemic venous pressure with jugular distention, hepatic engorgement, and dependent edema. Exertional fatigue and dyspnea are common complications. Thickening of the pericardium is seen on echocardiography or a computed tomography (CT) scan.

#### ◆ Interventions: Responding

The focus of collaborative management is to promote COMFORT and treat the cause of pericarditis before severe complications occur.

#### Promoting Comfort.

The health care provider usually prescribes NSAIDs for pain associated with pericarditis. Patients who do not obtain pain relief and who do not have bacterial pericarditis may receive corticosteroid therapy. Help the patient assume positions of COMFORT—usually sitting upright and leaning slightly forward. If the pain is not relieved within 24 to 48 hours, notify the primary health care provider. Colchicine 0.5 mg orally twice a day for 3 months has been shown to prevent pericarditis recurrence.

The various causes of pericarditis require specific therapies. For example, bacterial pericarditis

(acute) usually requires antibiotics and pericardial drainage. The usual clinical course of acute pericarditis is short term (2 to 6 weeks), but episodes may recur. Chronic pericarditis caused by malignant disease may be treated with radiation or chemotherapy, whereas uremic pericarditis is treated by hemodialysis. The definitive treatment for chronic constrictive pericarditis is surgical excision of the pericardium (**pericardiectomy**).

Monitor all patients for **pericardial effusion**, which occurs when the space between the parietal and visceral layers of the pericardium fills with fluid. This complication puts the patient at risk for **cardiac tamponade**, or excessive fluid within the pericardial cavity.

#### **Emergency Care: Acute Cardiac Tamponade.**

Acute cardiac tamponade may occur when small volumes (20 to 50 mL) of fluid accumulate rapidly in the pericardium and cause a sudden decrease in cardiac output (CO). If the fluid accumulates slowly, the pericardium may stretch to accommodate several hundred milliliters of fluid. Report any suspicion of this complication to the health care provider immediately. Findings of cardiac tamponade include:

- Jugular venous distention
- **Paradoxical pulse**, also known as *pulsus paradoxus* (systolic blood pressure 10 mm Hg or more higher on expiration than on inspiration) (**Chart 35-9**)

#### **Chart 35-9**

### **Best Practice for Patient Safety & Quality Care** QSEN

#### **Care of the Patient With Pericarditis**

- Assess the nature of the patient's chest discomfort. (Pericardial pain is typically substernal. It is worse on inspiration and decreases when the patient leans forward.)
- Auscultate for a pericardial friction rub.
- Assist the patient to a position of comfort.
- Provide anti-inflammatory agents as prescribed.
- Explain that anti-inflammatory agents usually increase COMFORT within 48 hours.
- Avoid the administration of aspirin and anticoagulants because these may increase the possibility of tamponade.
- Auscultate the blood pressure carefully to detect paradoxical blood pressure (*pulsus paradoxus*), a sign of tamponade:
- Palpate the blood pressure and inflate the cuff above the systolic pressure.
- Deflate the cuff gradually and note when sounds are first audible on expiration.
- Identify when sounds are also audible on inspiration.
- Subtract the inspiratory pressure from the expiratory pressure to determine the amount of *pulsus paradoxus* (>10 mm Hg is an indication of tamponade).

- Inspect for other indications of tamponade, including jugular venous distention with clear lungs, muffled heart sounds, and decreased cardiac output.
- Notify the health care provider if tamponade is suspected.

- Decreased heart rate, dyspnea, and fatigue
- Muffled heart sounds
- Hypotension

*Cardiac tamponade is an emergency!* The health care provider may initially manage the decreased CO with increased fluid volume administration while awaiting an echocardiogram or x-ray to confirm the diagnosis. Unfortunately, these tests are not always helpful because the fluid volume around the heart may be too small to visualize. Hemodynamic monitoring in a specialized critical care unit usually demonstrates compression of the heart, with all pressures (right atrial, pulmonary artery, and wedge) being similar and elevated (plateau pressures).

