Egg yolks are offered after 6 months of age. Egg yolks contain the bulk of the iron content of eggs; the white contains the bulk of protein. Egg yolk alone should be given at first because the protein of the egg white can lead to allergy or can be difficult for an infant to digest. Eggs may be hard-boiled (then a little formula or breast milk can be added to the mashed yolk to make it more liquid) or purchased as commercial baby food. Soft boiling or poaching is not usually recommended because salmonella, the chief offending microorganism that may be in eggs, may not be killed by these methods. Also, thorough cooking makes protein easier to digest.

### *Table Food*

With the introduction of solid food, encourage parents to establish a three-meal-a-day pattern, if that is the family's lifestyle, and to have the infant join the family at the table. If an individual infant is too distracted by the activity at a family table to eat well, parents may find the infant eats more if fed first and then given a cracker to chew on while just sitting at the table and being with the family.

Commercial junior foods are now prepared without excessive additives and are convenient for parents who have little time to prepare food. Generally, however, encourage parents to use homemade foods rather than relying on commercially prepared junior or toddler foods (often labeled as level 4 foods) as much as possible so the infant will have less difficulty switching to a parent's cooking when older.

Mashed potatoes or peas and cut-up meatloaf are examples of table foods that infants older than 6 months of age like to eat and busy parents can prepare quickly. If hot dogs are offered, caution parents to cut them into small bite-size portions; otherwise, their shape is dangerous if aspirated. As infants begin teething, they may enjoy dried bread or teething biscuits.

Remind parents that high chairs are one of the most dangerous pieces of baby equipment they own. Urge them to always fasten the restraint and never leave an infant unattended in a high chair because even a 6-month-old can squirm out of a chair with little effort. This is important to keep in mind as well when feeding infants in a hospital setting.

### **Establishment of Healthy Eating Patterns**

Some parents may need to be reminded that there are no hard-and-fast rules for infant feeding. The rules are only guidelines based on what seems to work well with most infants. Encourage them to individualize their approach according to the cues their child is giving them for readiness and to understand that refusing a teaspoonful of carrots is refusing a teaspoonful of carrots and nothing more.

Most infants, however, eat hungrily, so feeding problems tend to be reported more frequently as a second-year or toddler problem than as an infant concern. If an infant does refuse to eat, ask the parents what foods they are offering. Have them list exactly the types and amounts of foods the child ate the day before (a 24-hour dietary recall history). It may be apparent from this that enough is being eaten in a day's time and the parents' expectations are unrealistic for the child's size and age.

If intake is inadequate and the child is, indeed, a fussy eater, ask about the parents' methods of feeding. For example, infants generally accept the new experience of eating from a spoon better when they are hungry, not when their stomach is full. Some babies, however, particularly those with an intense temperament, may be so hungry at mealtime that they cannot tolerate the frustration of spoon feeding until some of their hunger is relieved. They may need to drink 2 or 3 oz of formula or nurse at the breast for a few minutes before they will eat a spoonful of food.

If infants are fatigued or overstimulated, they also may not eat well. Providing a quiet environment away from older brothers or sisters or other distractions before mealtime might be a solution to this problem.

Encourage parents not to force infants to eat if they do not seem hungry. Healthy, happy infants will be hungry at mealtime and will eat. Those who refuse a meal may be tired, distracted, or perhaps ill. Forcing only leads to regurgitation or, if they are ill, vomiting. Infants who are eating and not thriving or not eating and therefore are not thriving should be examined by their primary care provider to determine if a cause such as a metabolic disorder or failure to thrive exists (see [Chapters 48](#) and [55](#)).

## Weaning

Mothers are advised to exclusively breastfeed for the first 6 months and continue breastfeeding for the full first year with complementary solids. Infants are capable of approximating their lips to a cup, and they can drink effectively from one at about 9 months of age. The sucking reflex begins to diminish in intensity between 6 and 9 months, which makes this the time to consider weaning from a bottle.

To wean from either formula or breast milk, the parent needs to choose one feeding a day and begin offering fluid by the new method at that feeding. Choosing a time of day that is not an infant's fussy period is helpful; other than that, the time is unimportant. After 3 days to 1 week, when an infant has become acclimated to the one change, the parent then changes a second feeding and so on. Should an illness such as an upper respiratory infection occur or should the child have teething discomfort, there will be setbacks. Infants also usually need more fluid during hot weather than cold weather because of increased perspiration. No set number of weeks should be prescribed to complete weaning.

## Self-Feeding

At approximately 6 months of age, infants become interested in handling a spoon and

beginning to feed themselves. Their coordination, unfortunately, has not developed enough for them to use a spoon without a great deal of spilling, so they are much more adept at feeding themselves with their fingers (Fig. 29.19). Parents concerned with neatness can spread newspapers, a plastic tablecloth, or a towel on the floor around a high chair to catch most of the dropped food, and then let the child practice. When an infant becomes fatigued or frustrated at attempts of self-feeding, a parent can then quietly help without making an issue of it.

**Figure 29.19** Self-feeding is not always a neat process for young children.

When infants play with their food by squeezing it through their fingers or dabbing it in their hair, it is time to end the meal. Infants who are hungry eat; those who are full, play.

### **A Vegetarian Diet**

An infant eating a vegetarian diet should continue to be breastfed or ingest an iron-fortified commercial formula for the entire first year. If a milk allergy is present, a soy-based formula can be substituted. As soon as they are introduced to solid food, they can begin vegetarian foods (Amit, 2010). As with all infants, an assortment of foods should be provided, including vegetables such as peas, potatoes, and carrots; fruits such as apples, prunes (which are high in iron), and bananas; infant cereal; tofu; wheat germ; legumes; brewer's yeast; and synthetic vitamin D. Feeding fortified cereal throughout

the first year will ensure that iron stores are built. If the diet is to include dairy products, these can be added toward the end of the first year as usual.

Because vegetarian diets are high in fiber, infants who eat them may have more frequent and looser than usual bowel movements. Teach parents to change diapers frequently to avoid skin irritation. Using less fibrous, more concentrated forms of protein, such as tofu and powdered nuts rather than green vegetables, can minimize this problem.

A sound vegetarian diet can be easily designed for the older infant who prefers finger foods because many vegetables, fruits, and grains such as pieces of oranges, peaches, tomatoes, and crackers are easily eaten this way.

## PROMOTING INFANT DEVELOPMENT IN DAILY ACTIVITIES

In the first year, caring for an infant—feeding, bathing, dressing, and so forth—occupies what may seem like nearly all of the parents’ waking hours. All of these basic care-related activities provide important opportunities for parents and infants to get to know one another and to become used to each other’s unique personalities and patterns. Nurses can play a key role in teaching parents about these activities and stressing their importance.

### Bathing

Except in very hot weather, an infant does not need a bath every day. If a parent is tired and would not enjoy bath time or if some days are just too rushed, a complete bath can be omitted, with only the infant’s face, hands, and diaper area washed. Some infants do need their head and scalp washed frequently (i.e., every day or every other day) to prevent **seborrhea**, a scaly scalp condition often called cradle cap (Lyon, 2011).

If seborrhea lesions do develop, they adhere to the scalp in yellow, crusty patches. The skin beneath them may be slightly erythematous. The patches can be softened by oiling the scalp with mineral oil or petroleum jelly and leaving it on overnight. The crusts can then be removed by shampooing the hair the next morning. A soft toothbrush or fine-toothed comb can be used to help remove them.

Bath time should be enjoyable for an infant and can serve many functions other than just the obvious one of cleanliness (Fig. 29.20). Especially during the second half of the first year, a child enjoys poking at soap bubbles on the surface of the water or playing with bath toys. Bath time also helps an infant learn different textures and sensations and provides an opportunity to exercise and kick as well as a good opportunity for a parent to touch and communicate with the child. Teach parents never to leave infants alone in a tub even if they are supported by an infant seat because they could easily slip under the water and drown.

**Figure 29.20** An infant enjoys bath time with his big brother. Parents should always watch carefully while infants and toddlers are in the tub.

### Diaper-Area Care

The most effective means of promoting good diaper-area hygiene is to change diapers frequently, about every 2 to 4 hours. However, it is rarely good practice to interrupt the child's sleep to change diapers. If an infant develops a rash from sleeping in wet diapers, air drying or sleeping without a diaper may be a solution.

At each diaper change, parents should wash the skin with clear water or a commercial alcohol-free (and perfume-free if an infant has sensitive skin) diaper wipe and then pat or allow the skin to air dry. Routinely using an ointment such as zinc oxide or petroleum ointment to keep urine and feces away from an infant's skin is good prophylaxis. Parents should not use baby powder, as it is a potential source of aspiration. Following a diaper change, remind parents to wash their hands to reduce the possibility of spreading infection.

### Dental Care

It is well accepted that exposing developing teeth to fluoride is one of the most effective ways to promote healthy tooth formation and prevent tooth decay. A water level of 0.3 ppm fluoride in water is recommended because this is the level that protects tooth enamel best yet does not lead to staining of teeth. In communities where the water supply does not provide enough fluoride or where parents prefer to drink unfluoridated bottled water or use unfluoridated well water, the use of an oral fluoride supplement (fluoride drops) beginning at 6 months of age or the use of fluoride toothpaste or rinses after tooth eruption is recommended (AAP, 2011a). Urge parents to ask about the

presence of fluoride in the drinking water in their community and help them to determine what, if any, supplementation is necessary.

Toothbrushing can begin even before teeth erupt by rubbing a soft washcloth over the gum pads. This eliminates plaque and reduces the presence of bacteria, creating a clean environment for the arrival of first teeth. Once teeth erupt, all surfaces should be brushed with a soft brush or washcloth once or twice a day. Children lack the coordination to brush effectively until they are school age, so parents must be responsible for this activity well past infancy (Milgrom & Chi, 2011). Toothpaste is not necessary for an infant because it is the scrubbing that removes the plaque. An initial dental checkup should be made before 2 years of age, and checkups should continue at 6-month intervals until adulthood.

## Dressing

Clothing for infants should be easy to launder and simply constructed, so neither dressing nor undressing are a struggle. When they begin to creep, infants need long pants to protect their knees. Until they begin to walk, they need only soft-soled shoes or merely socks or booties to keep their feet warm. Even when they begin walking, the soles of their shoes need only be firm enough to protect their feet against rough surfaces. Extremely hard soles and high ankle sides are unnecessary.

## Sleep

Sleep needs and habits vary greatly among infants, but most require 10 to 12 hours of sleep at night and one or several naps during the day. Parents are advised to let a baby sleep in a separate space close by rather than in their bed so the parents do not awaken at every toss and squeak and possibly avoid infant suffocation. Doing so also allows infants to learn to quiet themselves and go back to sleep should they awaken briefly. Caution parents not to place pillows in an infant's crib. Always place an infant on his or her back to sleep because this position markedly reduces the incidence of sudden infant death syndrome (SIDS) (AAP, 2011b). In addition to supine positioning, use of a firm sleep surface, breastfeeding, room sharing without bed sharing, routine immunizations as shown in Table 29.1, considering the use of a pacifier, and avoidance of overheating, closed spaces, and exposure to tobacco smoke are other suggestions for helping to prevent the syndrome (Scollan-Koliopoulos & Koliopoulos, 2010) (see Chapter 26 for a further discussion of SIDS).

## Exercise

Infants benefit from outings in a carriage or stroller because sunlight provides a natural source of vitamin D. In hot weather, caution parents to protect an infant from sunburn by exposing the child to the sun for only very short periods, beginning with 3 to 5 minutes the first day, a little more the next day, and so on up to 15 to 20 minutes at a time. The sun is most intense between 10 am and 3 pm, so early mornings and late

afternoons are the best times for infants to be outside. These short time spans are necessary because the use of sunscreen is not recommended in children until they are at least 6 months old.

Toward the end of the first year, infants need space to crawl and then to walk, such as in an enclosed outdoor play space. In addition to providing fresh air, going for leisurely walks while pointing out the sights of the world—trees, birds, dogs, houses, neighbors—helps children develop language and allows for quality time with a parent. Parents can judge how much outdoor clothing to put on an infant by how much they need themselves.

Caution parents to supervise infants using walkers because they can be seriously injured if they maneuver the walker too near a stairway and fall the length of the steps.

## PROMOTING HEALTHY FAMILY FUNCTIONING

A primary task of parents during the infant year is to learn to interpret infants' cues so they can better decipher their needs. This becomes an easier task by 2 months of age, when infants can indicate by their particular cry whether they are feeling cold, hungry, wet, or lonely.

### Parental Concerns and Problems Related to Normal Infant Development

Some of the difficulties parents are apt to have in evaluating the health of infants are shown in [Table 29.4](#). Both new and experienced parents may need reassurance and answers to questions about child care procedures or health during the infant period because they have not yet learned to interpret infant cues. The unique characteristics of each child require at least some adjustment from parents.

**TABLE 29.4 COMMON DIFFICULTIES PARENTS EXPERIENCE IN EVALUATING THE HEALTH OF INFANTS**

Difficulty	Suggestions for Improving Assessment
Evaluating pain	Infants manifest pain by fussiness or crying if it is sharp pain. They reveal arm and leg pain by immobility of the body part, ear pain by brushing or tugging at the ear, and stomach pain by pulling up the legs against the abdomen.
Evaluating degree of reduced activity	Infant has lack of interest in smiling or interaction; may lie supine with legs nonflexed (frog-legged) as if exhausted.
Evaluating infant temperature	All parents should learn how to take an axillary or tympanic temperature so they can report a specific degree of fever rather than a subjective finding, such as “feels hot.”
Evaluating	Count the number of times vomiting and/or diarrhea has occurred.

amount of vomiting or diarrhea	Estimating amount in comparison with what the child ate is helpful as well as estimating an amount (e.g., a cupful). Knowing whether diapers are soaked or stained with stool helps to estimate severity of diarrhea. Caution parents that vomiting and diarrhea are always serious in infants; if these occur, they should alert their primary healthcare provider and ask for advice.
--------------------------------	---

## Teething

Most infants have little difficulty with teething, but some appear very distressed by the process. Generally, gums are sore and tender before a new tooth breaks the surface. As soon as the tooth is through, the tenderness passes (Kiran, Swati, Kamala, et al., 2011).

Because of this pain, infants can be resistant to chewing for a day or two and be slightly cranky, possibly because they are a little hungry from not eating as much as usual. High fever, seizures, vomiting or diarrhea, as well as earache are never normal signs of teething. An infant with any of these symptoms has an underlying infection or disease process that requires further evaluation.

Rubbing the gumline with a finger or a soft cloth can help a new tooth erupt and so can be effective (Plutzer, Spencer, & Keirse, 2011). Teething rings that can be placed in the refrigerator or freezer provide soothing coolness against tender gums. Remind parents that an infant who is teething will place almost any object in the mouth to chew on, so parents must screen articles within the baby's reach to be certain they are edible or safe to chew on.

Many over-the-counter medicines are sold for teething pain. As a rule, these should be discouraged, especially if they contain benzocaine, a topical anesthetic. If applied too far back in the throat, this could interfere with a gag reflex. Infant's or children's liquid acetaminophen (Tylenol) may be given for teething discomfort after parents check with their primary care provider for the correct dose. As a rule, they always need to check with their infant's healthcare provider before giving any over-the-counter drug this way to be certain that pain enough to warrant an analgesic is simple teething discomfort.

## Thumb-Sucking

Sucking is a surprisingly strong need in early infancy: Sonograms demonstrate thumb-sucking as early as in utero. Many infants begin to suck a thumb or finger at about 3 months of age and continue the habit through the first few years of life. The sucking reflex peaks at 6 to 8 months, whereas thumb-sucking peaks at about 18 months.

Parents can be assured that thumb-sucking is normal and does not deform the jaw in infancy. It does not cause "baby talk" or any of the other speech concerns commonly attributed to it. Children who continue the habit into school age, however, can have changes in their dental arch that leads to asymmetric concerns such as crossbite (Montaldo, Montaldo, Cuccaro, et al., 2011). The best approach for parents is to be certain an infant has adequate sucking pleasure and then to ignore thumb-sucking.

Making an issue of it rarely causes a child to stop; if anything, it may intensify and prolong it.

### **Use of Pacifiers**

Whether to use pacifiers is a question that parents must settle for themselves depending on how they feel about them and their infant's needs. Benefits of pacifiers include the following: They appear to be comforting to an infant, they may aid in pain relief, and there is a decreased risk of SIDS. Risks associated with them are an increased incidence of acute otitis media (ear infection), possibly a negative impact on breastfeeding, and dental malocclusion, particularly if usage is greater than 2 to 3 years (Nelson, 2012).

An infant who completes a feeding and still seems restless and discontent, who actively searches for something to put into the mouth, or who sucks on hands and clothes may need a pacifier. Babies who have colic crave sucking and enjoy pacifiers because their abdomen hurts, and they interpret this as a hunger sensation. If a child is formula fed, parents should check nipples to be certain the holes are small and the rubber is sturdy so their infant can suck hard enough to derive pleasure. If the nipples are satisfactory, parents could offer a pacifier after feeding for more sucking. Theoretically, a child whose sucking needs are met in infancy will not crave as much oral stimulation later in life and is less likely to become a pencil chewer, cigarette smoker, nail biter, or the like.

A major drawback of pacifiers is the problem of cleanliness. They tend to fall on the floor or sidewalk and are then put back into an infant's mouth. If not well constructed, they may come apart and the nipple part may be aspirated. Hanging a pacifier on a string around an infant's neck could cause strangulation.

Parents should attempt to wean a child from a pacifier any time after 3 months of age and certainly during the time the sucking reflex is fading at 6 to 9 months. Weaning after this age is difficult because a pacifier becomes a comfort mechanism, like a warm blanket or fuzzy toy to which a child may continue to cling.

### **Head Banging**

Some infants rhythmically bang their head against the bars of a crib for a period of time before they fall asleep, an action that can be a distressing behavior for parents. Besides fearing their children will hurt themselves, they may have heard blind children or those with mental illness or an autism spectrum disorder do this and worry their child is ill in some way.

Head banging in this limited fashion—beginning during the second half of the first year of life and continuing through to the preschool period, associated with naptime or bedtime, and lasting under 15 minutes—can be considered normal. Children use this measure to relax and fall asleep. Investigating stress factors operating in the house may be helpful. If some of the stress can be relieved (such as the parents' overestimation of the child's development, marital discord, illness in another family member), the head

banging may decrease or it may have already become such an engrained habit that it will persist for months or even years.

Advise parents to pad the rails of cribs so infants cannot hurt themselves and reassure them this is a normal mechanism for the relief of tension in children of this age. No therapy should be necessary. Excessive head banging done to the exclusion of normal development or activity, head banging past the preschool period, or if associated with other symptoms suggests a pathologic basis; such children need a referral for further evaluation (Singer, 2011).

## Sleep Concerns

Infants should be placed on their backs to sleep until they are able to roll over on their own at around 4 months of age. Co-sleeping is discouraged due to safety concerns. Breastfed babies tend to wake more often than those who are formula fed because breast milk is more easily digested, and so infants become hungry sooner. In late infancy, the problem of waking at night and remaining awake for an hour or more can become common. Although an infant may be content and not cry during this time, parents are reluctant to sleep while a child is awake, so they may become extremely fatigued. Suggestions for eliminating or at least coping with night waking include delaying bedtime by 1 hour, shortening afternoon naps, not responding immediately to infants at night so infants can have time to fall back to sleep on their own, and providing soft toys or music to allow infants to play quietly alone during this wakeful time.

Reassuring parents that infants take varying lengths of time to adjust to night sleeping is helpful in assuring them their child is not ill. Suggesting parents use the time they are awake at night to do things such as solve a problem at work, watch a late show, or plan a shopping list may help them view the situation as a constructive time rather than a concern. If infants have difficulty falling or staying asleep, this is not correlated with long-term sleep disorders (Price, Wake, Ukoumunne, et al., 2012).

## Constipation

Breastfed infants are rarely constipated because their stools tend to be naturally loose. Constipation may occur in formula-fed infants from something as simple as if their diet is deficient in fluid. This can be corrected simply by offering more fluid.

Some parents misinterpret the normal pushing with bowel movements of a newborn and report that their infant is constipated. When infants defecate, their faces do turn red, and they grimace and grunt. As long as stools are not hard and contain no evidence of fresh blood (as might occur with a rectal fissure), this is not constipation but normal infant behavior.

If hard bowel movements are present beyond 5 or 6 months of age, encourage parents to check with the infant's primary healthcare provider about measures to relieve this. Adding foods with bulk, such as fruits or vegetables, and increasing fluid intake generally relieves the problem. Apple juice (3 or 4 oz) or prune juice (0.5 to 1 oz daily)

may be given as a temporary measure.

All infants with a history of true constipation (exceedingly hard or no bowel movements) should be examined for an anal fissure or tight anal sphincter. Softening stools and thereby relieving the pain of defecation often solves the problem and helps the fissure to heal. If an unusually tight anal sphincter exists, parents will be given instructions to manually dilate the sphincter two or three times daily until it dilates sufficiently.

Hirschsprung disease (aganglionic megacolon, or lack of nerve innervation to a portion of the colon) may be manifested early in life as constipation. If no stool is present in the rectum of a constipated infant on rectal examination, this disease is suggested ([Sundaram, Hoffenberg, Kramer, et al., 2011](#)). A careful history must then be taken to assess for other symptoms of Hirschsprung disease: ribbonlike stools, bouts of diarrhea, and a distended abdomen (see [Chapter 45](#)).

Chronic constipation also may occur in children with congenital hypothyroidism (decreased functioning of the thyroid gland). An infant with constipation should be carefully observed for characteristic signs of hypothyroidism, such as lethargy, protruding tongue, and failure to meet developmental milestones (see [Chapter 48](#)). Infants with either of these disorders need therapy to correct the disorder.

## Loose Stools

Many new parents are unfamiliar with the consistency or color of normal newborn stools, so they mistakenly report normal stooling as diarrhea. Stools of breastfed infants are generally softer than those of formula-fed infants. If a mother takes a laxative while breastfeeding, an infant's stools may be very loose. An infant who is formula fed can have loose stools if the formula is not diluted properly. Occasionally, loose stools may begin with the introduction of vegetables or fruit.

A serious reason for loose stools is celiac disease or the inability to process gluten (sometimes termed malabsorption syndrome) (see [Chapter 45](#)). The inability to digest fat and fat-soluble vitamins, accompanied by a distended abdomen, are other common symptoms of celiac disease; an infant needs a referral to a primary care provider for this.

When talking to a parent about loose stools, ask them how long the infant has been having them, the number of stools per day, their color and consistency, and whether there is any mucus or blood in them. Also, is there associated fever, cramping, or vomiting? Does an infant continue to eat well? Appear well? Seem to be thriving? Is an infant wetting at least six diapers daily?

Infants with associated signs and symptoms such as fever, cramping, vomiting, loss of appetite, a decrease in voiding, and weight loss should be examined by their healthcare provider because this suggests an infectious process. If in doubt as to whether their child is ill, teach parents to err on the side of phoning their healthcare provider. Dehydration occurs rapidly in a small infant who is not eating and is losing body fluid through loose stools ([Mehal, Esposito, Holman, et al., 2012](#)).

## Colic

Colic is paroxysmal abdominal pain that generally occurs in infants under 3 months of age and is marked by loud, intense crying (Shergill-Bonner, 2010). Infants pull their legs up against their abdomen, their faces become red and flushed, their fists clench, and their abdomens become tense. If offered a bottle, an infant with colic will suck vigorously for a few minutes as if starved and then stop as another wave of intestinal pain occurs.

The cause of colic is unclear and probably results for several reasons. It may occur in susceptible infants from overfeeding or from swallowing too much air while feeding. Formula-fed babies tend to have more symptoms than breastfed babies, possibly because they swallow more air while drinking or because formula is harder to digest.

Although infants continue to thrive despite colic, the condition should not be dismissed as unimportant. It is a distressing and frightening problem for parents because their infant is not only in acute pain but also the distress persists for hours, usually into the middle of the night, allowing no one in the family to get adequate rest. This creates a difficult beginning to a parent–child relationship, which needs to be strong and binding for parents to enjoy parenting and for an infant to thrive in their care.

Take a thorough history of an infant with signs of colic because an intestinal obstruction or infection can mimic an attack of colic and be misinterpreted by the casual interviewer. With colic, symptoms of abdominal pain typically last up to 3 hours a day and occur at least 3 days every week; bowel movements are normal. Constipation; narrow, ribbonlike stools; and the presence of blood or mucus suggest other problems.

If the infant is bottle fed, ask about the type of formula used, how it is prepared, and if parents hold the baby upright and burp the infant adequately after feeding. For a breastfed baby, ask about the mother's diet (Is she avoiding "gassy" food such as cabbage?).

A number of interventions can be helpful to recommend to relieve colic symptoms. For example, both breastfed and formula-fed infants may feel more comfortable with small, frequent feedings to prevent distention and discomfort. Offering a pacifier can be comforting. Reducing stimuli, taking infants for car rides, or playing a music box that simulates the sound of a heartbeat are often reported as being helpful (Gahagan, 2011). Dietary changes have little effect, although there is some evidence using hydrolyzed protein, probiotics or prebiotics, or a soy-based formula for bottle-fed babies may be helpful (Iacovou, Ralston, Muir, et al., 2011; Thomas & Greer, 2010).

Some parents try placing a hot water bottle on their infant's stomach for comfort, but this should be discouraged. A basic rule for any abdominal discomfort is to avoid heat in case appendicitis is developing. This is highly unlikely in so young an infant, but parents will remember they once used heat and may use it again when the child is older. Hot water bottles and heating pads also might burn the delicate skin of infants.

Caution parents to check with their primary care provider before using herbs or home remedies such as star anise to be certain what they have heard to be effective is

safe for infants (Madden, Schmitz, & Fullerton, 2012). They should use the same precaution for chiropractic or acupressure therapy.

As a final measure, it is important to think of colic as a family problem or else a vicious circle may gradually begin. An infant cries and the parents may become tense and unsure of themselves. An infant then senses the tension and develops more colic. Some parents benefit from planning relief time from infant care to relieve their stress level and prevent this cycle. Box 29.7 shows an interprofessional care map illustrating both nursing and team planning to address such a problem as infant colic.

## BOX 29.7

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR AN INFANT WITH COLIC

You meet Ms. Simpson, 19 years old, at a pediatric clinic when she brings in her 2-month-old son, Bryan. She looks tired and tells you she is exhausted because her baby is “awake all night, crying constantly.” When you weigh Bryan, you find he has gained weight well. When you talk to him, he demonstrates a social smile.

**Family Assessment:** Infant lives with single parent and her family (baby’s grandfather, grandmother, 26-year-old uncle, and 22-year-old aunt). Mother works as an exotic dancer from 12 noon to 6 pm daily; grandmother cares for infant during this time.

**Client Assessment:** Well-proportioned, 2-month-old male. Height and weight at 50th percentile on growth chart. Currently bottle-fed with intake of approximately 4 oz of commercial formula every 4 hours. Has two or three soft yellow stools daily. The mother reports, “His face gets red and he pulls his legs up against his belly and cries every night from 6 pm ‘til 2 am. Why is he so good for my mother in the afternoon but cries at night for me? Why does he hate me so much?”

The physical examination on Bryan was within normal limits. His nurse practitioner diagnosed colic as the cause of his crying.

**Nursing Diagnosis:** Compromised family coping related to difficulty managing infant crying episodes

**Outcome Criteria:** Parent voices increased confidence in caring for infant and increased feeling of control over situation within 1 week; infant sleeps for at least 1 hour during 6 pm to 2 am period.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess infant’s total day to identify why	Make suggestions as needed to see if	Infants with different caretakers can	Parent details a day history for infant.

	crying seems confined to evenings.	different caregivers use consistency in care.	have difficulty adjusting to changing feeding techniques.	
<i>Teamwork and Collaboration</i>				
Nurse/nurse practitioner	Determine which nurse practitioner is available for care team.	Contact nurse practitioner to do a physical exam to ensure infant is healthy.	A physical exam will differentiate symptoms of colic from other, more serious problems.	Nurse practitioner completes the physical exam and makes recommendations.
<i>Procedures/Medications for Quality Improvement</i>				
Nurse/primary care provider	Assess what steps parent has taken to try to relieve symptoms.	Suggest the use of a pacifier, sitting the infant upright, feeding in quiet environment, riding in car, etc.	Both sucking on a pacifier and an upright position may promote passage of gas.	Parent states she is willing to try new measures such as a pacifier.
<i>Nutrition</i>				
Nurse	Assess how parent prepares formula and technique used for feeding and burping infant.	Review methods for formula preparation, bottle holding, and burping as needed.	Proper techniques can minimize the amount of air swallowed.	Parent describes correct formula preparation and infant feeding methods. Confirms other family members are consistent.
<i>Patient-Centered Care</i>				
Nurse	Assess what parent knows about colic, including its incidence, usual timing, symptoms, etc.	Educate parent about common characteristics of colic, including duration, timing, and	Education promotes better understanding of the problem, hopefully alleviating stress.	Parent states she understands how common colic is and that the crying is from pain, not related to her personally.

intensity of crying.

*Psychosocial/Spiritual/Emotional Needs*

Nurse/nurse practitioner	Assess why parent is taking the fact the infant cries only during her care time personally.	Reassure parent it's a coincidence colic occurs at the time she is giving care.	Reassurance that the problem is not the mother's fault can aid in objective problem solving.	Parent states she understands the problem is not a personal one.
Nurse	Assess parent's level of stress about constant crying.	Caution parent that crying in infants produces frustration in adults. Help plan respite time if necessary.	Acknowledging frustration helps to validate feelings. Time away can help relieve tension.	Parent states she is frustrated but also ready to work on solving the problem.

*Informatics for Seamless Healthcare Planning*

Nurse	Urge the parent to call for further suggestions if needed. Stress that colic usually resolves by 3 months of age.	Advise parent to contact clinic if measures are ineffective by 1 week.	Assurance that continuing support will be available can help relieve stress.	Parent agrees to call in 1 week if crying has not improved.
-------	---	--	--	---

In about 85% of infants, colic disappears almost magically at 3 months of age, probably because it becomes easier to digest food and an infant maintains a more upright position by this time, which allows less gas to form.

**What If . . . 29.3**

**Bryan's mother asks the nurse if changing her work shift so that her mother cares for Bryan during his awake time would help solve her problem. Would the nurse agree with her?**

## Spitting Up

Almost all infants spit up, although formula-fed babies appear to do this more than breastfed babies, possibly due to overfeeding. Ask parents to carefully describe what they mean by “spitting up.” How long has the baby been doing it? How frequently? What is the appearance of the spit-up milk? Almost all milk that is spit up smells at least faintly sour, but it should not contain blood or bile.

The baby who spits up a mouthful of milk (rolling down the chin) two or three times a day (or sometimes after every meal) is experiencing normal, early-infancy spitting up. Associated signs such as diarrhea, abdominal cramps, fever, cough, cold, or loss of activity suggest illness. If an infant is spitting up so forcefully that milk is projected 3 or 4 ft away, it may be the beginning of pyloric stenosis (an abnormally tight valve between the stomach and duodenum), which requires surgical intervention. If the spitting up is a large amount with each feeding, parents may be describing gastroesophageal reflux, in which a lax cardiac sphincter and esophagus allow for the regurgitation of gastric contents into the esophagus. This also requires medical attention (see [Chapter 45](#)).

Burping the baby thoroughly after a feeding often limits spitting up. Parents may try sitting an infant in an infant chair for half an hour after feeding. Changing formulas generally is of little value. Reassure parents spitting up decreases in amount as the baby becomes better at coordinating swallowing and digestive processes (the cardiac sphincter matures). In the meantime, a bib can protect the baby’s clothing and the parent. After a few months, the child will naturally stay in an upright position longer, and gravity will help to correct the problem.

## Diaper Dermatitis

Some infants have such sensitive skin that diaper dermatitis (diaper rash) is a problem from the first few days of life. It occurs for a number of reasons.

When parents do not change a child’s diapers frequently, feces is left in contact with skin, and irritation may result in the perianal area. Urine that is left in diapers too long breaks down into ammonia, a chemical extremely irritating to infant skin. Ammonia dermatitis of this type is generally a problem in the second half of the first year of life, when an infant is producing a larger quantity of urine than before. For some infants, however, it is a problem from the first week.

Frequent diaper changing, applying an ointment, and exposing the diaper area to air may relieve the problem. Some infants may have to sleep without diapers at night to solve the problem. If a diaper area is covered with lesions that are bright red, with or without oozing, that last longer than 3 days, and appear as red pinpoint lesions, suspect a fungal (monilial or candidiasis) infection that will also need therapy (an antifungal medicine such as Nystatin). Fungal infections of this type are discussed in [Chapter 43](#).

Whenever the entire diaper area is erythematous and irritated so the outline of the diaper on the skin can be identified, an allergy to the material in the diaper or to laundry

products if a commercially washed or home-washed diaper is being used is suggested. Changing the brand or type of diaper or washing solution usually alleviates this problem.

### Miliaria

Miliaria, or prickly heat rash, occurs most often in warm weather or when babies are overdressed or sleep in overheated rooms. Clusters of pinpoint, reddened papules with occasional vesicles and pustules surrounded by erythema usually appear on the neck first and may spread upward to around the ears and onto the face or down onto the trunk.

Bathing an infant twice a day during hot weather, particularly if a small amount of baking soda is added to the bath water, may improve the rash. Eliminating sweating by reducing the amount of clothing on an infant or lowering the room temperature should bring almost immediate improvement and prevent further eruptions.

### Baby-Bottle Tooth Decay Syndrome

Putting an infant to bed with a bottle can result in decay of all the upper teeth and the lower posterior teeth (Bishop, 2011) (Fig. 29.21). Decay occurs because, while an infant sleeps, liquid from the propped bottle continuously soaks the upper front teeth and lower back teeth (the lower front teeth are protected by the tongue). The problem, called **baby-bottle syndrome**, is most serious when the bottle is filled with sugar water, formula, milk, or fruit juice. The carbohydrate in these solutions ferments to organic acids that demineralize the tooth enamel until it decays.

**Figure 29.21** Baby-bottle syndrome. Notice the extensive decay in the upper teeth. (From K. L. Boyd, DDS/Custom Medical Stock

Photograph.)

To prevent this problem, advise parents never to put their baby to bed with a bottle. If parents insist a bottle is necessary to allow a baby to fall asleep, encourage them to fill it with water and use a nipple with a small hole to prevent the baby from receiving a large amount of fluid. If the baby refuses to drink anything but milk, the parents might dilute the milk with water more and more each night until the bottle contains water only.

### **Obesity in Infants**

Obesity in infants is defined as a weight greater than the 90th to 95th percentile on a standardized height/weight chart. Obesity occurs when there is an abnormal increase in the number of fat cells because of excessive calorie intake. Preventing obesity in infants is important because the extra fat cells formed at this time are likely to remain throughout childhood and even into adulthood. If a child becomes obese because of overingesting milk, iron-deficiency anemia may also be present because of the low iron content of both breast and commercial milk. Once infant obesity begins, it is difficult to reverse, so prevention is the key (Taylor, Heath, Galland, et al., 2011).

Overfeeding in infancy often occurs because parents were taught to eat everything on their plate, and they continue to instill this concept in their children. This appears to be the case most often with formula-fed infants whose parents urge them to empty their bottle or finish a cereal serving. It can occur any time parents automatically feed an infant when the child cries rather than investigating what the cry might really mean. As a general rule, an infant should take no more than 32 oz of formula daily and shouldn't be breastfeeding more often than every 2 hours. When solid food is introduced, a bottle of water can be substituted for formula at one feeding to reduce calories. Nonfat milk should not be given because it contains so little fat that essential fatty acid requirements may not be sufficient to ensure cell growth.

Another way to help prevent obesity is to add a source of fiber, such as whole-grain cereal and raw fruit, to an infant's diet. These prolong the stomach-emptying time, so they can help reduce food intake. Caution parents about giving infants who are obese foods with high amounts of refined sugars, such as pudding, cake, cookies, and candy. Encourage parents to learn more about balanced nutrition and to provide this for their entire family.

### **Concerns of the Family With an Infant With Unique Needs**

An infant born with a cognitive or physical challenge is usually hospitalized immediately after birth for diagnosis and treatment. This can result in delayed bonding because the newborn is separated from the parents during this critical time. Encourage parents to regularly visit an intensive care nursery to help form a strong parent-child attachment. If parents cannot visit, urge them to telephone the hospital as frequently as they can to ask about their child. E-mailing them photographs or posting them by the infant's crib for parents to take home are other ways to encourage bonding.

Many of the developmental events of the infant year (e.g., social smile, laughing out loud, reaching for an object, uttering the first word, sitting, talking) are activities that encourage parent–child interaction because they make an infant fun to be with and naturally make a parent want to spend more time with the child. Children who are cognitively challenged may not reach these milestones. Children who are physically challenged may be unable to achieve them as well if they cannot reach up and pat their mother’s face or hold out arms to be picked up by the father. If infants leave the hospital with a cast or other equipment such as a ventilator for care, parents may be so concerned with these items that they cannot initiate normal singing and playing activities with their children.

To encourage a good parent–child relationship, point out the positive things the infant can do. Perhaps the child’s facial expression says, “Pick me up,” even though he doesn’t reach up with his hands, or perhaps his eyes follow his mother’s actions even though he can’t yet call to her.

Helping parents to interact more fully with their infants this way helps to build a sense of trust in the infant. Keeping painful procedures to a minimum when infants are ill is also important in helping infants achieve a positive outlook on the world (Stevens, Abbott, Yamada, et al., 2011).

Without this sense of trust, children have difficulty expressing themselves to others, and they may not believe they are lovable or that people would want to interact with them. Individuals who are physically challenged, no matter what their ages, need people around them to give them help at whatever point they cannot meet their own needs. It is unfortunate when children who are physically challenged cannot reach out for help because they have difficulty developing a sense of trust.

Infants who are cognitively or physically challenged or chronically ill experience the same health and growth problems as other infants such as colic or diaper rash. Parents may be reluctant to mention these concerns at healthcare visits because they believe such problems pale in comparison to the child’s primary illness or condition. When taking the health histories of children with chronic or long-standing medical problems, ask parents about these secondary concerns. “What about everyday things? Any problems there?” Treat these concerns seriously, so parents can feel confident about bringing them to your attention at future healthcare visits. Also mention they are part of normal infant development so parents can begin to view their child apart from his or her illness.

Discomfort from diaper rash and colic may actually occur more frequently in babies with other illnesses than those who are well because a parent may not want to bother an ill infant with physical care or burp the infant as long or as often as they would a well child. The bowel movements of children who are physically disabled or chronically ill may be looser than normal because of a liquid diet or medicine. Their urine may be more concentrated because of reduced intake. These conditions make diaper rash more apt to occur. Offering anticipatory guidance to parents can go a long way toward helping them avoid these special concerns of infancy.

## QSEN Checkpoint Question 29.6

### PATIENT-CENTERED CARE

When planning care for an infant who has unique needs, the nurse best promotes the parents' psychosocial well-being by which means?

- Lowering the family's expectations around their infant's skills
- Clearly describing the etiology of the infant's development deficits
- Encouraging the family to have more children
- Emphasizing what the infant can do more than what he or she cannot do

Look in [Appendix A](#) for the best answer and rationale.

### Nutrition for the Infant With Unique Needs

Ill infants may tire too easily to suck long enough to take in adequate feedings. If any degree of neurologic involvement exists, sucking and swallowing reflexes may not be coordinated. If an infant has some gastrointestinal disorders, feeding may be impossible.

To ensure adequate calorie and protein intake, infants may need to be maintained on nasogastric tube or gastrostomy feedings, or total parenteral nutrition. Because these methods limit the amount of sucking that is possible and sucking provides pleasure as well as satisfying thirst, this is a major loss. Provide an infant with nonnutritive sucking experiences such as a pacifier if possible (which is acceptable with the parent's and the infant's condition) to fill this need. Help parents find time each day to hold the infant equal to the time they would have held the child if fed by breast or bottle to make parenting more satisfying and more like the role they planned (Wilken, 2012).

Infants who are ill for a long time may not eat solid foods eagerly once they are introduced because they are not hungry enough to be interested in a new eating method. Help parents to experiment with different foods to find a taste that does appeal to ill children or teach them to limit foods to only those that the child appears to like most from all five food groups.

#### What If... 29.4

The nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to infant care (see [Box 29.1](#)). What would be a possible research topic to explore pertinent to this goal that would be applicable to Bryan and his family and that would also advance evidence-based practice?

### KEY POINTS FOR REVIEW

- The infant period is from 1 month to 12 months of age. Children typically double their birth weight at 4 to 6 months and triple it at 1 year.
- Infants develop their first tooth at about 6 months; by 12 months, they have six to

eight teeth.

- Important gross motor milestones during the infant year are lifting the chest off a bed at 2 months, sitting at 6 to 8 months, creeping at 9 months, cruising at 10 to 11 months, and walking at 12 months.
- Important fine motor accomplishments are the ability to pass an object from one hand to the other (7 months of age) and a pincer grasp (10 months of age).
- Important milestones of language development during the first year are differentiating a cry (2 months of age), making simple vowel sounds (5 to 6 months of age), and saying two words besides “ma-ma” and “da-da” (12 months of age). The more infants are spoken to, the easier it is for them to acquire language.
- Providing infants with proper toys for play helps development. All infant toys need to be checked to be certain they are too large to be aspirated (wider than a toilet paper roll).
- Important milestones of vision development are the ability to follow a moving object past the midline (3 months of age) and ability to focus securely without eyes crossing (6 months of age).
- According to [Erikson \(1993\)](#), the developmental task of the infant year is the development of a sense of trust versus mistrust. Helping parents spend quality time with their infant helps a sense of trust to develop and helps in planning nursing care that not only meets QSEN competencies but that also best meets the family’s total needs.
- Safety is important. Infants must be protected from falls and the aspiration of small objects. Skills an infant cannot accomplish one day, such as crawling (which can lead to danger), may be accomplished the next.
- Solid food is generally introduced into an infant’s diet at 6 months of age. Before infants can eat solid food, they must lose their extrusion reflex.
- Common concerns related to infant development include teething, thumb-sucking, use of pacifiers, sleep problems, constipation, colic, diaper dermatitis, baby-bottle syndrome (decayed teeth from sucking on a bottle of formula while they sleep), and obesity. Nurses play a key role in teaching parents about these problems and suggestions to deal with them.
- Remember that parent–infant attachment is critical to mental health. Urge parents to continue to give as much care as possible to ill infants to maintain this important relationship.

### CRITICAL THINKING CARE STUDY

Alicia Scinta is a 3-month-old you meet in an emergency room because she has mild diarrhea. Her mother tells you Alicia is a “picky eater,” and “no wonder she’s sick.”

Her mother works weekends as a drugstore clerk so Alicia is cared for at a child care center on the weekends. Her father, a university professor, tells you he’ll watch her weekends “later on, when she’s more fun.”

1. Alicia’s mother said she was a “picky eater.” What questions would you want to ask to discover why she says that?
2. Alicia is cared for at a child care center every weekend. What questions would you want to ask about the center to evaluate if they are encouraging Alicia’s infancy developmental task?
3. Mr. Scinta says he’ll watch Alicia later “when she’s more fun.” What features of a 3-month-old could you point out to him to help convince him she is fun to care for now?

# 30

## Nursing Care of a Family With a Toddler

*Jason is a 2.5-year-old boy you see at a pediatric clinic. His mother tells you he has changed completely in the past 6 months from an easy-to-care-for baby into a “monster” who refuses to do anything she asks. The only word he says anymore is “no.” He has a temper tantrum every night at dinner over some type of food. She tells you this has changed parenting from “fun” to “a real chore.”*

*The previous chapter discussed the growth and development of infants and the abilities that infants develop in the first year. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur during the toddler years and that form the basis for care and health teaching for this age group.*

**What advice could you give Jason’s mother to help her regain a positive view of parenting?**

### KEY TERMS

**assimilation**

**autonomy**

**deferred imitation**

**discipline**

**lordosis**

**parallel play**

**preoperational thought**

**punishment**

### OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe normal growth and development of a toddler as well as common parental concerns.
2. Identify 2020 National Health Goals related to the toddler age group that nurses can help the nation achieve.

3. Assess a toddler for normal growth and development milestones.
4. Formulate nursing diagnoses related to toddler growth and development or parental concerns regarding growth and development.
5. Identify expected outcomes for nursing care of a toddler as well as help parents manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care to promote normal growth and development of a toddler, such as discussing toddler developmental milestones with parents.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of toddler growth and development with the interplay of the nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

During the toddler period, the age span from 1 to 3 years, enormous changes take place in a child and, consequently, in a family. During this period, children accomplish a wide array of developmental tasks and change from largely immobile and preverbal infants who are dependent on caregivers for the fulfillment of most needs to walking, talking young children with a growing sense of **autonomy** (independence). To match this growth, parents must also change during this period.

If parents enjoyed caring for an infant because time could be spent rocking or singing to the child, they may not enjoy being the parents of a toddler because now their task is to support their child's growing independence by letting the child experiment with toys or other activities. In contrast, some parents thrive during this time as they enjoy playing with this more active child. Because healthy children and families are constantly being challenged by the process of normal development this way, parents often have questions about how to guide their child in different situations and how to cope with special needs and concerns relevant to this age (Nelson, 2013). **Box 30.1** shows 2020 National Health Goals that speak to the toddler age group.

### BOX 30.1

#### Nursing Care Planning Based on 2020 National Health Goals

A number of 2020 National Health Goals relate specifically to safety during the toddler years. These include:

- Increase the use of child automotive restraints in children 3 years of age and under from a baseline of 72% to 79%.
- Eliminate or improve elevated blood lead levels in children from a target level of

0.9% of children to a target level of 0%.

- Increase the percentage of persons 2 years of age and older who have had a dental visit in the past 12 months from a baseline of 44.5% to 49%.
- Maintain the rate of deaths caused by poisonings from a baseline at 13.1 out of 100,000 (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by continuing to educate parents about the importance of using car seats and childproofing their homes against household and lead poisoning.

### *Nursing Process Overview*

## FOR HEALTHY DEVELOPMENT OF A TODDLER

### ASSESSMENT

Whether a child is seen for a routine checkup or has come to a healthcare center because of a specific health concern, assessment begins with a careful health history. Asking parents about a toddler's ability to carry out activities of daily living offers assessment information not only on the child's developmental progress but also offers important clues about the child–parent relationship. Because parents see their children daily, they are the best source of information and opinion on when a child seems to be acting “out of sorts” or “different” (a typical sign a child may not be feeling well).

Careful observation is another crucial element of the nursing assessment of a toddler, although toddlers may not show typical behavior at a healthcare visit (e.g., may not talk, may cling to a parent instead of demonstrating walking).

### NURSING DIAGNOSIS

Nursing diagnoses related to growth and development of toddlers usually focus on the parents' eagerness to learn more about the parameters of normal growth and development or issues of safety or care. Examples include:

- Health-seeking behaviors related to normal toddler development
- Deficient knowledge related to the best method of toilet training
- Risk for injury related to impulsiveness of the toddler
- Interrupted family process related to need for close supervision of a 2-year-old
- Readiness for enhanced family coping related to the parents' ability to adjust to the new needs of the child
- Risk for imbalanced nutrition, more than body requirements, related to fast food choices
- Disturbed sleep pattern related to lack of bedtime routine

### OUTCOME IDENTIFICATION AND PLANNING

To help parents resolve a concern during the toddler period, focus largely on family education and anticipatory guidance. Urge them to establish realistic goals and

outcomes so they can meet the rapidly changing needs of their toddler and learn to cope with typical toddler behaviors. Otherwise, parents can expect too much of a toddler and grow frustrated instead of enjoying being a parent of a child this age.

### IMPLEMENTATION

When teaching about typical toddler behavior, teach parents that a good rule is to think of a toddler as a visitor from a foreign land who wants to participate in everything the family is doing but doesn't know the customs or the language.

Also teach parents not only how to approach a current problem but also how to learn adequate methods for resolving similar situations that are sure to arise in the future. If parents do not learn methods that can be applied throughout their child's growing years, they may win battles but lose wars. For instance, parents may find that if they promise a child a treat when the child is in the middle of a temper tantrum, that will stop the tantrum, but it will not prevent other tantrums from occurring in the future (and, in fact, may encourage them). Health visits provide opportunities to help parents learn healthier coping techniques as well as a time to demonstrate effective communication skills so parents can improve their interactions with their child.

### OUTCOME EVALUATION

Expected outcomes must be evaluated frequently during the toddler period because children change so much and learn so many new skills during this time that their abilities and associated parental concerns can change from day to day. Examples of expected outcomes include:

- Parents state the child maintains a consistent bedtime routine within the next 2 weeks.
- Parents state they have childproofed their home by putting a lock on kitchen cupboards by the next clinic visit.
- Grandmother states she has modified usual activities to conserve strength to care for toddler granddaughter by 1 week's time.

## Nursing Assessment of a Toddler's Growth and Development

An assessment of a toddler begins with the child's physical growth and skill development. [Box 30.2](#) describes a typical toddler appearance. [Table 30.1](#) provides some guidelines to help parents evaluate illness at this age.

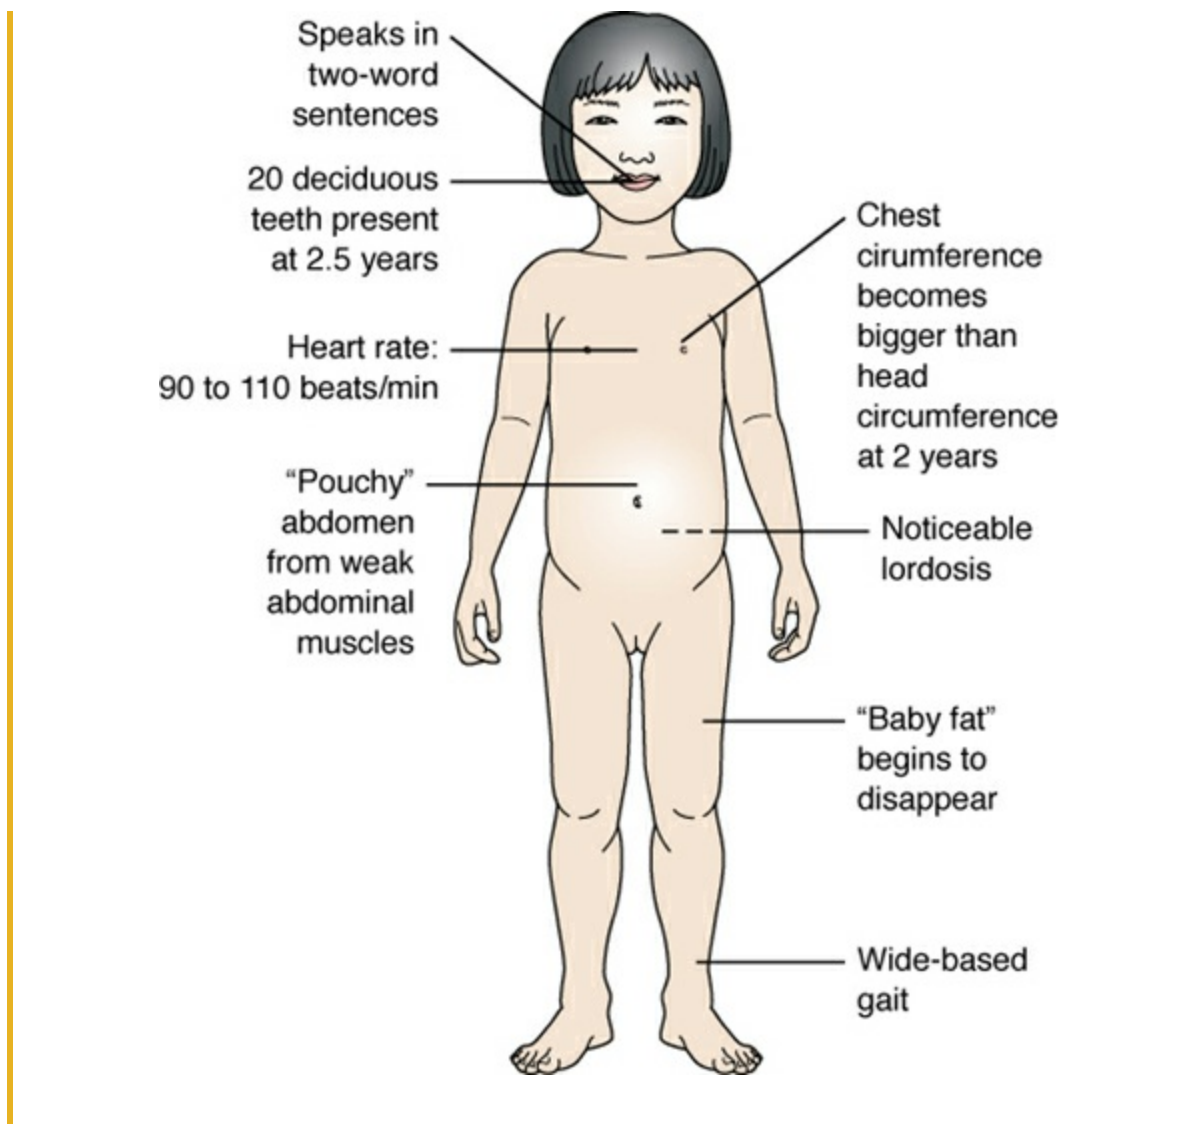

BOX 30.2

**Nursing Care Planning Using Assessment**

**Appearance Of The Average Toddler**

**TABLE 30.1 PARENTAL DIFFICULTIES IN EVALUATING ILLNESS IN TODDLERS**

<b>Problem</b>	<b>Guidelines for Parents</b>
Evaluating seriousness of illness	Toddlers typically answer “no” to almost all questions; therefore, a question such as “Does your arm hurt?” may bring a “no” response even if an arm does hurt. Observing children for indications of illness (e.g., holding an arm stiffly, rubbing abdomen, crying when they void) is more helpful. Many toddlers do not know the words to describe a feeling of nausea or a sore throat. They reveal these symptoms by not eating. If the child is normally a light eater, as many are, it is difficult for a parent to appreciate these signs.
Differentiating tiredness from illness	Toddlers tend to whine or sleep when they are either tired or ill. Reviewing the child’s day and activities often helps to evaluate what is happening. If the child is not tired (it is not nap or

	bedtime) or if there is not a break in usual routine, crying and whining or temper tantrums suggest illness.
Evaluating nutritional intake	Toddlers are normally fussy eaters compared to infants. Evaluating children as to whether they are active and growing is better than assessing any one day's food intake.
Age-specific diseases to be aware of	<p>The toddler period is an important age to assess speech development; children should be further evaluated if they cannot use simple sentences composed of a noun or pronoun and verb ("me go") by 2 years of age.</p> <p>As children begin to walk, they should be observed for an abnormal gait. Osteomyelitis (bone infection) occurs with a high frequency in toddlers; symptoms of limping, swollen joints, or arm or leg pain should be regarded as serious until ruled otherwise.</p> <p>Toddlers contract 10–12 mild upper respiratory infections a year. Otitis media (middle ear infection) may occur as a complication of these. The child with an upper respiratory infection who suddenly develops a high fever and pulls or manipulates his or her ears should be seen by a primary care provider.</p> <p>Children who attend day care programs have a high incidence of hepatitis A, <i>Giardia</i>, and <i>Shigella</i> infections. Teach parents to report jaundice or diarrhea promptly to a healthcare provider to detect these infections.</p>

## PHYSICAL GROWTH

Although toddlers are making great strides developmentally, their physical growth begins to slow.

### Weight, Height, Head Circumference, and Body Mass Index

Plot weight and height on a standard growth chart for toddlers (available at <http://thePoint.lww.com/Flagg8e>) at each healthcare visit to determine if progress is normal for that particular child. If a child is not yet walking, continue to measure height with the child lying down. A child gains only about 5 to 6 lb (2.5 kg) and 5 in. (12 cm) a year during the toddler period, much less than the rate of growth during the infant year. As subcutaneous tissue, or baby fat, begins to disappear toward the end of the second year, the child changes from a plump baby into a leaner, more muscular little girl or boy. A toddler's appetite decreases accordingly, yet adequate intake of all nutrients is still essential to meet energy needs (Whitney & Rolfes, 2013).

Head circumference increases only about 2 cm during the second year compared to about 12 cm during the first year. Head circumference equals chest circumference at 6 months to 1 year of age. By 2 years, chest circumference should have grown greater than that of the head.

Body mass index (BMI) screening is completed at 24 months to identify toddlers who are overweight or underweight. A good website to use to calculate a child's BMI is the one available via the Centers for Disease Control and Prevention (CDC) website (<https://nccd.cdc.gov/dnpabmi/calculator.aspx>).

## Body Contour

Toddlers tend to have a prominent abdomen because, although they are walking well, their abdominal muscles are not yet strong enough to support abdominal contents as well as they will be able to do later (Fig. 30.1A). They also have a forward curve of the spine at the sacral area (**lordosis**). As they become more experienced at walking, this will correct itself naturally. In addition, many toddlers waddle or walk with a wide stance (see Fig. 30.1B). This stance seems to increase the lordotic curve, but it keeps them on their feet.

**Figure 30.1** The physical characteristics of toddlers. **(A)** Toddlers typically have a prominent abdomen. **(B)** Toddlers typically walk with an unsteady gait for better stability.

## Body Systems

Body systems continue to mature during this time.

- Respirations slow slightly but continue to be mainly abdominal.
- Heart rate slows from 110 to 90 beats/min.
- Blood pressure increases to about 99/64 mmHg.
- The brain develops to about 90% of its adult size.
- In the respiratory system, the lumens of vessels enlarge progressively so the threat of lower respiratory infection lessens.
- Stomach secretions become more acid; therefore, gastrointestinal infections also

become less common.

- Stomach capacity increases to the point a child can eat three meals a day.
- Control of the urinary and anal sphincters becomes possible with complete myelination of the spinal cord so toilet training is possible.
- Immune globulin (Ig)G and IgM antibody production becomes mature at 2 years of age. The passive immunity obtained during intrauterine life is no longer operative.

### **QSEN Checkpoint Question 30.1**

#### **QUALITY IMPROVEMENT**

The nurse provides patient education to Jason’s father who had asked if it is normal for his 2-year-old son to spread his feet wide apart when he walks. Which of his statements suggests that he received accurate teaching?

- “Jason may be all right, but toddlers with dislocated hips also walk that way.”
- “A wide-spaced gait is a common characteristic of toddlers.”
- “Most toddlers walk with feet close together to better stabilize themselves.”
- “His shoes may not have a good arch and this could be causing him to walk unsteadily.”

*Look in Appendix A for the best answer and rationale.*

### **Teeth**

Eight new teeth (the canines and the first molars) erupt during the second year. All 20 deciduous teeth are generally present by 2.5 to 3 years of age (Bishop, 2011).

### **DEVELOPMENTAL MILESTONES**

The developmental milestones of the toddler years are less numerous but no less dramatic than those of the infant year because this is a period of slow and steady, not sudden, growth. Toddler development is influenced to some extent by the amount of social contact and the number of opportunities children have to explore and experience new degrees of independence. It is strongly influenced by individual readiness for a new skill. Table 30.2 highlights growth and development milestones of gross and fine motor skills, language, and play during the toddler years.

**TABLE 30.2 MILESTONES OF TODDLER GROWTH AND DEVELOPMENT**

<b>Age (in Months)</b>	<b>Fine Motor</b>	<b>Gross Motor</b>	<b>Language</b>	<b>Play</b>
15	Puts small pellets into small bottles; scribbles	Walks alone well; can seat self in chair; can creep up	4–6 words	Can stack two blocks; enjoys being read to; drops toys for

	voluntarily with a pencil or crayon; holds a spoon well but may still turn it upside down on the way to mouth	stairs		adult to recover (exploring sense of permanence)
18	No longer rotates a spoon to bring it to mouth	Can run and jump in place; can walk up and down stairs holding onto a person's hand or railing; typically places both feet on one step before advancing	7–20 words; uses jargoning; names one body part	Imitates household chores such as dusting; begins parallel play (playing beside, not with, another child)
24	Can open doors by turning doorknobs; unscrew lids	Walks up stairs alone, still using both feet on same step at same time	50 words; two-word sentences (noun or pronoun and verb), such as “Daddy go,” “Dog talks”	Parallel play evident
30	Makes simple lines or strokes for crosses with a pencil	Can jump down from chairs	Verbal language increasing steadily; knows full name; can name one color and holds up fingers to show age	Spends time playing house, imitating parents' actions; play is “roughhousing” or active

## Language Development

Toddlerhood is a critical time for language development, although even this varies among children because to master language, children need practice time. A child who is 2 years old and does not talk in two-word, noun–verb simple sentences needs a careful assessment to determine the cause because this implies underdevelopment. Parents are often worried a lack of language means their child has an autism spectrum disorder (ASD) (Barbaro & Dissanayake, 2012). It is true that a delay in language can represent the first symptom of autism, but it also may only be a temporary phenomenon until the child fully grasps the essence of speech.

A word that is used frequently by toddlers and that is a manifestation of their developing autonomy is “no.” Toddlers may use the word to mean they are refusing a task, that they do not understand it, or they may only be practicing a sound they have noticed has potent effects on those around them.

To learn other words, children need to be exposed to words through conversation and having books read to them. Language develops quickest if parents respect what toddlers have to say so children grasp the use and purpose of language. Watching television promotes little learning in toddlers because the activity is passive, and it is difficult to discern how language causes action. [The American Academy of Pediatrics \(AAP, 2012\)](#) recommends severely limiting television viewing until at least 2 years of age.

Urge parents to encourage language development by naming objects (e.g., ball, block, music box, doll) as they play with their child or when they give the toddler something (“Here is your drink of water,” “Let’s put on these pajamas,” etc.). This helps children grasp the fact that words are not meaningless sounds but that they apply to people and objects and have uses.

Always answering a child’s questions is another good way to do this. Be certain answers for toddlers are simple and brief because they have such a short attention span.

Still, other toddlers do not develop language readily because they are not called on to use it. When they point at an object, someone hands it to them; when they climb into their high chair, someone places a meal in front of them. To assess whether parents are encouraging language development, ask them what happens when the child wants something. Do they provide opportunities for the child to ask for things? Children should not be made to name an object before they can have it because their vocabulary is so limited, but parents can reinforce language by voicing the request (e.g., “You want the ball?”). Reading aloud is another effective way to strengthen vocabulary. Reading the exact words in a book is not as important at this age as is pointing to the pictures and describing what the picture shows, such as “See Jane throwing the ball?” “Look, that dog took that ball!” Reading this way can also have the additional benefit of strengthening parent–child bonds and offering respite for parents who are tired of more active games (Landry, Smith, Swank, et al., 2011).

Children who are very active may use fewer words than children who are less active

because active children are too busy doing things to describe what it is they are doing. Such children probably have a large unexpressed vocabulary, however, or understand more words (comprehensive vocabulary) than can be expressed (expressive vocabulary).

Because children learn language from imitating what they hear, if they are spoken to in baby talk, their enunciation of words can be poor; if they hear examples of bad grammar, they will not use good grammar. Remind parents that pronouns are difficult for children to use correctly; many children are 3.5 or 4 years of age before they can separate the different uses of “I,” “me,” “him,” and “her.” Bilingual children often interchange words from both languages.

### **QSEN Checkpoint Question 30.2**

#### **INFORMATICS**

Toddlers learn a great deal about oral communication in the course of their development. The nurse expects Jason, a 2-year-old, to have mastered which statement?

- a. “Red tomatoes.”
- b. “Daddy come.”
- c. “Old MacDonald.”
- d. “Please, please.”

Look in [Appendix A](#) for the best answer and rationale.

## **Emotional Development**

Children change a great deal in their ability to understand the world and how they relate to people during the toddler years.

### **Autonomy**

The developmental task of the toddler years according to [Erikson \(1993\)](#) is the development of a *sense of autonomy versus shame or doubt* (see [Chapter 28](#)). Children who have learned to trust themselves and others during the infant year are better prepared to do this than those who have not learned to trust themselves or others.

To develop a sense of autonomy is to develop a sense of independence. A healthy level of autonomy is achieved when parents are able to balance independence with consistently sound rules for safety.

### **Socialization**

Once toddlers are walking well, they become resistant to sitting in laps and being cuddled. This is not lack of a desire for socialization but a function of being independent. At 15 months, children are still enthusiastic about interacting with people, providing those people are willing to follow them where they want to go. By 18 months,

toddlers imitate the things they see a parent doing, such as “study” or “sweep,” so they seek out parents to observe and imitate. By 2 or more years of age, children become aware of gender differences and may point to other children and identify them as “boy” or “girl.”

### Play Behavior

All during the toddler period, children play beside other children, not with them. This side-by-side play (**parallel play**) is not unfriendly but is a normal developmental sequence that occurs during the toddler period (Fig. 30.2). Caution parents that if two toddlers are going to play together, they must provide similar toys because an argument over one toy is likely to occur (Levine, 2011).

**Figure 30.2** Toddlers play beside, but not with, other children (parallel play).

The toys toddlers enjoy most are those they can play with by themselves and that require action. Trucks they can make go, squeaky frogs they can squeeze, rocking horses they can ride, pegs they can pound, and a toy telephone they can talk into are all favorites. These are all toys children can control, giving them a sense of power in manipulation, which is an expression of autonomy (Fig. 30.3).

**Figure 30.3** Toddlers enjoy toys they can manipulate. (India Picture/Shutterstock.com)

Some parents are not prepared for this change in play habits in their child. They wonder why a child who used to play quietly in his crib is now more interested in banging trucks together. However, they need only watch a toddler tug a pull toy, stop to see if it is following, walk again, and stop and look to see if it is still following to understand the feeling of accomplishment involved in manipulating toys.

At 15 months of age, children are still in a put-in, take-out stage, so they continue to enjoy stacks of boxes that fit inside each other. They enjoy throwing toys out of a playpen or from a high chair tray as long as someone will pick them up and return them again and again.

The 18-month-old child walks securely enough to enjoy pull toys. Toys should be strong enough to take a great deal of abuse because children this age may use toys in ways other than those for which they were designed. For example, an infant will sit and softly stroke a stuffed cat; however, a toddler will pick it up by the tail and swing it, pound it, or pull at it. There is no need for parents to correct children about the way they are using a toy as long as it is safe and appears to give satisfaction. If toddlers find a toy frustrating because they are holding or using it incorrectly, showing them the right way will ease frustration.

By age 2 years, when toddlers begin to spend time imitating adult actions in their play such as wrapping a doll and putting it to bed or “driving the car,” they begin to use fewer toys than before. The act of imitating has become their play. By the end of the toddler period, both boys and girls begin to like roughhousing and spend at least part of every day in this very active, stimulating type of play (Fig. 30.4). Encouraging parents to schedule this type of play outdoors, where vases or other prized possessions cannot

be broken, makes it more acceptable.

**Figure 30.4** Toddlers usually enjoy rough and tumble play.

A child who feels a need for active play is notably not easy to get to sit down and eat, fall asleep, or play quiet games and so may be described as “trouble.” It is good to explore with parents the amount of outside or roughhousing time they allow a child each day. Stroller walks are good because they provide fresh air and sunshine, but toddlers also need opportunities to engage in strenuous activity such as running and jumping (Hodges, Smith, Tidwell, et al., 2012). Because of this rough activity, most toddlers have at least one black-and-blue mark on their legs at all times from tripping over their feet while trying to run too fast or from jumping or bumping into a chair or doorway. Examine these and document their presence but don’t mistake them for child maltreatment (Hooker, Ward, & Verrinder, 2012).

### *What If . . . 30.1*

**Jason’s mother tells the nurse, “I arrange play dates for Jason but he never shares his toys. How can I make him do that?” How would the nurse best answer her?**

## **Cognitive Development**

As a toddler, a child enters the final stages of Piaget’s sensorimotor thought and the beginning of the preoperative period at approximately 12 months (see [Chapter 28](#))

(Piaget, 1952). During the fifth and sixth stages of the sensorimotor phase, toddlers are described as “little scientists” because of their interest in trying to discover new ways to handle objects or new results that different actions can achieve. For instance, by trial and error, toddlers discover that cats do not like baths and cookies on the center of a table can be reached by pulling them down using the tablecloth. Obviously, toddlers need supervision for these types of scientific investigations because they can lead to errors or injury.

Infants, when they want to retrieve a ball that rolled under a chair, crawl under the chair or along the same path the ball took. Many children at 15 months of age are able to follow a different path (walk in back of the chair) to obtain the object because they can project where it will stop rolling. This results from increased awareness that the ball is permanent and, even if it follows a different direction from the one the child must take, it will be there to retrieve.

By stage 6 of cognitive development (between 18 and 24 months of age), toddlers are able to try out various actions mentally rather than having to actually perform them—the beginning of problem solving or symbolic thought. They may have difficulty viewing one object as being different from another, however. On a walk through a department store decorated with teddy bears, for example, children are not sure whether they are seeing a succession of bears or if the same bear keeps reappearing as if it is following them through the store, asking to be taken home.

Children at this stage have a type of faulty reasoning (prelogical reasoning) that can lead them to wrong conclusions and faulty judgment. Daddy is shaving; therefore, he must be going to work because he went to work after he shaved yesterday. If you made a toddler’s bed yesterday and he was taken to surgery afterward, he may cry at the sight of you approaching his crib with clean sheets today, thinking he will have to go to surgery again.

Children at this stage are also able to remember an action and imitate it later (**deferred imitation**); they can do such things as pretend to drive a car or put a baby to sleep because they have seen this previously and not just in the recent past. Object permanence becomes complete.

At the end of the toddler period, children enter a second major period of cognitive development termed **preoperational thought** and begin to use a process termed **assimilation**. Because they are not able to change their thoughts to fit a situation, they learn to change the situation (or how they perceive it). This ability is what causes toddlers to use toys in the “wrong” way. For example, if a child is given a toy hammer, instead of pounding with it, she may shake it to see if it rattles (i.e., the child has changed the toy’s use to fit her thoughts, or used assimilation).

## Planning and Implementation for Health Promotion of a Toddler and Family

Toddlers tend to develop many upper respiratory and ear infections but otherwise come to healthcare facilities most often for health maintenance visits (recommended at 15, 18, and 24 months of age) and for important immunizations. These visits allow you to focus on health promotion and provide the opportunity for early detection of any growth and development delays. [Table 30.3](#) lists specific areas to assess during these visits.

**TABLE 30.3 HEALTH MAINTENANCE SCHEDULE, TODDLER PERIOD**

<b>Well-Child Visits (Typically Scheduled at 15, 18, 24, and 30 Months)</b>		
<i>Area of Focus</i>	<i>Methods</i>	<i>Frequency</i>
Health history	Health interview	Every visit
Physical health	Physical examination	Every visit
Developmental milestones	History and observation	Every visit
	Ages & Stages Questionnaire	18- and 24-month visits
Autism spectrum disorder screening	Observation and language assessment	18- and 24-month visits
Growth milestones	Height and weight plotted on standard growth chart	Every visit
	Head circumference	15-, 18-, and 24-month visits
	Body mass index	Beginning at 24-month visit
Nutrition	History, observation; height and weight information	Every visit
Parent–child relationship	History and observation	Every visit
Social/behavior assessment	History and observation	Every visit
Vision and hearing	History and observation	Every visit
Dental health	History and physical examination	18- or 34-month visit
	Dental appointment	Every 6 months
	Fluoride varnish	Recommended each visit
Anemia	Hematocrit/hemoglobin	Risk assessment at 15 and 30 months
Lead screening	Point-of-care rapid lead screening	24 months and more frequently if at elevated risk
Tuberculosis	Purified protein derivative (PPD) test	If indicated based on risk

Urinalysis	Clean-catch urine	Based on symptoms
Dyslipidemia	Cholesterol level	24-month visit if indicated based on risk

### Immunizations

(Administer immunization in accordance with healthcare agency policies. Check history and past records and inform caregiver about any risks and side effects before administration [[www.cdc.gov/vaccines/schedules](http://www.cdc.gov/vaccines/schedules)].)

Diphtheria, tetanus, and pertussis	DTaP	15-month visit (4th)
Haemophilus influenzae type B	HiB	15-month visit (4th)
Pneumococcal vaccine	PVC	15-month visit if not previously immunized
Hepatitis A	HepA	12- or 18-month visit (1st and 2nd)
Hepatitis B	HepB	15- or 18-month visit (3rd)
Influenza	IIV	Yearly
Measles, mumps, and rubella	MMR	12- or 15-month visit (1st)
Inactivated poliomyelitis	IPV	12- or 15-month visit (3rd)
Varicella vaccine	VAR	12- or 15-month visit (1st)

### Anticipatory Guidance

<i>Area of Focus</i>	<i>Methods</i>	<i>Frequency</i>
Toddler care	Active listening and health teaching	Every visit
Expected growth and developmental milestones before next visit	Health teaching	Every visit
Poison and unintentional	Educate parents about toddler safety, such as using car seats and bicycle	Every visit

injury prevention	helmets, locking up poisons, and such precautions as removing drawstrings from hooded clothing to prevent strangulation; provide telephone number of national poison control center (1-800-222-1222).	
<b>Problem Solving</b>		
Any problems expressed by caregiver during course of the visit	Active listening and health teaching regarding temper tantrums, toilet training, negativity	Every visit

Source: American Academy of Pediatrics, Committee on Practice and Ambulatory Medicine. (2012). *Recommendations for preventive pediatric health care*. Washington, DC: Author; Centers for Disease Control and Prevention. (2013). *Birth–18 years & “catch up” immunization schedules*. Washington, DC: Author.

Routine health maintenance visits also provide opportunities to support parents through the normal crises of the toddler period. Ways to encourage parents to promote healthy development of independence in their toddler include listening carefully to their concerns, asking questions to help separate the objective circumstances surrounding a problem from the parents’ possible emotional biases, and providing guidelines on how to handle specific problems.

## PROMOTING TODDLER SAFETY

Accidents (unintentional injuries) are the major cause of death in infants through late adolescents in the United States (CDC, 2012a). Unintentional ingestions (poisoning) and auto accidents are the types of unintentional injuries that occur most frequently in toddlers (Beirens, van Beeck, Brug, et al., 2010).

Although poisoning can involve medicine such as acetaminophen (and there is a growing concern of illegal or prescription drug ingestions even in toddlers), it most often occurs from ingestion of cleaning products. Aspiration or ingestion of small objects such as watch or hearing aid batteries, pencil erasers, or parts of crayons is also a major danger for children of this age (Litovitz, Whitaker, & Clark, 2010). Urge parents to childproof their home by putting all poisonous products, drugs, and small objects out of reach by the time their infant is crawling, and certainly by the time their infant is walking, to avoid these problems (Lee & Marcdante, 2011).

Other unintentional injuries that occur frequently in toddlers include motor vehicle accidents, burns, falls, drowning, and playground injuries. These occur because toddlers’ motor ability jumps ahead of their judgment. To prevent serious injury, teach parents to be alert as to what their toddler is doing at all times.

By the end of the toddler period, children can walk surely; if they are left outside to play, they can very quickly travel a block away. Because they have no judgment

concerning moving cars, they walk across streets with no regard for oncoming cars. Because they cannot swim well, parents need to check whether backyard pools—another area prone to unintended injury—are securely fenced (Bowman, Aitken, Robbins, et al., 2012).

For safety in automobiles, parents should keep their toddlers in rear-facing seats until age 2 years, or until the child reaches the maximum height and weight for their particular seat. Following that, children need to ride in a car seat with a five-point restraint (Fig. 30.5). Car seats should be placed in the back seat so the child is not struck by the passenger seat airbag (AAP, 2013). Remind parents that it is unsafe to leave a toddler alone in a car. One way for a parent to be reminded that the child is in the back seat is to always place a purse or briefcase in the back seat alongside the child's car seat.

**Figure 30.5** Toddlers should use a car seat with a five-point restraint while riding in an automobile until they are 2 years of age.

Toddlers need to wear a helmet as soon as they begin riding a tricycle. Although parents are becoming conscientious about using car seats, they are not as conscientious about using toddler or booster car seats or helmets for bicycle riding, so these are areas where health teaching is necessary (Macy, Clark, Freed, et al., 2012).

Some 15-month-old children are able to climb over the side rails of their cribs and enjoy exploring the house early in the morning before anyone else is awake. Parents

might have to move their child to a regular bed with a side rail as early as this time to keep the child from falling when climbing out of a crib. A safety gate on the door of his or her room is another way to keep a toddler contained and safe.

As the child reaches 2 years of age and begins to imitate housework or repairing a car, parents must be sure the child does not use real cleaning compounds or sharp tools. **Box 30.3** summarizes unintentional injury prevention measures to encourage parents to take with their toddler.

### BOX 30.3

#### Nursing Care Planning Based on Family Teaching

#### UNINTENTIONAL INJURY PREVENTION MEASURES FOR TODDLERS

**Q.** Jason’s mother tells you, “My toddler is constantly on the go. How can I keep him safe?”

**A.** Injury prevention has to be constant while your child is a toddler. Try the following precautions:

#### Potential Unintended Injury

#### Prevention Measure

Motor vehicles	Maintain your child in a car seat; do not be distracted by the child from safe driving. Do not allow the child to play outside unsupervised. Do not allow the child to operate electronic garage doors or play near lawn mowers or snow blowers. Supervise toddlers with pedaling toys (e.g., look before crossing driveways, do not cross streets) but do not expect toddler will obey these rules at all times (i.e., stay close by).
Falls	Keep house windows closed or keep secure screens in place. Place gates at top and bottom of stairs. Supervise at playgrounds. Do not allow child to walk with sharp object in hand or mouth. Raise crib rails and check to make sure they are locked before walking away from crib.
Aspiration	Examine toys for small parts that could be aspirated; remove toys that appear dangerous. Do not feed toddler popcorn or nuts; caution child not to eat while running. Do not leave toddler alone with a balloon.
Drowning	Do not leave toddler alone in a bathtub or near water (including buckets of cleaning water). Fence pools; insist

	toddlers wear safety “floats” or life vests; supervise at all times when near water.
Animal bites	Do not allow toddler to approach strange dogs. Supervise child’s play with family pets.
Poisoning	Never present medication as candy. Buy medications with childproof caps; put away immediately after use. Never take medication in front of child. Place all medication and poisons in locked cabinets or overhead shelves where child cannot reach them. Never leave medication in parents’ purse or pocket where child can reach it. Always store food or substances in their original containers. Know the names of houseplants and find out if they are poisonous. (Call national poison control center for information: 800-222-1222.) If unsure if plants are safe, hang them or set them on high surfaces beyond toddler’s grasp. Be certain small batteries or magnets are out of reach. Post telephone number of national poison control center by the telephone or add as a contact on a cell phone: (800-222-1222). Inspect toys to be certain if they were manufactured in another country that they are free of lead-based paint.
Burns	Cook on the back burners of stove if possible; turn handles of pots toward back of stove to prevent toddler from reaching up and pulling them down. If a vaporizer is used, use a cool-mist type rather than a steam vaporizer so child cannot be scalded. Keep screen in front of fireplace or heater. Monitor toddlers carefully when they are near lit candles. Do not leave toddlers unsupervised near hot-water faucets; check temperature setting for hot-water heater so thermostat is not over 125°F. Do not leave coffee/tea pots on a table where child can reach them. Never drink hot beverages when a child is sitting on your lap or playing within reach. Buy flame-retardant clothing. Do not allow toddlers to blow out matches (teach fire is not fun); store matches out of reach. Keep electric wires and cords out of toddlers’ reach; cover electrical outlets with safety plugs.

## General

Know whereabouts of toddlers at all times. Toddlers can climb onto chairs or high stools they could not manage before, can turn door knobs and go places they could not go before, and are able to pull a television set over on top of themselves.

Be aware the frequency of injuries increases when the family is under stress and therefore less attentive to children. Special precautions must be taken at these times.

Be aware some children are more active, curious, and impulsive and therefore more vulnerable to unintentional injury than others.

### *QSEN Checkpoint Question 30.3*

#### **EVIDENCE-BASED PRACTICE**

As television sets become larger and thinner, viewing becomes easier. To investigate if television sets can also be a threat to young children, researchers reviewed a Canadian trauma database over a 15-year period as to how many emergency room visits were caused by a television set falling onto a young child. They identified a total of 179 injuries (20 to 24 per year). Toddlers were the most frequently injured age group, and head and neck injuries were the most common consequences of a television pulled down onto a young child (Mills, Grushka, & Butterworth, 2012).

Based on the study and the AAP recommendations on television viewing, the nurse advises Jason's parents to take which action?

- a. Encourage Jason to watch television in his room where the television set is smaller.
- b. Teach Jason to always watch television from a distance of no less than 12 feet.
- c. Teach Jason to use the remote control so he can watch television safely by himself.
- d. Allow Jason to watch television only when a parent is free to supervise his actions.

*Look in Appendix A for the best answer and rationale.*

### **Lead Screening**

The CDC has set as a goal the elimination of elevated blood lead levels in children (CDC, 2012b). All children between the ages of 6 months and 6 years who live in communities with buildings built before 1950 and immigrant children who might have been exposed to sources of lead in another country should be tested for the presence of lead in their body (lead poisoning). Elevated lead levels are caused by eating, chewing, or sucking on objects (e.g., windowsills, paint chips, furniture) that are covered with

lead-based paint. Although federal law has prohibited the use of lead in the manufacture of both interior and exterior paints since the mid-1970s, many older houses are still coated with lead-based paint. Additional sources of lead poisoning can include:

- Toys manufactured in countries where restrictions on lead are not enforced or cribs that were painted with lead-based paint
- Soil around the exterior of the house and contaminated food grown there
- Dust or fumes created by home renovation
- Pottery made with lead glazes or jewelry made from lead or lead alloys
- Colored print in newspapers or older lead-based water pipes
- Lead dust brought home on the clothing of parents who work with lead products such as batteries

Lead-based gasoline used to be a concern but is no longer available in the United States. Because lead is toxic to body tissue, ingestion of it leads to serious damage to the brain and nervous system, kidneys, and red blood cells. Levels as low as 5 µg/dl can cause learning and behavioral problems (CDC, 2012b). High levels may result in seizures, cognitive challenges, coma, and even death. Although 10 µg/dl was the standard to define lead toxicity for the past decade, the new lower level of 5 µg is proposed as the best way to help prevent minimal damage (Kuehn, 2012).

Beginning symptoms of lead poisoning include irritability, headache, fatigue, and abdominal pain. Often, however, there are no symptoms before damage occurs, which is why blood screening is essential. The CDC (2012b) recommends screening for all children between the ages of 9 and 12 months at least once and again at 18 or 24 months of age. A small amount of blood taken by a finger prick is analyzed. A positive result (over 5 µg/dl) must be confirmed by further testing. The long-term effects of lead poisoning and therapy are discussed in Chapter 52.

### ***QSEN Checkpoint Question 30.4***

#### **SAFETY**

Jason's grandmother often visits the family. When she does, she brings a number of medications with her. The nurse teaches the family to follow which precautions about unintentional poisoning?

- a. Advise the grandmother to keep her medicine in her purse and stress that no one should open her purse but her.
- b. Show Jason his grandmother's pills and emphasize that he is not permitted to touch them.
- c. Assure the grandmother that as long as her vials of medicine have childproof caps, there is no danger.
- d. Buy the grandmother a medicine case that locks and place it on a high shelf when she visits.

*Look in Appendix A for the best answer and rationale.*

## PROMOTING NUTRITIONAL HEALTH IN TODDLERS

Because growth slows abruptly after the first year of life, a toddler's appetite is usually less than an infant's. Children who ate hungrily 2 months earlier now may sit and play with their food. It is important to educate parents that, while the child is still an infant, this decline in food intake will occur, so they will not be concerned when it happens. Because the actual amount of food eaten daily varies from one child to another, teach parents to place a small amount of food on a plate and allow their child to eat it and ask for more rather than serve a large portion that the child cannot finish. One tablespoonful of each food served is a good start. Also, cleaning a plate gives a child a feeling of independent functioning, whereas leaving food uneaten suggests that parents expected something more.

Because mothers are urged to breastfeed for the entire first year, many mothers begin weaning from breastfeeding or bottle feeding during the toddler years. Recommend that mothers do this gradually in order to avoid confrontation. Additional tips for weaning are discussed in [Chapter 29](#).

Allowing self-feeding is a major way to both strengthen independence in a toddler and improve the amount of food consumed. Offering finger foods such as pieces of chicken, slices of banana, pieces of cheese, and crackers and allowing a choice between two types of food helps promote independence while exposing children to varied foods ([Whitney & Rolfes, 2013](#)). Toddlers usually prefer to eat the same type of food over and over because of the sense of security this offers. Most toddlers insist on feeding themselves and generally will resist eating if a parent insists on feeding them. An independent child may react to repeated attempts at being fed by refusing to eat at all.

### Toddler Nutrition Requirements

Parents may become frustrated when trying to provide adequate nutrition for their toddler because of a toddler's varying and unpredictable appetite and food preferences. Although a toddler's daily food consumption may vary greatly, energy needs are generally met when sufficient food is supplied in a positive environment.

- Sedentary children ages 1 to 3 years should consume 1,000 kcal daily; active children in this age group may need up to 1,400 kcal daily ([U.S. Department of Agriculture, 2012](#)).
- Calories are best supplied by a variety of foods spaced into three meals a day.
- Protein and carbohydrate needs are often those most easily met during the toddler period; diets high in sugar should be avoided to help prevent toddler obesity.
- Fats should generally not be restricted for children under 2 years old; however, children over 2 years old should have a total fat intake between 30% and 35% of calories, with most fat coming from sources of polyunsaturated and monounsaturated fatty acids, such as fish, nuts, and vegetable oils, the same as adults.
- Trans fats should be kept to a minimum.

- Adequate calcium and phosphorus intake is important for bone mineralization. Milk should be whole milk until age 2 years, after which 2% milk can be introduced ([Whitney & Rolfes, 2013](#)).

## **A Vegetarian Diet**

Vegetarian diets are adequate for toddlers if parents are well informed about needed vitamins and minerals ([Chisholm, 2011](#)). A vegetarian diet can be easily designed for a toddler who prefers finger foods because many vegetables, fruits, and grains such as pieces of oranges, peaches, raisins, chickpeas, and crackers are easily eaten this way. The use of fortified soy milk prevents fluid, protein, vitamin B<sub>12</sub>, and calcium deficiencies. Tofu should be served often to supply protein.

## **PROMOTING TODDLER DEVELOPMENT IN DAILY ACTIVITIES**

A toddler's new independence and developing abilities in self-care, such as dressing, eating, and to a limited extent hygiene, present special challenges for parents. Learning how to promote autonomy yet maintain a safe, healthful environment should be a major goal for the family.

### **Dressing**

By the end of the toddler period, most children can put on their own socks and underpants ([Fig. 30.6](#)). Some may also be able to pull on slacks, pullover shirts (the sleeves of a shirt often confuse a toddler), or simple dresses. Parents may be reluctant to encourage toddlers to dress themselves because it is easier and quicker for a parent to do so. Also, a toddler who is dressed by parents will (usually) be wearing clothes in the correct way. When toddlers dress themselves, they invariably put shoes on the wrong feet and shirt and pants on backward. Encourage parents to give up perfection for the benefit of the child's developing sense of autonomy. If they feel they must change the child's clothes, urge them to begin with a positive statement, such as "You did a good job," before making the switch.

**Figure 30.6** Getting dressed by himself is a fun morning activity for this older toddler.

Don't judge whether the parents encourage self-dressing by what they do at a healthcare-setting visit. In this setting, parents may dress a child quickly to show the child that the examination is over, or they may simply be in a hurry to get home.

As soon as children are up on their feet and walking, they need shoe soles that are firm enough to provide protection from rough surfaces. However, toddlers do not need extremely firm or ankle-high shoes. Because a toddler's arches are still developing, it is better for their arches to provide foot support rather than having it provided by shoes. Sneakers are an ideal toddler shoe because the soles are hard enough for rough surfaces and arch support is limited.

## Sleep

The amount of sleep children need gradually decreases as they grow older ([Gahagan, 2011](#)). They may begin the toddler period napping twice a day and sleeping 12 hours each night and end it with one nap a day and only 8 hours of sleep at night. Parents who are not aware that the need for sleep declines at this time may view a child's disinterest in sleeping as a problem (about 10% of parents report toddler-age sleep problems ([Byars, Yolton, Rausch, et al., 2012](#))). If a child has difficulty falling asleep at night, it may be time to omit or shorten an afternoon nap. If a child is so short tempered at dinnertime that eating is impossible, perhaps the child needs two naps a day. Some toddlers begin having night terrors or awake crying from a bad dream and so may receive little sleep because they are reluctant to fall back asleep ([Bhargava, 2011](#)). Night terrors are further discussed in [Chapter 31](#).

When toddlers are tired, they naturally fall asleep. They may begin to resist naps,

however, as well as nighttime sleep as they become aware for the first time that activities go on while they sleep. Caution parents when they say, “We’ll do this after naptime,” that they wait until then to do it. Otherwise, a child may be reluctant to nap the next day for fear of missing another activity. Also, parents must be sure older siblings do not point out to a toddler all the exciting things a toddler missed while napping.

Other toddlers resist naptime as part of their developing negativism. Parents might minimize this by including a nap as part of lunchtime routine, not as a separate activity (i.e., the child always goes from the table directly to bed as if the two things are connected). The parent can state simply, “It’s naptime now,” and then give a secondary choice: “Do you want to sleep with your teddy bear or your rag doll?” Toward the end of the toddler period, when children are ready to omit their afternoon naps, they may still be agreeable to a “shoes off” or “quiet play” period until they begin to attend school full-time.