The health care provider may elect to perform a **pericardiocentesis** to remove fluid and relieve the pressure on the heart. Under echocardiographic or fluoroscopic and hemodynamic monitoring, the cardiologist inserts an 8-inch (20.3-cm), 16- or 18-gauge pericardial needle into the pericardial space. When the needle is positioned properly, a catheter is inserted, and all available pericardial fluid is withdrawn. A pericardial drain may be placed temporarily. Monitor the pulmonary artery, wedge, and right atrial pressures during the procedure. The pressures should return to normal as the fluid compressing the heart is removed, and the signs and symptoms of tamponade should resolve. In situations in which the cause of the tamponade is unknown, pericardial fluid specimens may be sent to the laboratory for culture and sensitivity tests and cytology.

## Nursing Safety Priority QSEN

### Action Alert

After the pericardiocentesis, closely monitor the patient for the recurrence of tamponade. Pericardiocentesis alone often does not resolve acute tamponade. Be prepared to provide adequate fluid volumes to increase CO and to prepare the patient for emergency sternotomy if tamponade recurs.

If the patient has a recurrence of tamponade or recurrent effusions or adhesions from chronic pericarditis, a portion or all of the pericardium may need to be removed to allow adequate ventricular filling and contraction. The surgeon may create a pericardial window, which involves removing a portion of the pericardium to permit excessive pericardial fluid to drain into the pleural space. In more severe cases, removal of the toughened encasing pericardium (pericardiectomy) may be necessary.

## Rheumatic Carditis

### ❖ Pathophysiology

**Rheumatic carditis**, also called *rheumatic endocarditis*, is a sensitivity response that develops after an upper respiratory tract infection with group A beta-hemolytic *Streptococci*. It occurs in almost half of patients with rheumatic fever. The precise mechanism by which the infection causes inflammatory lesions in the heart is not established; however, inflammation is evident in all layers of the heart. The inflammation results in impaired contractile function of the myocardium, thickening of the pericardium, and valvular damage.

Rheumatic carditis is characterized by the formation of Aschoff bodies (small nodules in the myocardium that are replaced by scar tissue). A diffuse cellular infiltrate also develops and may be responsible for the resulting heart failure (HF). The pericardium becomes thickened and covered with exudate, and a serosanguineous pleural effusion may develop. The most serious damage occurs to the endocardium, with inflammation of the valve leaflets developing. Hemorrhagic and fibrous lesions form along the inflamed surfaces of the valves, resulting in stenosis or regurgitation of the mitral and aortic valves (McCance et al., 2014).

### ❖ Interprofessional Collaborative Care

Rheumatic carditis is one of the major indicators of rheumatic fever. The common signs and symptoms are:

- Tachycardia
- **Cardiomegaly** (enlarged heart)
- Development of a new murmur or a change in an existing murmur
- Pericardial friction rub
- Precordial pain
- Electrocardiogram (ECG) changes (prolonged P-R interval)
- Indications of HF
- Evidence of an existing streptococcal infection

Primary prevention is extremely important. Teach all patients to remind their primary health care providers to provide appropriate antibiotic therapy if they develop the indications of streptococcal pharyngitis:

- Moderate-to-high fever
- Abrupt onset of a sore throat
- Reddened throat with exudate
- Enlarged and tender lymph nodes

Penicillin is the antibiotic of choice for treatment. Erythromycin (Eryc, Erythromid) is the alternative for penicillin-sensitive patients.

Once a diagnosis of rheumatic fever is made, antibiotic therapy is started immediately. Teach the patient to continue the antibiotic administration for the full 10 days to prevent re-infection. Suggest ways to manage fever, such as maintaining hydration and taking antipyretics. Encourage the patient to get adequate rest.

Explain to the patient and family that a recurrence of rheumatic carditis is most likely the result of reinfection by *Streptococcus*. Antibiotic prophylaxis is necessary for the rest of the patient's life to prevent infective endocarditis discussed earlier in this chapter (see **Infective Endocarditis**).