As with any other activity of this period, a toddler loves a bedtime routine: bath, pajamas, a story, toothbrushing, being tucked into bed, having a drink of water, choosing a toy to sleep with, and turning out the lights. Parents must be careful, however, not to let a child maneuver them into such a long procedure that sleep is delayed considerably past the time initially set. Although toddlers need to be independent, they also need a feeling of security. Just as adults like to know there are guardrails along steep mountain roads, toddlers like to see parents as firm, consistent people who can be counted on to be reliable over and over, especially when they’re tired.

Many toddlers are ready to be moved out of a crib into a youth bed or regular bed with protective side rails or a chair strategically placed beside it by the end of the toddler period. Remind parents to stress that sleeping in a regular bed does not give children the right to get in and out of bed as they choose. Some toddlers do well if they are allowed to sleep in a regular bed and a folding gate is placed across the door to their room. This arrangement gives them a feeling of independence but still keeps them safe. When first moved to a bed without side rails, many children are found sleeping on the floor of the room in the morning. There is no harm in this unless it is cold or drafty. Dressing the child in warm pajamas or putting a blanket on the floor might be solutions to help parents accept this.

## **Bathing**

The time for a toddler’s bath should depend on the parents’ and the child’s wishes and schedule. Some parents prefer to bathe a toddler before the evening meal because it has a quieting effect and prepares the child for eating; others prefer to give it at bedtime because it has a relaxing effect and helps a child sleep. However, the time is not as important as the attempt to establish a sense of routine and a sense that life has order. Learning to be independent is sometimes frightening, and there is security in knowing that certain events are predictable.

Toddlers usually enjoy bath time, and parents should make an effort to make it fun by providing a toy, such as a rubber duck or plastic fish. Bath time is usually so enjoyable for toddlers that parents can use it as a recreational activity or something to do on a rainy day when they can find nothing else to interest their child. Remind parents that although toddlers can sit well in a bathtub, it is still not safe to leave them unsupervised. They might slip and get their head under water or reach and turn on the hot-water faucet and scald themselves (Hutchings, Barnes, Maddocks, et al., 2010). Parents shouldn't add bubble bath to the water because its use is associated with vulvovaginitis and possibly urinary tract infections, especially in girls (S. Smith, 2011).

## Dental Care

Toddlers often need between-meal snacks. To help prevent dental caries from frequent snacking, encourage parents to offer fruit (e.g., bananas, pieces of apple, orange slices) or protein foods (e.g., cheese, pieces of chicken) for snacks rather than high-carbohydrate items such as cookies to limit exposure of the child's teeth to carbohydrate (G. A. Smith & Riedford, 2012). Calcium (found in large amounts in milk, cheese, and yogurt) is especially important for the development of strong teeth and so are other good snack foods. In addition, children should continue to drink fluoridated water or, if not available, receive fluoride supplements so all new teeth form with cavity-resistant enamel (Tubert-Jeannin, Auclair, Amsallem, et al., 2011).

Remind parents not to put a child to bed with a bottle of milk or juice to help prevent the development of caries. Toddlers need a toothbrush they recognize as their own. Toward the end of the toddler period, they can begin to do the brushing themselves under supervision (almost all children need some supervision until about age 8 years). Remind parents that it is better for a child to brush thoroughly once a day, probably at bedtime, than to do it poorly many times a day. After brushing, parents can use dental floss to clean between their child's teeth and remove plaque.

Urge parents to schedule a first dental visit with a dentist skilled in pediatric dental care by 12 months of age. Screenings and assessment of dentition can begin as early as 6 months of age but should occur no later than 24 months of age. Dental services can begin by age 3 years (Hoeft, Barker, & Masterson, 2011).

Parents can prepare their child for this first visit and subsequent visits by reading a story about a dentist visit, maintaining a positive attitude about the visit, avoiding the use of frightening words such as "drill" or "shot," and answering their child's questions honestly without going into too much detail. Because children rarely have cavities this early, the visit is usually painless and sets a positive stage for future dental supervision visits.

## PROMOTING HEALTHY FAMILY FUNCTIONING

Because learning self-reliance is the primary goal of a child during the toddler period, some parents who enjoyed caring for their child as an infant may find it difficult to have

their authority challenged by a toddler. Help parents to understand their responses to these attempts at independence are crucial to the healthy development of their child. Although the child still needs firm limits to feel secure, a child must be given room to make independent decisions in areas the parents feel they do not need to control. Someone outside of the family, such as a nurse, can provide an important perspective on this issue.

At bedtime, naptime, or anytime they are tired, toddlers may become much more like their old selves, wanting to sit on a parent's lap and be rocked or picked up and carried. This does not signal babyish behavior or regression in a toddler; it is a natural state between infant and preschool ages.

## PARENTAL CONCERNS ASSOCIATED WITH THE TODDLER PERIOD

Parental concerns of the toddler period usually arise because of a conflict over autonomy.

### Toilet Training

Toilet training is one of the biggest tasks a toddler tries to achieve. There are so many theories concerning toilet training that understanding the procedure can become one of the biggest tasks of this period for parents. Most first-time parents ask when to start, when training should be completed, and how to go about it (Box 30.4). You can explain to parents that toilet training is an individualized task for each child. It should begin and be completed according to a child's ability to accomplish it, not according to a set schedule (Kiddoo, 2012).

BOX 30.42

#### Nursing Care Planning to Respect Cultural Diversity

In the United States, toilet training is usually introduced during the toddler period. Like so many other aspects of childrearing, however, the time when parents begin these activities is culturally determined. In other countries, toilet training may be started as soon as a child can sit—at about 6 months. Although praise is used in the United States as a common means of encouraging toddlers to learn new tasks, other cultures believe praise could bring a child harm by attracting evil spirits; instead, strategies of shame or strict discipline are used. Being aware that childrearing practices are not consistent across the world is a help in understanding why parents approach childrearing problems differently and why childrearing advice must be individualized.

Before children can begin toilet training, they must have reached three important developmental levels, one physiologic and the other two cognitive:

- They must have control of rectal and urethral sphincters, usually achieved by the time they walk well.
- They must have a cognitive understanding of what it means to hold urine and stools until they can release them at a certain place and time.
- They must have a desire to delay immediate gratification for a more socially accepted action.

Because physiologic development is cephalocaudal, the rectal and urethral sphincters are not mature enough for control in most children until at least the end of the first year, when tracts of the spinal cord are myelinated to the anal level. A good way for a parent to know a child's development has reached this point is to wait until the child can walk well independently.

Toilet training need not start this early, however, because cognitively and socially, many children do not understand what is being asked of them until they are 2 or even 3 years old. The markers of readiness are subtle, but as a rule, children are ready for toilet training when they begin to be uncomfortable in wet diapers. They demonstrate this by pulling or tugging at soiled diapers, or they may bring a parent a clean diaper after they have soiled so they can be changed (Fig. 30.7).

**Figure 30.7** Toddlers are interested in toilet training as an expression

of autonomy.

Teach parents not to underestimate the difficulty of the task they are expecting their child to achieve. Toddlers live by a pleasure principle: They want what they want when they want it. Before they can complete toilet training, they must be able to give up an immediate pleasure—relieving themselves whenever they have the urge—to gain other pleasure later on—improved physical comfort and another step in growing up. Guidelines for how to toilet train a toddler are shown in [Box 30.5](#).

### BOX 30.5

#### Nursing Care Planning to Empower a Family

#### COMMON GUIDELINES FOR TOILET TRAINING

**Q.** Jason’s mother asks you, “How can I tell if my 2-year-old is ready for potty training? And if he is, how do I start?”

**A.** Try the following suggestions:

1. Children are physically ready for toilet training when they can walk securely. Plan 1 or 2 weeks of psychological “readiness” activities such as showing your child “grown up” pants and how other family members use the toilet, activities that will help him realize the task of toilet training is a step toward growing up, not something only toddlers do.
2. Check that training pants pull down readily and slacks are free of complicated buttons or grippers; otherwise, your child will have accidents because he cannot undress quickly enough.
3. Purchase either a potty chair that sits on the floor or an infant seat that is placed on the regular toilet. If you choose a toilet seat, place a footstool in front of the toilet so your child has some support for his feet.
4. Begin with defecation training because this is so much easier to grasp than urination. Sit your child on the potty chair or toilet at the time he usually defecates, such as when he wakes up in the morning.
5. Praise your child if he does defecate. Remind him to wash his hands afterward.
6. Be careful not to flush the toilet while your child is sitting on it because 2-year-old children are unable to realize they will not be flushed away. Encourage your child to flush the toilet independently after you have helped him get redressed.
7. Do not allow a child to remain on a potty chair for much longer than 10 minutes (less than that if he is resistant). Also, do not allow your child to use the chair to eat or as a play table, so he doesn’t become confused as to its purpose.
8. If your child does not seem ready on a day-to-day basis, return him to diapers for a short period. Be careful not to make this feel like failure or equate “good” with being dry and “bad” with being wet. Continue with readiness activities. Reintroduce training pants and attempt toilet training again when your child

seems more ready.

9. When children have mastered defecation, it's time to include urination. Boys enjoy standing to urinate and aiming at objects in a toilet bowl, such as pieces of breakfast cereal.
10. Some toddlers have difficulty remaining dry at night until they are 3 to 4 years old. Do not pressure your child to accomplish nighttime dryness but assume he is doing the best he can. Change him to training pants for the night by explaining (not punitively) that it is hard to keep dry while he sleeps. After your child has been dry during the night for about 1 month, he has probably mastered nighttime dryness.
11. Do not wake your child during the night and carry him to the bathroom to void. This system may keep him dry during the night, but it does not help him stay dry for long periods. It may even prolong nighttime wetness because it conditions him to void every 4 hours instead of retaining urine for 8 hours while he sleeps.

Some toddlers smear or play with feces, often at about the same time that toilet training is started. This occurs because they have become fully aware of body excretions but have no adult values toward them; stools seem little different from the modeling clay they play with. This activity can be minimized by providing toddlers with play substances of similar texture and by changing diapers immediately after defecation. Teach parents to accept this behavior for what it is: enjoyment of the body and of the self and the discovery of a new substance. After a child is fully toilet trained, this activity rarely persists.

### Ritualistic Behavior

Although toddlers spend a great deal of time every day investigating new ways to do things and trying activities they have never done before, they also enjoy ritualistic patterns. They will use only “their” spoon at mealtime or only “their” blanket at bedtime. They will not go outside unless a mother or father locates their favorite cap.

The child who seems to need an excessive number of objects to cling to or an excessive number of routines, however, may be trying to say, “I need more guidelines, more rules. Don't let me be quite so independent.”

#### *What If . . . 30.2*

**Jason's mother tells the nurse he is toilet trained, but when he's admitted to the hospital for minor surgery, he refuses to use the toilet. How would the nurse best respond?**

### Negativism

As part of establishing their identities as separate individuals, toddlers typically go

through a period of extreme negativism. They do not want to do anything a parent wants them to do. Their reply to every request is a very definite “no.”

It is easy for parents to believe their authority is being questioned when this happens and to worry children are becoming so disrespectful they will have difficulty getting along in the world. They can be baffled by the extreme change from happy, cooperative infants who lived to please them to irritating, uncooperative toddlers. They may need some help to realize that this is not only a normal phenomenon of toddlerhood but also a positive stage in development. This change indicates toddlers have learned that they are separate individuals with separate needs. It is important toddlers do this if they are to grow up to be persons who are independent and able to take care of their own needs and desires.

Parents who went away from home for the first time for college or camp might remember they behaved similarly. They may recall they rarely slept or ate sensibly; they tried, in effect, to break every rule their parents used to enforce on them. Most regained their equilibrium in time to find a midpoint between irresponsible independence and common sense. If parents can recall such circumstances, it helps them to understand that this behavior in their toddler is not specific to the age but to the first feeling of independence. They can also remember they meant no vindictiveness by their behavior, so they can realize their child means none either. This understanding can help to put the child’s “no” into a better light.

Once it runs its course, extreme negativism will pass. In the meantime, the more parents try to make children obey them, the more children are likely to resist. Some long-term parent–child interaction problems begin during this period because parents insist on being obeyed totally or are inconsistent in their approach.

A toddler’s “no” can best be reduced by limiting the number of questions asked of the child. A father does not really mean, for example, “Are you ready for dinner?” He means, “Come to the table. It’s dinnertime.” A mother asks, “Will you come take a bath now?” She means, “It’s time for your bath.” Making a statement instead of asking a question in this way can avoid a great many negative responses.

A toddler needs experience in making choices, however. To provide the opportunity to do this, a parent could give a secondary choice. “No” is not allowed for the major task, so the parent states, “It’s bath time now” but then says, “Do you want to take your duck or your toy boat into the tub with you?” Other example is “It’s lunchtime. Do you want to use a big or little plate?” or “It’s time to go shopping. Do you want to wear your jacket or your sweater?” Although this solution is simple, it is one parents may not arrive at by themselves because finding a solution to a problem is always more difficult for the person in the middle of the problem than it is for an objective observer. Once they are helped to practice this approach, however, parents usually find it helpful in smoothing out the friction caused by the negativism of the toddler period (Box 30.6).

#### BOX 30.6

### Nursing Care Planning Tips for Effective Communication

Jason's mother has brought 2-year-old Jason to the clinic for a health maintenance visit.

Jason is rambunctious and uncooperative. His mother is obviously frustrated.

*Tip:* Use positive language and encourage patient involvement. Offer focused choices that minimize “no” responses. Avoid commands and attempts to bribe the child.

**Nurse:** Jason, I need to listen to your heart so you must be very quiet. Would you rather sit quietly on the chair or the table?

**Jason:** Table.

**Nurse:** All right, Jason, jump up.

Jason climbs onto the table and starts to fidget.

**Ms. Matthis:** Jason, sit still for the nurse.

**Jason:** No!

**Nurse:** If you'd like, you can use the stethoscope for a few seconds. Do you want to listen to your mom's heart or my heart?

**Jason:** Mom's.

**Nurse:** Great, now we will both be very quiet so you can hear.

Jason listens to his mother's heart.

**Nurse:** Good, now it's my turn.

**Jason:** Okay. (Jason hands back the stethoscope.)

The nurse listens to Jason's heart.

## Discipline

Some parents ask during the last part of the infant year or the early toddler period when they should start to discipline their child, or when toddlers are old enough for punishment to be acceptable. Remind parents that discipline and punishment are not interchangeable terms. **Discipline** means setting rules or road signs so children know what is expected of them. **Punishment** is a consequence that results from a breakdown in discipline or the child's disregard of the rules that were learned.

Parents should begin to instill some sense of discipline early in life because part of it involves setting safety limits and protecting others or property (e.g., a child must stay away from the fireplace or heater, she must not go into the street, she must not hit other children). Enforcing most limits of this type arises out of the day-to-day interactions with the child and out of the rhythm of child care, not out of a set procedure such as “Today, I'm going to teach discipline.” Two general rules to follow include:

1. Parents need to be consistent.

2. Rules are learned best if correct behavior is praised rather than wrong behavior punished.

A “time-out” is a technique to help children learn that actions have consequences. To use a time-out effectively, parents first need to be certain their child understands the rule they are trying to enforce (e.g., “You can’t hit people. If you hit your brother, you’ll have time-out.”). Parents should give one warning. If the child repeats the behavior, parents select an area that is nonstimulating, such as a corner of a room or a hallway. The child is directed to go immediately to the time-out space. The child then sits there for a specified period of time. If the child cries or shows any other disruptive behavior, the time-out period doesn’t begin until there is quiet. When the specified time has passed, the child can return to the family. A guide as to how long children should remain in their time-out chair is 1 minute per year of age (e.g., a 2-year-old would stay in the corner for 2 minutes). Using a timer that rings when time is up is an effective way to let children know when they can return to the family.

### *QSEN Checkpoint Question 30.5*

#### **TEAMWORK & COLLABORATION**

Jason’s mother would prefer to use a time-out for punishment. What should the nurse teach Jason’s mother or his daycare setting caregivers about the use of this technique?

- a. The child should sit still for as many minutes as his age.
- b. The child should sit still for as many minutes as he misbehaved.
- c. Time-out activities can include quiet play or reading books.
- d. Children are not ready for time-outs until school age.

*Look in [Appendix A](#) for the best answer and rationale.*

### **Separation Anxiety**

As discussed in [Chapter 29](#), fear of being separated from parents begins at about 6 months of age and persists throughout the preschool period. This universal fear in this age group is known as separation anxiety. Toddlers who have separation anxiety have difficulty accepting being separated from their primary caregiver to spend the day at a day care center or if they or their primary caregiver is hospitalized. [Chapter 36](#) discusses nursing responsibility for care of toddlers in the hospital as well as the reactions of toddlers to the separation caused by hospitalization and the methods used to minimize these reactions.

Parents may ask what they can do about this problem. They believe they have a right to leave their child in a babysitter’s or center’s care, but how can they tolerate the crying at the door? Most toddlers react best to separation if a regular babysitter is employed or if the day care center has consistent caregivers. It helps if toddlers have fair warning they will have a babysitter. For example, they could be told, “Mommy is fixing dinner early because Mommy and Daddy are going to visit some friends tonight.

Marsha is going to come and babysit for you. She'll put you to bed. When you wake up in the morning, Mommy and Daddy will be here again."

No matter how well prepared toddlers are, they may cry when the babysitter actually appears or may greet the babysitter warmly only to cry when the parents reach for their coats. It helps if parents say goodbye firmly, repeat the explanation they will be there when the child wakes in the morning, and then leave. Prolonged goodbyes only lead to more crying. Sneaking out prevents crying and may ease the parents' guilt, but it can strengthen a child's fear of abandonment and so should be discouraged. This applies to leaving after hospital visits as well.

### ***QSEN Checkpoint Question 30.6***

#### **PATIENT-CENTERED CARE**

Jason replies to every request by his mother with, "No!" His mother admits that she is exasperated and embarrassed by this, and she states that she is desperate to change this behavior. How can the nurse best meet the mother's expressed learning needs?

- a. Have her tell Jason she doesn't want him to say no anymore.
- b. Instruct her to answer all Jason's questions by saying, "No!"
- c. Encourage her to reduce the number of questions she asks Jason.
- d. Tell her to explain he is not using good communication skills.

*Look in Appendix A for the best answer and rationale.*

## **TEMPER TANTRUMS**

Almost every toddler has a temper tantrum at one time or another. The child may kick; scream; stomp feet; shout, "No, no, no"; flail arms and legs; bite; or bang his or her head against the floor.

Temper tantrums occur as a natural consequence of toddlers' development. They occur because toddlers are independent enough to know what they want, but they do not have the vocabulary or the wisdom to express their feelings in a more socially acceptable way (J. A. Green, Whitney, & Potegal, 2011). For example, temper tantrums occur most often when children are tired, just before naptime or bedtime, or during a long shopping trip or visit. They may be a response to an unrealistic request by a parent, such as asking a child to comb her hair before she is coordinated enough to do so, asking her to pick up toys before she has a feeling of family responsibility, or asking her to share before she can understand what that means. Tantrums may also occur if parents are saying "no" too frequently with regard to such things as touching the coffee table, using a spoon, or running and jumping, thus making children feel constantly thwarted. A tantrum may also be a response to difficulty making choices or decisions or to pressure from activities such as toilet training. Such children need to express feelings in some way and do so with temper tantrums. These episodes are not only taxing for the parents but are also energy consuming for children.

Some children hold their breath as part of a temper tantrum until they become cyanotic. This occurs when a child is provoked; the child develops a distended chest (a halt after inspiration), often has air-filled cheeks, and shows increasing distress as the body registers oxygen want. Ignoring the child will make it an ineffective technique for expressing frustration or getting what is wanted. True breath holding is an unprovoked neurologic problem in which children, under stress, appear to “forget” to breathe in or halt breathing after expiration, usually at the peak of anger. They become so short of breath they slump to the floor. True breath holding needs follow-up to separate it from temper tantrums (see [Chapter 49](#)).

**Box 30.7** offers suggestions for managing temper tantrums. Probably the best approach is for parents to simply tell a child that they disapprove of the tantrum and then ignore it. They might say, “I’ll be in the bedroom. When you’re done kicking, you come into the bedroom, too.” Children who are left alone in a kitchen this way will usually not continue a tantrum but will stop after 1 or 2 minutes and rejoin their parents. Parents should then accept the child warmly and proceed as if the tantrum had not occurred. This same approach works well for nurses caring for hospitalized toddlers.

### BOX 30.7

#### Nursing Care Planning Based on Family Teaching

#### MANAGING TODDLER’S TEMPER TANTRUMS

**Q.** Jason’s mother tells you, “I’ve had it with temper tantrums. I can’t stand to watch another one.”

**A.** Here are suggestions to prevent them:

Try to determine the reason for the behavior:

- Do tantrums always occur just before bedtime? If so, you might schedule an earlier bedtime or an afternoon nap.
- Do tantrums occur every time you go shopping? If so, perhaps it would help to schedule two shorter trips each week rather than one long one.
- Do tantrums occur whenever you ask the child to do something? If so, is the child being asked to perform tasks that are not age appropriate?
- Do tantrums occur in response to not being able to make a decision? If so, you may have to limit the number of choices you are asking of the child.

Next, be certain it seems like a tantrum, not something more:

- Is there a possibility you are mistaking seizure activity for temper tantrums?
- Could you be confusing neurologic breath holding with a temper tantrum?

Lastly, think through what you do when the child has a tantrum:

- Do you give either material or emotional bribes (e.g., “Come and get a cookie”)? This method is rarely effective because, by acceding to the child’s wishes, you are encouraging your child to have more tantrums because they are so rewarding.
- Do you punish the child? Toddlers have a right to express opinions; they just need

to be guided to learn a more controlled and mature way of doing that.

- Do you role model adult behavior in managing anger or frustration? For example, if your child shouts or kicks, do you respond, “I can shout as loud as you”? Instead of showing the child a better way to express feelings, this reinforces the way the child is responding.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for compromised family coping related to toddler behavior

**Outcome Evaluation:** Family states temper tantrums now occur less than two times daily.

Helping parents correct problems early may limit the number of tantrums they must deal with; however, it will not prevent them because parents cannot anticipate all the circumstances that will cause this reaction. In fact, parents should not feel they must prevent all of them; after all, they are parents, not mind readers. As the child matures, increases his or her vocabulary, and is capable of better responses to stress situations, tantrums begin to fade by themselves. [Box 30.8](#) shows an interprofessional care map illustrating both nursing and team planning to address such a problem as temper tantrums.

### BOX 30.8

#### Nursing Care Planning

### AN INTERPROFESSIONAL CARE MAP FOR A TODDLER WITH TEMPER TANTRUMS

Jason is a 2.5-year-old boy you see at a pediatric clinic. His mother tells you he has changed completely in the past 6 months from an easy-to-care-for baby into a “monster” who refuses to do anything she asks. The only word he says anymore is “no.” He has a temper tantrum every night at dinner over some type of food. She tells you this has changed parenting from “fun” to “a real chore.”

**Family Assessment:** Child lives with two parents in three-bedroom home. Father is a ferry boat captain; works 6 days a week. Mother works as a secretary at local university. Finances are “good. We’ve worked hard to get where we are.”

**Patient Assessment:** Well-nourished 2-year-old boy. Physical findings within normal limits. Mother reports the child is having temper tantrums “at least 20 times a day. He throws himself on the floor and pounds his head and fists.” Mother unable to describe any precipitating factors for the tantrums. She states, “He seems to have them just when I start to do something. I could be playing with him one minute, and

then I get up to do something, like answer the phone or start dinner, and he starts.” Mother reports picking up the child immediately because she fears he will hurt himself. “I just don’t know what to do anymore.”

**Nursing Diagnosis:** Health-seeking behaviors related to measures for dealing with and reducing the number of temper tantrums.

**Outcome Criteria:** Mother describes measures to manage tantrums and reports tantrums have decreased to fewer than four a day by end of 1 week.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Ask mother to describe a typical day; document when tantrums occur and situations that seem to provoke them.	Make suggestions to eliminate cause of distress as revealed by assessment.	Temper tantrums can increase with stress and inability of child to feel independent.	Mother reviews a typical day and identifies times when tantrums are most apt to occur.
<i>Teamwork and Collaboration</i>				
Nurse/primary healthcare provider	Assess if child has possible neurologic symptoms.	Refer child for full neurologic workup if physical exam suggests the need.	Temper tantrums can be confused with seizures if a careful history is not taken.	Mother agrees to further neurologic testing if suggested.
<i>Procedures/Medications for Quality Improvement</i>				
Nurse/nurse practitioner	Assess what measures mother thinks would prevent temper tantrums best.	Work with the mother to develop actions such as ignoring the tantrum and encouraging the mother not to pick up child unless there is actual danger of injury.	Temper tantrums are a method to express emotion. Rewarding the behavior prevents the child from learning more mature methods of coping with frustration.	Mother voices agreement to try suggested solutions and to telephone clinic in 3 days if there is no improvement.

*Nutrition*

Nurse practitioner	Assess if child appears well nourished and assess usual dietary pattern.	Because tantrums occur at meal time, review with mother if her actions are different at this time than others.	Eating is an area in which children want to express independence.	Mother lists foods that allow child independent eating, which she will try to serve, to keep meals tantrum-free.
--------------------	--	--	---	--

*Patient-Centered Care*

Nurse	Assess mother's knowledge of toddler behavior and temper tantrums.	Review normal toddler growth and development, explaining that some temper tantrums during this period are natural occurrences.	Information about normal toddler growth and development provides a foundation for further teaching and instruction.	Mother states she understands tantrums occur because of toddler's limited capabilities to express desires.
Nurse	Assess why mother is so fearful her child will hurt himself during a tantrum.	Inform the mother that children rarely hurt themselves during tantrums.	Increased knowledge about the minimal risk of injury during tantrums should help to alleviate the mother's anxiety.	Mother states she has increased understanding about the danger of tantrums.

*Psychosocial/Spiritual/Emotional Needs*

Nurse/nurse practitioner	Assess what mother feels would be most helpful to relieve her degree of stress and frustration.	Suggest she arrange for "time out" breaks for herself by having husband or friend relieve her.	Short periods away from the child can allow her to regroup her thinking.	Mother describes a plan to receive more help with child care from friend because husband is home only 1 day per week.
--------------------------	---	--	--	---

## Informatics for Seamless Healthcare Planning

Nurse/nurse practitioner	Review with mother the plan for added support and interventions.	Instruct the mother to keep a diary of the child's behavior and measures used during the next week. Set up an appointment for a telephone conference next week to review the diary and discuss the child's behavior.	Keeping and reviewing a diary aids in evaluating the child's behavior and the effectiveness of the methods used. A follow-up telephone call provides an additional opportunity for feedback, teaching, and support.	Mother states she will follow suggestions for managing tantrums and will keep telephone and clinic appointments for follow-up care.
--------------------------	--	--	---	---

### What If... 30.3

**Although the nurse is caring for Jason in the hospital, he has a temper tantrum in the middle of a busy hallway. Would the nurse ignore it or move him to a quieter place?**

## CONCERNS OF THE FAMILY WITH A TODDLER WHO HAS UNIQUE NEEDS

It may be difficult for children with handicaps or disabilities to achieve a sense of autonomy or independence because they may never be totally independent. However, it is important for these children to develop as strong a sense of autonomy as possible so they see themselves as independent and can work to become increasingly self-sufficient as they grow older.

Nursing actions designed to help the challenged or chronically ill child develop a sense of autonomy are outlined in [Table 30.4](#). Most important are such actions that allow toddlers to do as much for themselves as possible. If toddlers have physical limitations, for example, they may be unable to explore freely or may not have the physical ability to pound and manipulate toys as the average toddler does. They do, however, have the ability to work at a project while they sit in a chair at a table.

### **TABLE 30.4 NURSING INTERVENTIONS TO HELP A PHYSICALLY CHALLENGED OR CHRONICALLY ILL CHILD DEVELOP A SENSE OF AUTONOMY**

Area	Nursing Action
Nutrition	A special diet may limit typical finger foods. Use imagination to offer other foods not usually eaten this way as finger foods. Allow child to help pour liquid diet for a tube feeding. Toddlers are frightened by vomiting because they have no control over it. Comfort afterward. Check for possibility that child is nauseated. Toddlers have no way to express this other than by not eating.
Dressing changes	<p>A child can hold pieces of tape or put tape in place to maintain sense of control. The child can remove an old bandage if it is not contaminated. Allow the child to view his or her incision and watch dressing changes, explaining each step of a procedure as you perform it helps the child maintain control.</p> <p>Restrain only those body parts necessary during a procedure to allow a child a sense of control.</p> <p>Remove all supplies after a procedure or the child may “redo” the dressing.</p>
Medication	Allow children no choice as to whether a medicine will be taken. Do allow a child to choose a “chaser,” such as milk or juice, after oral medicine. Do not ask a toddler to indicate a choice of site for an injection or intravenous insertion. This is too advanced a decision for a toddler to handle.
Rest	Locate or create a ritual for bedtime (e.g., put child into bed, tuck him in, say, “Goodnight, Bobby.” Tuck in bear. Say, “Goodnight, Bear”). Allow a choice of toy or cover but not a choice of bedtime or naptime hour.
Hygiene	Allow a child a choice of bathtub toy or clothing. Allow a child to wash face and hands to gain control of the situation. Allow the child to put toothpaste on a brush, but you should brush or “touch up” teeth afterward to ensure all plaque has been removed.
Pain	Encourage a child to express pain (e.g., “Say ‘ouch’ when I pull off the tape”). Help channel a child’s self-expression to what is acceptable (the child may shout, for example, but may not kick).
Stimulation	Provide a toddler with a toy that can be manipulated, such as boxes that fit inside one another and can be taken out again, trucks that can be pushed, and pegs that can be pounded. In a healthcare setting, items can usually be found that fit together (e.g., boxes from central supply, plastic vials from the pharmacy). Another action toy: Buy a nonlatex balloon and tie it to the crib side to be used as a punching bag; another one tied to the foot of the crib can serve as a leg exerciser.

Elimination	A child who is toilet trained needs to be encouraged to continue to use a potty chair or toilet during an illness. Help children with ureter or bowel stomas to help with changing bags so they are as independent in bowel function as possible.
-------------	---

A toddler with a long-term illness or who is physically challenged can be expected to exhibit normal toddler behaviors, such as temper tantrums, and to have normal outlooks, such as negativism. Parents whose child is uncoordinated or has a neurologic disease may mistake temper tantrums for seizure activity. Investigate such activity carefully and explain to parents the difference between the two. Parents may also mistake particular toddlers' insistence on having their own way as a manifestation of illness. Remind these parents the behavior is more often an indication of age and development rather than of illness so that they can respond appropriately.

Toilet training is difficult for a child who is hospitalized at periodic intervals because success usually requires a consistent caregiver; in addition, hospitalization can result in regressive behaviors. If a chronically ill child has difficulty with ambulation, soiling accidents may occur beyond the usual age because of an inability to reach a bathroom easily.

Children who survive a long-term illness are sometimes referred to as medically fragile or vulnerable children (M. Green & Solnit, 1964). Some parents tend to protect and shelter such a child, and you may have to remind them that, even though the toddler is chronically ill, he or she will demand independence and has the right to explore. A child who uses a lower extremity prosthesis, for example, might prefer to crawl somewhere rather than wait for help to put the prosthesis in place. Although this degree of independence is good, parents may have to limit how it is expressed so the child will learn how to use the prosthesis (e.g., they could make a rule the child must use the prosthesis to walk but can choose whether to use a spoon when eating).

### **Autism Spectrum Disorder**

Classic ASD is a complex range of neurodevelopment disorders characterized by communication difficulties, poor social interaction, and frequent repetitive and stereotyped movements (Fountain, Winter, & Bearman, 2012). It occurs in all ethnic and socioeconomic groups, as frequently as 1 in 88 children, and more frequently in boys than in girls. Milder forms of the disorder are termed Asperger syndrome, Rett syndrome, childhood disintegrative disorder, or pervasive developmental disorder not otherwise specified (usually referred to as PDD-NOS).

Symptoms begin to appear slightly in infancy but are usually obvious enough during the toddler years for parents to become concerned because their child tends not to speak any words, does not make eye contact with others, and has difficulty interacting with playmates, preferring instead to watch a spinning toy, water swirling down the toilet, or repeating sing-song repetitive phrases.

Children need to be screened for autism symptoms by 12 months of age and again at

18 and 24 months of age by observation and parent report. Additional symptoms and therapy for autism are discussed in [Chapter 54](#).

### **Nutrition and the Physically Challenged or Chronically Ill Toddler**

All toddlers need experience feeding themselves if at all possible, but allowing a child with neurologic deficits do this can be difficult for parents. Help them accept the accidents that occur, and suggest finger foods if possible.

If children are on a special diet, it may be difficult to prepare finger foods. If they are tube fed, they receive no experience at all with finger foods. For these children, parents should try to provide other, comparable experiences in independence, such as letting them choose what toy to take to bed or what clothing to wear.

#### *What If . . . 30.4*

**The nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to toddler growth and development (see [Box 30.1](#)). What would be a possible research topic to explore pertinent to this goal that would be applicable to Jason’s family and that would also advance evidence-based practice?**

### **KEY POINTS FOR REVIEW**

- Erikson’s developmental task for the toddler period is to form a sense of autonomy or independence versus shame or doubt.
- Toddlers make great strides forward in development, but their physical growth slows.
- A critical milestone of toddler development is being able to form two-word sentences (a noun and a verb) by 2 years of age.
- Toddlers are capable of preoperational thought or are able to deal much more constructively with symbols than they could while infants.
- Important aspects of toddler care are promoting safety, toddler development, and healthy family functioning because all three of these facets help in planning nursing care that not only meets QSEN competencies but that also best meets a family’s total needs.
- Toddler appetites decrease from those of the infant, so children eat proportionally less than they did as infants.
- Common concerns of parents during the toddler period are toilet training, ritualistic behavior, negativism, temper tantrums, discipline, and separation anxiety.
- Promoting autonomy in the child who is physically challenged or chronically ill calls for creative planning because there may be many tasks that must be done for the child to be certain they are done safely.

## CRITICAL THINKING CARE STUDY

Bobby is a 2.5-year-old boy you meet at a pediatric clinic because he has a “tummy ache.” He lives with his single mother in a one-bedroom apartment on the third floor of a rent-controlled building. His mother tells you he doesn’t get outside much because she’s afraid to walk to the local park because it is “owned” by a street gang. Bobby sleeps with her in a double bed. Yesterday, he got up before her; she found him sitting on a kitchen counter near the stove. She adds, “His father wants him to be a baseball player. I just want him to learn enough words so he can say when he needs to use a bathroom.”

1. What are some safety precautions you would want to discuss with Bobby’s mother?
2. The walls of this family’s apartment are painted with automobile paint his father secured from his job as a car painter. Would you be concerned with the use of such paint?
3. Bobby does not yet speak in sentences. What questions would you want to ask his mother to help determine if his development is delayed?

# 31

## Nursing Care of a Family With a Preschool Child

*Cathy Edwards is a 3-year-old you meet at a health maintenance visit. Her father cares for her at present because her mother is hospitalized with preterm labor for a second pregnancy. Her father tells you he is concerned because Cathy talks constantly with an imaginary friend named Emma. She makes up stories about events that can't possibly be true. When corrected, Cathy stutters so badly no one can understand her. Her father is also concerned because his daughter cries when he leaves her at daycare.*

*The previous chapter described toddler growth and development and the abilities children develop during that period. This chapter adds information about the changes, both physical and psychosocial, that occur during the preschool years. Such information builds a base for care and health teaching for this age group.*

**Is Cathy's father describing typical preschool behavior, or does Cathy need a referral to a child care specialist?**

### KEY TERMS

**broken fluency**

**bruxism**

**conservation**

**ectomorphic body build**

**egocentrism**

**Electra complex**

**endomorphie body build**

**genu valgus**

**intuitional thought**

**Oedipus complex**

**secondary stuttering**

### OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe normal growth and development as well as common parental concerns of the preschool period.
2. Identify 2020 National Health Goals related to the preschool period that nurses can help the nation achieve.
3. Assess a preschooler for normal growth and developmental milestones.
4. Formulate nursing diagnoses related to preschool growth and development or common parental concerns.
5. Identify expected outcomes for nursing care of a preschooler as well as help parents manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care related to normal growth and development of a preschooler, such as preparing a preschooler for an invasive procedure.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of preschool growth and development with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

---

The preschool period traditionally includes the years 3, 4, and 5. Although physical growth slows considerably during this period, personality and cognitive growth continue at a rapid rate. Therefore, this is also an important period of growth for parents because they may be unsure how much independence and responsibility for self-care they should allow their rapidly maturing child. Most children of this age want to do things for themselves—choose their own clothing and dress themselves, feed themselves independently, wash their own hair, and so forth. As a result, parents of a preschooler may find their child dressed in one red and one green sock, going to preschool with unwashed ears, or trying to eat soup with a fork. They need reassurance that this behavior is typical because it is the way children explore and learn about new experiences (Fergusson, Boden, & Horwood, 2013).

Parents may also need some guidance in separating those tasks that a preschooler can accomplish independently from those that still require some adult supervision so they can set sensible limits. Setting limits protects children from harming themselves or others while participating in all the interesting experiences available to them. [Box 31.1](#) lists 2020 National Health Goals related to this in-between toddler and school-age period.

**BOX 31.1**

A number of 2020 National Health Goals are designed to target the preschool population. They include:

- Increase the number of states and the District of Columbia with laws requiring helmets for bicycle riders under 15 years of age, from 19 states to 27 states.
- Decrease acute middle ear infections (otitis media) among children from 246 out of 1,000 to 221 out of 1,000.
- Increase the proportion of children aged 19 to 35 months who receive the recommended doses of diphtheria, tetanus, and pertussis (DTaP); polio; MMR; Haemophilus influenzae type B (HiB); hepatitis B; varicella; and PCVs from 44.3% to 90%.
- Increase the rate of use of forward-facing child car seats among children age 1 to 3 years from a baseline of 72% to 79%.
- Reduce the proportion of children 3 to 11 years exposed to secondhand smoke from 52.2% to 47% (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by alerting parents to these concerns as well as by serving as consultants at child care and preschool settings to be certain that preschoolers are protected against secondhand smoke, that recommended automobile restraints are used, and that children are fitted with helmets before beginning bicycle riding.

### *Nursing Process Overview*

#### FOR HEALTHY DEVELOPMENT OF A PRESCHOOLER

##### **ASSESSMENT**

Regular assessment of a preschooler includes obtaining a health history and performing both a physical and developmental evaluation at healthcare visits. Preschoolers may speak very little during a health assessment; they may even revert to baby talk or infantile actions such as thumb-sucking if they find a health visit stressful. A history that details their usual performance level is therefore important for accurate evaluation.

Assess a child's weight, height, and body mass index (BMI) according to standard growth charts (available at <http://thePoint.lww.com/Flagg8e>). Keep in mind that these charts are based on average weights and heights of white American children, so children from other racial backgrounds may not completely conform with these norms (i.e., they may fall into the lower or upper percentiles). Also assess a child for general appearance. Does the child appear alert? Happy? Active? Preschoolers typically have 6 to 12 respiratory infections per year; therefore, many of them will have one at the time of a health assessment.

## **NURSING DIAGNOSIS**

Nursing diagnoses for preschoolers typically center on health promotion or unintentional injury prevention. Examples include:

- Health-seeking behaviors related to developmental expectations
- Risk for injury related to increased independence outside the home
- Delayed growth and development related to frequent illness
- Risk for imbalanced nutrition, more than body requirements, related to fast food choices
- Risk for poisoning related to maturational age of the child
- Parental anxiety related to lack of understanding of childhood development

## **OUTCOME IDENTIFICATION AND PLANNING**

For many parents, preschool is a difficult time because a child is at an in-between stage—no longer an infant, although not yet ready for formal school. Planning and establishing expected outcomes for care of children at this age often begin with establishing a schedule for discussing normal preschool development with the parents. Planning for unintentional injury prevention such as how to cross streets safely becomes increasingly critical as children begin to enjoy experiences away from home. It is also important to plan opportunities for adventurous activities and interaction with other children. Parents may find it helpful to be referred to online resources for further information (see [Chapter 28](#)).

## **IMPLEMENTATION**

Preschool children imitate moods as well as actions. An important nursing intervention, therefore, is role-playing a mood or attitude you would like a child to learn. To project an attitude that a health assessment is an enjoyable activity, you might suggest preschoolers participate by listening to their heart or coloring the table paper. Unintentional injury prevention is also best taught by role modeling (e.g., a parent always crosses streets at the corner, a parent doesn't start the car until seatbelts are in place).

## **OUTCOME EVALUATION**

An evaluation of expected outcomes needs to be continuous and frequent. Because growth during this period is more cognitive and emotional than physical, parents may report little growth. Evaluating specific areas can help them appreciate that progress has occurred. Examples of expected outcomes might include:

- Child states importance of holding parent's hand while crossing streets.
- Parent states realistic expectations of 3-year-old child's motor ability by next visit.
- Mother reports she has prepared her 4-year-old for new baby by next visit.

# **Nursing Assessment of a Preschooler's Growth and**

## Development

An assessment of preschoolers needs to include physical, cognitive, and developmental growth (Box 31.2).

BOX 31.2

### Nursing Care Planning Using Assessment

#### APPEARANCE OF THE AVERAGE PRESCHOOLER

#### PHYSICAL GROWTH

A definite change in body contour occurs during the preschool years. The wide-legged gait, prominent lordosis, and protuberant abdomen of the toddler change to slimmer, taller, and much more childlike proportions. Contour changes are so definite that future body type—**ectomorphic body build** (slim body build) or **endomorph body build**

(large body build)—becomes apparent. Handedness also begins to be obvious. A major step forward is a child's ability to learn extended language, which is achieved not only by motor development but also by cognitive development. Children of this age who are exposed to more than one language or who live in a bilingual family have a unique opportunity to master two languages with relative ease because of this increased cognitive ability.

Lymphatic tissue begins to increase in size, particularly the tonsils; levels of immune globulin (Ig)G and IgA antibodies increase. These changes tend to make preschool illnesses more localized (e.g., an upper respiratory infection remains localized to the nose with little systemic fever).

Physiologic splitting of heart sounds may be present for the first time on auscultation; innocent heart murmurs may also be heard for the first time. This type of murmur occurs because of the changing size of the heart in reference to the thorax because the anteroposterior and transverse diameters of the chest have not yet reached adult proportions. Pulse rate decreases to about 85 beats/min, and blood pressure holds at about 100/60 mmHg.

The bladder is easily palpable above the symphysis pubis; voiding is frequent enough (9 or 10 times a day) that play must be interrupted, and voiding accidents may occur if a child becomes absorbed in an activity.

A child who earlier in life had an indeterminate longitudinal arch in the foot generally demonstrates a well-formed arch now. Muscles are noticeably stronger, so activities such as gymnastics become possible. Many children at the beginning of the period exhibit **genu valgus** (knock-knees); this disappears with increased skeletal growth at the end of the preschool period.

### **Weight, Height, Body Mass Index, and Head Circumference**

Weight gain is slight during the preschool years; the average child gains only about 4.5 lb (2 kg) a year. During these years, appetite remains the same as it was during the toddler years, a level perhaps considerably less than some parents would like or expect.

Height gain is also minimal during this period: only 2 to 3.5 in. (6 to 8 cm) a year on average. Head circumference is not routinely measured at physical assessments on children over 2 years of age because it changes little after this time.

### **Teeth**

Children generally have all 20 of their deciduous teeth by 3 years of age; permanent teeth don't replace these until school age. Preserving these teeth is important because they hold the position for the permanent teeth as the child's jaw grows larger. If a deciduous tooth has to be removed, children need conscientious follow-up to be certain a space for a permanent tooth remains (de Amorim Lde, Estrela, & da Costa, 2011).

## **DEVELOPMENTAL MILESTONES**

Each year during the preschool period marks a major step forward in gross motor, fine motor, and language development. Play activities change focus dramatically as the preschooler learns new skills and understands more about the world (Fig. 31.1). Table 31.1 summarizes major milestones of the period.

**Figure 31.1** Preschoolers like to imitate the roles of adults as they learn about the world around them.

**TABLE 31.1 SUMMARY OF PRESCHOOL GROWTH AND DEVELOPMENT**

Age (in Years)	Fine Motor Skills	Gross Motor Skills	Language	Play
3	Undresses self; stacks tower of blocks; draws a cross	Runs; alternates feet on stairs; rides tricycle; stands on one foot	Vocabulary of 900 words	Able to take turns; very imaginative
4	Can do simple buttons	Constantly in motion; jumps; skips	Vocabulary of 1,500 words	Pretending is major activity
5	Can draw a six-part figure; can lace shoes	Throws overhand	Vocabulary of 2,100 words	Likes games with numbers or letters

### Language Development

The extent of a 3-year-old child’s vocabulary varies depending on how much the child

has been encouraged to ask questions or participate in conversations (Box 31.3). A child typically, however, has a vocabulary of about 900 words and uses it to ask questions constantly, up to 400 a day, such as “Why is snow cold?” “How do worms hear?” and “What does your tongue do?” A child needs simple answers to such questions to encourage curiosity, vocabulary building, and questioning. Words that sound alike but mean different things such as “whether” and “weather” can be confounding to children of this age. If a parent tells a child her shoes should go on with the buckles on the outside, she may seem to understand but return in a few minutes to ask, “Why do I have to go outside to put on my shoes?”

### BOX 31.3

#### Nursing Care Planning to Respect Cultural Diversity

Whether children are allowed to ask questions is culturally determined and can make a difference in how much vocabulary a child uses. In a society in which children are expected to be seen and not heard, a preschool child may not have the same expressive vocabulary as a child who has been encouraged to ask questions. Recognition that differences among cultures can affect levels of development means assessments must be individualized and meaningful in terms of the cultural milieu.

**Egocentrism**, or perceiving that one’s thoughts and needs are better or more important than those of others, is also strong during the preschool period. Preschoolers cannot believe that not everyone knows facts they know; if asked, “What is your name?” they may reply, “Don’t you know it?” As a part of egocentrism, preschoolers define objects mainly in relation to themselves, so a spoon is “what I eat with,” not a curved metal object; a crayon is “what I write with,” not an orange wax object.

Four- and 5-year-old children enjoy participating in mealtime conversation and can describe an incident from their day in great detail. Remember that preschoolers tend to imitate language exactly, so if they hear less-than-perfect language, this is the language pattern they adopt. They may imitate and use “bathroom language” because of the attention from adults this generates.

Preschoolers are egocentric, so they define objects in relation to themselves (e.g., a key is not a metal object but “what I use to open a door,” a car is not a means of transportation but “what Mom uses to take me to school”).

### Play

Preschoolers do not need many toys because, with an imagination keener than it will be at any other time in life, they enjoy games that use imitation such as pretending they are a teacher, cowboy or cowgirl, firefighter, or store clerk. Many preschoolers have imaginary friends at this stage (Nielsen, 2012), which often exist until children formally begin school.

Four- and 5-year-olds divide their time between roughhousing and imitative play. Five-year-olds become interested in group games or reciting songs they have learned in kindergarten or preschool.

***QSEN Checkpoint Question 31.1***

**INFORMATICS**

Cathy, who is 3 years old, constantly asks questions. When teaching her father about communication skills in children of this age, the nurse should state that a child of Cathy's age typically asks how many questions in a day?

- a. Around 50
- b. 100 to 200
- c. 300 to 400
- d. 600 or more

*Look in Appendix A for the best answer and rationale.*

**EMOTIONAL DEVELOPMENT**

Children change a great deal in their ability to understand their world and how they relate to other people during the preschool years.

**Initiative**

The developmental task for the preschool-age child is to achieve a sense of initiative versus guilt (Erikson, 1993). Children with a well-developed sense of initiative like to explore because they have discovered that learning new things is fun.

If children are criticized or punished for attempts at initiative, they can develop a sense of guilt for wanting to try new activities or to have new experiences. Those who leave the preschool period with a sense of guilt can carry it with them into school situations. They may even have difficulty later in life making decisions about everything from changing jobs to choosing an apartment because they cannot envision that they are capable of solving the associated problems that will come with change.

To gain a sense of initiative, preschoolers need exposure to a wide variety of experiences and play materials so they can learn as much about how things work as possible. They are ready to explore outside their homes such as enjoying a trip to the zoo or an amusement park (Fig. 31.2). They enjoy going with their family on vacation. These types of experiences lead to increased vocabulary (e.g., at the zoo, words such as giraffe, elephant, and bear come alive because they are transferred from abstract concepts to the actual animals).

**Figure 31.2** Preschoolers like exposure to new events and places. Here, a 3-year-old child is eager to explore the woods during a hike with the family.

Urge parents to provide play materials that encourage creative play, such as finger paints, soapy water to splash or blow into bubbles, sand to build castles, and modeling clay or homemade dough to mold into figures or make into pretend cookies. These are messy activities, so some parents prefer not to allow a child to indulge in them more than once a week, but any experience with free-form play is helpful.

Preschoolers tend to have such active imaginations that they need little guidance in this type of play. They smear both hands into clay or finger paint and create instinctively. What they make may not be recognizable; it is the enjoyment of feeling the material and how they can manipulate it that captures the experience.

### **Imitation**

Imitating the actions of the people around them peaks during preschool age. Role modeling this way should be fun and does not have to be accurate. If a child is pretending to be a police officer who is busy putting out fires or a firefighter who is stopping playmates from speeding, the fact that the child is freely imitating a role is more important than getting the role absolutely correct. If a parent is concerned that a

child should recognize these roles more accurately, it is usually best to suggest that the parent not to stop the play but rather to explain where firefighters work and that their job is to put out fires the next time they drive past the fire station.

Children generally imitate those activities best that they see their parents performing at home. A young girl will set the table for breakfast, eat with her “spouse,” help clean off the table, and leave for work. A young boy might work on his computer, pretend to feed a doll, and put the doll to bed as he has seen his father do with a younger sibling. In addition to learning what activities adults carry out at home, preschoolers should also be introduced to their parents’ work environments. Such visits not only provide a visual context for the parent’s job but also let a child learn such words as photocopier, assembly line, legal brief, or fax machine.

## Fantasy

Toddlers cannot differentiate between fantasy and reality; they believe cartoon characters they see on television are real. Preschoolers, however, begin to make this differentiation. They may become so engrossed in a fantasy role that they fear they are “stuck” in the fantasy and are no longer themselves. Such intense involvement in play is part of “magical thinking,” which is active at this age (i.e., believing thoughts and wishes can come true).

Parents sometimes strengthen this feeling without realizing it, so they (and you) need to be careful in this regard. A preschooler, like Cathy for example, whom you care for in the hospital might be pretending she is a white rabbit. When you walk into her room, you are aware of the game, so you might say, “That’s strange; I don’t see Cathy anywhere. All I see is a white rabbit.” Cathy may be frightened that she has actually become a white rabbit; how will she ever get home again? A better response from you would be to support the imitation—this is age-appropriate behavior and a good way to explore roles—by saying instead, “What a nice white rabbit you’re pretending to be.” This both supports the fantasy and yet reassures the child she is still herself.

## Oedipus and Electra Complexes

Although the development of Oedipus and Electra complexes may have been overstated by Freud—possibly because of gender bias—many children do seem to manifest such behavior (Erreich, 2011). An **Oedipus complex** refers to the strong emotional attachment a preschool boy demonstrates toward his mother; an **Electra complex** is the attachment of a preschool girl to her father. A daughter demonstrating this complex might prefer to always sit beside her father at the table, or she may ask for her father to tuck her in at night. She makes a point that she is “Daddy’s girl.” A mother who is not prepared for this behavior may feel hurt and cut off from family interaction. A father may feel the same way when his son wants to sit beside his mother and prefers her to be the one to tuck him in for the night.

Parents can be assured this phenomenon of competition and romance in

preschoolers is a normal part of maturing. Some parents may need help in handling feelings of jealousy and anger, however, particularly if a child is vocal in expressing feelings toward a parent.

## **Gender Roles**

Preschoolers begin to be aware of the difference between sexes and so need to be introduced to both gender roles. Encourage single parents to plan opportunities for their children to spend some time with adults other than themselves, such as a grandparent, a friend, or a relative of the opposite sex, for this experience. If a child is hospitalized during the preschool period, a nurse could readily fill this role.

Many parents do not want their child to grow up as they did, with a fixed gender role as a result of stereotyping. Help them understand that parents reinforce such attitudes by their actions as well as by their words. For example, a father may tell his son it is important for both boys and girls to do housework, but if the father never does dishes, he is teaching his son that managing a household is not a man's job.

## **Socialization**

Because 3-year-olds are capable of sharing, they play with other children their age much more agreeably than do toddlers, which makes the preschool period a sensitive and critical time for socialization. Preschoolers who are exposed to other playmates have an easier time learning to relate to people than those raised in an environment where they rarely see other children of the same age (Paulus & Moore, 2012) (Fig. 31.3).

**Figure 31.3** The preschool child moves past parallel play to make new friendships.

Although 4-year-olds continue to enjoy play groups, they may become involved in arguments more than they did at 3 years of age, especially as they become more certain of their role in the group. This development, like so many others, may make parents worry that a child is regressing. However, it is really forward movement that involves some testing and identification of their group role.

Five-year-olds begin to develop “best” friendships, perhaps on the basis of who they walk to school with or who lives closest to them. The elementary rule that an odd number of children will have difficulty playing well together generally pertains to children at this age: two or four will play, but three or five will quarrel.

### **Cognitive Development**

According to [Piaget \(1969\)](#), cognitive development is still preoperational by 3 years of age, although children during this period also enter a second phase called **intuitional thought**. During this second phase of development, children learn by asking questions such as “How come?” and “Why?” Piaget named this stage “intuitive thought” because he believed that children tend to be so certain of their knowledge and understanding that

they are unaware of how they gained this knowledge initially. Children in the intuitive substage may still demonstrate many advances in cognitive skills. They may shift from using only magical beliefs to using rational beliefs to explain situations or events that they had not experienced previously. Very young children may explain that a new building “grew out of the ground,” whereas older children understand it was built.

Intuitive children show a style of thinking he called “centration.” These children typically are focused on the characteristic of an object or person, and they base their decisions or judgment on that one characteristic (as opposed to considering multiple characteristics). For example, a 4-year-old who was asked to put toys into groups might focus his or her attention on the color of the toy instead of the shape or the material from which they are constructed. Centration also means that preschoolers cannot make mental substitutions and often feel they are always right. It’s important to remember this when explaining procedures to preschoolers. They cannot see your side of the situation, they cannot hurry because you must have something done by 10 o’clock, and they cannot hold still just because you want them to.

Preschoolers are not yet aware of the property of **conservation**. This means that if they have two balls of clay of equal size, but one is squashed flatter and wider than the other, they will insist the flatter one is bigger (because it is wider) or the intact one is bigger (because it is taller). They cannot see that only the form, not the amount, has changed. This inability to appreciate conservation has implications for nursing care because it means preschoolers are not able to comprehend that a procedure performed two separate ways is the same procedure. If the nurse before you, for example, told a child to turn on his right side and then his left side while his bed was made, you may have to allow him to turn those same ways or he will insist you are making his bed wrong. Decentering, combined with the concept of conservation, appear prior to more sophisticated logical thinking abilities.

## **Moral and Spiritual Development**

Children of preschool age determine right from wrong based on their parents’ rules because they have little understanding of the rationale for these rules or even whether the rules are consistent. If asked the question, “Why is it wrong to hit other children?” the average preschooler answers, “Because my mother says so.” Because preschoolers depend on their parents to supply rules for them, when faced with a new situation, they may have difficulty understanding the rules they know also apply to the new situation such as a hospital.

Preschoolers begin to have an elemental concept of spirituality if they have been provided some form of religious training. Belief in an outside force aids in the development of conscience; however, preschoolers tend to do good out of self-interest rather than because of strong spiritual motivation (Kohlberg, 1984). Children at this age enjoy the security of religious holidays and religious rituals such as prayer before meals because these rituals offer them the same reassurance and security as a familiar nursery rhyme read over and over.

### What If... 31.1

Cathy, 3 years old, understands the rule “Don’t steal from a store.” Would she also understand “Don’t steal from a hospital”?

## Planning and Implementation for the Health Promotion of a Preschooler and Family

Preschoolers are old enough to begin to take responsibility for their own actions. Children’s safety, nutritional health, daily activities, and family functioning are all affected by this increased responsibility.

### PROMOTING PRESCHOOLER SAFETY

As preschoolers broaden their horizons, safety issues must also widen. By age 4 years, children may project an attitude of independence and the ability to take care of their own needs. However, they still need supervision to be certain they do not injure themselves or other children while roughhousing and to ensure they do not stray too far from home. Their interest in learning adult roles may lead them to exploring the blades of a lawn mower or an electric saw or a neighbor’s pool (Bowman, Aitken, Robbins, et al., 2012). Because they imitate adult roles so well, they may imitate taking medicine if they see family members doing so. It’s also not too early to think about gun safety or being certain any gun in their home is locked away separate from its ammunition (Senger, Keijzer, Smith, et al., 2011).

A final area to consider is automobile safety. Preschoolers must be reminded repeatedly to buckle their booster seat and not to walk in back of or in front of automobiles. Otherwise, a preschooler’s thought “I want to play with Mary across the street” can be so quick and so intense that the child will run into the middle of the street before remembering street safety rules. Additional safety points for the preschool period are summarized in Box 31.4.

#### BOX 31.4

#### Nursing Care Planning to Empower a Family

### COMMON SAFETY MEASURES TO PREVENT UNINTENTIONAL INJURIES TO PRESCHOOLERS

**Q.** Cathy’s father says to you, “My preschooler is so active! How can I keep her safe?”

**A.** All of the safety measures that apply to toddlers also apply to preschoolers. In

addition, try these tips:

<b>Possible Unintentional Injury</b>	<b>Prevention Measure</b>
Motor vehicles	Teach safety with tricycles (e.g., look before crossing driveways, do not cross streets). Teach the child to always hold hands with an adult before crossing a street. Teach parking lot safety (e.g., hold hands with an adult, do not run behind cars that could be backing up). Teach children to consistently wear helmets when beginning bicycle riding.
Falls	Always supervise a preschooler at a playground. Remove drawstrings from hooded clothing. Help the child to judge safe distances for jumping or safe heights for climbing.
Drowning	Teach beginning swimming.
Animal bites	Do not allow the child to approach strange dogs. Supervise the child's play with family pets.
Poisoning	Never present medication as a candy. Never take medication in front of a child. Never store food or substances in containers other than their own. Post the telephone number of the poison control center by the telephone or as a cell phone contact number (1-800-222-1222). Teach the child that medications are a serious substance and not for play.
Burns	Store matches in closed containers. Do not allow the preschooler to help light birthday candles or fireplaces; fire is not fun or a treat.
Community safety	Teach the preschooler that not all people are friends (e.g., "Do not talk to strangers or take candy from strangers"). Define a stranger as someone the child does not know, not someone odd looking. Teach the child to say "no" to people whose touching he or she does not enjoy, including family members. (When a child is sexually maltreated, the offender is usually a family member or close family friend.)
General	Know the whereabouts of the preschooler at all times.

Be aware the frequency of unintentional injuries increases when parents are under stress. Special precautions must be taken at these times.

Some children are more active, curious, and impulsive and therefore more vulnerable to unintentional injuries than others.

## Keeping Children Safe, Strong, and Free

The preschool years are not too early a time to educate children about the potential threat of harm from strangers or how to address bullying behavior (from children or adults) at preschool or at play (Jonson-Reid, Kohl, & Drake, 2012) through such measures as:

- Cautioning a child never to talk with or accept a ride from a stranger
- Teaching a child how to call for help in an emergency (yelling or running to a designated neighbor's house if outside, or dialing 911 if near a phone)
- Describing what police officers look like and explaining that police can help in an emergency situation
- Explaining that if children or adults ask them to keep secrets about anything that has made them uncomfortable, they should tell their parents or another trusted adult, even if they have promised to keep the secret
- Explaining that bullying behavior from other children is not to be tolerated and should be reported so they can receive help managing it

It is often difficult for parents to impart this type of information to preschoolers because they don't want to terrify their child about the world. They also can't imagine their child will ever be in a situation in which the information will be needed. If the information is presented in a calm and everyday manner, however, children can use it to begin to build safe habits that will help them later when they are old enough to walk home from school alone or play with their friends unsupervised.

## Motor Vehicle and Bicycle Safety

Because of front seat airbags, preschoolers need to be buckled into car seats or booster seats in the back seat (American Academy of Pediatrics, 2012). Urge parents to stress the important role of seat belts in preventing injury and to make a rule that the car does not move until seat belts are fastened. Many preschoolers outgrow their car seats during this period (when they reach about 40 lb) and need to graduate to a booster-type seat. Remind parents to check the position of the shoulder harness in both types of seat so the belt doesn't cross a child's face or throat.

Preschool is also the right age to promote bicycle safety because falls off bicycles are a major cause of severe head injuries in this age group (Agarwal & Pruthi, 2010). To prevent such injuries, preschoolers need a safety helmet approved for children their age and size. Encourage parents who ride bicycles to demonstrate safe riding habits by

wearing helmets as well. Seeing a parent routinely wearing a helmet may well be the most compelling reason for a preschooler to wear one.

### *What If... 31.2*

**Cathy tells the nurse she knows to not leave preschool with anyone who is strange. Is that the same as knowing not to leave with a stranger?**

## **PROMOTING THE NUTRITIONAL HEALTH OF A PRESCHOOLER**

Like the toddler period, the preschool years are not a time of fast growth, so preschool children are not likely to have ravenous appetites (Raman, 2011). Being certain they get enough daily exercise helps to improve this. A sense of initiative, or learning how to do things, can be strengthened by allowing a child to prepare simple foods, such as making a sandwich or spreading jelly on toast.

Most children are hungry after preschool and enjoy a snack when they arrive home. Because sugary foods can dull a child's appetite for dinner and it is not too soon to begin measures to prevent childhood obesity, urge parents to offer snacks such as fruit, cheese, or milk rather than cookies and a soft drink or juice (Bevan & Reilly, 2011).

### **Preschool Nutrition Requirements**

As with all age groups, foods selected for preschoolers should include variety (U.S. Department of Agriculture, 2012) and be based on MyPlate ([www.choosemyplate.gov](http://www.choosemyplate.gov)) recommendations. Preschoolers may not eat a great deal of meat because it can be hard to chew. Many parents ask whether their preschooler needs to take supplementary vitamins to make up for this. As long as a child is eating foods from all five food groups and meets the criteria for a healthy child such as being alert and active with height and weight within normal averages, additional vitamins are probably unnecessary.

If parents do give vitamins, remind them that a child will undoubtedly view a vitamin as candy rather than medicine because of the attractive shapes and colors of preschool vitamins, so they must be stored out of reach. Caution parents not to give more vitamins than the recommended daily amount, or poisoning from high doses of fat-soluble vitamins or iron can result.

### **A Vegetarian Diet**

A vegetarian diet is usually colorful and therefore appeals to preschoolers. Vegetables, fruits, and grains are also healthy snack foods.

If vegetarian diets are deficient in any aspects, it is usually in calcium, vitamin B<sub>12</sub>, and vitamin D. Check to be sure a child is ingesting a variety of calcium sources (e.g., green leafy vegetables, milk products) because calcium is very important for bone growth. Vitamin D is found in fortified cereals and milk. Vitamin B<sub>12</sub> is found almost

exclusively in animal products, so a child on a vegetarian intake may need a supplemental source (Whitney & Rolfes, 2013).

## PROMOTING THE DEVELOPMENT OF THE PRESCHOOLER IN DAILY ACTIVITIES

The preschooler has often mastered the basic skills needed for most self-care activities, including feeding, dressing, washing (with supervision), and toothbrushing (again, with supervision).

### Dressing

Many 3-year-olds and most 4-year-olds can dress themselves except for difficult buttons, although conflict may occur over what the child will wear. Preschoolers prefer bright colors or prints and so may select items that are appealing in color rather than matching. As with other preschool activities, however, children need the experience of choosing their own clothes. One way for parents to solve the problem of mismatching is to fold together matching shirts and slacks so a child sees them as a set rather than individual pieces. If children insist on wearing mismatched clothing, urge parents to make no apologies for their appearance. A simple statement, “Mark chose his own clothes today” explains the situation. Anyone who understands preschoolers appreciates that the experience children gain in being able to select their own clothing is worth more than a perfect appearance by adult standards.

### Sleep

Many toddlers, who go through a typical negative phase, resist taking naps no matter how tired they are. Preschoolers, however, are more aware of their needs; when they are tired, they often curl up on a couch or soft chair and fall asleep. Many, particularly those who attend afternoon child care or preschool, give up afternoon naps. If they nap at preschool, they may have some difficulty going to sleep at the usual bedtime established at home.

On some occasions, even though they may be tired, children in this age group may refuse to go to sleep because of fear of the dark and may wake at night terrified by a bad dream (Byars, Yolton, Rausch, et al., 2012). This means that preschoolers may need a night-light turned on, although they did not need one before. A helpful suggestion for parents is to screen out frightening stories or TV watching just prior to bedtime and to be certain when the light in their bedroom is dimmed, it has a soothing atmosphere (no staring teddy bears or evil smiling dolls). [Box 31.5](#) is an interprofessional care map for a child with preschool fears.

BOX 31.5

Nursing Care Planning

## AN INTERPROFESSIONAL CARE MAP FOR A PRESCHOOLER WITH FEARS

Cathy Edwards is a 3-year-old whom you meet at a health maintenance visit. Her father tells you he is concerned because Cathy talks constantly with an imaginary friend named Emma. She makes up stories about events that can't possibly be true. When corrected, Cathy stutters so badly that no one can understand her. Her father is also concerned because his daughter cries when he leaves her at child care.

**Family Assessment:** The family lives in a rented apartment in the inner city. The mother, a stay-at-home mom, is hospitalized with complications of a second pregnancy. The father works as a city police detective.

**Patient Assessment:** A 3-year-old girl within normal limits for height, weight, and development. The child is currently enrolled in an all-day preschool program while the mother is hospitalized. The father picks the child up after his work. The father arrived late to pick the child up from preschool last week. She states, "He forgot me." The child refuses to return to preschool. When he tries to drop her off now, she cries, sticks her finger in her mouth to make herself vomit, and complains her stomach hurts.

**Nursing Diagnosis:** Fear related to separation and abandonment during preschool period.

**Outcome Criteria:** The child verbalizes fear. The father demonstrates measures to minimize the child's fears; reports by 2 weeks that crying episodes at school have decreased.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Ask father to detail a 24-hour day for the family to gain clear picture of child's role and capabilities.	Father describes differences in family life since wife has been hospitalized and strain it causes on Cathy.	People are unable to solve a problem until the extent of the problem is clear.	Father details a typical day and expresses his wish to continue or not continue the preschool experience for Cathy.
<i>Teamwork and Collaboration</i>				
Nurse/nurse practitioner	Assess if father feels referral to child guidance service is	Encourage the father to talk with the preschool staff	Discussion with care providers can help reinforce the	Father states he will consult with preschool staff to help

	necessary to help reduce fear.	about the problem and common methods to decrease a child's fear.	measures used by the father to provide consistency and thereby help to minimize a child's fears.	solve the problem.
--	--------------------------------	--	--	--------------------

*Procedures/Medications for Quality Improvement*

Nurse	Assess what father knows about measures to reduce fear in preschoolers.	Instruct the father in measures to help reduce child's fear, such as reinforcing the time he will return, calling if he's running late, and posting memo to self to pick her up.	Reassurance helps to reduce a child's fear of abandonment.	Father describes steps he will take to be certain he will not be late again at preschool for pickup.
-------	---	--	--	--

*Nutrition*

Nurse	Assess if child uses threat of vomiting at any other time.	Stress that effect of eating disorders is potentially dangerous.	Frequent vomiting in young children can lead to fluid and electrolyte imbalances.	Father states whether he has ever seen pseudovomiting before.
-------	--	--	---	---

*Patient-Centered Care*

Nurse/nurse practitioner	Assess father's knowledge of typical preschool fears such as abandonment and fear of the dark.	Review with the father the typical fears experienced by the preschooler, including those of separation and abandonment.	Knowledge of normal growth and development helps to reduce the father's anxiety about the behavior and possible causes.	Father acknowledges he deals mainly with adults in his business; expresses desire to learn more about preschool period.
--------------------------	--	---	---	---

*Psychosocial/Spiritual/Emotional Needs*

Nurse	Explore with child why she is so fearful her father will not return for her.	Encourage the father to set up a special time for himself and his daughter in the evening or on weekends so they have a consistent close time.	Special time for a father and daughter enhances the parent-child relationship. Consistently adhering to this time helps to foster a sense of trust and security and shows he is dependable.	Father states he will plan for a special time each week, even if it is difficult to arrange because of wife's hospitalization and his irregular work schedule.
-------	--	--	---	--

*Informatics for Seamless Healthcare Planning*

Nurse	Assess if father would find a follow-up telephone call helpful.	Arrange for a follow-up telephone call (if desired) in 1 week.	Follow-up provides additional support and means for evaluating the effectiveness of the methods used.	Father states he is receptive to follow-up care.
-------	---	--	---	--

**QSEN Checkpoint Question 31.2**

**EVIDENCE-BASED PRACTICE**

Many preschoolers have difficulty falling asleep or wake during the night with nightmares. To see if changes in the type of television watched could improve preschooler's sleep, researchers encouraged half of a group of families studied to replace television watching with quality educational and prosocial video content through use of an initial home visit and follow-up telephone calls over 6 months. Among the 565 children studied, the most common sleep problem was delayed sleep onset (38%). Results at the end of 18 months showed that children in the intervention group had significantly lower odds of any sleep problems ([Garrison & Christakis, 2012](#)).

Based on the study, what is the best advice the nurse could give the Edwards family?

- Don't allow Cathy to watch television until she is 5 years of age.
- Encourage Cathy to watch specific DVDs that her parents choose for her.

- c. Discuss with Cathy that TV does not necessarily reflect reality.
- d. Allow her to only watch cartoons so she won't be seeing violence.

*Look in [Appendix A](#) for the best answer and rationale.*

## Exercise

The preschool period is an active phase, so preschool play tends to be vigorous. Roughhousing helps relieve tension and should be allowed as long as it does not become destructive. In addition, preschoolers love time-honored games such as ring-around-the-rosy, London Bridge, or other more structured games they were not ready for as toddlers. Promoting these types of active games and reducing television watching can be steps toward helping children develop motor skills as well as prevent childhood obesity (Hodges, Smith, Tidwell, et al., 2012; Mitka, 2012).

## Hygiene

Preschoolers can wash and dry their hands adequately if the faucet is regulated for them (so they do not scald themselves with hot water). When possible, parents should turn down the temperature of the water heater in their home to under 120°F to help prevent scalds.

Although preschoolers certainly sit well in bathtubs, they should still not be left unsupervised at bath time in case they decide to add more hot water or to practice swimming and then be unable to get their head out of the water again. Some girls develop vulvar irritation (and perhaps bladder infections) from exposure to bubble bath so parents shouldn't add such products to the water (S. Smith, 2011). Although not well studied, cranberry juice may help prevent these infections the same as in adult women (Goldman, 2012).

Children this age are not paragons of neatness and may not clean their hands thoroughly. Preschoolers do not clean their fingernails or ears well, either, so these areas often need "touching up" by a parent or older sibling. Using a nonirritating shampoo and hanging a mobile over the tub so they have a reason to look up while their hair is rinsed helps make hair washing a fun procedure.

## Care of Teeth

If independent toothbrushing was not started as a daily practice during the toddler years, it should be started during preschool (G. A. Smith & Riedford, 2012). One good toothbrushing period a day is often more effective than more frequent half-hearted attempts. Electric or battery-operated toothbrushes are favorites of preschoolers and can be used safely if the child is taught not to use it or any other electrical appliance near a basin of water. Although many preschoolers do well brushing their own teeth, parents must check that all tooth surfaces have been cleaned. Parents should also floss the child's teeth because this is a skill beyond a preschooler's motor ability.

Preschoolers should continue to drink fluoridated water or receive a prescribed oral

fluoride supplement if fluoride is not provided in the water supply (Tubert-Jeannin, Auclair, Amsallem, et al., 2011). Encouraging children to eat apples, carrots, chicken, or cheese for snacks rather than candy or sweets is yet another way to prevent tooth decay. If a child is allowed to chew gum, it should be the sugar-free variety.

A first visit to a dentist should be arranged no later than 2 years of age for an evaluation of tooth formation because deciduous (baby) teeth must be preserved to protect the dental arch. Dental services can be performed at 3 years of age. If a tooth has to be pulled for any reason, this can cause the permanent teeth to drift out of position or the jaw not to grow enough to accommodate them (Merlino & Gigli, 2012). Because initial visits usually reveal no cavities, this should be a pain-free experience and should help implant the idea that dentists like to help rather than hurt.

Teeth grinding (**bruxism**) may begin at this age as a way of “letting go,” similar to body rocking, which children do for a short time each night before falling asleep. Children who grind their teeth extensively may have greater than average anxiety. Children who have cerebral palsy may do this because of the spasticity of jaw muscles. If grinding is extensive, the crowns of the teeth can actually become abraded. The condition can advance to such an extent that tooth nerves become exposed and painful. If damage is evident, refer the family to a pediatric dentist so the teeth can be evaluated, repaired (capped), and conserved.

### *What If . . . 31.3*

**Cathy’s father tells the nurse she hates to take a bath and brush her teeth. What suggestions could the nurse make to help Cathy enjoy these bedtime activities more?**

## **PROMOTING HEALTHY FAMILY FUNCTIONING**

An important role of preschooler parents is to respect creativity. Some who enjoyed maintaining a gentle rhythm of care for an infant can have difficulty being the parents of a preschooler because more flexibility and creativity are required. Other parents come into their own as their child reaches 3 years; they delight in encouraging imaginative games and play.

Part of encouraging creativity is encouraging vocabulary building. One way for parents to do this is to read aloud to their child; another is to answer questions so the child sees language as an organized system of communication. Answering a preschooler’s questions can be difficult, because the questions are frequently philosophical, not fact finding such as, “Why is grass green?” A child may listen to an explanation of chlorophyll but then repeat the question, regardless of the clarity of the explanation, because the parent underestimated the depth of the question. The child did not want to know what makes grass green but why, philosophically, it is not red, blue, or yellow. The obvious answer to that is “I don’t know.” Parents who are confident can

give this answer without feeling threatened. Parents who are less sure of themselves may feel extremely uncomfortable when they realize they do not know the answer to what a 4-year-old is asking (Box 31.6).

### BOX 31.6

#### Nursing Care Planning Tips for Effective Communication

Cathy is being seen for a health maintenance visit. You overhear her father talking to his daughter in the waiting room.

*Tip:* Preschoolers ask 300 to 400 questions a day as they explore their world. Encourage parents to more completely answer their child's questions by explaining they are helping to build their child's vocabulary. Parents sometimes try to discourage questions by offering minimal answers, and discouraging questions can become the habitual method of interaction.

**Cathy:** Why do we have to wait so long?

**Mr. Edwards:** It's how things work here.

**Cathy:** Why?

**Mr. Edwards:** People have to take turns. We're waiting for our turn.

**Cathy:** Why is that girl here? Is she sick?

**Mr. Edwards:** She might be. Some children are here because they're sick and some are just here for a checkup like you.

**Cathy:** When are we going home?

**Mr. Edwards:** As soon as the nurse practitioner checks you over.

**Cathy:** What's that girl's name?

**Mr. Edwards:** I don't know. Do you want to ask her?

### Discipline

Preschoolers have definite opinions on things such as what they want to eat, where they want to go, and what they want to wear, and these opinions may bring them into opposition with parents. A major parental responsibility when this happens is to guide a child through these struggles without discouraging the child's right to have an opinion. A "time-out" is a useful technique for parents to correct behavior throughout the preschool years (see Chapter 30). Although the technique has some critics, it allows parents to discipline without using physical punishment and allows a child to learn a new way of behavior without extreme stress. Time-out periods should be as many minutes long as the child is old, so 3 to 5 minutes is appropriate for preschoolers.

## PARENTAL CONCERNS ASSOCIATED WITH THE PRESCHOOL PERIOD

A number of common health problems and fears usually arise during the preschool years.

### Common Health Problems of the Preschooler

The mortality of children during the preschool years is low and becoming lower every year as more infectious diseases are preventable. This results in the major cause of death being automobile accidents, followed by poisoning and falls ([Centers for Disease Control and Prevention \[CDC\], 2012](#)).

Even though the number of major illnesses is few in this age group, the number of minor illnesses, such as common colds and ear infections, are high. Children who live in homes in which parents smoke have a higher incidence of ear (otitis media) and respiratory infections than others ([Yilmaz, Caylan, & Karacan, 2012](#)). Children who attend child care or preschool programs also have an increased incidence of gastrointestinal disturbances (vomiting and diarrhea) and upper respiratory infections from the exposure to other children unless frequent hand washing is stressed at the setting ([Sun & Sundell, 2011](#)).

Children may demonstrate frequent whining or clinging behavior because of this parade of constant minor infections. Assess to be certain such constant illness is not causing parents to perceive a child as sickly or not able to cope with everyday life so they don't begin to discourage independence in favor of overprotection. As parents become more experienced in handling these conditions, their perception of whether an illness is serious or not and their ability to cope with them will change.

[Table 31.2](#) shows the recommended health maintenance schedule for preschoolers. [Table 31.3](#) lists common problems parents may have in evaluating a preschooler's illness.

**TABLE 31.2 HEALTH MAINTENANCE SCHEDULE, PRESCHOOL PERIOD**

Area of Focus	Methods	Frequency
<i>Assessment</i>		
Health history	Health interview	Every visit
Physical health	Physical examination	Every visit
Developmental milestones	History, observation	Every visit
	Formal Denver Developmental Screening Test (DDST-II)	Before start of school
Growth milestones	Height and weight plotted on standard growth chart; body mass index	Every visit

	(BMI) and physical examination	
Hypertension	Blood pressure	Every visit
Nutrition	History, observation; height and weight information	Every visit
Parent–child relationship	History and observation	Every visit
Social behavior	History and observation	Every visit
Vision and hearing defects	History and observation	Every visit
	Preschool E stereo and audiometer testing	Before start of school
Autism spectrum disorder screening	History and observation	At 18 and 24 months
Dental health	History, physical examination	Every visit
	Dental visit	Every 6 months
	Fluoride varnish	Recommended each visit
Dyslipidemia	Cholesterol, triglycerides	If indicated by risk
Lead	Blood analysis (depending on risk in area)	If indicated by risk
Tuberculosis	Purified protein derivative (PPD) test (if there are high-risk factors)	If indicated by risk

### *Immunizations*

(Administer immunization in accordance with healthcare agency policies. Check history and past records and inform caregiver about any risks and side effects before administration [[www.cdc.gov/vaccines/schedules](http://www.cdc.gov/vaccines/schedules)].)

Diphtheria, pertussis, and tetanus	DTaP 5	Before start of school
Measles, mumps, and rubella (MMR)	MMR #2	Before start of school
Poliomyelitis (inactivated)	IPV #4	Before start of school
Varicella	VAR #2	Before start of school
Influenza	IIV	Yearly
Pneumococcal	Pneumococcal conjugate vaccine	May be indicated

	(PCV)	before school in susceptible children
<i>Anticipatory Guidance</i>		
Preschool care	Active listening and health teaching	Every visit
Expected growth and developmental milestones before next visit	Active listening and health teaching	Every visit
Unintentional injury prevention	Counseling about street and personal safety	Every visit
<i>Problem Solving</i>		
Any problems expressed by caregiver during course of the visit	Active listening and health teaching regarding preschool illnesses and imaginative play	Every visit

**TABLE 31.3 PARENTAL DIFFICULTIES EVALUATING HEALTH PROBLEMS IN THE PRESCHOOL CHILD**

Difficulty	Helpful Suggestions for Parents
Evaluating seriousness of illness or condition	Preschoolers are eager to please and tend to answer all questions such as “Does your stomach hurt?” with a yes. Observing the child for signs of illness (e.g., refusing to eat, holding an arm stiffly, having to go to the bathroom frequently) is often more productive as an evaluation technique.
Evaluating bowel and bladder problems	Preschoolers are independent in toilet habits for the first time, so parents do not have diaper contents to evaluate. Frequent trips to the bathroom, rubbing the abdomen, and holding genitals are the usual signs of bowel or bladder dysfunction.
Evaluating nutritional intake	Preschoolers begin to eat away from home at friends’ houses or at child care, or stay overnight with grandparents for the first time, so parents have less opportunities to observe daily food intake as accurately as before. Observing whether a child is growing and is active is better than monitoring any one day’s intake.

Evaluating bed-wetting	Many preschoolers continue to have occasional enuresis at night until school age. If other signs are present (e.g., pain, low-grade fever, listlessness), a child should have a urine culture because persistent bed-wetting can indicate a low-grade urinary tract infection.
Evaluating activity versus hyperactivity	Many lay magazines have articles on hyperactivity in children. Parents wonder whether their active child could be hyperactive. As a rule of thumb, if a child can sit through a meal (when he is hungry), watch a half-hour television show (that is his favorite), or sit still while his favorite story is read to him, he is not hyperactive.
Age-specific diseases to be aware of	<p>Preschool age is a time for vision and hearing assessment because, for the first time, a child is able to be tested by a standard chart or by audiometry tests.</p> <p>Urinary tract infections tend to occur with a high frequency in preschool-age girls.</p> <p>A language assessment should be done if a child is not able to make wants known by complete, articulated sentences by age 3 years (exceptions are transposing w for r and broken fluency: “I want-want-want to go”).</p>

## Common Fears of the Preschooler

Because preschoolers’ imaginations are so active, this leads to a number of fears such as fear of the dark, mutilation, and separation or abandonment. These can rise in incidence when combined with the stress of an illness, hospitalization, or unsafe conditions in the child’s community (Kushnir & Sadeh, 2011). Although most of these fears can be handled by comforting from parents, in some children, fears are so intense that they need therapy such as desensitization in order for the fear to be conquered.

### Fear of the Dark

The tendency to fear the dark is an example of a fear heightened by a child’s vivid imagination: a stuffed toy by daylight becomes a threatening monster at night. Children awaken screaming because of nightmares. They may be reluctant to go to bed or go back to sleep by themselves unless a light is left turned on or a parent sits nearby.

If parents are prepared for this fear and understand it is a phase of growth, they are better able to cope with it. It is generally helpful if they monitor the stimuli their children are exposed to, especially around bedtime. This includes television, adult discussions, and frightening stories. Parents are sometimes reluctant to leave a child’s light on at night because they do not want to cater to the fear. Leaving on a dim night-light, however, can solve the problem and costs only pennies. Children who awake

terrified and screaming need reassurance that they are safe and that whatever was chasing them was a dream and is not in their room (Fig. 31.4). Most preschoolers do not remember in the morning that they had such a dream; however, they remember for a lifetime that they received comfort when they needed it.

**Figure 31.4** Having mom close by after a bad dream is a comfort to a preschooler.

If parents take sensible precautions against fear of the dark or nightmares and a child continues to have this kind of disturbance every night, it may be a reaction to undue stress, which needs to be investigated and eliminated. Giving sleep medication to counteract the sleep disturbance does not solve the basic problem, so this is rarely recommended. Fear of the dark and sleep disturbances both can become intensified in a hospital setting and require careful planning to relieve (Linder & Christian, 2011).

### Fear of Mutilation

Fear of mutilation is also significant during the preschool age, as revealed by the intense reaction of a preschooler to even a simple injury such as falling and scraping a knee or having a needle inserted for an immunization. A child cries afterward not only from the pain but also from the intrusiveness of the injury or procedure. Part of this fear arises because preschoolers do not know which body parts are essential and which ones—like an inch of scraped skin—can be easily replaced. According to Freud, boys develop a fear of castration because, developmentally, they are more in tune with their body parts and are starting to identify with the same-sex parent as they go through the Oedipal phase (Zepf, Ullrich, & Seel, 2016).

Preschoolers can be worried that if some blood is taken out of their bodies, all of

their blood will leak out. They often lift a bandage to peek at an incision or cut to see if their body is still intact underneath. They dislike procedures such as needlesticks, rectal temperature assessments, otoscopic examinations, or having a nasogastric tube passed into their stomach. They need good explanations of the limits of healthcare procedures, such as clarifying a tympanic thermometer does not hurt or a finger prick heals quickly as well as distraction techniques in order to feel safe.

### ***QSEN Checkpoint Question 31.3***

#### **PATIENT-CENTERED CARE**

Cathy keeps her entire family awake at night because she is so afraid of the dark. The nurse teaches Cathy's parent to take which action to help overcome this fear?

- a. Assure Cathy the room's window is locked so no one can kidnap her.
- b. Suggest Cathy temporarily sleep in the living room in front of the television set for safety.
- c. Buy a night-light for Cathy's room and inspect the room to be certain it appears safe.
- d. Teach Cathy that her fear is not grounded in reality.

*Look in [Appendix A](#) for the best answer and rationale.*

### **Fear of Separation or Abandonment**

Fear of separation is yet another major concern for preschoolers. Their sense of time is still so distorted that they cannot be comforted by assurances such as "Mommy will pick you up from preschool at noon." Their sense of distance is also limited, so making a statement such as "I work only a block away" is not reassuring. Relating time and space to something a child knows better, such as meals, television shows, or a friend's house, is more effective. For example, stating, "Mommy will pick you up from preschool after you have had your snack" is apt to be more comforting than "Mommy will pick you up at 3 PM."

Caution parents to be sensitive to such fears when they talk about missing children or if they have their preschooler's photo or fingerprints taken for identification. Children whose chief fear is that they will be abandoned or kidnapped might be alarmed someone will take them away from their parents and not understand their fingerprints are being taken to keep them safe.

A hospital admission or going to a new school often brings a child's fear of separation to the forefront. Help parents thoroughly prepare preschoolers for these experiences so they can survive them in sound mental health (see [Chapter 35](#)). Help them give clear instructions on when they will visit the child in the hospital.

### **Behavior Variations**

A combination of a keen imagination and immature reasoning results in a number of

other common behavior variations in preschoolers.

## Telling Tall Tales

Stretching stories to make them seem more interesting is a phenomenon frequently encountered in preschoolers. For example, after a trip to the zoo, if you ask a preschooler, “What happened today?” a child perceives you want something exciting to have happened, and so might answer, “A bear jumped out of his cage and ate the boy next to me.” This is not lying, but merely supplying an expected answer. Parents may be concerned that tall tales of this nature can lead to chronic lying if supported. Caution them not to encourage this kind of storytelling but instead help the child separate fact from fiction by saying, “That’s a good story, but now, tell me what really happened.” This conveys the idea that the child has not told the truth, yet does not squash imagination or initiative (Talwar & Crossman, 2011). On the other hand, parents must be alert to not dismiss important information inadvertently such as children reporting an adult molesting them.

### *QSEN Checkpoint Question 31.4*

#### **SAFETY**

Cathy’s father, a police detective, says that he and his wife wish to take measures to prevent Cathy from being kidnapped. What action should the nurse recommend to this family?

- a. Limit playdates to Cathy’s own home.
- b. Withdraw Cathy from daycare to limit her exposure to other adults.
- c. Describe common kidnapping culprits the father knows.
- d. Be certain Cathy understands not to leave daycare with anyone but her parents.

*Look in Appendix A for the best answer and rationale.*

## Imaginary Friends

Many preschoolers have an imaginary friend who plays with them (Nielsen, 2012). They tell a parent to “wait for Eric” or to “set a place at the table for Lucy.” Although imaginary friends are a normal, creative part of the preschool years and can be invented by children who are surrounded by real playmates as well as by those who have few friends, parents may find them disconcerting. If so, let parents know that as long as their child has exposure to real playmates and imaginary playmates do not take center stage in children’s lives or prevent them from socializing with other children, they should not pose a problem and often leave as quickly as they come. In the meantime, pretend friends can encourage language development, may provide an outlet for a child to express innermost feelings, or serve as a handy scapegoat for behavior about which a child has some conflict.

Parents can help their preschooler separate fact from fantasy about their imaginary friend by saying, “I know Eric isn’t real, but if you want to pretend, I’ll set a place for him.” This response helps a child understand what is real and what fantasy is without restricting imagination or creativity.

## Difficulty Sharing

Sharing is a concept that first comes to be understood around the age of 3 years. Before this, children engage in parallel play (two children need two toys and two spaces to play because they cannot pass one toy back and forth or play together). Around 3 years of age, children begin to understand some things are theirs, some belong to others, and some can belong to both. For the first time, they can stand in line to wait for a drink, take turns using a shovel at a sandbox, and share a box of crayons. Sharing does not come easily, however; children who are ill or under stress have greater difficulty with it than usual.

Assure parents that sharing is a difficult concept to grasp, and, as with most skills, preschoolers need practice to understand and learn it (Sutherland & Friedman, 2012). Parents may need to help a child learn property rights as part of learning to share, such as “This is my private drawer and no one touches what is in it but me.” “That is your private box, and no one touches the things in it but you.” “A shovel is ours and can be used by everyone playing in the sand pile.” Defining limits and exposing children to these three categories (i.e., mine, yours, ours) helps them determine which objects belong to which category.