## Cardiomyopathy

### ❖ Pathophysiology

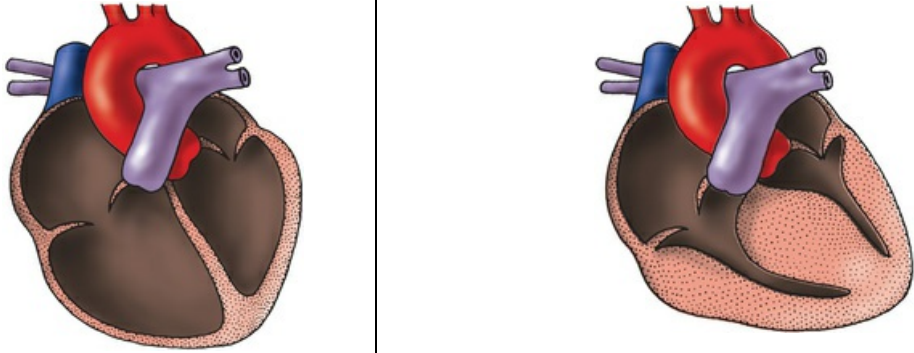

**Cardiomyopathy** is a subacute or chronic disease of cardiac muscle, and the cause may be unknown. Cardiomyopathies are classified into four categories on the basis of abnormalities in structure and function: dilated cardiomyopathy, hypertrophic cardiomyopathy, restrictive cardiomyopathy, and arrhythmogenic right ventricular cardiomyopathy (Table 35-5). **Dilated cardiomyopathy (DCM)** is the structural abnormality most commonly seen. DCM involves extensive damage to the myofibrils and interference with myocardial metabolism. Ventricular wall thickness is normal, but both ventricles are dilated (left ventricle is usually worse) and systolic function is impaired. Causes may include alcohol abuse, chemotherapy, infection, inflammation, and poor nutrition. Decreased CO from inadequate pumping of the heart causes the patient to experience dyspnea on exertion (DOE), decreased exercise capacity, fatigue, and palpitations.

**TABLE 35-5**

**Pathophysiology, Signs and Symptoms, and Treatment of Common Cardiomyopathies**

DILATED CARDIOMYOPATHY	HYPERTROPHIC CARDIOMYOPATHY	
	NONOBSTRUCTED	OBSTRUCTED
<b>Pathophysiology</b> Fibrosis of myocardium and endocardium Dilated chambers Mural wall thrombi prevalent	Hypertrophy of all walls Hypertrophied septum Relatively small chamber size	Same as for nonobstructed except for obstruction of left ventricular outflow tract associated with the hypertrophied septum and mitral valve incompetence

		
<b>Signs and Symptoms</b>		
Fatigue and weakness Heart failure (left side) Dysrhythmias or heart block Systemic or pulmonary emboli S <sub>3</sub> and S <sub>4</sub> gallops Moderate to severe cardiomegaly	Dyspnea Angina Fatigue, syncope, palpitations Mild cardiomegaly S <sub>4</sub> gallop Ventricular dysrhythmias Sudden death common Heart failure	Same as for nonobstructed except with mitral regurgitation murmur Atrial fibrillation
<b>Treatment</b>		
Symptomatic treatment of heart failure Vasodilators Control of dysrhythmias Surgery: heart transplant	For both: Symptomatic treatment Beta blockers Conversion of atrial fibrillation Surgery: ventriculomyotomy or muscle resection with mitral valve replacement Nitrates and other vasodilators <i>contraindicated</i> with the obstructed form	

The cardinal features of **hypertrophic cardiomyopathy (HCM)** are asymmetric ventricular hypertrophy and disarray of the myocardial fibers. Left ventricular hypertrophy leads to a stiff left ventricle, which results in diastolic filling abnormalities. Obstruction in the left ventricular outflow tract is seen in most patients with HCM. In about half of patients, HCM is transmitted as a single-gene autosomal-dominant trait (McCance et al., 2014). Some patients die without any symptoms; whereas others have DOE, syncope, dizziness, and palpitations. Many athletes who die suddenly probably had hypertrophic cardiomyopathy.

**Restrictive cardiomyopathy**, the rarest of the cardiomyopathies, is characterized by stiff ventricles that restrict filling during diastole. Symptoms are similar to those of left or right HF or both. The disease can be primary or caused by endocardial or myocardial disease such as sarcoidosis or amyloidosis. The prognosis for this type of cardiomyopathy is poor.