## Regression

Some preschoolers, generally in relation to stress, revert to behavior they previously outgrew, such as thumb-sucking, negativism, loss of bladder control, and inability to separate from their parents. Although the stress that causes this may take many forms, it is usually the result of such things as a new baby in the family, a new school experience, seeing frightening and graphic television news or programming, stress in the home from financial or marital difficulties, or separation caused by hospitalization.

Help parents understand that regression in these circumstances is normal, and a child’s thumb-sucking is a little different from the parents’ reaction to stress (e.g., smoking many cigarettes, nail biting, overeating), so it’s easier for them to accept and understand. Obviously, removing the stress is the best way to help a child discontinue this behavior. The stresses mentioned, however, are not ones that are easily controlled. New babies cannot be returned, irreparable marriages cannot be patched together, frightening news happens every day, and hospitalizations do occur.

Techniques for minimizing the stress of hospitalization for preschoolers are discussed in [Chapter 35](#). Children’s reactions to severe and prolonged stress are discussed in [Chapter 54](#). Children undergoing less severe stress can be assured that although situations are changing, the important aspect of their life—that someone still

loves them and will continue to take care of them—is not. The manifestations of stress, such as thumb-sucking, are best ignored; calling them to a child’s attention merely causes more stress because, in addition to experiencing the primary stress, it makes children aware they are not pleasing their parents.

## Sibling Rivalry

Jealousy of a brother or sister may first become evident during the preschool period because this is the first time children have enough vocabulary to express how they feel (i.e., know a name to call) and partly because preschoolers are more aware of family roles and how responsibilities at home are divided (Snowling, 2011). For many children, this is also the time when a new brother or sister is born.

A firstborn child is rarely allowed the privileges of a second child. The parents are untried, unsure of how far they should let a first child venture or what level of responsibility a child could accept, allowing the firstborn to serve as the “trial run” for all children who come after. Children as young as preschool can tell when a younger sibling is allowed behavior that is not tolerated in them. They are little appeased by the explanation, “Your brother is just a baby.”

To help preschoolers feel secure and to promote self-esteem during this time, reminding them that there are things they can do that a younger sibling is not allowed to do and supplying them with a private drawer or box for their things that parents or other children do not touch can be helpful. A private box serves as a defense against younger children who do not yet appreciate property rights.

## Preparing for a New Sibling

Introduction of a new sibling is such a major happening that parents need to take special steps to be certain their preschooler will be prepared (Volling, 2012). There is no rule as to when this preparation should begin, but it should be before the time the child begins to feel the difference the new baby will make. This is perhaps when the mother first begins to look pregnant. It is certainly before parents begin to make physical preparations for the new child. It is always less frightening to understand why things are happening, no matter how distasteful they may be rather than hear people whispering or having people obviously evading the issue. The unknown is always more fearful than a definite event because those can be faced and conquered.

Help parents not to underestimate the significance of a bed to a preschool child because it is security, consistency, and “home.” If their preschooler is sleeping in the crib that will be used for the new baby, it’s usually best if the preschooler can be moved to a bed about 3 months in advance of the birth. Parents might explain, “It’s time to sleep in a new bed now because you’re a big girl.” The fact that the child is growing is a better reason for such a move than because a new brother or sister needs their bed. The latter may be a direct route to sibling rivalry and jealousy.

If children are to start preschool or child care, it’s also best if they can do so either

before the new baby is born or 2 or 3 months afterward. That way, children can perceive starting school as a result of maturity and not of being pushed out of the house by the new child.

If the mother will be hospitalized for the birth, parents should be certain their child is prepared for this separation. Because the mother is likely to go to the hospital during the night, it is unrealistic to expect a child to be happy to learn in the morning about the arrival of a new sibling when he realizes the new baby has taken away his mother. Some communities offer preparation for birth classes for preschoolers, the same as for parents, or to include children in adult preparation courses to help them master this new experience.

Encourage women to maintain contact with their preschooler during the short time they are hospitalized for the new birth. Some preschoolers may react very coldly to their mothers, turning their head away and refusing to come to them after even a few days of separation when they return home. This is a reaction not to the new baby but to the separation, and the same phenomenon that may occur when a child returns home after being hospitalized (see [Chapter 35](#)). Allowing the child to visit in the hospital can help relieve this type of separation anxiety.

Ask pregnant women or couples what kind of preparation they are making for older children and ask the mother of a new baby how everything is working out. Most parents find the problem of jealousy is bigger than they anticipated and welcome a few suggestions about how to provide more time for their preschooler during the day or which activities a preschooler would especially enjoy ([Fig. 31.5](#) and [Box 31.7](#)).

**Figure 31.5** A preschooler greets a new baby sister. She feels special as dad explains how important it is to be a big sister.

BOX 31.7

## ANTICIPATORY GUIDANCE TO HELP MINIMIZE SIBLING RIVALRY

**Q.** Cathy's father says to you, "Cathy's acting jealous of her new sister and she's not even born yet. What can we do to reduce sibling jealousy?"

**A.** This isn't a simple problem, but the following suggestions might be helpful:

- After returning home from the hospital with the baby, devote attention to your preschooler and spend some special time together after the baby has gone to bed.
- When friends and family visit, encourage them to spend time with the preschooler as well as the baby. If they bring gifts for the baby, it is often wise for them to bring a small present for the preschooler as well.
- So your preschooler doesn't come to expect gifts (promoting sibling rivalry), teach her to help open the baby's gifts. Explain it is the baby's birthday and on her birthday she will receive gifts, too.
- Don't ask your preschooler a question such as "Do you like your new sister?" It is better to express feelings of empathy such as "New babies cry a lot. It's hard to get used to that, isn't it?"
- Provide special time for your preschooler during each day, so when you say, "Mommy and Daddy love you just the same," it seems real. This might be a quiet time for talking or reading.
- While feeding the baby, read or tell a story to your preschooler. Some children enjoy feeding a doll while a parent feeds the baby or giving a doll a bath while the baby has one.

### *Concept Mastery Alert*

A new baby makes a significant difference in a child's life. To reduce the child's feeling of being "replaced" by the new baby, significant changes, such as starting preschool, should be done either well before the new baby is born or 3 to 4 months afterward.

### *QSEN Checkpoint Question 31.5*

## TEAMWORK & COLLABORATION

Cathy's family is expecting a new baby. When Cathy is visiting the birthing center, the nurse should promote which behavior as a means of fostering family bonding during this time of transition?

- a. Take action to help Cathy spend as much time with her mother and the infant as possible.
- b. Teach Cathy about the ways that her life might change after the birth of the

- baby.
- c. Remind Cathy that her parents love her very much.
  - d. Explain to Cathy that she's very lucky because sisters grow up to become best friends.

---

*Look in [Appendix A](#) for the best answer and rationale.*

---

## **Sex Education**

During the preschool age, children become acutely aware of the difference between boys and girls. Possibly, this is a normal progression in development, and, possibly, this may be the first time they are exposed to the genitalia of the opposite sex as they watch while a new brother or sister has a diaper changed, they see other children using the bathroom at a preschool, or they see a parent nude.

Preschoolers' questions about genital organs are simple and fact finding; for example, "Why does James look like that?" or "How does Jasmine pee?" Explanations should be just as simple: "Boys look different from girls. The different part is called a penis." It is important that parents do not convey that these body parts are never to be talked about so they leave an open line of communication for sexual questions.

Occasionally, girls attempt to void standing up as they have seen boys doing, and boys may try to void sitting down as they try to use this new body knowledge.

It is common for preschoolers to engage in masturbation while watching TV or before they fall asleep at night. The frequency of this may increase under stress, as does thumb-sucking. If observing a child doing this bothers parents, suggest they explain certain things are done in some places but not in others. Children can relate to this kind of direction without feeling inhibited, just as they can accept the fact they use a bathroom in private or eat only at the table. Calling unnecessary attention to the act can increase anxiety and cause increased, not decreased, activity.

Because this may be the time a new brother or sister comes into the family, it is also the most likely time for questions such as "Where do babies come from?" Because a child is asking a simple fact-finding question, parents usually find a simple, factual answer to this type of question is best, such as "Babies grow in a special place in a mother's body called a uterus." Saying "uterus" rather than "tummy" prevents children from envisioning babies and food all mixed together in their mother's stomach ([Fig. 31.6](#)).

**Figure 31.6** Preschool children have the beginnings of sexual awareness and are interested in learning where babies grow. (Taeke Henstra/Science Source/Photo Researchers, Inc.)

It is so natural for preschoolers to ask about where babies come from that those who do not ask are exceptions and may not be asking because they sense from a preliminary exploratory question that the subject is closed. A parent could introduce the subject by visiting a new baby in the neighborhood with the child or pointing out a neighbor who is pregnant. Visiting new kittens or puppies can also offer the chance to introduce the subject. If a new brother or sister will be born at a birthing center or at home, many parents may want their preschooler to be present at the birth. Encourage parents to prepare children thoroughly for this experience, or else the sight of their mother in pain and the wonder of birth can become an overwhelming and negative experience rather than a positive one for them (see [Chapter 14](#)).

Preschool children generally do not ask how babies get inside mothers to start growing or how babies get out at the end of the process.

Many books for children explain the birth process, same-sex parenting, and adoption. These are helpful for parents to read to a child to increase understanding if they feel the child is ready for longer explanations. Correct terminology should be used when providing an explanation to a child.

### **QUALITY IMPROVEMENT**

The nurse is drafting an educational handout for parents of preschoolers that addresses the topic of sex education. What guideline should be included in this educational material?

- a. Tell your child that you will explain these matters when they are old enough to start kindergarten.
- b. Emphasize the fact that sexual intercourse between adults must always be consensual.
- c. Describe some of the differences between boys and girls in clear and accurate terms.
- d. Distract your child from questions about sexuality for as long as possible.

*Look in [Appendix A](#) for the best answer and rationale.*

Another important part of sex education for preschoolers is teaching them to avoid sexual maltreatment, such as not allowing anyone to touch their body unless they and their parents agree that it is all right (Pérez-Fuentes, Olfson, Villegas, et al., 2012). Because children have been taught this, remember to ask permission before giving nursing care that involves touching, especially before procedures such as catheterization or clean catch urines (see [Chapter 32, Box 32.4](#)).

### **Choosing a Preschool or Child Care Center**

A school or child care experience is helpful for preschoolers because peer exposure seems to have a positive effect on social development (Gubbels, Van Kann, & Jansen, 2013). Children who have learned to be comfortable in a preschool group, for example, approach school comfortably and ready to learn; children who have played only infrequently in groups during the preschool age can be so busy adjusting to this new concept that they are left behind in learning new skills in kindergarten or first grade. Most parents enroll their child in a child care program because both parents work outside their home. A parent who is at home full-time has to weigh whether it would be best for a child to have socialization experiences or to not diminish the family time.

The terms “child care center” and “preschool” are often used interchangeably, so parents cannot depend on the name of a school to define its structure. Traditionally, the main purpose of a child care center is to provide child care while parents work or are otherwise occupied. A preschool is dedicated to stimulating children’s sense of creativity and initiative and introducing them to new experiences and social contacts that they would not ordinarily receive at home. Head Start programs and many modern child care centers fulfill both functions (Wrobel, 2012).

If there are other 3- or 4-year-old children in a neighborhood with whom a child has almost daily contact and if a parent can supervise organized play dates and projects

(providing peer interaction, in which working together is the key), a preschool program may not be necessary. However, if all the neighborhood children are either older or younger or there is only one other child available to play with during the day, a preschool experience will probably be beneficial. Parents with large families point out that their child gets ample exposure to groups because every meal is a “group session.” This is not a peer group, however, so this situation does not offer the same experience as does preschool.

Be sure parents investigate preschools or child care centers carefully before they enroll their child to be certain their child will not only be safe there but also that the child will have an enjoyable experience. Guidelines to aid parents in this assessment are shown in [Table 31.4](#).

**TABLE 31.4 QUESTIONS TO USE IN EVALUATING CHILD CARE CENTERS**

<b>Question</b>	<b>Finding</b>
<i>Management</i>	
How long has the center been in operation?	Length of operation does not necessarily indicate quality, but it allows you to locate other parents who have used the center to ask about their experience there.
Is the center licensed, registered, approved, or inspected by the appropriate agency?	Ask in your local community what agency has the responsibility for licensing child care centers. If not licensed, its quality is suspect.
What are the qualifications of staff members?	If staff members are teachers, more learning activities will be provided; staff should be qualified to perform cardiopulmonary resuscitation.
Is there a fast turnover rate of staff?	A fast turnover rate means little continuity of care will be provided (and probably suggests dissatisfaction with center administration).
What is the child–staff ratio?	A ratio of three or four children to one staff member provides time for quality interaction.
What is the center’s policy on parental visits?	Parents should be able to drop in at any time. Be wary of facilities that restrict parental visiting in any way.
<i>Physical Environment</i>	
Is there adequate space in the	There should be opportunities for rough-and-tumble and imaginative play in addition to naptime areas and table

center?	activities.
Does the space appear safe?	Stairways should be fenced. No paint should be peeling.
Can children get in and out of the building easily?	A first-floor plan is safest. Fire exits should be well marked. An evacuation plan should be practiced.
Is there a safe play area for children outside?	Find out how often children are taken outside: once or twice a day, or only occasionally for “outings”?
Is there a quiet place for naps?	Ask if a child can nap if tired or has to wait until a set naptime.
Can the bathroom be reached easily?	Both potty chairs and small toilet seats should be available.
If food is provided, does it meet preschool recommendations?	Food should be preschool friendly and healthy, not just high-fat snacks.
Is there adequate refrigeration?	Food poisoning is a concern without refrigeration.

---

### *Staff Philosophy*

---

Are the caregivers warm and affectionate toward children?	Watch how they greet children. They should ask questions and listen to answers.
Do caregivers spend most of their time performing janitorial tasks (cleaning) or devoting their time to children?	It is best if the cleaning staff are separate from the care staff.
Is each child assigned to a particular caregiver on a continuing basis?	Ask caregivers to describe their care pattern; if this is not planned, little continuity of care results.
Are the children provided	Imaginative items, such as a puppet theater, finger paint, and water play, should be included.

stimulating toys and equipment?	
How do caregivers discipline children? Do they yell or treat the children roughly?	The method should reflect the parents' philosophy. Staff should be able to talk to children calmly without raising their voices in anger.
Is there a planned curriculum?	There should be specific goals the caregivers hope to accomplish.
Can the child pursue an individual interest?	Play or learning activities should be individualized.

### *Healthcare Protocols*

How does the center care for an ill child?	There should be access to a nurse. Staff should be able to evaluate for illness.  They should know actions to take in an emergency.
What precautions do caregivers take to prevent the spread of infection?	The counter where diapers are changed should be wiped with a disinfectant; tissues and hand-washing facilities should be present.
Does the center follow good sanitary practices?	Be sure the center requires waterproof disposable diapers to minimize contamination of the environment and other children and separates diaper-changing areas from other activities, especially anything related to food handling. Observe caregivers changing diapers. Do they wash hands after each change? Are children encouraged to wash their hands before eating?
Under what conditions are children not allowed to attend the center?	A center should have a very specific policy on what illness symptoms require a child to be kept home, and they should enforce this policy strictly. For instance, a runny nose may be acceptable, but a fever is not, and children with chickenpox should be kept at home until the lesions are covered with scabs. Children with special needs should be integrated into usual activities.

### *Children's Behavior*

Do the children appear happy and	Observe for at least one morning.
----------------------------------	-----------------------------------

relaxed?

Do children rush to greet any new visitors? This could be a sign of boredom with their center's activities and a strong need for adult attention.

To continue to evaluate their child's school experience, urge parents to make a habit of asking children what happened at school, what they learned, and the names of any new friends. For the remainder of the growing years, school will have important influences on their child's development. By taking an active role in education, parents influence what and how their child learns.

Child care centers may be responsible for the spread of infectious disease among those age 5 years and under because bringing together children from so many different homes to one setting each day increases the risk of spreading contagious disease. Preschoolers in child care settings may develop frequent upper respiratory infections or gastrointestinal illnesses. Outbreaks of cytomegalovirus and human parvovirus (fifth disease) make working in such centers a particular hazard to pregnant women because such illnesses are potentially teratogenic. To prevent the spread of infection, children need to wash their hands frequently and cover their mouths with their sleeve when coughing. Child care centers where infants are enrolled need to take special precautions against hepatitis A or parasitic infections because these can be spread by caregivers not washing their hands or not washing tables after changing diapers. Hepatitis may be subclinical in the preschooler, but other members of the preschooler's family can develop overt symptoms as the illness spreads through the family, making vaccinations important (CDC, 2011).

### Preparing a Child for School

At the end of the preschool period, children begin a formal school experience as they enter kindergarten. Parents may wonder whether their child is old enough for this, especially if a child's birthday is in the late summer or early fall. If this is a concern, urge parents to discuss their concern with school officials to determine whether their child should be registered for kindergarten or delayed for a year. Because school involves a great deal of children's time and influences their future greatly, it's important for parents to take time to prepare preschoolers not only physically, by being certain their immunizations are up-to-date (see [Table 31.2](#)), but also emotionally.

Essential to this preparation is the parents' attitude. If school is discussed as something to look forward to, as an adventure that will be satisfying and rewarding, a child comes to look forward to it as a positive experience. If school is presented as a punishment ("Wait until you get into first grade—your teacher will make you behave"), there can be little delight in anticipating it.

If a child was not attending preschool, some parents may have to change their child's daily routine a few months in advance of beginning school to accustom the child

to waking earlier or going to bed earlier. School has so many new components that it's wise for parents to try to eliminate as many distractions as possible.

If a child is to ride a bus to school, a parent might take a child on a municipal bus as an introduction to this form of transportation. If a child is to walk to school, a trial walk is in order. In either instance, safety should be stressed such as "Don't walk behind the bus because the driver can't see you" and "Wait for the crossing guard to help you cross the street."

If a child will be required to take a lunch to school, a parent can introduce this new experience by preparing a bagged lunch at home. If a child is to purchase lunch at school, the parent can play "cafeteria" at home by serving a buffet-style meal and letting the child practice walking from one dish to another to select food.

Some kindergartens suggest that children should know how to tie their shoes, name basic colors, and print their name before they begin. Parents should familiarize themselves with any such suggestions from the school, but the wisdom of requiring these skills can be questioned. Identifying colors should be established by this age, but some children are not coordinated enough at 4 to 5 years of age to tie their shoes or to print. A better contribution for parents to make toward their children's achievement in school is to instill in their children the concept that learning is fun, and that their child may not always be able to do all the things other children can do, but trying to do one's best is what is important. Trying to make children complete fine motor tasks for which they are not developmentally prepared does not instill that concept.

For children to do well in a formal school setting, they must be able to follow instructions and sit at a table and chair for a short work period. When some parents examine their child's day, they are surprised to realize how few instructions they give the child in a day. They put on the child's coat, pick up the child's toys, and lead the child to the table for dinner. Similarly, they never encourage their child to spend any time in a chair, which is something the child will have to do for at least short periods in school. Coloring at a table rather than on the floor will introduce this situation without any problem.

Finally, going to school is a form of separation and a new experience if a child has not attended child care or preschool, so parents must make preparations for this. It might be good to arrange to have a child stay with another caregiver such as a grandparent for part of a day. Staying at school can then be compared with that successful event.

These are minimum preparations parents can complete to ready their child for school. Caution both parents and children that no matter how hard they try, not everything can be anticipated; school will bring some new happenings that are not expected. If a child has been led to believe learning is fun and new experiences are enjoyable (creating a strong sense of initiative), solving these unpredictable problems is good preparation for the thousands of surprise experiences ahead.

## **Broken Fluency**

Developing language is such a complicated process that children from 2 to 6 years of

age typically have some speech difficulty. A child may begin to repeat words or syllables, saying, “I-I-I want a n-n-new spoon-spoon-spoon.” This is called **broken fluency** (repetition and prolongation of sounds, syllables, and words). It is often referred to as **secondary stuttering** because the child began to speak without this problem and then, during the preschool years, develops it. Unlike the adult who stutters, children are unaware that they are not being fluent unless it is called to their attention. You may need to remind parents that this is a part of normal development and, if accepted as such, will pass (Nippold & Packman, 2012). It is resolved most quickly if parents follow a few simple rules, including:

- Do not discuss in the child’s presence that he or she is having difficulty with speech because this can make the child conscious of speech patterns and compound the problem.
- Listen with patience rather than interrupt or ask the child to speak more slowly or to start over. These actions make the child aware speech is repetitious, and broken fluency increases.
- Always talk to the child in a calm, simple way to role model slow speech. If adults talk quickly, the child imitates this pattern and has difficulty speaking clearly.
- Protect space for the child to talk if there are other children in the family. Rushing to say something before a second child interrupts is the same as rushing to conform to adult speech.
- Do not force a child to speak if he or she does not want to. Do not ask preschoolers to recite or sing for strangers.
- Do not reward a child for fluent speech or punish for nonfluent speech. Broken fluency is a developmental stage in language formation, not an indication of regression or a chronic speech pattern.

### “Bathroom Language”

Many preschoolers imitate the vocabularies of their parents or older children in the family so well during this time that they incorporate swear words into their vocabularies if they hear these used. Parents may have to be reminded that children do not necessarily understand what the word they are using means; they have simply heard it, just as they have heard hundreds of other words and have decided to use it. Correction should be unemotional such as, “That’s not a word I like to hear you say. When you’re angry, why don’t you say ‘fudge’ [or whatever]?” The correcting is no different from that involved when a child uses poor grammar. If parents become emotional, a child realizes the value of such a word and may continue using it for the attention it creates.

## CONCERNS OF THE FAMILY WITH A PRESCHOOLER WITH UNIQUE NEEDS

Learning how to do things when you have physical or cognitive limitations can be very

frustrating. A preschooler with a disability has a greater need for problem-solving skills than the average child because even simple procedures such as eating or getting dressed can be difficult if their physical challenge limits the options (see [Chapter 54](#)).

Physically challenged or chronically ill preschoolers should attend a preschool program if at all possible because of the socialization benefits. If a child must remain in bed, parents may be reluctant to offer potentially messy experiences like finger paint. A large tray of dry oatmeal or other breakfast cereal with sand shovels or cars and trucks is a neater substitute activity for such a child. Although not necessarily tidy, these substances (which are available even in a hospital setting) can be vacuumed away easily at the finish of play. [Table 31.5](#) lists nursing actions that can aid a chronically challenged child to solve problems and develop a sense of initiative.

**TABLE 31.5 NURSING INTERVENTIONS TO ENCOURAGE A SENSE OF INITIATIVE IN THE PRESCHOOLER WITH SPECIAL NEEDS**

Consideration	Nursing Actions
Nutrition	Serving toast or sandwiches cut into animal shapes with cookie cutters, cereal in the form of alphabet characters, or food arranged on a plate to make a face appeals to the imagination and may make a preschooler with a limited appetite more interested in eating. Respect the child’s food preferences because trying to eat a nonfavorite food is difficult for everyone.
Dressing changes	Allow preschoolers to measure and cut tape or draw a face on it. Allow child to see the incision site. Explain the steps of dressing change as you work to reduce unknowns and areas of fear. Provide extra bandages to put on a doll so the child can see that bandages are not to be feared.
Medicine	Allow the child to choose a “chaser” such as juice or milk after oral medicine. Choosing a site for injection or intravenous line is too advanced for the preschooler; do not suggest such choices.
Rest	Provide a light in the room or bring the child’s bed into the hallway so fear of the dark is reduced and the child can deal solely with problems based in the real world. Identify sounds the preschooler might hear in the hospital, such as an air conditioner turning on, and explain what these are.
Hygiene	Allow the child to choose bathtub toys and clothing to wear after a bath. Allow the child to wash his or her own hands and face. Allow the child to splash in water as a play activity as well as for cleanliness.

Pain	<p>Encourage the preschooler to express pain.</p> <p>Allow the child to handle a syringe or suction catheter, and give “shots” or suction to a doll to alleviate anger or fear.</p> <p>Encourage the child to ask for analgesic if necessary.</p>
Stimulation	<p>Guessing games encourage a sense of initiative. Draw a dog or a house and ask the child to close his or her eyes while you add one more detail to the drawing, such as an ear or a chimney, then ask the child to identify the new item. Reverse the game and ask the child what you erased from the drawing, or allow the child to do his or her own drawing.</p> <p>Provide manipulative toys, such as finger paint, soapy water, clay, or dry cereal to use as sand.</p> <p>Allow the preschooler to accompany you to other departments is a way of teaching more about the hospital.</p> <p>Use “Simon Says” games not only for socialization but also to urge treatments, such as deep-breathing exercises.</p> <p>Encourage use of the playroom for socialization.</p> <p>Encourage the child to interact with his or her family by drawing pictures for siblings or telephoning home.</p>

## Nutrition and the Preschooler With Special Needs

Experiences with eating help to reinforce a sense of initiative in preschoolers. Chronically ill preschoolers who are limited in the foods they can eat (e.g., perhaps they can eat only soft foods) or in their ability to help with food preparation may miss this reinforcement. If their appetite is diminished because of illness to the point where they take little or nothing orally, it is still important that they continue to join the family at meals if at all possible. In most households, this is a time for socialization, and preschoolers are ripe for the learning that goes with this type of daily interaction.

### *What If... 31.4*

**The nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to preschool growth and development (see Box 31.1). What would be a possible research topic to explore pertinent to this goal that would be applicable to Cathy’s family and that would also advance evidence-based practice?**

## Unfolding Patient Stories: Jackson Webber • Part 1

**Jackson Webber**, age 3, is diagnosed with generalized seizures and started on phenobarbital. His mother is single and employed full time. The mother is concerned

about his recent developmental regression and how that will affect his return to child care. What education can the nurse provide on normal growth and development for a 3 year old and the relationship between developmental milestones and the new onset of an illness? What questions can the nurse ask to evaluate the adequacy and safety of the child care center that Jackson attends when considering his new diagnosis of seizures? (Jackson Webber's story continues in [Chapter 49](#).)

Care for Jackson and other patients in a realistic virtual environment: [vSim \(thepoint.lww.com/vSimMaternityPed\)](#). Practice documenting these patients' care in DocuCare ([thepoint.lww.com/DocuCareEHR](#)).

## KEY POINTS FOR REVIEW

- Although preschoolers grow only slightly and gain just a little weight, they seem much taller than when they were toddlers because their contour changes to more childlike proportions.
- Erikson's developmental task for the preschool period is to gain a sense of initiative versus guilt, or to learn how to do things. Play materials ideal for this age group are those that stimulate creativity, such as modeling clay or colored markers.
- Promoting childhood safety is a major role because preschoolers' active imaginations can lead them into dangerous situations; stressing this helps in planning nursing care that not only meets QSEN competencies but that also best meets a family's total needs.
- Common parental concerns during the preschool period are broken fluency, imaginary friends, difficulty sharing, and sibling rivalry. Preschoolers may develop a number of universal fears, such as fear of the dark, mutilation, and abandonment.
- The preschool age is often the time when a new sibling is born. Helping parents offer good preparation for this is necessary to prevent intense sibling rivalry.
- Preschoolers are still operating at a cognitive level that prevents them from understanding conservation (objects have not changed substance even if they have changed appearance).
- Preschoolers are self-centered (egocentric) so it is difficult for them to share and view someone else's side of a problem. They need good explanations of how a procedure will benefit them before they can agree to it.
- Many preschoolers begin preschool programs or child care. Late in the preschool period, they may be enrolled in kindergarten. Parents often appreciate guidance on how to prepare their children for these new experiences.
- Preschoolers who have special needs may have difficulty achieving a sense of initiative because they may be limited in their ability to participate in activities that stimulate initiative. They may need special playtimes set aside for stimulation and learning.

## CRITICAL THINKING CARE STUDY

Calvin Saunders is a 4-year-old who lives with his single mom and 6-year-old brother, David. Calvin stays with his grandmother 2 days a week and with his father 3 days a week because his mother works full-time in a local grocery store. His BMI is 27 (overweight).

1. At preschool, Calvin pushes and shoves other children rather than plays well with them. What suggestions could you make to his mother to improve his social relationships?
2. Calvin speaks with broken fluency. His mother jokes, “If he yelled ‘fire,’ we’d all burn to death before we understood him.” She saw a movie where a king learned not to stutter by singing so, although it’s expensive, she has enrolled Calvin in a boy’s chorus. Is this her best approach to helping Calvin speak clearly?
3. Calvin’s mother doesn’t supervise Calvin or his older brother while they warm up snacks in the microwave. Is Calvin mature enough to do this independently?

## Nursing Care of a Family With a School-Age Child

*Shelly Lewis is an 11-year-old girl who recently started middle school. Her mother tells you that Shelly, who is overweight, says she likes school and wants to try out for cheerleading, but she has developed a lot of nervous habits such as nail biting since she started attending her new school. Her mother asks you if this is “normal.”*

*The previous chapter discussed developmental aspects of the preschool child. This chapter focuses on the changes, both physical and psychosocial, that occur during the school-age years and provides the foundation for health education for this age group.*

**How would you advise Shelly’s mother?**

### KEY TERMS

**accommodation**

**caries**

**class inclusion**

**conservation**

**malocclusion**

**nocturnal emissions**

### OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe the normal growth and development pattern and common parental concerns of the school-age period.
2. Identify 2020 National Health Goals related to school-age children that nurses can help the nation achieve.
3. Assess a school-age child for normal growth and developmental milestones.
4. Formulate nursing diagnoses related to both school-age children and their families.
5. Establish expected outcomes for nursing care of school-age children to help

children and parents manage seamless transitions across differing healthcare settings.

6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care to promote normal growth and development of a school-age child, such as counseling parents about helping their child adjust to a new school.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of growth and development in school-age children with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

---

The term “school age” refers to children between the ages of 6 and 12 years. Although these years represent a time of slow physical growth, the school-age child’s cognitive growth and development continue to proceed at rapid rates. There are many differences among children at each year of this age group. For example, 7- and 10-year-old children have very different needs and outlooks than do 11- and 12-year-old children. Because of these big differences, always assess children as individuals to understand the particular developmental needs of each child based on what developmental status has been achieved, not on what stage you think the child should have reached (Lowe, Godoy, Rhodes, et al., 2013).

Unlike the infant or toddler periods, when progress is marked by obvious new abilities and skills such as the ability to sit up or roll over or the ability to speak a full sentence, the development of a school-age child is much more subtle. In addition, the child may demonstrate contradictory responses. For example, what the child enjoys on one occasion may change over time. It is not uncommon for a child to ask his or her parents for a guitar and lessons and subsequently lose interest in music and prefer another activity. School-age children become increasingly more influenced by the attitudes of their friends. They may select activities based on the interests of their peers. Parents who don’t understand this normal aspect of development may engage in excessive conflicts with their child. The school-age period is the initiation of independent decision making. Parents unprepared for this may experience conflicts with their child. [Box 32.1](#) lists 2020 National Health Goals related to the school-age period.

#### BOX 32.1

#### Nursing Care Planning Based on 2020 National Health Goals

A number of 2020 National Health Goals address the health of the school-age

population:

- Increase the proportion of public and private schools that require daily physical education for elementary school students from a baseline of 3.8% to a target of 4.2%; for middle school students, from 7.9% to 8.6%.
- Increase the proportion of public and private schools that require students to wear appropriate protective gear when engaged in school-sponsored physical activities from 76.8% to 84.5%.
- Reduce the proportion of children who have dental caries (in permanent or primary teeth) to no more than 49% from a baseline of 54.4%.
- Increase age-appropriate vehicle restraint system use in children from 78% to 86%.
- Increase the number of states that require helmet use by bicyclists from 19 to 27 states ([U.S. Department of Health and Human Services, 2010](#); see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by urging children to begin and maintain a consistent exercise program, to brush teeth and go for dental checkups regularly, and to follow safety rules for bicycles and automobiles.

### *Nursing Process Overview*

## FOR HEALTHY DEVELOPMENT OF A SCHOOL-AGE CHILD

### ASSESSMENT

History and physical examination are used to assess growth and development of school-age children. History questions include school progress and extracurricular activities. School-age children are interested and able to contribute to their own health history. The school-age child may be interviewed with his or her parent and separately depending on the circumstances. During a physical examination, be attentive to the school age child's need for privacy when undressed. Parents of school-age children often mention behavioral issues or conflicts during yearly health visits. This is a time period where children begin to express their own opinions and beliefs.

School personnel may be involved in a child's health care as optimal school functioning has the greatest potential when a child is healthy physically, emotionally, and socially.

### NURSING DIAGNOSIS

Common nursing diagnoses pertinent to growth and development during the school-age period include:

- Health-seeking behaviors related to normal school-age growth and development
- Readiness for enhanced parenting related to improved family living conditions
- Anxiety related to slow growth pattern of child
- Risk for injury related to deficient parental knowledge about safety precautions

for a school-age child

### **OUTCOME IDENTIFICATION AND PLANNING**

When identifying expected outcomes and planning care, keep in mind that school-age children tend to enjoy small or short-term projects rather than long, involved ones. In her early school years, a child with diabetes, for example, may gain a feeling of achievement by learning to assess her own serum glucose level, but she may have difficulty continuing glucose assessments on a regular basis.

Behavior problems need to be well defined before outcomes are identified and interventions planned. Often, it is enough for parents to accept the problem as one consistent with normal growth and development. Refer parents to helpful websites and other resources when appropriate (see [Chapter 28](#)).

### **IMPLEMENTATION**

School-age children are interested in learning about adult roles, so this means they will watch you to note your attitude as well as your actions in a given situation. When giving care, keep in mind that children this age feel more comfortable if they know the “hows” and “whys” of actions. This means that they may not cooperate with a procedure until they are given a satisfactory explanation of why it must be done.

### **OUTCOME EVALUATION**

Yearly health visits covering both physical and psychosocial development are important at this age ([American Academy of Pediatrics \[AAP\]](#), 2016). Examples of expected outcomes include:

- Parent states that he permits the child to make his own age-related decisions.
- Child identifies books he has read together with parents in the past 2 weeks.
- Child states he understands the variations of growth as related to the growth chart.
- Child does not sustain injuries from sports activities.

## **Growth and Development of a School-Age Child**

The school-age period is a relatively long time span, and even though growth is slow, children grow and develop extensively during this time period.

### **PHYSICAL GROWTH**

The average annual weight gain for a school-age child is approximately 3 to 5 lb (1.3 to 2.2 kg); the increase in height is 1 to 2 in. (2.5 to 5 cm). Children who did not lose a lordosis and knock-kneed appearance during the preschool period lose this now.

By 10 years of age, brain growth is complete, so fine motor coordination becomes refined. As the eye globe reaches its final shape at about this same time, an adult vision level is achieved. If the eruption of permanent teeth and growth of the jaw do not correlate with final head growth, malocclusion with teeth malalignment may be present

(Massignan, Cardoso, Porporatti, et al., 2016).

The immune globulins IgG and IgA each reach adult levels, and lymphatic tissue continues to grow in size until about age 9 years. The resulting abundance of tonsillar and adenoid tissue in early school children is often mistaken for disease because the tonsils seem to fill the entire back of the throat. This may also result in temporary conduction deafness from eustachian tube obstruction until the tissue recedes normally. The appendix is also lined with lymphatic tissue, so swelling of this tissue in the narrow tube can lead to trapped fecal material and inflammation (appendicitis) in the early school-age child (Bishop, 2011). Frontal sinuses develop at about 6 years, so sinus headaches become a possibility (before then, a headache in children is rarely caused by a sinus infection) (Smith, 2011).

The left ventricle of the heart enlarges to be strong enough to pump blood to the growing body. Innocent heart murmurs may become apparent due to this extra blood crossing heart valves. The pulse rate decreases to 70 to 80 beats/min; blood pressure rises to about 112/60 mmHg. Maturation of the respiratory system leads to increased oxygen–carbon dioxide exchange, which increases exertion ability and stamina. Scoliosis may become apparent for the first time in late childhood (Fletcher & Bruce, 2012). All school-age children older than 8 years should be screened for this at all health appraisals (see Chapter 51).

### Sexual Maturation

At a set point in brain maturity, the hypothalamus transmits an enzyme to the anterior pituitary gland to begin production of gonadotropic hormones, which then activate changes in the testes and ovaries to cause puberty. Hormone changes that occur with puberty are discussed in detail in Chapter 5. Table 32.1 describes the usual order in which secondary sex characteristics develop.

**TABLE 32.1 CHRONOLOGIC DEVELOPMENT OF SECONDARY SEX CHARACTERISTICS**

Age (in Years)	Boys	Girls
9–11	Prepubertal weight gain occurs.	Breasts: elevation of papilla with breast bud formation; areolar diameter enlarges.
11–12	Sparse growth of straight, downy, slightly pigmented hair at base of penis. Scrotum becomes textured; growth of penis and testes begins. Sebaceous gland secretion	Straight hair along the labia; vaginal epithelium becomes cornified. pH of vaginal secretions becomes acidic; slight mucous vaginal discharge is present. Sebaceous gland secretion increases. Perspiration increases.

	increases. Perspiration increases.	Dramatic growth spurt.
12–13	Pubic hair present across pubis. Penis lengthens. Dramatic linear growth spurt. Breast enlargement may occur.	Pubic hair grows darker; spreads over entire pubis. Breasts enlarge, still no protrusion of nipples. Axillary hair present. Menarche occurs.

Timing of the onset of puberty varies widely, between 8 and 14 years of age (Edmonds, 2012), partly due to genetic and cultural differences, and is rated according to Tanner stages (shown in Chapter 33). The length of time it takes to pass through puberty until sexual maturity is complete also varies. Sexual maturation in girls usually occurs between the years of 12 and 18; in boys, between 14 and 20 years. Puberty is occurring increasingly earlier, however, and in a class of 11-year-old sixth graders, it is not unusual to discover more than half of the girls are already menstruating. This change in the onset of puberty is important because it means, for sex education to be effective, parents or schools must introduce this material as early as when their children are in grade school. Precocious puberty is an abnormal onset of puberty and is discussed in Chapter 47.

### Sexual and Physical Concerns

The changes in physical appearance that come with puberty can lead to concerns for both children and their parents. The school-age period is a time for parents to discuss with children the physical changes that will occur and the sexual responsibility these changes dictate. This is also a time to reinforce previous teaching with children that their body is their own, to be used only in the way they choose. Specific measures for children to help prevent sexual maltreatment are discussed later in this chapter. Nurses can play a major role in this type of education (Breuner & Mattson, 2016).

In both sexes, puberty brings changes in the sebaceous glands. Under the influence of androgen, glands become more active, setting the stage for acne (see Chapter 33). Vasomotor instability commonly leads to blushing; perspiration also increases.

### *Concerns of Girls*

Prepubertal girls are usually taller by about 2 in. (5 cm) or more than preadolescent boys because their typical growth spurt begins earlier. In a culture in which boys are expected to be taller than girls, this can cause concern. Sometimes, a girl notices the change in her pelvic contour when she tries on a skirt or dress from the year before and realizes her hips are becoming broader. She may misinterpret this finding as a gain in weight and attempt a crash diet. You can assure her that broad bone structure of the hips is part of an adult female profile.

Girls are usually conscious of breast development. A girl who develops ahead of her peers may tend to slouch or wear loose clothing to hide the size of her breasts. Another girl studies herself in a mirror and wonders whether her breasts are going to develop enough. Breast development is not always symmetrical, so it is not unusual for a girl to have breasts of slightly different sizes. After the condition has been checked during a physical examination to assure her that no tumors are present to make one breast larger or that the other is diseased in some way to make it smaller, she can be reassured this development is normal. Supernumerary (additional) nipples may darken or increase in size at puberty. Be sure girls understand that a supernumerary nipple is affected by the hormones in her body in the same way as other breast tissue, so she isn't concerned by the accessory nipple enlarging with puberty or in a future pregnancy.

Early preparation for menstruation is an important preparation for future childbearing and for a girl's concept of herself as a woman (AAP, 2016) (Box 32.2). A girl who is told menstruation is a normal function that occurs every month in all healthy women has a different attitude toward her body than a girl who wakes up one morning to find blood on her pajamas and is told bluntly, "You'd better get used to that. You'll have to put up with it for the rest of your life." In the first instance, the girl can trust her body: It is doing what every woman's body does. In the second instance, the girl may feel her body is out of control. How can she accept and enjoy growing up if it involves something so unpredictable?

### BOX 32.2

#### Nursing Care Planning Tips for Effective Communication

Shelly, 11 years old, comes into the nurse's office at her school in her gym clothes. She was sent to the office because she refused to change into her school clothes. She asks to go home because she needs to change her clothes. She is crying and asking the nurse to call her mother.

*Tip:* Through effective communication and listening, you can help them talk about their problems and concerns. In the past, when topics such as menstruation were discussed only in whispers, and neither television nor magazines advertised tampons or medicine for menstrual discomfort, most 11-year-old children had little idea about what to expect at puberty. Today, with this information readily available, it is easy to forget that preadolescents still may not know much about what to expect at puberty.

**Nurse:** Hello, Shelly. What can I do for you?

**Shelly:** I'm having cramps.

**Nurse:** Are you having your period?

**Shelly:** No. I haven't started them yet.

**Nurse:** Can you describe your cramps to me?

**Shelly:** Both my sisters started their periods when they were 10.

**Nurse:** Are you sick to your stomach?

**Shelly:** I'm the only girl in my gym class who doesn't have her period yet.

**Nurse:** You sound as if you're more worried about that than what you came in for.

**Shelly:** I need to know why I'm so different. Will I be able to have children?

**Nurse:** Let's talk about that.

In addition to an explanation of the reason for menstrual flow, girls need an explanation of proper hygiene and reassurance they can bathe, shower, and swim during their periods. They can use either sanitary napkins or tampons; if they choose tampons, they must take precautions to avoid toxic shock syndrome (see [Chapter 47](#)).

Girls also need to know that vaginal secretions will begin to be present. If this is not explained, a girl may fear needlessly she has contracted an infection. Explain that any secretions that cause vulvar irritation should be evaluated by a healthcare provider because this does suggest infection.

Most girls have some menstrual irregularity during the first year or two after menarche (the start of menstruation). This occurs primarily because a girl's cycles are at first anovulatory. With added maturity and the onset of ovulation, cycles become more regular.

Irregular periods can cause concern because girls need to know when their periods will occur so they can get used to this new phenomenon and learn to trust their bodies ([AAP, 2016](#)). A girl in college can explain matter-of-factly that she prefers not to go to the beach because she is having her period, but for a preadolescent, this topic may be too sophisticated and too emotionally charged to discuss openly. Preteenagers want to be able to plan activities to avoid having to make such explanations.

This means that menstrual irregularity can be a significant concern for preadolescents. A girl may fear that irregular periods indicate a hormone imbalance. She may worry about her future ability to conceive, or she may be ill informed about how conception occurs and may fear irregularity of her periods means that she is pregnant. Both malnourishment and obesity possibly influence menstrual regularity. Emotions can also affect consistent cycles. If irregularity continues beyond the first year, a careful history of the girl's nutrition; overall health; and school, social, and home adjustment should be taken. Dysmenorrhea, or painful menstruation, is discussed in [Chapter 47](#).

For a nominal charge, manufacturers of sanitary napkins or tampons will mail an introductory kit of their products, together with well-illustrated, factual booklets, to introduce girls to menstruation. Such kits are useful if they supplement a parent's or a nurse's discussion, but they should not take the place of individual discussions.

### *Concerns of Boys*

Boys who are not prepared for the physical changes of puberty worry about them in the

same way as girls. Just as girls become keenly aware of breast development, boys become aware of increasing genital size. If they do not know testicular development precedes penis growth, they can worry that their growth will be inadequate.

Hypertrophy of breast tissue (gynecomastia) can occur in prepubescent boys, most often in those who are obese. A youth with this condition may be concerned a breast tumor is present or may feel embarrassed about his growing breasts. He can be assured that this is a transitory phenomenon and, although it makes him self-conscious, will fade as soon as his male hormones become more mature and active.

Some boys can also become concerned because although they have pubic hair, they cannot yet grow a beard or do not have chest hair, which are outward, easily recognized signs of maturity. You can assure them that pubic hair normally appears first and that chest and facial hair may not grow until several years later.

As increased seminal fluid begins to be produced, boys begin to notice ejaculation during sleep, termed **nocturnal emissions** (Widaman & Helm, 2012). Preadolescent boys may believe the old myth that loss of seminal fluid is debilitating; also, boys may have heard the term “premature ejaculation” and worry this is a forewarning of a problem in years to come. Both are fallacies.

### *Concerns for Transgender Children*

Transgender children identify with the gender that is not their natal (sex assigned at birth) sex. Studies on the mental health of transgender children reported a higher incidence of psychosocial disorders such as depression and anxiety (Olson, Durwood, DeMeules, et al., 2015). Children who are supported by their family may experience less anxiety and depression. A study by Olson et al. (2015) sought to compare the difference in anxiety and depression scores, as rated by their parents, between transgender children (ages 3 to 12 years) and a control group. Seventy-three children were recruited in each group, including 49 siblings in the control group. The mean age was 7.5 years. The children were recruited from support groups, a website, conferences, and word of mouth. The results of the depression scores between the transgender children and the control group were not statistically different. The results of the anxiety scores were slightly higher in the transgender children compared with the control group but not in the preclinical or clinical range. The findings may be difficult to generalize to all children as the family income was \$125,000 or more in 50% or more of each group. The majority of the children in the study were self-identified by the parents as White/non-Hispanic. The study was promising in supporting the premise that family and community support is a protective factor for transgender children. All children benefit from being treated as unique individuals unrelated to their gender preference. Transgender children are no different in this respect. In the past, it was thought that gender preference was fluid until the child reached late adolescence. It is now known that gender preferences are often identified in early childhood (Sherer, 2016). This would indicate that support for transgender children should begin early in childhood. It is important that children are not ridiculed or isolated secondary to their gender

preference because exposure to positive interaction with adults regardless of gender preference is helpful in promoting healthy child development.

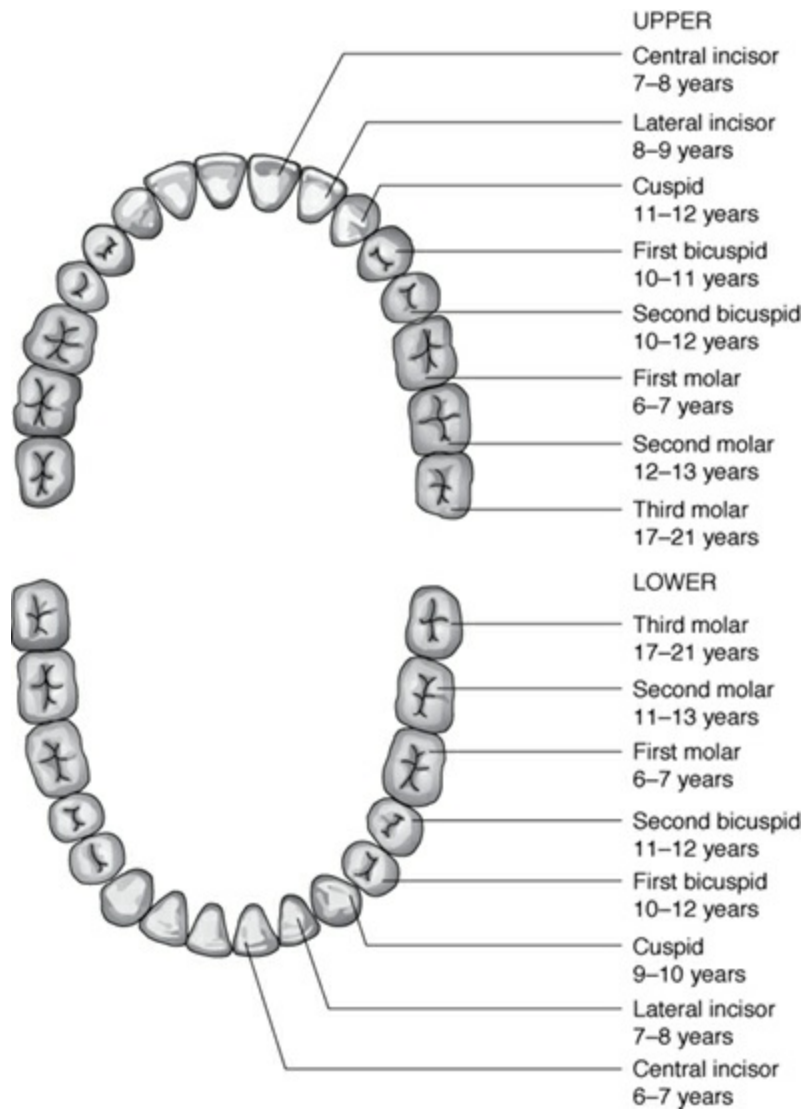

## Teeth

Deciduous teeth are lost and permanent teeth erupt during the school-age period (Fig. 32.1). Because of this, the average child gains 28 teeth between 6 and 12 years of age: the central and lateral incisors; first, second, and third cuspids; and first and second molars (Fig. 32.2).

**Figure 32.1** Early school-age children typically have a missing upper incisor as deciduous teeth are replaced by permanent teeth.

**Figure 32.2** The eruption pattern of permanent teeth.

## DEVELOPMENTAL MILESTONES

As with all ages, you can measure school-age children’s progress by whether they meet typical developmental milestones.

### Gross Motor Development

School-age development is summarized in [Table 32.2](#). At the beginning of the school-age period (age 6 years), children endlessly jump, tumble, skip, and hop. They have enough coordination to walk a straight line, many can ride a bicycle, and they learn to skip rope with practice.

**TABLE 32.2** SUMMARY OF SCHOOL-AGE DEVELOPMENT

Age (in Years)	Physical Development	Psychosocial and Cognitive Development

6	A year of constant motion; skipping is a new skill; first molars erupt.	First-grade teacher becomes authority figure; adjustment to all-day school may be difficult and may lead to nervous manifestations of fingernail biting, etc. Defines words by their use (e.g., a key is to unlock a door, not a metal object).
7	Central incisors erupt; difference between sexes becomes apparent in play (e.g., video games vs. dolls); spends time in quiet play.	A quiet year; striving for perfection leads to this year being called an eraser year. Learns conservation (e.g., water poured from tall container to a wide, flat one is the same amount of water); can tell time; can make simple change.
8	Coordination definitely improved; eyesight fully develops; playing with friends becomes important.	“Best friends” develop; whispering and giggling begin; can write in cursive as well as print; understands concepts of past, present, and future.
9	All activities done with friends	Friend or club age; a 9-year-old club is formed to spite someone, has secret codes, is all boy or all girl; clubs disband and reform quickly.
10	Coordination improves.	Ready for camp away from home; collecting age; likes rules; ready for competitive games.
11	Active, but awkward and ungainly	Insecure with members of opposite sex; repeats off-color jokes.
12	Coordination improves.	A sense of humor is present; is social and cooperative.

A 7-year-old child appears quiet compared with the more active 6-year-old. Gender differences usually begin to manifest themselves in play: where girls may gravitate to more traditional female roles and activities and boys may gravitate to more traditional male roles and activities.

The movements of 8-year-olds are more graceful than those of younger children, although, as their arms and legs grow, they may appear awkward in their play and eating habits. They ride a bicycle well and enjoy sports such as gymnastics, soccer, and hockey.

Nine-year-olds are on the go constantly, as if they always have a deadline to meet. They have enough eye–hand coordination to enjoy baseball, basketball, and volleyball.

By 10 years of age, children are more interested in perfecting their athletic skills than they were previously.

At 11 years of age, many children feel awkward because of their growth spurt and drop out of sports activities rather than look ungainly attempting them. They may channel their energy into constant motion instead: drumming fingers and tapping pencils or feet. This fall in sports participation may bother parents who see sports as the key to popularity, self-esteem, fitness, and teamwork.

Twelve-year-olds plunge into activities with intensity and concentration. They often enjoy participating in sports events for charities such as walkathons. They may be refreshingly cooperative around the house, able to handle a great deal of responsibility and complete given tasks.

### Fine Motor Development

Six-year-olds can easily tie their shoelaces. They can cut and paste well and draw a person with good detail. They can print, although they may routinely reverse letters. Seven-year-olds concentrate on fine motor skills even more than they did the year before. This has been called the “eraser year” because children are never quite content with what they have done. They set too high a standard for themselves and then have difficulty performing at that level.

By 8 years of age, children’s eyes are developed enough so they can read regular-size type. This can make reading a greater pleasure and school more enjoyable (Fig. 32.3). Eight-year-olds are able to write script in addition to print. They enjoy showing off this new skill in cards, letters, or projects. By age 9 years, their writing begins to look mature and less awkward.

**Figure 32.3** One of the biggest discoveries of childhood is that

reading and writing are fun. These are activities that can help a child pass the hours during an illness.

Older school-age children begin to evaluate their teachers' ability and may perform at varying levels depending on each teacher's expectations. The middle school curriculum involves more challenging science and mathematics courses than previously and includes good literature. This may be a child's first exposure to reading as a fulfilling and worthwhile experience rather than just as an assignment and may be the time a child is "turned on" to reading.

## Play

Play continues to be active at age 6 years; however, when children discover reading as an enjoyable activity that opens doors to other worlds, they can begin to spend quiet time with books. Many children spend hours playing increasingly challenging video games, an activity that can either foster a healthy sense of competition or create isolation from others.

By 7 years of age, children require more props for play than when they were younger. To be a police officer, for example, a 7-year-old may need a badge and gun, whereas before, a pointed finger sufficed. This is the start of a decline in imaginative play, which will continue unless a child receives adequate encouragement to use imagination. At age 7 years, children begin to prefer teenage dolls if they play with dolls, and their coordination is good enough that they can button the miniature dresses and pull on the tiny boots.

Around 7 years of age, children also develop an interest in collecting items such as baseball cards, dolls, rocks, or marbles. The type of item is not as important as the quantity. These collections become structured as a child reaches 8 years of age; time is spent sorting and cataloging. Most girls and boys of this age also enjoy helping in the kitchen with jobs such as making cookies and salads or frosting cakes. They start to be more involved in simple science projects and experiments. Eight-year-olds also like table games but hate to lose, so they tend to avoid competitive games. They may change the rules in the middle of a game to keep from losing.

Nine-year-olds play hard. They wake in the morning, squeeze in some activity before school, and plan something the moment they arrive home again. They may have difficulty going to bed at night because they want to play just one more game. Play is rough; children are not as interested in perfecting their skills as they will be in another year. Some parents or coaches expect children of this age to be more interested in perfecting their skills, so conflicts can arise.

Many schools begin music lessons for children at about 9 years of age. Children do well if others in their group are taking similar lessons. Talent for music or art becomes evident, and children respond with new interest in school or wherever they are exposed to these arts. Nine years of age is also a time when children use social media. This is an activity parents need to supervise as they may not realize that their accounts are

available to the public and potential child predators.

Many 10-year-olds spend most of their time playing screen games. Boys and girls play separately at age 10 years, although interest in the opposite sex is apparent. Boys show off as girls pass their group; girls talk loudly or giggle at the sight of a familiar boy. Girls become more interested in the way they look and dress. Slumber parties and campouts become increasingly popular.

During their 10th year, children become very interested in rules and fairness. Before this time, they gave younger children breaks in games, allowing extra turns or hints. Now, they strictly enforce rules (Fig. 32.4). Club activities become structured, with a president, a secretary, and rules of order.

**Figure 32.4** By 10 years of age, children are ready for competition. These two children enjoy a game of chess.

Children age 11 and 12 years enjoy dancing and playing table games; they are accommodating enough again to be able to play with younger siblings who need the rules modified to their advantage. Time with friends is often spent just talking. Twelve-year-olds typically like to do jobs around the house or babysitting for money. State laws vary on when a child may care for younger children without adult supervision. Both boys and girls seem to feel they are on the verge of something great and anxiously wait to turn 13 years old and become teenagers. The website [www.healthychildren.org](http://www.healthychildren.org) provides guidance for parents on developmental norms.

## LANGUAGE DEVELOPMENT

Six-year-olds talk in full sentences, using language easily and with meaning. They no longer sound as though talking is an experiment but appear to have incorporated language permanently. They still define objects by their use (e.g., a key is to unlock a door, a fork is to eat with).

Most 7-year-olds can tell the time in hours, but they may have trouble with concepts such as “half past” and “quarter to,” especially with the prevalence of digital clocks. They know the months of the year and can name the months in which holidays fall. They can add and subtract and make simple change (if they have had experience), so they can go with a parent to a store and make simple purchases. Much of children’s talk is concerned with these concepts as they practice them and show them off for family or friends.

Because children discover “dirty” jokes at about age 9 years, they like to tell them to friends or try to understand those told by adults. They use swear words to express anger or just to show other children that they are growing up. They may have a short period of intense fascination with “bathroom language,” as they did during the preschool years. As before, if parents want to discourage this, it should be made clear that they find such language unacceptable, and they refrain from using it themselves in their child’s presence.

By 12 years of age, children can carry on an adult conversation, although stories are limited because of a lack of experience.

## **EMOTIONAL DEVELOPMENT**

Ideally, children enter the school-age period with the ability to trust others and with a sense of respect for their own worth. They can accomplish small tasks independently because they have gained a sense of autonomy. They should have practiced or mimicked adult roles, learned to share, discovered that learning is an adventure, and grasped the idea that doing things is more important and more rewarding than watching things being done (a sense of initiative).

### **Developmental Task: Industry Versus Inferiority**

During the early school years, children attempt to master their new developmental step: learning a sense of industry or accomplishment (Erikson, 1993). If gaining a sense of initiative can be defined as learning how to do things, then gaining a sense of industry is learning how to do things well.

If children are prevented from achieving a sense of industry or do not receive rewards for accomplishment, they can develop a feeling of inferiority or become convinced they cannot do things they actually can do. These children can have difficulty tackling new situations later in life (e.g., new job, new school, new responsibility) because they cannot envision how they will be successful in handling them. This can result in frustration in school or work activities.

The questions a preschool child asks reflect curiosity, such as “how,” “why,” and

“what.” During the early school years, children concentrate their questions on the “how” of tasks: “Is this the right way to do this?” “Am I making this right?” and “Is this good?” Often, school-age children will comment, “I can’t do anything right” because their craft project falls short of expectations. School-age children need reassurance that they are doing things correctly, and this reassurance is best if it comes immediately after a task is completed.

### *Concept Mastery Alert*

Children benefit from honest praise and are quick to identify praise that is undeserved. Situations in which the child can be successful—and for which they can receive honest and deserved recognition—are vital to the development of confidence.

The books preferred by school-age children have many short chapters; children experience a sense of accomplishment as they finish each chapter. Small chores that can be completed quickly also give this type of reward. Children can survey their finished work and see they have done a good job. A child may dislike vacuuming, for instance, because the rug may not look very different when the task is complete. Picking up the scattered contents of a toy box, however, is a task that clearly makes a difference in the appearance of the room and so offers a reward.

Hobbies and projects also are enjoyed best if they are small and can be finished within a short time. Most school-age children, for example, prefer putting together two or three fairly simple model-car kits to assembling one extremely complicated kit. The three kits offer three rewards, whereas the involved one delays the reward so long that the child may become bored and never complete it. With adolescence will come more respect for quality. Teenagers realize that if they want the better model, they will have to spend the extra energy and attention and that quality products involve quality work (Fig. 32.5).

**Figure 32.5** Assembling this simple model in a short time helps a school-age child gain a sense of industry. (© Stephen Frisch/Stock Boston.)

### Home as a Setting to Learn Industry

Parents of a school-age child may need to take a step forward in development along with their child. For the first time, they realize their child has begun to look to other role models than themselves. Parents who enjoyed fostering imagination in a preschooler may feel frustrated when a school-age child chooses to conform to rules and insists on the “right way” to do things. They may feel they have failed to encourage the child’s creativity, but conformity is vital to children at this age. It is how they learn more about their world’s rules (Weisleder, Cates, Dreyer, et al., 2016).

Children 8 or 9 years of age begin to spend more and more time with their peers and less time with their family. They forget to do household chores they once enjoyed, such as setting the table or mowing the lawn, or they may do the work sloppily so they have more time to spend with their friends. Although this may seem like a regression in behavior, it is actually a step of independence away from the parents and into the larger world, a developmental step toward helping them become emotionally mature. This is

an example of a new role the child is trying out, one of many that will be tried in the process of reaching maturity, when an eventual “right fit” is found.

### School as a Setting to Learn Industry

Adjusting to and achieving in school are two of the major tasks for this age group. Ideally, a child’s teacher will think of learning as fun and will encourage a child to plunge into new experiences.

Schools are increasingly assuming responsibility for education about sex, safety, avoidance of substances of abuse, and preparation for family living. These discussions are generally superficial, however, and, if the classes are large, may raise more questions than they answer. Although learning these skills with peers helps children learn other people’s opinions in these areas, such classes should not replace parental teaching.

### Structured Activities

The Girl Scouts, the Boy Scouts, the Camp Fire Girls, and 4-H clubs are respected school-age activities. If the local chapters are well run by leaders who understand children’s needs, they can provide hours of constructive activity and strengthen a sense of industry. Merit badge systems are geared to the needs of school-age children, offering small but frequent rewards. As with school activities, parents should determine the worth of each organization for their individual child.

Urge parents to evaluate competitive sports programs as well. Before children can compete successfully in these, they must be able to lose a game without feeling devastated—in other words, be able to say, “I lost because I played badly,” not “I lost because I am a bad person.” Children do not usually develop sufficient ego strength to do this until they are about 10 years old.

Another problem to consider with organized contact sports is the possibility of athletic injuries. Encourage parents to consider their child’s maturity and the risk of injury (see [Chapter 52](#)) before they decide whether team competition is right for their child ([Theisen, Frisch, Malisoux, et al., 2012](#)). Parents should encourage children to vary the type of sport throughout the year to avoid repetitive use injuries by using the same muscle groups.

### Problem Solving

An important part of developing a sense of industry is learning how to solve problems. Parents and teachers can help children develop this skill by encouraging practice. When a child asks, “Is this the right way to do this?” a parent can encourage problem solving by saying, “Let’s talk about possible ways of doing it” rather than offering a quick solution.

The world depends on machinery, so mishaps and breakdowns (and therefore sudden changes) do occur. A child who can create an indoor playhouse with a card table

and blanket when it is too wet or cold to use an outdoor one will be able, as an adult, to problem solve another solution to a data distribution problem when a computer malfunctions. This attitude of optimism rather than pessimism toward problem solving produces adults who rarely say, “It can’t be done.” Just as important, it leaves these adults with confidence, a sense of pride, and feeling good about themselves because they have control of their environment and abilities.

### *QSEN Checkpoint Question 32.1*

#### **QUALITY IMPROVEMENT**

According to Erikson, a sense of industry or accomplishment is the developmental task of the school-age period. When planning care, what would be the best activity to introduce to Shelly to help her achieve this?

- a. Encourage her to establish a new club.
- b. Suggest she begin a diary in which she records her secret thoughts.
- c. Help her with spelling so over a year’s time she becomes an expert at this.
- d. Locate small projects she could complete in 1 day and feel rewarded.

*Look in [Appendix A](#) for the best answer and rationale.*

### **Learning to Live With Others**

School-age children are sometimes so interested in tasks and in accomplishing physical projects that they forget they must work with people to achieve these goals. A good time to urge children to learn compassion and thoughtfulness toward others is during the early school years, when children are first exposed to large groups of other youngsters. Writing thank you letters or shoveling an older neighbor’s sidewalk are examples of activities that can help children develop empathy toward others.

Learning to give a present without receiving one in return or doing a favor without expecting a reward is also a part of this process, and this can be taught by example. Children should see their parents doing such things with an attitude not of “What will I get out of this?” but “What can I contribute?”

Children may show empathy toward others as early as 20 months, but cognitively, they cannot relate others’ experiences to their own until about 6 years of age. Therefore, it is usually ineffective to lecture a child by saying, “That was cruel to call Mary names.” The child may feel she had every right to do so. A better technique is to ask children to put themselves in Mary’s place for a minute and imagine how they would feel if they were Mary. A school-age child will generally be able to do this and understand why name-calling hurts. Following this, a simple statement such as “It doesn’t feel good to be called names, does it?” may suffice.

### **Socialization**

Six-year-old children play in groups, but when they are tired or under stress, they

usually prefer one-to-one contact. In a first-grade classroom, for example, students compete actively for a few minutes of special time with their teacher. At the end of a day, they enjoy spending individual time with parents. You may have to remind parents that this is not babyish behavior but that of a typical 6-year-old.

Seven-year-olds are increasingly aware of family roles and responsibility. Promises must be kept because 7-year-olds view them as definite, firm commitments. Children this age tattle because they have such a strong sense of justice (Loke, Heyman, Forgie, et al., 2011).

Eight-year-olds actively seek the company of other children. Most 8-year-old girls have a close girlfriend; boys have a close boyfriend. Girls begin to whisper among themselves as they share secrets with close friends, annoying both parents and teachers.

Nine-year-olds take the values of their peer group very seriously. They are much more interested in how other children dress than in what their parents want them to wear. This is typically the friend or club age because children form groups, usually "spite clubs." This means if there are four girls on the block, three form a club and exclude the fourth. The reason for exclusion is often unclear; it might be that the fourth child has a chronic disease, she has more or less money than the others, she was at the dentist's the day the club was formed, or simply that the club cannot exist unless there is someone to exclude. Such clubs typically have a secret password and secret meeting place. Membership is generally all girls or all boys.

If an excluded child does not react badly to being shut out, the club will probably disband after a few days because its purpose is lost. The next day, the excluded member may meet with two others and snub a different child. Parents need to use caution deciding whether to intervene with this type of play because loyalties shift quickly: The child who is club president today may be the excluded one tomorrow.

Because they are so ready for social interaction, 9-year-olds are ready for activities away from home, such as a week at camp. They can take care of their own needs and are mature enough to be separated from their parents for this length of time. Going to camp before this age usually results in homesickness and can be a negative introduction to being away from home.

Although 10-year-olds enjoy groups, they also enjoy privacy. They like having their own bedroom or at least their own dresser, where they can store a collection and know it is free from parents' or siblings' eyes. One of the best gifts for a 10-year-old is a box that locks.

Girls become increasingly interested in boys and vice versa by 11 years of age. Favorite activities are mixed-sex rather than single-sex ones. Children of this age are particularly insecure, however, and girls tend to dance with girls, whereas boys talk together in corners. Better socialization patterns need not be rushed. Just as infants crawl before they walk, so 11-year-olds must attempt many awkward and uncomfortable social experiences before they become comfortable forming relationships with the opposite sex.

Twelve-year-olds feel more comfortable in social situations than they did the year

before. Boys experience erections on small provocation and so may feel uncomfortable being pushed into boy–girl situations until they learn how to better control their bodies. Because some children develop faster than others, every group has some members who are almost adolescent and some who are still children, making social interactions sometimes difficult.

**QSEN Checkpoint Question 32.2**

**INFORMATICS**

Shelly belonged to a series of clubs when she was 9 years old. How would the school nurse describe the typical characteristic of a 9-year-old’s club to the nursing student?

- a. Clubs have formal rules and regulations.
- b. Clubs are designed to help shy children get outside of their “comfort zone.”
- c. Clubs invariably exclude one or more children.
- d. Clubs always include both boys and girls.

*Look in [Appendix A](#) for the best answer and rationale.*

**COGNITIVE DEVELOPMENT**

The age from 5 to 11 years is a transitional stage where children undergo a shift from the preoperational thought they used as preschoolers to concrete operational thought or the ability to reason through any problem they can actually visualize ([Piaget, 1969](#)) ([Fig. 32.6](#)).

**Figure 32.6** School-age children learn concrete operational thought or concentrate on phenomena they can actually see occurring. For example, children may have closely catalogued collections of action

figures, science specimens, sports materials, or books and spend much time attending to and enhancing such collections.

Children can use concrete operational thought because they learn several new concepts during school age, such as:

- **Decentering**, the ability to project one's self into other people's situations and see the world from their viewpoint rather than focusing only on their own view.
- **Accommodation**, the ability to adapt thought processes to fit what is perceived such as understanding that there can be more than one reason for other people's actions. A preschooler might expect to see the same nurse in the morning who was there the evening before, whereas a school-age child will understand that different nurses work different shifts.
- **Conservation**, the ability to appreciate that a change in shape does not necessarily mean a change in size. If you pour 30 ml of cough medicine from a thin glass to a wide one, the preschooler will say that one glass holds more than the other; a school-age child will know that both glasses hold an equal amount.
- **Class inclusion**, the ability to understand that objects can belong to more than one classification. A preschooler is able to categorize items in only one way, for example, stones and shells are found at the beach; a school-age child can categorize them in many ways such as by different materials or by a difference in sizes and shapes, not just that they are found at the beach.

These cognitive developments lead to some of the typical changes and characteristics of the school-age period. Decentering enables a school-age child to feel compassion for others, which was not possible in younger years. Because understanding the principle of conservation is possible, a school-age child is not fooled by perceptions as often as before. The ability to classify objects leads to the collecting activities of the school-age period. Class inclusion is also necessary for learning mathematics and reading, systems that categorize numbers and words.

### *What If . . . 32.1*

**The nurse makes Shelly's hospital bed one day and then gives her an injection. What if the next day she begins to cry while the nurse is making her bed because she "doesn't want a shot"? The lack of what cognitive process led her to believe the nurse's actions would be exactly the same the second day?**

## **MORAL AND SPIRITUAL DEVELOPMENT**

School-age children begin to mature in terms of moral development as they enter a stage of *preconventional reasoning*, sometimes as early as 5 years of age (Kohlberg, 1984). During this stage, if asked, "Why is it wrong to steal from your neighbor?" school-age children will answer, "The police say it's wrong," or "Because if you do, you'll go to

jail.” They concentrate on “niceness” or “fairness” and cannot see yet that stealing hurts their neighbor, the highest level of moral reasoning. Because they are still limited in their ability to understand others’ views, they may interpret something as being right because it is good for them, not because it is right for humanity as a whole.

Remember that school-age children are rule oriented; when they ask for something, because they were good, they expect to receive what they are asking.

### *What If . . . 32.2*

**When the nurse tells Shelly it would be good if she lost some weight, she says the nurse isn’t being fair. Is this a typical school-age response?**

## Health Promotion for a School-Age Child and Family

Because of still limited judgment, school-age children need guidelines in reference to safety, nutrition, and daily care. These are always excellent topics for discussion at healthcare visits.

### PROMOTING SCHOOL-AGE SAFETY

School-age children are ready for time on their own without direct adult supervision. This means that they need good education on safety practices (Box 32.3). As with adults, unintentional injuries tend to occur when children are under stress or when they are distracted.

#### BOX 32.3

#### Nursing Care Planning Based on Family Teaching

#### COMMON SAFETY MEASURES TO PREVENT UNINTENTIONAL INJURIES DURING THE SCHOOL YEARS

**Q.** Shelly’s mother tells you, “She’s constantly on the go. How can I keep her free from accidents when I’m not always with her?”

**A.** Putting preventive steps in place, such the ones that follow, is the key.

#### Source of Unintentional Injury Preventive Measure

Motor vehicle	Encourage children to use seat belts and a booster seat if needed; role model seat belt use. Teach street-crossing safety; stress that streets are no place for roughhousing, pushing, or shoving. Teach parking lot and school bus safety (e.g., do not walk in back of parked cars, wait for crossing guard).
Bicycle	Teach bicycle safety, including wearing a helmet and not

	giving “passengers” rides.
Community	<p>Teach to avoid unsafe areas, such as train yards, grain silos, and back alleys.</p> <p>Stress to not go with strangers (parents can establish a code word with child; child does not leave school with anyone who does not know the word).</p> <p>Teach children to say “no” to anyone who touches them if they do not wish it, including family members (most sexual maltreatment is by a family member, not a stranger).</p> <p>Teach children not to arrange a meeting with people they meet on the Internet.</p> <p>For older school-age children, teach rules of safer sex so they know these rules before they need to use them a first time.</p>
Burns	<p>Teach safety with candles, matches, and campfires and that fire is not fun. Also teach safety with beginning cooking skills (e.g., be certain to include microwave oven safety, such as closing firmly before turning on oven; not using metal containers).</p> <p>Teach safety with sun exposure; use sun block.</p> <p>Teach to not climb electric poles.</p>
Falls	<p>Educate that roughhousing on fences or climbing on roofs is hazardous.</p> <p>Teach skateboard, scooter, and skating safety.</p>
Sports injuries	<p>Teach that wearing appropriate equipment for sports (e.g., face masks for hockey; mouthpiece and cup for football; helmet for bicycle riding, skateboarding, or in-line skating; batting helmets for baseball) is not babyish but smart management.</p> <p>Stress not to play to a point of exhaustion or in a sport beyond physical capability (no pitching baseballs or toe ballet for an early grade-school child).</p> <p>Use trampolines only with adult supervision to avoid serious neck injury.</p>
Drowning	<p>Teach how to swim; dares and roughhousing when diving or swimming are not appropriate. Stress not to swim beyond limits of capabilities.</p>
Drugs	<p>Help your child avoid all recreational drugs; prescription medicine should only be taken as directed. Teach to avoid</p>

	tobacco and alcohol.
Firearms	Teach firearm safety. Keep firearms in locked cabinets with bullets separate from gun.
General	School-age children should keep adults informed as to where they are and what they are doing; cell phones can help with this. Be aware the frequency of unintentional injuries increases when parents are under stress and therefore less attentive. Special precautions must be taken at these times. Caution that some children are more active, curious, and impulsive and therefore more vulnerable to unintentional injuries than others.

### **QSEN Checkpoint Question 32.3**

#### **Safety**

Teaching safety is an important area to consider for school-age children. Which advice would be best?

- a. “Keep your backpack filled to capacity to avoid falling on frequent trips back to your locker.”
- b. “As soon as you no longer need an automobile booster seat, you’ll no longer need a seatbelt either.”
- c. “Gaining weight isn’t serious in the school-age years; it only becomes a real problem after age 18 years.”
- d. “You’re old enough to tell if you are sick or not; your mother’s opinion isn’t as important as when you were younger.”

*Look in [Appendix A](#) for the best answer and rationale.*

School age is not too early for parents to look at the effect of carrying heavy backpacks on children’s posture. A backpack that weighs more than 10% of the child’s body weight is enough to cause a child to have to lean forward chronically to bear the weight. This can lead to chronic back pain ([Kistner, Fiebert, & Roach, 2012](#)).

Sexual maltreatment is an unfortunate and all-too-common hazard for children. Teaching points to help children avoid sexual maltreatment are summarized in [Box 32.4](#) (see also [Chapter 55](#)).

#### **BOX 32.4**

#### **Nursing Care Planning Based on Family Teaching**

#### **TEACHING POINTS TO HELP CHILDREN AVOID SEXUAL MALTREATMENT**

**Q.** Shelly’s mother wants to protect her daughter from being abused sexually. She asks you, “What are good rules to teach children without scaring them?”

**A.** A number of suggestions include:

1. Your body is your property and you can decide who looks at it or touches it.
2. Secrets are fun things to keep. If a person asks you not to tell about something that was done to you that you didn’t like, however, it’s not a secret. It’s all right to tell someone about it.
3. Don’t go anywhere with a stranger (a stranger is someone you do not know, not someone “strange”). Don’t be fooled by people asking you to give them directions or to go with them because your mother is sick or hurt or because they have lost a pet.
4. Being touched by someone you like is a good feeling. You don’t have to allow anyone to touch you in a way you don’t like. Don’t allow yourself to be left alone with a person you are uncomfortable with because that person touches you in a way you don’t like.
5. Avoid meeting with people you talk with on social media and the Internet because they may not be the age or the person whom they say they are.
6. A “private part” is the part of you a bathing suit touches. If anyone asks you to show them a private part or touches a private part, tell them to stop, and tell someone what happened.
7. If the person you tell doesn’t believe you, keep telling people until someone does believe you.

## **PROMOTING NUTRITIONAL HEALTH OF A SCHOOL-AGE CHILD**

Most school-age children have good appetites, although meals may be influenced by the day’s activity. If children have had a full day of active play, they may come to the dinner table ready to eat anything. If a day was filled with frustration—a child received a poor mark in school, had an argument with a friend, or has a big game to think about—the child’s appetite may be affected. This is no different from the way adults feel at times and so should be respected.

### **Establishing Healthy Eating Patterns**

School-age children should be encouraged to eat a healthy breakfast to ensure the ability to concentrate during the school day. It is helpful if parents model this behavior.

School-age children can help prepare a nutritious lunch to take to school. If they purchase lunch at school, healthy choices should be discussed with the child. Healthcare personnel can play an active role in nutrition education at health maintenance visits.

Many children qualify for a free or reduced-price school lunch and breakfast (Hirschman & Chriqui, 2012). A government-regulated school lunch provides milk (8 oz), protein (2 oz), one starch serving, a vegetable ( $\frac{3}{4}$  cup), and fruit ( $\frac{3}{4}$  cup). Serving

sizes vary according to age to provide one third of a child's nutrition requirements for a day (Fig. 32.7). Children with food allergies should be provided with alternative foods. Depending on the severity of the allergy, such as peanuts, they may need to sit at an allergy-free table at school.

**Figure 32.7** School lunch programs are being modified to better provide nutritious meals to school-age children.

Nutritious after-school snacks are important in this age group.

Poor eating habits developed in the school-age years may last through adulthood and lead to an increased risk of health-related diseases, such as type 2 diabetes, hypertension, cardiovascular disease, and obesity.

### **Fostering Industry and Nutrition**

As a part of fostering industry, school-age children usually enjoy helping to plan meals. They can prepare simple meals with healthy ingredients. They can assist with the preparation of more complex meals and learn the safe use of kitchen appliances such as the microwave and stove.

The development of proper etiquette is important in the school-age years. Parents can model this behavior for their child and encourage meals to be eaten at the table rather than while watching television. Meals eaten while watching television or performing another activity is a risk factor for obesity.

### **Recommended Dietary Intakes**

Although parents may have less to say about what a school-age child eats, it is important that the increasing energy requirements that come with this age (often in spurts) are met daily with foods of high nutritional value.

During the late school years, the recommended dietary intakes for children begin to be separated into different categories for girls then for boys because boys require more calories and other nutrients at this time. Both girls and boys require more iron in prepuberty than they did between the ages of 7 and 10 years. Adequate calcium and fluoride intake remains important to ensure good teeth and bone growth. A major deficit may be fiber because school-age children typically dislike vegetables.

### **A Vegetarian Diet**

School-age children who are vegetarians or vegans need to learn how to obtain essential nutrients whether they pack their lunch or purchase it at school. The consumption of adequate protein and calcium is important for muscle, bone, and dental development.

Foods highest in calcium are green leafy vegetables such as spinach and turnip greens, enriched bread, and cereals. Soybeans, legumes, grains, and immature seeds such as green beans, lima beans, and corn are relatively high in protein. Encourage outside activities for sun exposure to increase vitamin D. Iron may need to be supplemented as well, especially in girls with heavy menstrual flows ([Whitney & Rolfes, 2012](#)).

## **PROMOTING DEVELOPMENT OF A SCHOOL-AGE CHILD IN DAILY ACTIVITIES**

With life centered on school activities and friends, a school-age child still needs parental guidance for most daily activities because the habits and lifestyle patterns gained during this period will form the basis for the patterns of living later in life. [Figure 32.8](#) shows a day in the life of a family with school-age children. Along with nutritional needs, areas of concern for a school-age child and family include dressing, sleep needs, exercise, hygiene, and dental care.

**7:00 AM** The family sits down to a healthy breakfast. Claudia helps Laura with the butter.

**7:30 AM** John walks Marc to school, emphasizing safety when crossing the street.

**10:00 AM** Claudia and Laura bake a cake for the night's dessert. Four-year-old Laura enjoys practicing adult roles.

**3:00 PM** Marc and Laura play together after Marc gets home from school. Their cooperative play is punctuated by an occasional argument.

**Figure 32.8** A day in the life of a family with young children.

## Dress

Although school-age children can fully dress themselves, they are not skilled at taking care of their clothes until late in the school-age years. This is the right age, however (if not started already), to teach children the importance of caring for their own belongings. School-age children have definite opinions about clothing styles, often based on the likes of their friends, a popular sport, or a popular musician rather than the preferences of their parents. Help parents be aware that a child who wears different clothing than others may become the object of exclusion from a school club or group. In schools with a gang or bullying culture, children may not be able to wear a certain color or style lest they be mistaken for a gang member or become a bully's victim (White & Mason, 2011). A number of schools require uniforms or have a dress code to eliminate such concerns.

## Sleep

Sleep needs vary among individual children. Younger school-age children typically require 10 to 12 hours of sleep each night, whereas older children require about 8 to 10 hours. Most 6-year-olds are too old for naps but do require a quiet time after school to get them through the remainder of the day. Nighttime terrors may continue during the early school years and may actually increase during the first-grade year as a child reacts to the stress of beginning school.

During early school years, many children enjoy a quiet talk or a reading time at bedtime. At about age 9 years, when friends become important, children generally are ready to give up bedtime talks with parents in preference to phoning or text messaging a friend. Some parents may need some help to take at face value their child's statement, "I'm tired. I'd rather go to sleep," rather than feel rejected.

Children with television sets, electronic games, or smartphones in their bedrooms not only have shorter sleep times at night but also are more likely to be obese ([Chahal, Fung, Kuhle, et al., 2013](#)).

## Exercise

School-age children need daily exercise. Although they go to school all day, they do not automatically receive much exercise because school is basically a sit-down activity. Children who are bused or driven by a parent to school may therefore return home without having spent much time in active exercise.

Increasing time spent in exercise need not involve organized sports. It can come from neighborhood games, walking with parents or a dog, or bicycle riding. As children enter preadolescence, those with poor coordination may become reluctant to exercise. Urge them to participate in some form of daily exercise, however, or obesity or osteoporosis can result later in life ([Eagle, Sheetz, Gurm, et al., 2012](#); [Gunter, Almstedt, & Janz, 2012](#)).

## Hygiene

Children 6 or 7 years of age still need help in regulating bath water temperature and in cleaning their ears and fingernails. By age 8 years, children are generally capable of bathing themselves but may not do it well because they are too busy to take the time or because they do not find bathing as important as do their parents.

Both boys and girls become interested in showering as they approach their teen years. This can be encouraged because perspiration increases with puberty, along with sebaceous gland activity. When girls begin to menstruate, they may be afraid to take baths or wash their hair during their period if they have heard this is not safe. They need information that both of these practices are safe during their menses. Boys who are uncircumcised may develop inflammation under the foreskin from increased secretions if they do not wash regularly ([Meng & Tanagho, 2013](#)).

### **EVIDENCE-BASED PRACTICE**

Shelly has told the nurse she wants to try out for cheerleading when she gets to high school. This is a sport appealing to school-age children and adolescents because of its combinations of dance and gymnastics, the friendships that can develop, and the school status it almost automatically creates. To investigate what type of injuries typically occur with cheerleading, researchers reviewed all cheerleading injuries (over 4,000) presented to U.S. emergency departments during a 5-year period. The types of injuries most often seen were sprains/strains (44%), fractures (16%), and contusions (16%). The activities resulting in the most injuries were body collisions (29%), stunting (19%), tumbling (11%), and tossing (2.5%) (Currie, Fields, Patterson, et al., 2016).

Based on the study, how would the nurse best advise Shelly?

- a. Cheerleading will be good for her because she is likely to lose weight from the exercise.
- b. She will need to drink an extra source of calcium every day to avoid broken bones.
- c. She should pursue a sport or activity that is safer.
- d. She should be aware that cheerleading may be beneficial to her but does carry some risks.

*Look in Appendix A for the best answer and rationale.*

### **Care of Teeth**

With proper dental care, the average child today can expect to grow up cavity free. To ensure this happening, school-age children should visit a dentist at least twice yearly for a checkup, cleaning, and possibly a fluoride treatment to strengthen and harden the tooth enamel or sealants on secondary teeth (Tubert-Jeannin, Auclair, Amsallem, et al., 2011) (Fig. 32.9). Remind them that not all bottled water is fluoridated, so they don't want this to be their main source of drinking water. Some children develop a fear of dentists and, if a dentist visit was painful, want to avoid going at all. The advantage of frequent visits permits problems to be addressed early and familiarizes the child with the dental visit. Pedodontists specialize in caring for children's teeth and understand the developmental level of their patients. The parents of children who tend to develop caries might be encouraged to visit a pedodontist if one is available and affordable.

**Figure 32.9** Dental caries are the number one health problem in school-age children. Stress to parents that good dental health is important and encourage school-age children to visit a dentist twice a year.

School-age children have to be reminded to brush their teeth daily. For effective brushing, a child should use a soft toothbrush, fluoride-based toothpaste, and dental floss to clean between teeth to help remove plaque. Electric toothbrushes can be used safely by school-age children.

Snacks are best limited to high-protein foods such as chicken and cheese rather than candy. Fruits, vegetables, and cereals fortified with minerals and vitamins (not empty calorie ones) can all be fun after-school snacks for school-age children. If the child does eat candy, a type that is eaten quickly and dissolves quickly is better than slowly dissolving or sticky candy because these types stay in contact with the teeth longer.

***QSEN Checkpoint Question 32.5***

**TEAMWORK & COLLABORATION**

Shelly tells the nurse she collected “a ton of candy on Halloween. Because of how common this phenomenon is, in consultation with a dental hygienist, you would teach children that what type of candy is less likely to cause dental caries?

- a. Salt water taffy
- b. A chocolate bar
- c. Chewy caramels
- d. Hard candy

*Look in [Appendix A](#) for the best answer and rationale.*

## **PROMOTING HEALTH FAMILY FUNCTIONING**

To their parents’ annoyance, many 6-year-olds often quote their teacher as the final authority on all subjects. This may be the first time the parents see someone surpassing them in their child’s eyes, and accepting the situation can be painful. Children also cite their friends as guides for behavior; for example, “Mary Jane doesn’t have to go to bed until 10 o’clock” or “Carlos’s mother lets him go to the movies every Saturday.”

Parents may require help to realize these remarks are a normal consequence of being exposed to other adults and children. A simple statement such as “There are all kinds of ways to do things, but in our house, the rule is this” shows no criticism of Carlos’s or Mary Jane’s family yet conveys a special and secure “our house” feeling.

Parents may also need to be reminded that even the simplest tasks of everyday life require repeated practice before they can be accomplished well. The way parents correct children as they learn these tasks influences children’s opinions of themselves and their ability to continue learning. “Putting all the silverware in a pile is one way of putting it away; another way would be to divide spoons, forks, and knives separately” is always preferable to “What a silly way to put away silverware!” Comments such as “Can’t you do anything right?” or “Why don’t you ever do what I say?” should always be avoided because children will rise only to the level expected of them.

If parents have difficulty telling what a child’s completed project is supposed to be, the time-honored “Tell me about it” is preferable to “What is it?” It is good for parents to find a redeeming characteristic in a project, no matter how shakily it is put together: “I like the bright color you painted it” or “That must have been fun to make.”

Displaying and using children’s gifts are part of having school-age children in a family. A finger painting hung on the refrigerator door enhances, not detracts from, the most elegant home.

In talking to parents of school-age children, good questions to ask to estimate the degree of interaction that occurs in the home and whether parents are strengthening a child’s sense of accomplishment include:

- How do they correct the child when he or she does something wrong?
- Do they display school projects?
- Does the child have chores that are his or hers to accomplish?
- Do they ask the child to participate in family decision making?

## COMMON HEALTH PROBLEMS OF THE SCHOOL-AGE PERIOD

Children in their early school years may have many small health concerns such as head lice or ringworm (see [Chapter 43](#)). At the same time, they have one of the lowest rates of death and serious illness of any age group. The two causes of death seen most frequently are from unintentional injury and cancer. Minor illnesses are largely due to dental caries, gastrointestinal disturbances, and upper respiratory infections ([Heron, 2012](#)).

Because learning difficulties such as attention deficit hyperactivity disorder (ADHD) and autism spectrum disorders (ASDs) are identified during the school-age years, they are important parental concerns (see [Chapter 54](#)). [Table 32.3](#) shows the usual health maintenance pattern for a school-age child ([AAP, Committee on Practice and Ambulatory Medicine, 2012](#)). [Table 32.4](#) lists problems that parents may have in evaluating illnesses in school-age children.

**TABLE 32.3 HEALTH MAINTENANCE SCHEDULE, SCHOOL-AGE PERIOD**

Area of Focus	Methods	Frequency
<i>Assessment</i>		
Health history	Health interview	Every visit
Physical health	Physical examination	Every visit
Developmental milestones	History and observation	Every visit
Growth milestones	Height and weight plotted on standard growth chart; body mass index (BMI) and physical examination	Every visit
Hypertension	Blood pressure	Every visit
Nutrition	History and observation; height and weight information	Every visit
Parent–child relationship	History and observation	Every visit
Behavior or school problems	History and observation	Every visit
Vision and hearing disorders	History and observation	Every visit
	Formal Snellen or Titmus testing	At 7–9 years and 10–12 years
	Audiometer testing	At 7–9 years and 10–12 years

Dental health	History and physical examination	Every visit
Scoliosis	Physical examination	Yearly after age 8 years
Thyroid	Physical examination and history	Every visit after age 10 years
Dyslipidemia	Cholesterol and triglycerides	6–8 years and 10–12 years
Tuberculosis	Purified protein derivative (PPD) skin test	Depending on prevalence of tuberculosis in community
Bacteriuria	Clean-catch urine	At 6–7 years
Anemia	Hematocrit and hemoglobin	At 7–8 years and 11–12 years

### *Immunizations*

Check history and past records, inform caregiver about any risks and side effects, and administer immunization in accordance with healthcare agency policies.