**Arrhythmogenic right ventricular cardiomyopathy (dysplasia)** results from replacement of myocardial tissue with fibrous and fatty tissue. Although the name implies right ventricle disease, about a third of patients also have left ventricle (LV) involvement. This disease has a familial association and most often affects young adults. Some patients have symptoms, and others do not.

## ❖ Interprofessional Collaborative Care

### ◆ Assessment: Noticing

Findings in cardiomyopathy depend on the structural and functional abnormalities. For example, left ventricular or biventricular failure is characteristic of *dilated* cardiomyopathy (DCM). Some patients with DCM are asymptomatic for months to years and have left and/or right ventricular dilation confirmed on x-ray examination or echocardiography. Others experience sudden, pronounced symptoms of left ventricular failure, such as progressive dyspnea on exertion, orthopnea, palpitations, and activity intolerance. Right-sided HF develops late in the disease and is associated with a poor prognosis. Atrial fibrillation occurs in some patients and is associated with embolism.

The clinical picture of *hypertrophic cardiomyopathy* (HCM) results from the hypertrophied septum causing a reduced stroke volume (SV) and cardiac output (CO). Most patients are asymptomatic until late adolescence or early adulthood. The primary symptoms of HCM are exertional dyspnea, angina, and syncope. The chest pain is atypical in that it usually occurs at rest, is prolonged, has no relation to exertion, and is not relieved by the administration of nitrates. A high incidence of ventricular dysrhythmias is associated with HCM. Sudden death occurs and may be the first manifestation of the disease.

Echocardiography, radionuclide imaging, and angiocardiology during cardiac catheterization

are performed to diagnose and differentiate cardiomyopathies.

### ◆Interventions: Responding

The treatment of choice for the patient with cardiomyopathy varies with the type of cardiomyopathy and may include both medical and surgical interventions.

#### Nonsurgical Management.

The care of patients with dilated or restrictive cardiomyopathy is initially the same as that for HF. Drug therapy includes the use of diuretics, vasodilating agents, and cardiac glycosides to increase CO. Because patients are at risk for sudden death, teach them to report any palpitations, dizziness, or fainting, which might indicate a dysrhythmia. Antidysrhythmic drugs or implantable cardiac defibrillators may be used to control life-threatening dysrhythmias. To block inappropriate sympathetic stimulation and tachycardia, beta blockers (e.g., metoprolol) are used. If cardiomyopathy has developed in response to a toxin (such as alcohol), further exposure to that toxin must be avoided.

Management of obstructive HCM includes administering negative inotropic agents such as beta-adrenergic blocking agents (carvedilol) and calcium antagonists (verapamil). These drugs decrease the outflow obstruction that accompanies exercise. They also decrease heart rate (HR), resulting in less angina, dyspnea, and syncope. Vasodilators, diuretics, nitrates, and cardiac glycosides are contraindicated in patients with obstructive HCM because vasodilation and positive inotropic effects may worsen the obstruction (Sherrid & Arabadjian, 2012). Strenuous exercise is also prohibited because it can increase the risk for sudden death. Excess alcohol intake and dehydration should also be avoided. Depending on risk stratification, an implantable cardioverter defibrillator (ICD) may be recommended to prevent sudden cardiac death. Patients with HCM are encouraged to seek genetic counseling. First-degree relatives should be screened for the presence of HCM, and echocardiography should be offered starting at age 12.

#### Surgical Management

##### Myomectomy and Ablation.

The type of surgery performed depends on the type of cardiomyopathy. The most commonly used surgical treatment for obstructive HCM involves excising a portion of the hypertrophied ventricular septum to create a wider outflow tract (**ventriculomyomectomy**; also called *ventricular septal myectomy*). This procedure results in long-term improvement in activity tolerance for most patients.

**Percutaneous alcohol septal ablation** is another option for patients with HCM. Absolute alcohol is injected into a target septal branch of the left anterior descending coronary artery to produce a small septal infarction.

The patient with arrhythmogenic right ventricular cardiomyopathy who does not respond to drug therapy may have a radiofrequency catheter ablation or placement of an implantable defibrillator (see [Chapter 34](#) for discussion of these procedures).

##### Heart Transplantation.

**Heart transplantation** (surgical replacement with a donor heart) is the treatment of choice for patients with severe DCM and may be considered for patients with restrictive cardiomyopathy. The procedure may be done also for end-stage heart disease caused by coronary artery disease, valvular disease, or congenital heart disease.

##### Preoperative Care.

Criteria for candidate selection for heart transplantation include:

- Life expectancy less than 1 year
- Age generally less than 65 years
- New York Heart Association (NYHA) Class III or IV
- Normal or only slightly increased pulmonary vascular resistance
- Absence of active infection
- Stable psychosocial status
- No evidence of current drug or alcohol abuse

Once the candidate is eligible and a heart is available, provide preoperative care as described in Chapter 14.

### Operative Procedures.

The surgeon transplants a heart from a donor with a comparable body weight and ABO compatibility into a recipient less than 6 hours after procurement. In the most common procedure (**bicaval technique**), the intact right atrium of the donor heart is preserved by anastomoses at the patient's (recipient's) superior and inferior venae cavae. In the more traditional **orthotopic** technique, cuffs of the patient's right and left atria are attached to the donor's atria. Anastomoses are made between the recipient and donor atria, aorta, and pulmonary arteries (Fig. 35-5). Because the remaining remnant of the recipient's atria contains the sinoatrial (SA) node, two unrelated P waves are visible on the ECG.

FIG. 35-5 One technique for heart transplantation.

### Postoperative Care.

The postoperative care of the heart transplant recipient is similar to that for conventional cardiac surgery (see Chapter 38). However, the nurse must be especially observant to identify occult bleeding into the pericardial sac with the potential for tamponade. The patient's pericardium has usually stretched considerably to accommodate the diseased, hypertrophied heart, predisposing him or her to have concealed postoperative bleeding.

The transplanted heart is denervated (disconnected from the body's autonomic nervous system) and unresponsive to vagal stimulation. In the early postoperative phase, isoproterenol (Isuprel) may be titrated to support the heart rate and maintain cardiac output. Atropine, digoxin, and carotid sinus pressure are not used because they do not have their usual effects on the new heart. Denervation of the heart may cause pronounced orthostatic hypotension in the immediate postoperative phase. Caution the patient to change position slowly to help prevent this complication. Some patients also require a permanent pacemaker that is rate responsive to his or her activity level. The purpose is to increase CO and improve activity tolerance.

To suppress natural defense mechanisms (especially T- and B-cell function) and prevent transplant rejection, patients require a combination of immunosuppressants for the rest of their lives. Chapter 17 describes transplant rejection and prevention in detail.

## Critical Rescue

After surgery, perform comprehensive cardiovascular and respiratory assessments frequently according to agency or heart transplant surgical protocol. Chart 35-10 lists the signs and symptoms of rejection that are specific to heart transplant. Report any of these manifestations to the surgeon immediately! To detect rejection, the surgeon performs right endomyocardial biopsies at regularly scheduled intervals and whenever symptoms occur.

### Chart 35-10

## Best Practice for Patient Safety & Quality Care QSEN

### Assessing for Signs and Symptoms of Heart Transplant Rejection

- Shortness of breath
- Fatigue
- Fluid gain (edema, increased weight)
- Abdominal bloating
- New bradycardia
- Hypotension
- Atrial fibrillation or flutter
- Decreased activity tolerance
- Decreased ejection fraction (late sign)

Be very careful about handwashing and aseptic technique because patients are immunosuppressed from drug therapy. *Infection is the major cause of death* and usually develops in the immediate post-transplant period or during treatment for acute rejection.

About 50% of patients survive 10 years after transplantation (Gustafsson, 2016). Many of the surviving patients have a form of coronary artery disease (CAD) called **coronary artery vasculopathy (CAV)**, which presents as diffuse plaque in the arteries of the donor heart. The cause is thought to involve a combination of immunologic and nonimmunologic processes that result in vascular endothelial injury and an inflammatory response (Gustafsson, 2016). Because the heart is denervated, patients do not usually experience angina. Regularly scheduled exercise tolerance tests and angiography are required to identify CAV. Only a small percentage of patients with CAV benefit from revascularization procedures such as balloon angioplasty or coronary artery bypass surgery. Stents are beginning to show some promise in managing these patients. Replantation may be done in select patients.