Diphtheria, tetanus, and pertussis vaccine	(DTaP)	11–12 years
Hepatitis A vaccine	(HepA)	If not previously administered
Hepatitis B vaccine	(HepB)	If not administered in infancy or three injections were not completed
Human papillomavirus vaccine	(HPV or HPV4)	11 or 12 years; second injection 2 months later; third injection 6 months after first dose
Inactivated poliomyelitis vaccine	(IPV)	If four doses not previously administered
Influenza vaccine	(IIV)	Yearly
Meningococcal conjugate vaccine	(MCV4)	11–12 years
Pneumococcal vaccine	(PPSV)	To children at high risk
Measles, mumps, rubella vaccine	(MMR)	If two doses not previously administered
Varicella vaccine	(VAR)	At any age after 1 year if not previously immunized, or at 11–12 years if lacking

		reliable history of chickenpox
<i>Anticipatory Guidance</i>		
School-age care	Active listening and health teaching	Every visit
Expected growth and developmental milestones before next visit	Active listening and health teaching	Every visit
Unintentional injury prevention	Counseling about street and personal safety	Every visit
<i>Problem Solving</i>		
Any problems expressed by caregiver during course of the visit	Active listening and health teaching regarding cigarette smoking, substance abuse, sex education, school adjustment, etc.	Every visit

American Academy of Pediatrics, Committee on Practice and Ambulatory Medicine. (2012). *Recommendations for preventive pediatric health care*. Washington, DC: Author; and Centers for Disease Control and Prevention. *Birth–18 years & “catch up” immunization schedules*. Washington, DC: Author.

**TABLE 32.4 PARENTAL DIFFICULTIES EVALUATING HEALTH PROBLEMS IN THE SCHOOL-AGE CHILD**

<b>Difficulty</b>	<b>Helpful Suggestions for Parents</b>
Evaluating seriousness of illness	For the first time, a school-age child may view illness as a way to avoid unpleasant activities (e.g., school, a coach who asks too much, household chores). Evaluating whether the child has symptoms when asked to do a favorite thing often reveals the difference between exaggeration and an ill child (e.g., too sick to eat spinach, not too sick to eat ice cream; too sick to go to school, not too sick to go ice skating). If the child uses symptoms of illness as a means of avoiding situations, parents must evaluate what it is about the situation they could improve or see if some change should be made in their expectations.
Evaluating nutritional intake	Many school-age children eat lunch at school, and they may spend weekends away from home and weeks away at camp. As with all ages, noting whether they are growing and active is better than

	monitoring any one day's food intake.
Evaluating puberty changes	There is a wide variation in the time secondary sex characteristics occur (8–17 years for girls; 10–20 years for boys). Children should be examined if and when they or their parents are concerned pubertal changes are delayed or appearing too early.
Age-specific diseases to be aware of	<p>School age is a time to evaluate vision because vision changes occur with increased maturity of the eye globe. Squinting, rubbing the eyes, or poor marks in school may be signs of poor vision.</p> <p>Streptococcal sore throats occur frequently in early school-age children. Those with sore throats should be examined by a healthcare provider to prevent complications, such as glomerulonephritis or rheumatic fever, from developing. Girls, in particular, must be evaluated for scoliosis (curvature of the spine). Parents may detect this by noticing that a girl's skirt hangs unevenly or bra straps are uneven.</p> <p>Parents may need to be cautioned that vomiting or a headache in the morning that passes fairly quickly (at about the same time the school bus leaves) may be a symptom of school phobia, but a physical examination is in order because these are also symptoms of other conditions.</p> <p>Absence seizures, a neurologic condition that typically arises in the school-age years, can be confused with behavior problems if observation is not thorough (see <a href="#">Chapter 49</a>). Attention deficit hyperactivity disorder (ADHD) (see <a href="#">Chapter 54</a>) can also lead to behavior or inattention disorders.</p>

## Dental Caries

**Caries** (cavities) are progressive, destructive lesions or decalcification of the tooth enamel and dentin. When the pH of the tooth surface drops to 5.6 or below (which happens after children eat readily fermented carbohydrates, such as table sugar), acid microorganisms (acidogenic lactobacilli and aciduric streptococci) found in dental plaque attack the cementing medium of teeth and destroy it. Plaque tends to accumulate in deep grooves of the teeth and contact areas between teeth, making these areas most susceptible to dental decay. The enamel on primary teeth is thinner than on permanent teeth, so these are even more susceptible to destruction than permanent teeth. The distance from the enamel to the pulp is shorter also, so invasion of the tooth nerve can occur quickly. Neglected caries result in poor chewing and therefore poor digestion, abscesses and pain, and sometimes osteomyelitis (bone infection) if the jaw bone is involved.

As stated earlier, dental caries are largely preventable with proper brushing and use of fluoridated water or fluoride application. When caries do occur, it's important they be

treated quickly and the child's dental hygiene practices be evaluated and improved if necessary. Most importantly, children must believe that they have a stake in the health of their teeth, so even though they are cavity free, they willingly undertake the self-care measures necessary to ensure healthy teeth with parental support rather than parental command (Wen, Goldberg, Marrs, et al., 2012). Dental visits are recommended every 6 months. With the eruption of the permanent teeth, sealants can be applied at dental visits to lessen the development of dental decay.

## Malocclusion

The upper jaw in children matures during early childhood along with skull growth; the lower jaw reaches maturity more slowly, forcing teeth to make a prolonged series of changes until they reach their final adult alignment and position. Good tooth occlusion, in which the upper teeth overlap the lower teeth by a small amount and teeth are evenly spaced and in good alignment, is necessary for optimal formation of teeth, health of the supporting tissue, optimal speech development, and what most people view as a pleasant physical appearance. **Malocclusion** (a deviation of tooth position from the normal) may be congenital due to conditions such as cleft palate, a small lower jaw, or familial traits tending toward malocclusion. The condition can result later on from constant mouth breathing or abnormal tongue position (tongue thrusting). Thumb-sucking is still another possibility if it persists past the time of eruption of the permanent front teeth (6 to 7 years) (Sandler, Madahar, & Murray, 2011). The loss of teeth due to extraction or an unintentional injury may lead to malocclusion if not properly treated so that alignment is maintained.

Malocclusion may be either crossbite (sideways) or anterior or posterior. Children with a malocclusion should be evaluated by an orthodontist to see if orthodontic braces or other therapy is necessary. The time to begin correction varies with the extent of the malocclusion and jaw size. Braces are painful when they are first applied and at periodic visits when they are tightened to maintain pressure for further straightening. Some children develop mild, shallow ulcerations (canker sores) on the buccal membrane from friction of metal wires. Rubbing the offending wire with dental wax dulls the surface and gives relief. Oral acetaminophen or an agent such as Orajel (an over-the-counter drug) rubbed on the ulceration may also offer relief.

All children who wear braces need to brush their teeth well and be assessed periodically to see that they are brushing properly around the braces (a Waterpik is often recommended for thorough cleaning). They should use dental floss to remove plaque from around wires.

After the removal of braces, many children usually wear retainers to maintain the correction the braces achieved. Although braces are wired into place, retainers are not. Loss of a retainer can be a problem if it must be removed when eating; check bedside food trays of school-age children before removing them to be certain a child has not placed a retainer on the tray.

Show appropriate sympathy and help children problem solve if they are bothered by

the appearance of braces or wearing a retainer. Once thought of as implements to be made fun of, teeth braces have become such a common feature of life for schoolchildren that most children who wear them find comfort in not being the only one to suffer this indignity and, once used to their own appliances, experience little reluctance in letting their classmates see them. Some even view them as a mark of pride or a status symbol (Hamdan, Singh, & Rock, 2012).

## CONCERNS AND PROBLEMS OF THE SCHOOL-AGE PERIOD

Two of the most important disorders of the school-age period are ADHD and ASDs because these interfere so dramatically with school progress (see [Chapter 54](#)). Other problems concern language, fears, and responsibility.

### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Parental anxiety related to less-than-expected behavior of a school-age child

**Outcome Evaluation:** Parent states undesired behavior has decreased in frequency; parent feels less stress about the child's health or future.

## Problems Associated With Language Development

The common speech problem of the preschool years is broken fluency; the most common problem of a school-age child is articulation. The child has difficulty pronouncing *s*, *z*, *th*, *l*, *r*, and *w* or substitutes *w* for *r* (“westroom” instead of “restroom”) or *r* for *l* (“radies’ room” instead of “ladies’ room”). This is most noticeable during the first and second grades; it usually disappears by the third grade. Unless it persists, speech therapy for this normal developmental stage is not necessary.

## Common Fears and Anxieties of a School-Age Child

School-age children are old enough to experience adult reactions to problems at home or school.

### Anxiety Related to Beginning School

Adjusting to grade school is a big task for 6-year-olds ([AAP, Council on Early Childhood, Council on School Health, 2016](#)). Even if they attended preschool, grade school is different: The rules are firmer, and the elective feeling (e.g., “If I don’t like it, I can quit”) no longer applies. School is for keeps until age 16 years or longer, a time span too long for a young child to even imagine. Also, where preschool learning was carried out through fun activities, part of every day in grade school involves obvious

work (Box 32.5 shows an interprofessional care map for a child with school concerns). Some instances of anxiety may be a reflection of a parent’s anxiety (Pass, Arteche, Cooper, et al., 2012).

BOX 32.5

Nursing Care Planning

**AN INTERPROFESSIONAL CARE MAP FOR A SCHOOL-AGE CHILD BEGINNING MIDDLE SCHOOL**

Shelly Lewis is an 11-year-old girl who recently started middle school. Her mother tells you that, although Shelly, who is overweight, says she likes school and wants to try out for cheerleading, she has developed a lot of nervous habits such as nail biting since school started.

**Family Assessment:** Child lives with mother, stepfather, and three younger stepsisters in a four-bedroom home. Family owns a boarding kennel for dogs; both parents work full-time at business. Mother describes finances as “Okay. It’s hard with a big family.”

**Patient Assessment Child:** Child has been “chubby” since preschool. States she likes to read rather than play sports. Is in seventh grade (age appropriate). Observed to be restless in chair during conversation with mother about the new school. Mother states, “Her sisters have no trouble with change; she always does. Don’t you think if she lost weight she’d fit in better?”

**Nursing Diagnosis:** Anxiety related to beginning a new school.

**Outcome Criteria:** Child states she feels more comfortable with new school setting; nail biting has decreased in intensity; child agrees to begin weight-reduction program.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess what activities patient enjoys.	Review with patient the advantages of participating in activities that involve more exercise than reading. Support cheerleading; suggest walking with a friend.	Effective weight reduction calls for increased exercise. Books on tape can supply reading enjoyment while walking.	Child states she will try some active activity for at least 20 minutes each day.

---

*Teamwork and Collaboration*

---

Nurse/nurse practitioner	Assess if child would be interested in a weight-reduction class at the health center.	Suggest different options available such as a weight-loss group or a commercial weight-reduction program.	Children respond well to group activities. Other group members supply friendship as well as increase motivation.	Child states whether she would like to join a weight-reduction group.
--------------------------	---	---	--	---

---

*Procedures/Medications for Quality Improvement*

---

Nurse	Ask child to try to identify if she feels something is upsetting about the new school; if so, ask what it is.	Help child “walk through” a day at school and discuss how small changes could affect her fitting in to school.	Talking with the child allows her to share feelings and concerns openly and safely, possibly increasing her awareness of them and their impact on her.	Child describes a typical day and points she would like to see change.
-------	---	--	--	--

---

*Nutrition*

---

Nurse/nutritionist	Assess child’s intake by 24-hour recall history.	Review with child changes that would reduce calories, yet maintain her lifestyle.	Eleven-year-old children are old enough to take responsibility for what and when they eat.	Patient reviews her dietary intake and makes at least three suggestions on things she will attempt to change.
--------------------	--	---	--	---

---

*Patient-Centered Care*

---

Nurse	Assess if family members appreciate the stress a new school setting can create.	Review with mother and child ways to reduce stress when encountering new situations,	It is easy for parents to view 11-year-olds as able to handle new situations better than they can because of	Mother states she may have been taking the change in school too lightly and agrees to offer
-------	---	--	--	---

such as equating pseudomaturity. more support. them with something already known.

*Psychosocial/Spiritual/Emotional Needs*

Nurse/nurse practitioner	Assess family functioning with child's mother.	Stress that all children are individuals and what works for her stepsisters may not work for the patient.	Being constantly compared to siblings can create feelings of low self-esteem, which can lead to difficulty solving problems.	Mother states she will try to reduce comparisons to stepsisters to help reduce stress at home.
--------------------------	--	---	--	--

*Informatics for Seamless Healthcare Planning*

Nurse	Assess if child or mother thinks an early follow-up appointment would be helpful.	Arrange for a follow-up clinic appointment within 1 month with the mother and daughter if desired.	It is difficult for a family to make internal changes if they are too emotionally involved to be objective.	Mother and child express their preferences based on their future plans.
-------	---	--	---	---

Because school requires an adjustment, a health assessment of all school-age children should include an inquiry about progress in school by a question such as “How is Shelly doing in school?” followed by a second question “How does her teacher say she is doing?” If there is a discrepancy between those two answers, the situation bears study. Some parents may have to alter their expectations of how much their child should be achieving to conform to their child’s actual ability. This can obviously be difficult.

One of the biggest tasks of the first year of school is learning to read. It is best if parents have prepared children for this by reading to them since infancy, pointing to the words and pictures as they read. This helps children realize that sentences flow from left to right and that the words, not the pictures, tell the story. [Box 32.6](#) offers some useful hints to help parents encourage reading in their young school-age child.

**BOX 32.6**

**Nursing Care Planning to Respect Cultural Diversity**

With the activities of children in modern cultures turning more toward electronic games than opening books, reading for pleasure is threatened with becoming a lost art. A number of tips for making reading more enjoyable and increase cultural understanding for children include:

- Read books yourself to set an example so your child thinks of reading as an adult activity. If you spend most of your free time watching television, your child will think reading is mainly for children and assume that it is not important.
- Make reading more fun by encouraging your child to make practical use of what he or she reads. Ask the child to read culturally different recipes while you cook or to read road signs during a car trip.
- Play a treasure hunt game where you hide a small object, such as a favorite toy, and then write simple clues on slips of paper: “Look under a lamp,” “Look in a book,” and so on until your child has been led to the hidden object. Your child can develop writing skills by playing the same game for you to follow.
- Suggest to relatives that a gift certificate from a bookstore would be a good present. Let your child browse the store to select the book.
- Talk about books the child has read—what was good, what was bad, or what the child learned while reading.
- Read a book together as a bedtime family activity.

Many first graders are capable of mature action at school but appear less mature when they return home. They may bite their fingernails, suck their thumb, or talk baby talk. Some develop tics (irregular movements of isolated muscle groups), such as wrinkling the forehead, shrugging the shoulders, clearing the throat, or frequently blinking. Such movements may occasionally be confused with seizure activity. Tics, however, disappear during sleep and occur mainly when the child is subjected to stress or anxiety. Scolding, nagging, threatening, or punishing does not stop either tics or nail biting and invariably makes these problems worse. Methods such as using bad-flavored nail polish and restraining the child’s hands to prevent nail biting are also ineffective.

These behaviors stop when the underlying stress is discovered and alleviated. Urge parents to spend some time with the child after school or in the evening so the child continues to feel secure in the family and does not feel pushed out by being sent to school. If such behavior manifestations persist despite attempts to eliminate their cause, the family might benefit from formal counseling, cognitive behavioral therapy, and possibly pharmacology support for the child ([Pringsheim, Doja, Gorman, et al., 2012](#)).

### School Refusal or Phobia

School refusal is a fear of attending school. It is a type of “social phobia” similar to agoraphobia (fear of going outside the home) or separation anxiety disorder (SAD). Children who resist attending school this way develop physical signs of illness, such as vomiting, diarrhea, headache, or abdominal pain on school days. This lasts until after

the school bus has left or the child is given permission to stay home for the day.

A particular child may be reacting to a situation such as a harsh teacher, having to shower in gym class, or facing a class bully every day. In these instances, counseling may help the child manage the situation better. School refusal may also occur if the child is overly dependent on the parents or may be reluctant to leave home because of worry that younger siblings will usurp the parents' affection. The anxiety of separation may also result because the parent is overprotective of the child or is the one having the most difficulty separating.

Because the problem of school refusal is usually only partly the child's, the entire family generally requires counseling to resolve the issue. As a rule, once it has been established that the child is free of any illness and the resistance stems from separation anxiety or phobia, the child should be made to attend school. Reinforcement by parents to go to school this way helps to prevent problems such as school failure, peer ridicule, or a pattern of avoiding difficulties. Some children may benefit from a gradual program of school involvement, such as walking to school but not going in for one day, then going to school but staying for only 1 hour the next day, then staying for half a day, and so on until the child can stay all day every day. Give support to parents so they can matter-of-factly treat the child's illness symptoms (a great deal of reassurance that these symptoms are not major will be necessary) so they can take the child firmly to the bus or to the classroom.

Managing school refusal requires coordination among the school, the school nurse, and the healthcare provider who identifies the problem. A nurse is the ideal person to coordinate such efforts and to help parents allow the child some independence not only in going to school but also in other activities. A few children have such difficulty that they require formal counseling and pharmacologic therapy to overcome school refusal (Scheffer, 2011).

### *What If . . . 32.3*

**Shelly's mother tells the nurse that the many nervous habits she began since starting middle school are increasing. What suggestions would the nurse make to her mother regarding this?**

## **Homeschooling**

Because of religious or personal preference or because of disillusionment with the school system, a growing number of children are homeschooled today (Anthony & Burroughs, 2010). Because their main contact has been with well-educated parents at home, the vocabulary of homeschooled children may be advanced or may suggest they are older than their actual age. When discussing homeschooling with parents, assess if children have peer experiences, perhaps through participation in community sports teams or clubs. Ask if they receive exposure to other cultures or families, so they can

better adjust to people different from themselves later on at college or at a job.

### Children Who Spend Time Independently

Children whose parents both work outside the home may spend time alone without adult supervision for a part of each weekday. Such children have become a prominent concern because, in as many as 90% of families today in the United States, both parents work at least part time outside of the home. Few parents have work hours so flexible that they can always be at home when a child leaves for or returns from school.

Extended family members who once watched children after school are often working as well or may no longer be close at hand; many communities are no longer close-knit enough to have neighbors who can be depended on to help out with informal child care.

A major concern of children staying home alone is that they will experience an increased number of unintentional injuries, delinquent behavior, alcohol or substance abuse, or decreased school performance from a lack of adult supervision. For children who are responsible and feel safe in their community, however, a short period of independence every day may actually be beneficial because it encourages problem solving in self-care (Mack, Dellinger, & West, 2012).

Suggestions for parents whose children must spend time alone before or after school are shown in Box 32.7. Many communities and schools offer special after-school programs so children do not have to be home alone. Nurses are in a position to educate parents about such services so their children can feel both safe and stimulated creatively during this time. Both Boy and Girl Scouts, the Boys & Girls Clubs of America, and Camp Fire USA are examples of organizations that offer programs in many neighborhoods to help children adjust to being home alone. Many communities also organize hotline numbers that a child who is alone can call if a problem arises. At health visits, assess whether parents and a child appear to have a concern with or are uncomfortable about after-school arrangements. For a child who is extremely fearful or impulsive or who finds problem solving difficult, time alone after school may not be appropriate. Determine the individual circumstances and recommend changes as appropriate. State laws vary as to when children can provide self-supervision.

#### BOX 32.7

#### Nursing Care Planning to Empower a Family

#### TIPS FOR CHILDREN WHO SPEND TIME INDEPENDENTLY AND THEIR PARENTS

**Q.** Shelly stays by herself after school for a half hour each week day. Her mother asks you, “What are good tips for being sure it’s safe to let her do that?”

**A.** Think in a number of areas:

#### Safety Points for Children

Always lock doors and never show keys to others or indicate you stay home alone.  
When answering the telephone, say a parent is busy, not absent from home.  
Have a plan in the event you lose your key (e.g., stay with a neighbor).  
Don't go into the house if the door is open or a window is broken.  
Learn fire safety (practice a fire drill from all rooms of the house).  
Check in with parents by telephone or laptop when you first arrive home.  
Identify a caller before opening the door. Agree on a secret code word; you should not open the door or go with a person unless the person knows the word.  
Learn how to change light bulbs safely if it will be dark before parents return home.  
If appropriate, learn how to change fuses or reset circuit breaker switches.  
Learn how to report a fire and telephone police (practice this with your parents).

### **Safety Responsibilities for Parents**

Prepare a safety kit with bandages and such; include a flashlight in case of a power failure so children do not need to light candles.  
Plan after-school snacks that do not require cooking to prevent burns.  
Keep firearms locked, with the key in a place unknown to child.  
Keep a list of emergency telephone numbers (including parents' work numbers) by the telephone.  
Arrange with a neighbor who is usually home during the late afternoon for the child to stay there in an emergency.  
If an older child will be watching a younger one, be certain both children understand the rules laid down and the degree of responsibility expected.  
Be certain the child understands the rules that apply during other times also apply during independent time (e.g., never swim alone, do not play by the railroad tracks).

### **Parental Actions to Prevent Loneliness**

Leave messages on the refrigerator or in the bathroom that just say "hi."  
Leave a tape- or video-recorded message for the child to play when he or she first arrives home (make sure it is not full of tasks to do but is a welcoming message).  
Be certain to make parent-child time available after work to allow for quality relationship time.  
Each morning, help the child plan an activity for that day so he or she has something purposeful to look forward to during the time alone.  
Allow special privileges such as listening to music other members of the family do not like; consider allowing extra television hours during this time.  
Consider getting a pet. Even a caged animal, such as a hamster or a bird, offers companionship in a quiet house.  
Call the child if there will be a delay in arriving home; unexpected time alone is very frightening.  
Encourage the child to read; fictional characters can serve as friends as well as help to pass time.

Urge the child to network with other children who spend time alone as to how they use time effectively; talking on the telephone or e-mailing another child reduces loneliness for both.

### **Parental Actions to Increase Socialization**

Help the child plan after-school activities such as joining a science club for one afternoon a week.

Explore sports programs at school or in the community because these often are held after school.

Explore after-school programs at the school the child attends, or at a public library, a church, or a temple.

Network with other parents or ask for flex time so child supervision can be alternated after school.

Be certain the child has opportunities to socialize with friends on weekends or on days when either parent is home.

### **Parental Actions to Increase Self-Esteem**

Praise the child for the ability to take care of himself or herself for short time intervals (e.g., rather than scold him or her that there are cracker crumbs on the carpet).

Walk with the child through the empty house and together identify sounds (e.g., the click of the furnace turning on, the refrigerator starting to defrost), so they can determine the cause of sounds when home alone and not be frightened.

Help the child to view the quiet as a beneficial time in which they can do some things more efficiently, such as homework, than at noisy times.

Do not allow the child to use their time alone role to provoke parental guilt. Allow children to have some say in family spending so they can see how their time alone (which allows both parents to work) contributes to family unity and progress.

## **Sex Education**

It is important that school-age children be educated about pubertal changes and responsible sexual practices. Also, preteens should have adults they can turn to for answers to questions about sex. Ideally, these should be their parents, but because sex is an emotionally charged topic, some parents may be extremely uncomfortable discussing it with their children. As a result, healthcare personnel often become resource persons.

It's best if sex education is incorporated into health education classes throughout the school years in a manner that is appropriate to age and development. Topics to teach and discuss in a sex education course for both preadolescent boys and girls include:

- Reproductive organ function and physiology of reproduction, so children understand what menstruation is and why it occurs
- Secondary sexual characteristics, so children will understand what is happening in their bodies

- Male sexual functioning, including why the production of increased amounts of seminal fluid leads to nocturnal emissions
- The physiology of pregnancy and the possibility for unintended pregnancies, which will come with sexual maturity
- Responsibilities of sexual maturity
- Reproductive life planning measures and the principles of safer sex if appropriate to the cultural setting (see [Chapters 5 and 6](#)). Sexual orientation questions and concerns may arise at this time, and questions should be addressed honestly and openly.

Lesbian, gay, bisexual, and transgender (LGBT) youth may not obtain the same levels of care due to fear of discrimination. They may choose not to disclose their sexual orientation or gender identity to healthcare providers or they may avoid care completely. Nurses can take steps to improve health outcomes for LGBT youth by providing care that is affirming and inclusive ([Hadland, Yehia, & Makadon, 2016](#)).

A sex education course that includes films and discussions is helpful for preadolescents but never answers all of a preteen's questions (most youngsters would rather avoid asking a question than risk appearing ignorant in front of their peers in such a setting). Using an anonymous question box is one method to address questions and lessens the embarrassment that may occur with more a more public forum of asking questions. Urge parents or other health educators to watch films or read booklets with children to show they are truly available to answer questions.

## Stealing

During early school age, most children go through a period during which they steal loose change from their mother's purse or father's dresser. This usually happens at around 7 years of age, when children first learn how to make change and also discover the importance of money. Stealing occurs because, although a child is gaining an appreciation for money, this appreciation is not yet balanced by strong moral principles or an understanding of ownership.

Parents should explore the reason for the stealing, including:

- Do other children on the block receive an allowance and so have money for small items?
- Did their child make a bet that must be paid?
- Is a child buying a bully's friendship by purchasing gum or candy for that child?
- Does a child need more security and view money as security?

As a rule, early childhood stealing is best handled without a great deal of emotion. A parent should tell the child the money is missing. The importance of property rights should be reviewed: Mother's and father's money is theirs, the child's money is the child's, and they are not interchangeable. Youngsters who continue to steal past 8 years of age may require counseling because they should have progressed beyond this normal developmental step by this age ([Sourander, Fossum, Rønning, et al., 2012](#)).

Some shoplifting occurs with early school-age children, but the major problem with

this arises during preadolescence. Some of this happens for the same reason that past generations tipped over outhouses or untied the preacher's horse and buggy: It is a public act of rebellion against authority, a "coming of age" ritual. It usually occurs because of peer pressure such as when children believe they must have a certain type of clothing to belong to the "in" crowd. It can also be an initiation ritual for gang membership.

Shoplifting must be taken seriously by parents because it is a punishable crime, not a prank. Just as money missing from a purse should not be ignored, shoplifting should be confronted immediately to prevent children who succeed once from taking something even bigger the second time. Children should be asked how they came to possess the article and they should not be allowed to use it. Children should then be denied access to stores until they demonstrate more responsibility. A child who shoplifts more than once may need counseling because it reflects more than simple confusion about property rights.

As an overall principle, parents should set good examples if they expect their child to be honest. If one parent takes money from the other without permission, neither should be surprised to find their child attempting to do the same. If a parent unwraps items and eats them without paying for them in the supermarket, a parent cannot expect a child to do otherwise.

## **Violence or Terrorism**

Children basically view their world as safe, so it is a shock when violence such as a school shooting or reports of terrorists enter their lives (Dowdell, 2012). Common recommendations for parents to help children feel safe when they hear of these instances include:

- Assure children they are safe; even if the violence is in their community, their parents are actively involved in being certain they are not in danger.
- Observe for signs of stress such as sleep disturbances, fatigue, lack of pleasure in activities, or signs of beginning substance abuse.
- Do not allow children or adolescents to view footage of traumatic events over and over because this decreases their ability to feel safe.
- Watch news programs with children so it can be explained that the situation portrayed is not near them and that their child is safe.
- Explain that there are bad people in the world, and bad people do bad things, but not all people in a particular group or who look a particular way are bad. Lashing out at people who resemble them only causes more harm.
- Prepare a family disaster plan, including such things as bottled water, blankets, toiletries, pet supplies, appropriate clothing, flashlights, and information such as what immunizations their children have had (particularly tetanus) and, if a child is ill, a history of medical needs or care so that such items are ready in an emergency.
- Designate a "rally point" where the family will meet if ever separated by a

disaster or evacuation (AAP, 2012b).

Some parents may be reluctant to talk to their children about a disaster plan for the family, believing that these preparations will frighten children unnecessarily, but such preparations should have the major effect of increasing a feeling of safety, not decreasing it. Fear of the unknown is always more intense than a fear of something tangible.

## **Bullying**

A frequent reason school-age children cite for feeling so unhappy that they turn guns on classmates or commit suicide is because they were ridiculed or bullied to the point they could no longer take such abuse (Cooper, Clements, & Holt, 2012). Alert parents that Internet or texting bullying are both also possible and that a bully doesn't have to be in fact-to-face contact with their child to be harmful (D'Auria, 2014).

Traits commonly associated with school-age bullies include:

- Advanced physical size and strength for their age
- Aggressive temperament (both male and female)
- Parents who are indifferent to the problem or are permissive with an aggressive child
- Parents who typically resort to physical punishment
- There is the presence of a child who is a "natural victim" (e.g., small, insecure, with low self-esteem).

Bullying can be done face to face or through social media and/or texting.

Suggestions for school personnel to deal with bullies include:

- Supervise recreation periods closely.
- Intervene immediately to stop bullying.
- Insist if such behavior does not stop, both the school and parents will become involved.
- Advise parents to discuss bullying with their school-age child and help them understand that it should be reported to allow adults to intervene.
- Parents should monitor their child's social media and texting interactions.

If bullying behavior is ingrained, therapy may be needed to correct the behavior. Stopping bullying helps not only the victim but also the bully because statistics show that children with this type of aggressive behavior in grade school are more apt to be incarcerated as adults than others (AAP, 2012a).

## **Recreational Drug Use**

Once considered a college or high school problem, illegal drugs such as marijuana, cocaine, and amphetamines are now available to children as early as elementary school and certainly by the time they reach the seventh and eighth grades. Because they are available in so many homes, alcohol, inhalants, and prescription drugs have also become commonly abused by this age group (Blake & Davis, 2011; Young, Glover, &

Havens, 2012). Parents should be particularly aware of children who may be taking adult antidepressant drugs from home medicine cabinets because this is associated with suicide in young children (Adegbite-Adeniyi, Gron, Rowles, et al., 2012).

The use of hard drugs and alcohol and ways to encourage children to avoid their use are discussed in Chapter 33. Inhalants, which are easily available to school-age children for abuse, include airplane glue (toluene) and aerosolized cooking oil. Children do not become physically addicted to glue but do become psychologically dependent on it. To achieve the desired effect, they drop quantities of the glue into a paper bag and then sniff the fumes to experience a feeling of exhilaration or giddiness. This may seem like a harmless procedure, but, in high concentrations, glue fumes can cause extensive liver damage or enough pulmonary edema to be fatal. Cooking spray or computer keyboard cleaner gives this same effect. Because these products contain Freon, they can cause severe respiratory and cardiac irregularity (Baydala, 2010).

Children who report being happy and are able to communicate with their family are less likely to be regular users than others (Farmer & Hanratty, 2012). Parents should suspect recreational drug use if their child regularly appears irritable, inattentive, or drowsy.

Abuse of androgenic steroids or human growth hormone to enhance sports performance are yet other drugs that can be found in preteen children. Counsel children against this because abuse of steroids can lead to cardiovascular irregularities, uncontrollable aggressiveness, and possible cancer in later life (Oberlander & Henderson, 2012).

Cigarette smoking also begins in school-age children. With the sure knowledge that cigarette smoking plays a large part in the development of lung cancer and other serious respiratory illnesses, many parents assume their children will know better than to begin smoking. Smoking is viewed as an adult activity, however, so adopting the habit can be considered a giant step on the road to adulthood. Although the amount of cigarette advertising targeting young people as consumers has decreased, school-age children should still be taught to recognize advertising manipulation aimed at them. Caution children against experimenting with smokeless tobacco as well because this can lead to mouth and throat cancer, the same as smoking (Kamboj, Spiller, Casavant, et al., 2016). The use of e-cigarettes and vaping has increased, and the health risks of these products are still being uncovered (Duderstadt, 2015).

To discourage use of tobacco by school-age children, healthcare professionals and parents need to be role models of excellent nonsmoking health behavior in hope that children will follow their good examples.

### *QSEN Checkpoint Question 32.6*

#### **PATIENT-CENTERED CARE**

The school-age period is the time when many young people begin smoking. To design interventions that are effective and patient-centered, the nurse should begin by

acknowledging which of the following?

- a. Most children who try smoking do not like it.
- b. The media have occasionally exaggerated the risks of smoking.
- c. Many people view smoking as being an “adult” activity.
- d. Children under puberty cannot become addicted to smoking.

## CONCERNS OF THE SCHOOL-AGE CHILD AND FAMILY WITH UNIQUE NEEDS

A number of situations cause school-age children to have additional needs or concerns.

### The Child of Alcoholic Parents

Children who live with an alcoholic parent are at greater risk for having emotional problems than others because of the frequent disruption in their lives (Allen, Garcia-Huidobro, Porta, et al., 2016). In addition, because alcoholism may have a genetic base, children of alcoholics may be more likely to become alcoholics as adults. This makes it imperative for such children to learn effective coping behaviors. Immediate problems that can occur with children of alcoholic parents include:

- A feeling of guilt that they are the cause of the parent’s drinking
- Constant worry that the alcoholic parent will become sick or die, leaving the child alone; at the same time, the child may fear the alcoholic parent and wish the parent would leave
- A feeling of shame that prevents the child from inviting friends home or asking for help
- Decreased ability to trust adults because the parent has been unreliable so many times
- Poor nutrition and decreasing grades in school because the alcoholic parent’s behavior is so erratic that no regular schedule of bedtime or meals exists
- Anger at the alcoholic parent for drinking and at the nonalcoholic parent for not doing more to correct things
- Helplessness to change the situation

Such fears may be revealed by not only failing marks in school but also withdrawal from friends or social activities and delinquent behavior such as stealing. With adolescence may come depression, suicidal thoughts, or abuse of drugs or alcohol. School nurses are in an excellent position to identify such children, monitor their school progress, and refer them to organizations such as Al-Anon or Alateen ([www.al-anon.alateen.org](http://www.al-anon.alateen.org)) for support.

### The Child With a Long-Term Illness or Physical Cognitive Challenge

One of the biggest problems facing school-age children with a long-term illness or

physical challenges is time lost from school. This threatens not only their academic achievement but also their relationships with peers because it may make the child the “odd person out” with respect to making friends or joining clubs. Whether children are on home care or hospitalized, helping them to keep in contact with friends by texting, e-mail, or letters can help foster the socialization that is so important for continued development. Keeping up with schooling, whether it is homeschool or a distant learning option, is also important and an area where school nurses can play an important role (AAP, Council on School Health, 2016; Singer, 2013).

If at all possible, children with physical or cognitive challenges should attend regular schools and classes (inclusion) based on federal law (Public Law 99-457), which stipulates that all children have the right to equal education in the least restrictive environment possible (Sass-Lehrer & Bodner-Johnson, 1989). The decision as to which classroom would be best for an individual child is determined by a committee in each school system. You may need to advocate for a child with such a committee to demonstrate, for example, that although a child uses a wheelchair or needs continuous oxygen, the child will be able to contribute to regular classroom activities. It may be necessary to meet with a school nurse, teacher, or the child’s classmates (with the parents’ permission) to increase their understanding and acceptance of a child’s illness or to help arrange a period each day with a special resource teacher.

Urge parents of children with physical or cognitive challenges to assign them household chores just like other children and to allow them to participate in peer activities, such as Girl or Boy Scouts, in which accomplishment is encouraged. It is important for such children to develop a sense of industry or accomplishment so they can persevere in measures that will help them to be as independent as possible in the future (Fig. 32.10).

**Figure 32.10** A school-age child who is physically challenged is elated at a finish line. This accomplishment can go far toward her developing a sense of industry. (© Jose Carillo/Stock Boston.)

When you are caring for a school-age child who is chronically ill or physically challenged, choose short-term activities that can be completed independently, as with all school-age children. Conversely, be careful not to insult a child with tasks that are obviously not age appropriate. [Table 32.5](#) describes some nursing actions to help foster a sense of industry in children who are physically challenged or chronically ill.

**TABLE 32.5 NURSING ACTIONS THAT ENCOURAGE A SENSE OF INDUSTRY IN THE PHYSICALLY CHALLENGED OR CHRONICALLY ILL SCHOOL-AGE CHILD**

Category	Actions
Nutrition	Allow choices of food when possible and respect food preferences. Provide small food servings that child can finish, which encourages a sense of accomplishment.
Dressing	Ask for suggestions as to how bulky the child wants the dressing and where to apply tape.
Medicine	Teach the child the name and action of medicine. Encourage the child to keep track of medication times by clock or record. The child may feel more in control of injections or intravenous insertions

	if allowed to choose the site from among options offered. Allow the child to choose oral medicine form (capsules or liquid) if possible.
Rest	Establish clear rules for rest periods (e.g., reading or watching television is all right; playing a game is not).
Hygiene	Respect the modesty of a school-age child at an adult level. Allow as much choice as possible such as own clothing and timing of self-care.
Pain	Encourage the child to express and rate pain. Encourage the child to use distraction techniques, such as counting backward from 100 or imagery, during episodes of pain. Explain the source and cause of pain to give the child sense of mastery.
Stimulation	Encourage school work. Encourage activities that end in a product (e.g., putting together a picture puzzle rather than listening to a CD). Encourage paper-and-pencil games, such as connect the dots or tic-tac-toe. Card games provide social interaction and also encourage simple addition skills (make a deck from paper if one is not available). Don't suggest competitive games for children younger than age 10 years. Encourage using the playroom for socialization. Encourage the child to keep in contact with school friends by texting or e-mailing them.

### **Nutrition and the School-Age Child With a Challenge**

Food preparation and washing the dishes are times for socializing in most households. A school-age child who cannot be involved in these activities because of a physical challenge may need extra time during the day to make up for these lost socializing experiences, such as a specific hour set aside for talking or sharing a project that can be accomplished in one sitting.

When eating in cafeterias or at a friend's home, children who must eat special diets are usually tempted to select the same food as everyone else rather than limit what they choose. They may decline invitations rather than admit to requiring a special diet or needing help with eating. Ask at healthcare visits if any of these problems are present. Help children with special diets to plan ways they could be comfortable in social food-based settings such as bringing a party snack that is appropriate and can be easily eaten, or how to politely decline particular foods. Help children who are hospitalized to select a diet that is enjoyable as well as nutritious.

### **The Child Who Is Overweight or Obese**

In some communities, as many as 50% of school-age children are obese by body mass index guidelines. Some of these children have been overweight since infancy, and the natural prepubertal weight gain makes them become obese. Children with an endomorphic build (a natural tendency to accumulate body fat) are more likely to be obese at any time in life than those with a mesomorphic (normal) or ectomorphic (slender) build. Many families rely on fast-food meals several times a week, and such foods tend to be high in calories and fat and can lead to obesity. The lack of nutritional food in school lunches and the availability of foods of poor nutritional values available in vending machines compound the problem. Children of obese parents are also more apt to become obese, probably related to both genetic and environmental influences (E. Robinson & Sutin, 2016).

By preteen years, children who are obese begin to develop many of the same health problems as adults who are obese, such as hypertension, type 2 diabetes, and an elevated total cholesterol level, with possible atherosclerosis. They also may be ridiculed or bullied for their size and may be unable to participate on sports teams. This is strong evidence of the need for active measures to help preteens regulate their weight (Schantz, 2012). Children are influenced by promotional advertisements that influence food selection (Emond, Smith, Mathur, et al., 2015)

Those who become so obese that friends leave them out of activities or they cannot play sports because they tire so quickly may develop such a poor self-image they have little motivation for self-improvement. The type of weight-reduction program that will probably work best is one that emphasizes long-term lifestyle changes and contains features such as:

- An intake of about 1,200 calories a day (no more than 30% as fat), with lifestyle changes such as a structured family meal, eliminating eating or snacking in front of the television, decreasing portion sizes, and eliminating sugar-rich drinks.
- An active exercise program, including monitoring and limiting time spent in physical inactivity (e.g., watching television, playing computer and video games, surfing the Internet, texting).
- A counseling program to discuss aspects such as self-image and motivation to reduce weight.

Total caloric intake should not be reduced too drastically in children because they need calories to form new body tissue for continued growth. Caution children not to try faddish high-protein diets (as most adults should not) because such diets do not supply enough carbohydrates and may produce a heavy renal solute load (the breakdown product of proteins) to the kidneys. It helps if children aim to lose 5 lb over a short time rather than 50 lb over a year. This short-term goal coincides better with the task of developing industry.

Surgical techniques such as an intestinal bypass or lap band surgery are obviously extreme measures and inappropriate for children. Children who are obese might request one, however, in an attempt to avoid the not insignificant difficulty of long-term weight loss.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Altered family dynamics related to lack of motivation to reduce weight

**Outcome Evaluation:** Child states reasonable weight loss and exercise goals; discusses feelings about being overweight and reactions from schoolmates; expresses positive feelings about self-worth.

Motivating preteens to lose weight can be very difficult because they are not concerned when told that people who are obese do not live as long as average weight persons or that they have more heart attacks because this will happen so far in the future. They do, however, have a great respect for adults who are sympathetic to their problems. They follow better dietary regimens, therefore, if they are asked to do so by a respected adult, such as a nurse, or if they fear being left out of social interactions.

Overweight school-age children often do well if a healthy eating club is formed; they are not too young to participate in formal weight-control organizations. Having tangible support from other group members helps them follow tedious and monotonous nutrition patterns. As a way of increasing daily activity, preadolescents do well with formal exercise classes because, again, they enjoy the support from other children. In addition, encourage them to increase informal exercise, such as walking to and from school or walking a dog. Encourage coaches of childhood sports to accept children who are obese as part of a team, not because the child will necessarily benefit the team but because the exercise will benefit the child. Not only does exercise burn up calories but also if children's daylight hours are filled with activities and friends, they have less time to eat and spend less time in sedentary activities.

Lifestyle change is the ultimate goal for the entire family because obesity is usually a family problem. Rather than preparing special meals for just the child who is obese, the entire family probably needs to eat in a healthier manner. Because preadolescents do not generally prepare their own food, the person in the home who prepares meals requires as much information on the planned weight loss as the child. The old concepts that used to hold ("A clean plate is good" and "How can you leave food when people in other countries are starving?") may have to be changed so children and other family members reduce their intake appropriately. The importance of exercise should also be reflected in the home. Family members should not only encourage the child who is obese to exercise, but they should also partake in some form of daily activity with them. The encouragement of adequate fruit and vegetable consumption is helpful in achieving healthy eating patterns (Herrick, Rossen,

Nielsen, et al., 2015).

There is some danger in pointing out to preadolescents that they are overweight because some children can become so obsessed with losing weight that they develop eating disorders (see [Chapter 54](#)). Stressing that children should “become healthier” or “improve stamina” may be better advice than talking about losing weight ([Field, Sonnevile, Micali, et al., 2012](#)).

### *What If . . . 32.4*

**The nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to school-age growth and development (see [Box 32.1](#)). What would be a possible research topic to explore pertinent to this goal that would be applicable to Shelly’s family and that would also advance evidence-based practice?**

## **KEY POINTS FOR REVIEW**

- School-age children mature slowly but steadily. Their average annual weight gain is 3 to 5 lb; their increase in height is 1 to 2 in.
- At about age 10 years, children begin to develop secondary sex characteristics. Preparation for this helps them accept these changes positively.
- Deciduous teeth are lost, and permanent teeth erupt during the school-age period.
- Erikson’s developmental task for the school-age period is to gain a sense of industry or how to do things well.
- Common health problems during the school-age period include minor respiratory and gastrointestinal infections as well as dental caries and malocclusion.
- Common parental concerns during this period are language development, fears and anxieties, and behavior problems such as stealing and exposure to recreational drugs. Treating preventive strategies regarding these helps in planning nursing care that not only meets QSEN competencies but also best meets a family’s total needs.
- As many as 90% of parents of school-age children are dual-earner families. This means that many school-age children return home before their parents. Counseling families on ways to turn this independent time into a positive experience is helpful.
- Children in a concrete stage of operational thought are limited to understanding concepts that they can actually see. When health teaching, use concrete examples (actually let them hold a syringe, don’t just talk about it) to increase their understanding.
- School-age children thrive on rules. It is confusing for them when rules are changed (e.g., medicine will now be taken four rather than three times a day) unless they have a clear explanation of why the change is occurring.
- School-age children look for good adult role models; it is hard for them to feel confidence in an adult who isn’t honest with them or who fails to live up to their

expectations by not following through on promises.

- School-age children with a family tendency toward obesity may become overweight. Helping the family learn a healthier lifestyle is important.

### CRITICAL THINKING CARE STUDY

Georgia is a 6-year-old girl in the first grade whom you meet when working as a school nurse. She lives with her 10-year-old sister and her parents in a three-bedroom home. Her father works long shifts as a coal miner, and her mother cleans houses for a commercial housecleaning firm.