To delay the development of CAV, encourage patients to follow lifestyle changes similar to those with primary CAD (see Chapter 38). The provider may prescribe a calcium channel blocker such as diltiazem (Cardizem) to prevent coronary spasm and closure. Stress the importance of strict adherence to nutritional modifications and drug regimens. Teach the patient the importance of participating in a regular exercise program. Collaborate with the physical therapist and the cardiac rehabilitation specialist to plan the most appropriate exercise plan for the patient.

Discharge planning involves a collaborative, interdisciplinary approach. Patients require extensive health teaching for self-management and community resources for support. Counseling and support groups can help patients cope with their fear of organ rejection. Drug therapy adherence is crucial to prevent this problem. Continuing community-based care for patients with a heart transplant is similar to that for heart failure discussed earlier in this chapter.

# Get Ready for the NCLEX® Examination!

## Key Points

Review these Key Points for each NCLEX Examination Client Needs Category.

### Safe and Effective Care Environment

- Provide information about continuing care for patients with heart failure (HF) after discharge to the community.
- Assess whether patients with end-stage HF have advance directives. If not, provide information about them.
- Collaborate with members of the health care team when developing and implementing a plan of care for patients with HF. **QSEN: Teamwork and Collaboration**
- Teach patients about community support groups and resources such as the American Heart Association.

### Health Promotion and Maintenance

- Provide teaching about self-management at home for patients with HF (see [Table 35-4](#)).
- Monitor older adults who are taking digoxin for manifestations of toxicity. Monitor potassium levels to check for hypokalemia (see [Chart 35-5](#)). **QSEN: Safety**
- Teach patients taking ACE inhibitors, ARBs, or sacubitril/valsartan (Entresto) to change positions slowly to avoid orthostatic hypotension, especially older adults. **QSEN: Safety**
- Teach the patient with valvular dysfunction, cardiac infection, or cardiomyopathy the necessity of taking preventive antibiotic therapy before any invasive dental procedure. **QSEN: Evidence-Based Practice**

### Psychosocial Integrity

- Assess the patient for depression resulting from altered self-concept and anxiety.
- Assess the patient's coping skills. **QSEN: Patient-Centered Care**

### Physiological Integrity

- Assess the patient for manifestations of right- and left-sided HF (see [Charts 35-1](#) and [35-2](#)).
- Weigh daily and record intake and output of patients with HF.
- Assess for early signs and symptoms of pulmonary edema (e.g., crackles in the lung bases, dyspnea at rest, disorientation, confusion), especially in older adults. **QSEN: Safety**
- Assess for symptoms of worsening HF: rapid weight gain (3 lb in a week), a decrease in exercise tolerance lasting 2 to 3 days, cold symptoms (cough) lasting more than 3 to 5 days, nocturia, development of dyspnea or angina at rest, or unstable angina. **QSEN: Safety**
- Monitor the HF patient on beta blockers carefully for hypotension and bradycardia. **QSEN: Safety**
- Monitor the pulse of patients taking digoxin before administration and report to the health care provider a pulse that is not within the desired parameters.
- Monitor for manifestations of pulmonary edema as listed in [Chart 35-3](#).
- Place the patient in a sitting position and provide oxygen therapy at a high flow rate (unless otherwise contraindicated) if pulmonary edema is suspected. **QSEN: Evidence-Based Practice**
- Recognize that home care nurses perform and document focused physical assessments for cardiac patients as delineated in [Chart 35-4](#). **QSEN: Informatics**
- Monitor the patient with valvular dysfunction for atrial fibrillation, which may lead to hemostasis and mural thrombi. Monitor for an irregular cardiac rhythm and administer warfarin as

indicated.

- Document neurovascular status frequently because emboli from valvular disease may cause strokes. **QSEN: Informatics**
- Differentiate major types of cardiomyopathy as described in [Table 35-5](#).
- Observe for symptoms of heart transplant rejection as listed in [Chart 35-10](#).
- Provide care for patients with pericarditis as outlined in [Chart 35-9](#).