1. Georgia’s mother tells you she received a note from her teacher asking her to help Georgia “speak more clearly.” Is this a common concern with early school-age children? What further information do you need to know to evaluate whether this is a concern?
2. Georgia’s teacher is also concerned because Georgia does not share well. Is this a developmental step that Georgia should have already mastered?
3. Georgia’s mother wants her to be popular and so has enrolled her in dance classes two times per week, a school soccer club four times per week, violin lessons once per week, and a gymnastics class twice per week. Despite all the effort she puts in driving her daughter to all these sessions, the mother tells you Georgia doesn’t act grateful. She asks you why Georgia isn’t interested in making friends.

## Nursing Care of a Family With an Adolescent

*Raul is a 15-year-old teenager you meet at an adolescent clinic. His chief concern is a head cold. He has numerous acne lesions on his forehead and cheeks. His parents tell you Raul seemed depressed for a long time after his girlfriend broke up with him but now seems happy again. They are pleased to see him maturing so much that he recently gave away his collection of baseball cards to a young neighbor. You mention to Raul a decongestant would probably make him feel better. He asks you how many pills it would take to kill someone and then jokes he was kidding. His healthcare provider prescribes a decongestant and suggests Raul return in 6 months.*

*The previous chapter discussed school-age children and the capabilities children develop during that time period. This chapter adds information about the changes, both physical and psychosocial, which occur during adolescence. Such information builds a base for care and health teaching for this age group.*

**Did Raul have some needs that were not met by his clinic visit?**

### KEY TERMS

adolescence  
comedones  
formal operational thought  
glycogen loading  
identity  
puberty  
role confusion  
stalking  
substance use disorder

### OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe normal growth and development and common parental concerns of the adolescent period.
2. Identify 2020 National Health Goals related to adolescents that nurses could help the nation achieve.
3. Assess an adolescent for normal growth and development milestones.
4. Formulate nursing diagnoses related to adolescent growth and development or common parental concerns.
5. Identify expected outcomes for nursing care of an adolescent as well as help parents manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care related to growth and development or special needs of an adolescent, such as organizing a discussion group on ways to prevent substance use disorders.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of adolescent growth and development with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

**Adolescence** is generally defined as the period between ages 13 and up to 20 years, a time that serves as a transition between childhood and becoming a late adolescent. It can be divided into an early period (13 to 14 years), a middle period (15 to 16 years), and a late period (17 to 20 years). During all periods, adolescence is defined not so much by chronologic age as by physiologic, psychological, and sociologic changes. The drastic change in physical appearance and the change in expectations of others (especially parents) that occur during the period can lead to both emotional and physical health concerns (Sass & Kaplan, 2016).

Adolescents invariably feel a sense of pressure throughout this period because they are mature in some respects but still young in others. For example, an adolescent's sexual interests are awakening, yet personal or parental pressures discourage sexual exploration. An adolescent may not feel mature enough to live away from home, yet parents and teachers may urge the adolescent to apply for an out-of-town college. This duality causes a major dilemma or conflict for an adolescent, leading to many of the growth and developmental concerns of the age (Ahern & Norris, 2011). The 2020 National Health Goals related to adolescence are shown in [Box 33.1](#).

### BOX 33.1

#### Nursing Care Planning Based on 2020 National Health Goals

Health teaching in the adolescent years is important because healthy habits begun at this time can influence health over a lifetime. For this reason, a number of 2020 National Health Goals relate to adolescent health, including:

- Reduce the number of adolescents who are obese from a prevalence of 17.9% to 16.1%.
- Reduce the proportion of high school students engaging in binge drinking from 25.2% to 22.7%.
- Reduce cigarette use by adolescents from 19.5% to 16%.
- Reduce the rate of smokeless tobacco use by adolescents from 8.9% to 6.9%.
- Reduce the proportion of adolescents who are offered, sold, or given an illegal drug on school property from 22.7% to 20.4%.
- Reduce the proportion of adolescents who report they rode, during the previous 30 days, with a driver who was drinking alcohol from 28.3% to 25.5%.
- Reduce the rate of suicide attempts by adolescents from 1.9% to 1.7%.
- Increase the proportion of adolescents who meet current federal physical activity guidelines for aerobic physical activity from 18.4% to 20.2% ([U.S. Department of Health and Human Services, 2010](#); see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by educating adolescents about the use of cigarettes, smokeless tobacco, alcohol, and substance use disorder and by acting as support people for adolescents during times of crisis to help prevent self-injury or suicide.

### *Nursing Process Overview*

#### FOR HEALTHY DEVELOPMENT OF AN ADOLESCENT

##### **ASSESSMENT**

Health maintenance visits during adolescence may become more irregular because adolescents may not seek care from healthcare facilities on their own unless they are ill. Until adolescents need a physical examination for athletic or some other clearance, they are often not seen for health assessments. When adolescents are accompanied by their parents at health visits, it is best to obtain a health history separately from the adolescent to promote independence and responsibility for self-care. When performing physical examinations on adolescents, be aware they may be very self-conscious of their body. They need health assurance and appreciate comments such as “Your blood pressure is 120/70, which is healthy,” so they can learn more about their rapidly changing bodies.

##### **NURSING DIAGNOSIS**

Nursing diagnoses for adolescents can cover a wide range of topics. Frequently used diagnoses related to adolescents and their families include:

- Health-seeking behaviors related to normal growth and development
- Low self-esteem related to facial acne

- Anxiety related to concerns about normal growth and development
- Risk for injury related to peer pressure to use alcohol and drugs
- Risk for disease related to sexual activity
- Readiness for enhanced parenting related to increased knowledge of teenage years

## **OUTCOME IDENTIFICATION AND PLANNING**

When planning care with adolescents, respect the fact that they have a strong desire to exert independence or do things their own way. This means they are not likely to adhere to a plan of care that disrupts their lifestyle or makes them appear different from others their age. Because of this, including them in planning is essential so the plan will be agreeable and accepted. Establishing a contract, such as asking an adolescent to agree to take medication daily, may be the most effective means to reach a mutual understanding.

Remember that adolescents are very oriented to the present, so a program that provides immediate results, such as increased respiratory function, will usually be carried out well. In contrast, a regimen oriented toward the future, with long-term goals such as preventing hypertension at middle age, may not be as successful. This does not mean it is not important to teach adolescents about the necessity of reducing future health risks—by eating well, not smoking, and generally taking care of their bodies—but that information will be best accepted if geared as much as possible to specific, short-term benefits to their health. Refer patients and families to helpful websites and other resources when appropriate (see [Chapter 28](#)).

## **IMPLEMENTATION**

Adolescents tend to do poorly with tasks someone tells them they *must* do. Integrating the adolescents in their plan of care typically helps them be successful. Adolescents have little patience with adults who do not demonstrate the behavior they are being asked to achieve; a parent or nurse who smokes and asks an adolescent not to smoke, for example, will probably not be successful. For best results, evaluate how an intervention appears from an adolescent's standpoint before beginning teaching.

## **OUTCOME EVALUATION**

An evaluation of expected outcomes should include not only whether desired outcomes have been achieved but also whether adolescents are pleased with the outcome. Individuals will have difficulty accomplishing desired goals as adults unless they have high self-esteem that includes feeling secure in their new body image.

Examples of outcome criteria that might be established include:

- Patient states she feels good about herself even though she is the shortest girl in her class.
- Patient states he has not consumed alcohol in 2 weeks.
- Parents state they feel more confident about their ability to parent an adolescent.
- Patient states she feels high self-esteem despite persistent facial acne.

---

## Growth and Development of an Adolescent

Adolescents both grow rapidly and mature dramatically during the period from age 13 to 18 to 20 years.

### PHYSICAL GROWTH

The major milestones of physical development in the adolescent period are the onset of puberty at 8 to 12 years of age and the cessation of body growth around 16 to 20 years (Sass & Kaplan, 2013). Between these milestones, physiologic growth and development of adult coordination occur. At first, the gain in physical growth is mostly in weight, leading to the stocky, slightly obese appearance of prepubescence; later comes the thin, gangly appearance of late adolescence.

Most girls are 1 to 2 in. (2.4 to 5 cm) taller than boys coming into adolescence but generally stop growing within 3 years from menarche and so are shorter than boys by the end of adolescence. Boys typically grow about 4 to 12 in. (10 to 30 cm) in height and gain about 15 to 65 lb (7 to 30 kg) during their teenage years. Girls grow 2 to 8 in. (5 to 20 cm) in height and gain 15 to 55 lb (7 to 25 kg). Growth stops with closure of the epiphyseal lines of the long bones, which occurs at about 16 or 17 years of age in females and about 18 to 20 years of age in males.

Because the heart and lungs increase in size more slowly than the rest of the body, adolescents may have insufficient energy and become fatigued trying to finish the various activities that interest them. Pulse rate and respiratory rate decrease slightly (to 70 beats/min and 20 breaths/min, respectively), and blood pressure increases slightly (to 120/70 mmHg) by late adolescence. With adulthood, blood pressure becomes slightly higher in males than in females because more force is necessary to distribute blood to the larger male body mass.

All during adolescence, androgen stimulates sebaceous glands to extreme activity, sometimes resulting in acne, a common adolescent skin problem. Apocrine sweat glands (i.e., glands present in the axillae and genital area, which produce a strong odor in response to emotional stimulation) form shortly after puberty. Adolescents begin to notice they must shower or bathe more frequently than when they were younger in order to be free of body odor because of this change.

### Teeth

Adolescents gain their second molars at about 13 years of age and their third molars (wisdom teeth) between 18 and 21 years of age. Third molars may erupt as early as 14 to 15 years of age. The jaw reaches adult size only toward the end of adolescence, however. As a result, adolescents whose third molars erupt before the lengthening of the jaw is complete may experience pain and may need these molars extracted because they do not fit their jawline (Marciani, 2012).

### What If . . . 33.1

**Raul, a 15-year-old male, asks the nurse if he’s going to grow some more; being the shortest boy in his gym class makes him feel “left out.” Also, he asks if his teeth are white enough. Are these common concerns of adolescents?**

## Puberty

**Puberty** is the time at which an individual first becomes capable of sexual reproduction. A girl has entered puberty when she begins to menstruate; a boy enters puberty when he begins to produce spermatozoa. These events usually occur between ages 11 and 14 years. The age of first menstruation in girls is gradually decreasing from a mean of 13 years to 12.4 years, which is probably related to more weight gain in girls (Ledger, 2012). Puberty creates many questions for early teenagers about what is normal and what is not (Marván & Molina-Abolnik, 2012).

## Secondary Sex Changes

Secondary sex characteristics, such as body hair configuration and breast growth, are those characteristics that distinguish the sexes from each other but that play no direct part in reproduction. The secondary sex characteristics that began in the late school-age period (see Chapter 32) continue to develop during adolescence. Typical stages of sexual maturation are shown in Table 33.1.

**TABLE 33.1 SEXUAL MATURATION IN ADOLESCENTS**

Age (years)	Males	Females
13–15	Growth spurt continuing; pubic hair abundant and curly; testes, scrotum, and penis enlarging further; axillary hair present; facial hair fine and downy; voice changes happen with annoying frequency	Pubic hair thick and curly, triangular in distribution; breast areola and papilla form secondary mound; menstruation is ovulatory, making pregnancy possible
15–16	Genitalia adult; scrotum dark and heavily rugated; facial and body hair present; sperm production mature	Pubic hair curly and abundant; may extend onto medial aspect of thighs; breast tissue appears adult; nipples protrude; areolas no longer project as separate ridges from breasts; may have some degree of facial acne

16–17	Pubic hair may extend along medial aspect of thighs; testes, scrotum, and penis adult in size; may have some degree of facial acne; gynecomastia (enlarged breast tissue), if present, fades	End of skeletal growth
17–18	End of skeletal growth	

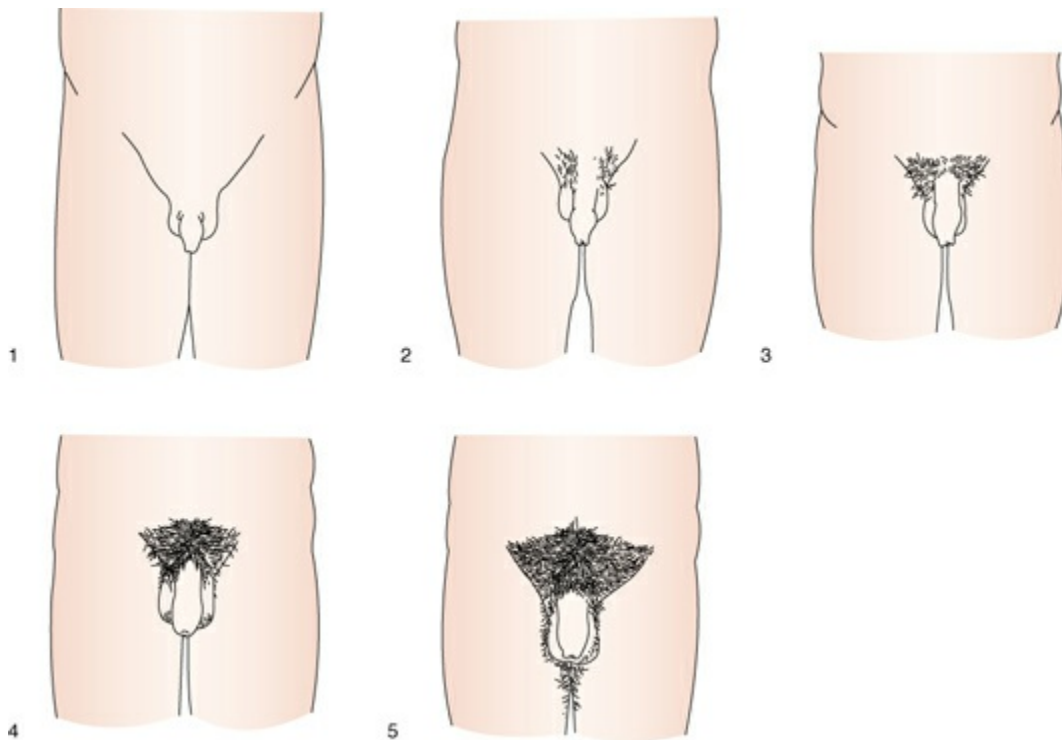

From Tanner, J. M. (1962). *Growth at adolescence* (2nd ed.). Oxford, United Kingdom: Blackwell.

Sexual maturity in males and females is classified according to Tanner stages, named after the original researcher on sexual maturity (Tanner, 1962). Tanner stages of female sexual development are shown in Figure 33.1, and stages of male genital growth are shown in Figure 33.2.

**Figure 33.1** (A) Female breast development. *Sex maturity rating 1* (not shown): Prepubertal; elevation of papilla only. *Sex maturity*

*rating 2*: Breast buds appear; areola is slightly widened and projects as a small mound. *Sex maturity rating 3*: Enlargement of the entire breast with no protrusion of the papilla or the nipple. *Sex maturity rating 4*: Enlargement of the breast and projection of areola and papilla as a secondary mound. *Sex maturity rating 5*: Adult configuration of the breast with protrusion of the nipple; areola no longer projects separately from remainder of breast. **(B)** Female pubic hair development. *Sex maturity rating 1*: Prepubertal; no pubic hair. *Sex maturity rating 2*: Straight hair extends along the labia and, between rating 2 and 3, begins on the pubis. *Sex maturity rating 3*: Pubic hair increases in quantity, becomes darker, and is present in the typical female triangle but in a smaller quantity. *Sex maturity rating 4*: Pubic hair more dense, curled, and adult in distribution but less abundant. *Sex maturity rating 5*: Abundant, adult-type pattern; hair may extend onto the medial part of the thighs. (Adapted from Tanner, J. M. [1962]. *Growth at adolescence* [2nd ed.]. Oxford, United Kingdom: Blackwell.)

**Figure 33.2** Male genital and pubic hair development. Ratings for pubic hair and for genital development can differ in a typical boy at any given time because pubic hair and genitalia do not necessarily develop at the same rate. *Sex maturity rating 1*: Prepubertal; no pubic hair; genitalia unchanged from early childhood. *Sex maturity rating 2*: Light, downy hair develops laterally and later becomes dark; penis and testes may be slightly larger; scrotum becomes more textured. *Sex*

*maturity rating 3*: Pubic hair extends across the pubis; testes and scrotum are further enlarged; penis is larger, especially in length. *Sex maturity rating 4*: More abundant pubic hair with curling; genitalia resemble those of an adult; glans has become larger and broader; scrotum is darker. *Sex maturity rating 5*: Adult quantity and pattern of pubic hair, with hair present along inner borders of thighs; testes and scrotum are adult in size. (Adapted from Tanner, J. M. [1962]. *Growth at adolescence* [2nd ed.]. Oxford, United Kingdom: Blackwell.)

### **QSEN Checkpoint Question 33.1**

#### **INFORMATICS**

The nurse realizes Raul is concerned about developing body odor and that he has consulted some websites that address this problem. The nurse recognizes a valid and reliable website would cite which aspect is true of body odor in adolescents?

- It is largely dependent on ethnicity and body type.
- It is caused by an increase in the activity of apocrine glands.
- Poor hygiene is the main cause of adolescent body odor.
- Body odor can result from clogged sebaceous glands.

Look in [Appendix A](#) for the best answer and rationale.

#### **DEVELOPMENTAL MILESTONES**

The same assessment categories of younger children continue to apply to adolescents.

#### **Play or Recreation**

Thirteen-year-old children change from school-age activities of active games to more adult forms of recreation such as listening to music, texting or chatting, or following a sports team's wins and losses. Team (or school) loyalty becomes intense and following a coach's instructions becomes mandatory, similar to the loyalty 6-year-old children showed toward their first-grade teacher. Overuse injuries from athletics occur in early adolescence until adolescents learn more about their limits and begin to respect the advice of adults on being well prepared and trained for sports participation.

Most adolescents spend a great deal of time just talking with peers as social interaction, either face-to-face or through electronic media. Conflict can arise if parents disapprove of the number of hours spent in this activity, afraid their children are wasting important hours, or at least exchanging a great deal of trivial conversation. For an adolescent, however, talking is no more a waste of time than was imaginative play as a preschooler. It is a major way they learn about values and responsibilities ([Box 33.2](#)).

#### **BOX 33.2**

#### **Nursing Care Planning to Respect Cultural Diversity**

In the United States, as in most developed countries, adolescence covers a long time span. In developing countries, in contrast, adolescence tends to be much shorter because children must take full-time jobs early in life to help support their families. Socioeconomic factors also influence the length of adolescence across all cultures. Recognizing that adolescents may have differing responsibilities and life experiences based on cultural expectations can be useful when making a progress assessment. In a family in which an adolescent is expected to begin working full-time or marry at an early age, you may need to include in health teaching factors such as occupational hazards or the effects of a job, family, and financial stress on an adolescent. Readiness for early childbearing may also be important.

Beginning at age 16 years, most adolescents want part-time jobs to earn money. Such jobs can teach young people how to work with others, accept responsibility, and how to save and spend money wisely. For their own sake and that of the children they will care for, if adolescents plan to babysit, they first need to learn basic rules of childcare and safety. In most communities, schools or Red Cross organizations offer courses in babysitting just for the teenager.

Many adolescents engage in charitable endeavors during middle to late adolescence as a form of recreation. They do well organizing and supervising swimming or gym programs for physically challenged children or participating in marathons. A high school club may be organized to send money to children overseas. These activities fulfill an adolescent's need for satisfying interaction with others as well as indicators of maturity and willingness to accept adult roles.

## EMOTIONAL DEVELOPMENT

According to Erikson (Dunkel & Harbke, 2017), the developmental task in early and mid-adolescence is to form a sense of identity versus role confusion. In late adolescence, it is to form a sense of intimacy versus isolation.

### Early Adolescent Developmental Task: Identity Versus Role Confusion

The task of forming a sense of **identity** is for adolescents to decide whom they are and what kind of person they will be. The four main areas in which they must make gains to achieve a sense of identity include:

1. Accepting their changed body image
2. Establishing a value system or what kind of person they want to be
3. Making a career decision
4. Becoming emancipated from parents

If young people do not achieve a sense of identity, they can have little idea what kind of person they are or may develop a sense of **role confusion** (Dunkel & Harbke, 2017). This can lead to difficulty functioning effectively as adults because they are unable, for example, to decide what stand to take on a particular issue or how to

approach new challenges or situations. This can lead them to exhibit acting-out (attention-getting) behaviors because they believe it is better to have a negative image than to have none at all.

## Body Image

Adolescents who were able to develop a strong sense of industry during their school-age years learned to solve problems and are best equipped to adjust to the changing body image that comes with adolescence. This adjustment to changes is not always easy, however, because adolescents can feel disappointed with their final height or general appearance.

As adolescents are usually their own worst critics with regard to their bodies, they may need help from healthcare providers to realize the characteristics that make someone creative, compassionate, and fun to be with, not one's physical appearance, are the qualities on which lasting relationships are built.

## Self-Esteem

Like body image, self-esteem may undergo major changes during the adolescent years and can be challenged by all the changes that occur during adolescence (Garzon & Dunn, 2013). Help parents understand how important it is for adolescents to have immediate successes such as making the high school basketball team or having a date for the senior prom. Parental comments, such as "When you're older, these things won't be so important," are not likely to erase the hurt that comes from being 16 years old and not being included in such major events. Compassionate understanding ("It's hard to be left out") is a better communication technique.

In recent years, a number of researchers have looked at the differences in the way boys and girls handle these emotional crises of adolescence. Several researchers have proposed that adolescence is a period of particular crisis for girls who are trying to find a place in a male-dominated society. The sociologist Carol Gilligan and her colleagues interviewed more than 500 girls between the ages of 7 and 16 years over a 5-year period and found many girls who, at age 11 years, were feisty, confident, and eager to speak their minds became hesitant to voice their opinions aloud by early adolescence, having pushed their earlier resistance "underground" (Gilligan, 1982; Taylor, Gilligan, & Sullivan, 1995). Gilligan (Gilligan, 1982; Taylor et al., 1995) tied this change to a growing realization among girls that their forthrightness may not be appealing to boys. They begin to self-censor, hoping to become more popular. Girls also struggle with a tug of war between valuing academic (or athletic) success (i.e., men's values) over maintaining close friendships (i.e., women's values).

Although the turmoil of adolescence can be just as confusing to boys as it is to girls, Gilligan (Gilligan, 1982; Taylor et al., 1995) hypothesized boys may feel less pressure as they become adults because they learn more easily to be competitive, independent, and separated from feelings. Girls, because they are encouraged to maintain their

concern for people throughout their lives, are caught in a conflict between that and being independent and competitive. This makes girls at risk for more conflicting feelings throughout adolescence.

Long-term psychological problems, notably eating disorders, which occur in both boys and girls, may be one unfortunate result of repressing inborn feelings in order to conform. Parents can help both girls and boys deal with these conflicts by encouraging them to maintain their honesty and integrity.

### Value System

Adolescents develop their values throughout their childhood as they interact with their family. As they increase the amount of time they spend with their peer group, they may question these values and participate in experiences that may put them at risk for physical and/or psychological harm. Identifying risk-taking behaviors and offering guidance and support is important in promoting the health of the adolescent.

### Social Coupling

In early adolescence, individuals tend to dress and behave similarly to other members of their peer group (Fig. 33.3). Bullying behavior may be directed at individuals who don't conform to or associate with a peer group. Bullying behaviors should be identified, and the appropriate interventions should be initiated.

**Figure 33.3** Adolescents have a need to interact with peers to learn more about themselves and others.

During adolescence, individuals begin to explore their sexual preferences and may question their gender identity. Encourage an open dialogue with adolescents to assist them to process their feelings and establish their own identity. Counseling may be helpful to assist with family communication if the family is not accepting.

### Career Decisions

The adolescent may identify an educational and career trajectory during self-discovery of personal positive attributes. This process may take several years to achieve, and it varies for each individual. It is common for adolescents to seek and experiment with multiple roles before reaching a decision that is rewarding. Some school-age children do poorly in school during preadolescence but, as soon as they choose a career, show increased interest in learning as they come to see education as relevant to their future.

### Emancipation From Parents

Emancipation from parents can become a major issue during the middle and late adolescent years for two reasons. Some parents may not yet be ready for their child to be totally independent, and some adolescents may not yet be sure they want to be on their own. They may fight bitterly for a right—for example, to stay out until midnight or later on a weekend—and then never use the privilege once they have gained it. Winning the battle may be more important than exercising the newly won right.

In many instances, the closer the tie adolescents feel with their parents, the more severe can be their struggle. As long as parents are reasonable in their restrictions, the amount of noise being made may be proof the ties are strong and separation or emancipation is not easy.

Encourage parents to give adolescents more freedom in areas such as choosing their own clothes or after-school activities; at the same time, help parents continue to place some restrictions on adolescent behavior (“You must drive the car safely,” “We must know where you go after school”). These are not unreasonable rules and actually help adolescents accept the responsibility that comes with independence.

Both parents and adolescents may need help to understand that emancipation does not mean severance of a relationship but rather a change in a relationship because people who are independent of one another can have even better relationships than those who are dependent on one another. It can be helpful to remind parents this step is actually no different from the one children accomplished when they grew from infants to toddlers, when they changed from wanting to be held and rocked to wanting to run. If parents can think of it in this light, they will gain a better perspective and may realize they will not lose the children because they become adults. There are ex-wives and ex-husbands. There are no ex-children.

### **Late Adolescent Developmental Task: Intimacy Versus Isolation**

Developing a sense of intimacy means a late adolescent is able to form long-term, meaningful relationships with persons of the opposite as well as their same sex (Erikson, 1950, 1968). Those who do not develop a sense of intimacy are left feeling isolated; in a crisis situation, they have no one to whom they feel they can turn to for help or support. A sense of intimacy is closely related to the sense of trust learned in the first year of life because, without the feeling that one can trust others, building a sense of intimacy is difficult.

Some adolescents require help from parents or other adults to differentiate between sound relationships and those that are based only on sexual attraction. Never do adolescents need an adult to listen to them more than when they are struggling with the heart-rending feelings of young love or wondering whether a particular love relationship is temporary or lasting.

Some parents may not be able to listen to their adolescent without interjecting their own opinions because they worry that relationships based on infatuation will lead to a sexual relationship. Parents should feel an obligation to inform their children of their feelings about early sexual relationships. At the same time, they have to be realistic that some adolescents will not follow their advice as shown by the rising rates of teenage pregnancy and sexually transmitted diseases, including HIV ([Centers for Disease Control and Prevention \[CDC\], 2012c](#)). If parents suspect their adolescent is sexually active, counsel them to be certain their child is knowledgeable about safer sex practices (see [Chapter 22](#) for a discussion of adolescent pregnancy).

Some adolescents may believe intense sexual yearnings or peer pressure can be alleviated only by a sexual act. They can be reassured that they are pleasant people to be with because of the many fine qualities they possess and that sexual intercourse can be delayed until two persons have come to know these qualities in each other and have made a mutual commitment based on a deeper level than simply physical passion.

In our busy modern society in which adolescents engage in such a variety of activities, they may need help learning how to project themselves into another person's situation and to ask themselves how the world looks from that position. This concept, *empathy*, is the ability to understand the feelings of another, or, in other words, a developed sense of intimacy in its finest form.

## Socialization

Early teenagers may feel more self-doubt than self-confidence when they meet another adolescent with whom they would like to begin a lasting relationship. The voices of most boys have not yet dependably deepened; this makes them unable to trust their voices to carry the serious tone they wish to convey. Most girls' bodies have not yet fully developed; they may look at themselves in a mirror, compare their profiles with those of models in popular magazines, and feel inadequate.

Both male and female early adolescents tend to be loud and boisterous, particularly when someone whose attention they would like to attract is nearby. They are impulsive and very much like 2-year-old children in that they want what they want immediately, not when it is convenient for others.

Many 13-year-olds begin to experience "crushes," or infatuations with schoolmates. At this age, however, they may spend more time longing for someone than they do instituting an in-depth and rewarding relationship. They have too little experience with life and too limited a frame of reference yet to know how to offer a deep commitment to another or accept one from that person.

By age 14 years, teenagers have become quieter and more introspective. They are

becoming used to their changing bodies, have more confidence in themselves, and feel more self-esteem.

Adolescents watch adults carefully during this period, searching for good role models with whom they can identify. They usually have a hero—a film star, writer, scientist, or athlete—whom they want to grow up to be like. They may form a friendship with an older adolescent, trying to imitate that person in everything from thoughts to clothing. If the older adolescent has dropped out of school or plays a particular sport, the younger person may express a wish to drop out or train for that sport, too.

Idolization of famous people or older adolescents of this nature fades as adolescents become more interested in forming reciprocal friendships. Attachments to older adolescents are often severed abruptly and painfully as older teenagers make it clear they are more interested in being with people their own age. Rejection by an older member of a pair forces the younger member to turn to his or her own-age friends and ends the intense hero worship so typical of early adolescence.

Most 15-year-olds fall “in love” five or six times a year. However, many of these relationships are based on attraction because of physical appearance, not because of inner qualities or characteristics that are compatible with their own. Because infatuation is fleeting, it can lead to extremely intense but brief attachments that fade once the two young people discover they have little in common. Beginning romantic attachments this often, however, does not mean their feelings are any less strong or that they feel any less pain when the relationship ends (Fig. 33.4).

**Figure 33.4** Although infatuation or love can be fleeting, adolescents may feel intensely for another.

By age 16 years, boys are becoming sexually mature (although they continue to grow taller until about 18 years of age). Both sexes are better able to trust their bodies than they were the year before. By age 17 years, they tend to have adult values and responses to events. They have left behind the childish behaviors they used in early adolescence—shoving and punching—to get the attention of others.

## **COGNITIVE DEVELOPMENT**

The final stage of cognitive development, the stage of **formal operational thought**, begins at age 12 or 13 years and grows in depth over the adolescent years, although it may not be complete until about age 25 years (Piaget, 1969). This step involves the ability to think in abstract terms and use the scientific method (i.e., deductive reasoning) to arrive at conclusions. The problems that adolescents are asked to solve in school depend on this type of thought. Problem solving in any situation depends on the ability to think abstractly and logically.

With the ability to use scientific reasoning, adolescents can plan their future. They

can create a hypothesis (What if I go to college? What if I don't?) and think through the probable consequences (In the long run, I'll earn more money, or I could begin earning money immediately).

## MORAL AND SPIRITUAL DEVELOPMENT

Because adolescents enlarge their thought processes to include formal reasoning, they are able to respond to the question "Why is it wrong to steal from your neighbor's house?" with "It would hurt my neighbor by requiring him to spend money to replace what I stole," rather than with the immature response of the school-age child, "The police will punish me." Some adolescents, however, may have difficulty envisioning a department store or a large corporation as capable of suffering economic loss from stealing, a concept that can contribute to the frequent practice of petty shoplifting at this age.

Almost all adolescents question the existence of God and any religious practices they have been taught (Kohlberg, 1984). This questioning is a natural part of forming a sense of identity and establishing a value system at a time in life when they draw away from their families.

### QSEN Checkpoint Question 33.2

#### QUALITY IMPROVEMENT

The nurse evaluates some of the anticipatory guidance that provided to Raul with the goal of fostering his sense of identity. The nurse identifies which statement as suggesting he is successfully working toward this goal? Select all that apply.

- a. "I'm debating whether I'd like to be a pilot or a race car driver."
- b. "I ask my parents at least once a week to let me do more things."
- c. "I handle money at my part-time job and it's sometimes tempting to take some of it."
- d. "I'm getting used to being so much taller than my younger sister."

Look in [Appendix A](#) for the best answer and rationale.

## Health Promotion for an Adolescent and Family

Because their judgments are still limited, adolescents still need guidelines in reference to safety, nutrition, and daily care. These are always excellent topics for discussion at healthcare visits.

### PROMOTING ADOLESCENT SAFETY

Unintentional injuries, most commonly those involving motor vehicles, are the leading cause of death among adolescents. Although teenagers are at the peak of physical and sensorimotor functioning, their need to rebel against authority or to gain attention

through risk-taking leads them to take careless actions, such as speeding or driving while intoxicated.

In the interest of an adolescent's safety and that of others, parents need to have the courage to insist on emotional maturity rather than age as the qualification for obtaining a driver's license. Adolescents need to take seriously the graduated licensing requirements for their state so they not only learn the techniques of safe driving but also learn a sense of responsibility toward others (Williams, McCartt, & Sims, 2016).

Some adolescents dismiss seat belts as childish and so need extra instruction that it is wise to use every safety precaution available when in a motor vehicle (Chen, Cao, & Logan, 2012). Equally dangerous for adolescents are motorcycles, motorbikes, and motor scooters, which are appealing because of their low cost and convenience in parking. Both drivers and riders should wear safety helmets to prevent head injury, long pants to prevent leg burns from exhaust pipes, and a full body covering to prevent abrasions in case of an accident. Advise adolescents who choose these forms of transportation to be as familiar with safety rules as automobile drivers and to wait until they are emotionally mature enough to use sound driving judgment.

Although drowning tends to occur in younger children, it does occur in adolescents when good swimmers go beyond their capabilities on dares or in hopes of impressing friends. Teaching water safety, such as not swimming alone or when tired, is as important as teaching the mechanics of swimming (CDC, 2012b).

Other common causes of death in adolescents are homicide and self-harm (i.e., suicide) (Swahn, Ali, Bossarte, et al., 2012). These are related to the easy accessibility of guns when added to depression, binge drinking, and impulsivity. Gang violence and the desire to protect themselves are additional factors. Unintentional gunshot injuries increase in early adolescence, often for the same reason that drowning increases: Youngsters want to impress friends by showing they can handle guns. Be certain that firearm safety is taught creatively through problem solving rather than lecturing because teenagers tend to rebel against such lectures or claim that they have heard it all before.

Athletic injuries, especially overuse injuries from poor conditioning, tend to increase in number during adolescence because of the vigorous level of competition that occurs in organized sports (Khan, Thompson, Blair, et al., 2012). Types of athletic injuries are discussed in Chapter 52. Health teaching measures to prevent unintentional injuries, especially while participating in athletics, are summarized in Box 33.3.

### BOX 33.3

#### Nursing Care Planning to Empower a Family

#### MEASURES TO PREVENT UNINTENTIONAL INJURIES IN ADOLESCENTS

**Q.** Raul's mother tells you, "My son doesn't always use mature judgment. How can I keep him safe from accidents?"

A. Teaching the following points can be helpful to him:

### Unintentional Health Teaching Measure Injury

Motor vehicle	Always use a seat belt whether a driver or a passenger. Never use a cell phone or text while driving. Do not drink alcohol while driving and always refuse to ride with anyone who has been drinking (name a designated driver or arrange with your parents to be picked up or provide money for a taxi). Wear a helmet and long trousers as driver or passenger on a motorcycle. Accepting dares has no place in safe driving. Take graduated driver programs seriously so you learn safe driving habits for both two-wheel and four-wheel vehicles.
Firearms	Always consider all guns loaded and potentially lethal. Learn safe gun handling before attempting to clean a gun or hunt.
Drowning	Learn how to swim. Follow safe water rules, such as never swimming alone, no diving into the shallow end of swimming pools, no hyperventilating before swimming underwater, and no swimming beyond one's own limit. Taking dares has no place in water safety.
Sports	Use protective equipment, such as facemasks for hockey and pads and a helmet for football. Do not attempt to participate beyond physical limits. Keep well hydrated by drinking fluid before and after play. Careful preparation for sports through training is essential to safety. Recognize and set one's own limit for sports participation.

## PROMOTING NUTRITIONAL HEALTH FOR AN ADOLESCENT

Adolescents experience such rapid growth that they may always feel hungry (Fig. 33.5). If their eating habits are unsupervised, because of peer pressure and when in a hurry to get to other activities, they tend to eat faddish or quick snack foods rather than more nutritionally sound ones. Some adolescents turn away from the basic MyPlate food groups to eat sweets, soft drinks, or empty-calorie snacks and so are left poorly nourished. This type of eating pattern, combined with a lack of exercise, also leads to obesity (Wengle, Hamilton, Manlhiot, et al., 2012).

**Figure 33.5** Adolescents experience rapid physical growth, so typically, they eat frequently. (© Billy Barnes/Stock Boston.)

One form of adolescent rebellion is to refuse to eat foods that parents stress as important. Parents who stock their kitchens with healthy snacks such as fruit and vegetables and who are willing to meet their adolescents halfway in terms of food preferences can be more certain their child is eating nutritious foods than if such foods aren't available. Giving an adolescent some responsibility for food planning or meals, such as making dinner every Wednesday night, can teach some important lessons about nutrition without conflict.

Adolescents who are slightly obese because of prepubertal changes may begin low-calorie or starvation diets during adolescence to lose weight. Some diet so excessively they develop eating disorders such as bulimia or anorexia nervosa (see [Chapter 54](#)). A weight-loss diet is appropriate during adolescence, but it must be supervised to ensure the adolescent is consuming sufficient calories and nutrients for growth. For example, many adolescents entirely omit breads and cereals to lose weight rather than just reducing the amounts they eat. Diets such as these can be deficient in vitamins B<sub>1</sub> (thiamine) and B<sub>2</sub> (riboflavin), which are necessary for growth.

### **Recommended Dietary Reference Intakes**

An adolescent needs an increased number of calories over that needed previously to support the rapid body growth that occurs. Foods must come from a variety of sources to supply necessary amounts of carbohydrates, vitamins, protein, and minerals.

The nutrients that are most apt to be deficient in both male and female adolescent diets are iron, calcium, and zinc. Iron is necessary to meet expanding blood volume requirements. Females require a high iron intake not only because of this increasing blood volume but also because iron begins to be lost with menstruation. Girls with a

heavy menstrual flow (i.e., menorrhagia) and especially those who participate in strenuous athletics may need to take an additional iron supplement to prevent iron-deficiency anemia (Bruinvels, Burden, Brown, et al., 2016).

Increased calcium and vitamin D plus physical exercise are necessary for rapid skeletal growth as well as to “stockpile” calcium to prevent osteoporosis later in life (Chouinard, Randall Simpson, & Buchholz, 2012). Zinc is necessary for sexual maturation and final body growth. Good sources of iron are meat and green vegetables, calcium is abundant in milk and milk products, and meat and milk are also high in zinc.

## Promoting Nutritional Health With a Varied Diet

### Vegetarian Diets

Because vegetables generally contain fewer calories than meat, adolescents need to consume large amounts of them to achieve an adequate caloric intake from a vegetarian diet. Textured vegetable protein or tofu can be added to meals to increase the amount of protein supplied and help meet adolescent growth needs (Case, 2016). Some adolescents may find it difficult to follow a vegetarian diet because it makes them different from their peers and limits the foods they can eat at parties or at school, such as pizza, meat tortillas, or hot dogs. Whether to continue to follow this type of diet is a decision an adolescent must make as part of achieving a sense of identity. Be certain that adolescents who have become semi-vegetarians in order to lose weight add enough protein to their food intake to sustain their rapid body growth (Timko, Hormes, & Chubski, 2012).

### Glycogen Loading

Athletes need more carbohydrate or energy than those who do not engage in strenuous activity; the source of carbohydrate that best sustains athletes comes from the breakdown of glycogen because this supplies a slow and steady release of glucose.

**Glycogen loading** is a procedure used to ensure there is adequate glycogen to sustain energy through an athletic event. Several days before a sports event, athletes lower their carbohydrate intake and exercise heavily to deplete muscle glycogen stores. They then switch to a diet high in carbohydrate. With the renewed carbohydrate intake, muscle glycogen is stored at two to three times the usual level, which supplies them with up to twice the glucose needed for sustained energy (Bagnulo, 2006).

Although used by many high school athletes, the effects of frequent glycogen loading in this age group are not well studied and so should be done cautiously. As a rule, the goals of nutrition that are best for everyone, such as eating a well-balanced diet rather than a diet that interferes with carbohydrate, fluid, or fat intake, are also the best rules for athletes.

## PROMOTING DEVELOPMENT OF AN ADOLESCENT IN DAILY

## ACTIVITIES

Adequate sleep, hygiene, and exercise are important health education topics for adolescents as these become an adolescent's responsibility rather than the responsibility of the parents.

### Dress and Hygiene

Adolescents are capable of total self-care and, because of their body awareness, may even be overly conscientious about personal hygiene and appearance. Both sexes try many types of shampoo, deodorant, breath fresheners, and toothpaste. They may take seriously (without admitting it) the content of ads showing that toothpastes or deodorants can help win an attractive person or gain instant success. Remember that when caring for hospitalized adolescents, providing time for self-care, such as shampooing hair, is important to include in an adolescent's nursing care plan.

Adolescents can be acutely aware of how their peers dress. When hospitalized, most teenagers seem to improve markedly when allowed to wear their own clothing rather than a hospital gown. Needing to look like everyone else is undoubtedly a factor in adolescent shoplifting. Only during late adolescence do teenagers discover that who they really are shows through their clothing.

### Care of Teeth

Adolescents are generally very conscientious about tooth brushing because of a fear of developing bad breath. They should continue to use a fluoride paste rather than a brand advertised as providing white teeth. They should also continue to drink fluoridated water to ensure firm enamel growth (Armfield, Spencer, Roberts-Thomson, et al., 2013), but they should also be careful to not use so much fluoride through the use of mouth rinses or toothpaste that they develop fluorosis (i.e., a blue discoloration of teeth). Teens with braces must be extremely conscientious about tooth brushing to prevent plaque buildup on hidden tooth surfaces. If they snack a great deal, and so their teeth are always exposed to bacterial erosion, some may develop a cavity for the first time during this period.

### Sleep

Although it is widely believed everyone needs 8 hours of sleep a night, some need more and others can adjust to considerably less. Because protein synthesis occurs most readily during sleep and adolescents are building so many new cells, this age group may need proportionately more sleep than any other age group (Short, Gradisar, Lack, et al., 2013). In addition, because this is a busy time with extracurricular activities and also a stressful period similar to first grade, adolescents may sleep restlessly as their mind reworks the day's tensions. Even long periods of sleep, therefore, may not leave them feeling refreshed. This is why adolescents, admitted to a hospital for even a minor illness, for example, may sleep as if exhausted. Even though frequent lack of sleep can

lead to chronic fatigue or depression, medication is not usually recommended for adolescents; instead, they are urged to reduce activity to get more sleep (Frost & Burns, 2012).

### **Exercise**

Just as with younger children, adolescents need exercise every day both to maintain muscle tone and to provide an outlet for tension. Unlike younger children, however, and although they are constantly on the go, adolescents often receive very little real exercise. They may ride a bus to school, sit for classes, and sit at a mall after school and talk to friends. They have put in a full day, yet most of their time was spent sitting. Because of this, adolescents who have had an injury and must learn an activity such as crutch walking usually need to do muscle-strengthening exercises at first, just as adults must.

Adolescents who are involved in structured athletic activities do receive daily exercise. If they have not participated in competitive sports before, however, they may need advice on increasing exercise gradually so they do not overdo it and consequently develop muscle sprains or other overuse injuries (Hoang, Coel, Vidal, et al., 2012).

### **Sun Exposure**

Because some adolescents spend a great deal of time outdoors participating in athletics, it is a critical time for them to avoid excessive sun exposure so they don't develop skin cancer (i.e., melanoma) from ultraviolet rays. Encourage teenagers to use sunscreen, avoid tanning beds, and report to their primary healthcare provider any skin mole that changes in shape or color. Do this as creatively as possible because teenagers have difficulty looking to the future and imagining how drastically the development of melanoma could affect their lives (Cohen, Brown, Haukness, et al., 2013).

## **PROMOTING HEALTHY FAMILY FUNCTIONING**

Early adolescents may have many disagreements with parents that stem partly from wanting more independence and partly from being so disappointed in their bodies. It may be helpful to counsel parents to appreciate that although it is not easy to live with a teenager, it is equally difficult to be the teenager.

When a child reaches about age 15 years, parent-child friction tends to peak. By this age, adolescents have discovered from careful observation that most adults are far from perfect. Teachers they previously thought were all knowing are revealed to have very human shortcomings. School marks may slump as a reflection of this "fallen angel" syndrome.

Adolescents discover even more faults in their parents and wonder, for instance, how they can exist with such outdated ideas. Adolescents may follow health advice poorly because they view healthcare personnel in the same light.

By the time they are 16 years old, adolescents generally become more willing to

listen and talk about problems. As a result, they may learn adults are not as inadequate as they previously thought. This changed perception does not mean an adolescent of 16 years is calm and quiet and free of parent–child discord. Adolescents may comprehend how hard it was for parents to get where they are, but they may not understand, for example, why they themselves are not allowed to stay out later than midnight on weekends.

Most 17-year-old adolescents, who have stayed in school, are usually high school seniors; for most of them, this year is likely to be stormy. Looking ahead to leaving a school system with which they may have been involved since they were very young may give them a feeling of losing security. Even if going away to college or beginning a full-time job seems exciting, it can also be an unwelcome change from the people and routines they feel so comfortable with to new contacts and new regulations that appear strange and even hostile.

The ambivalence that such feelings create makes some 17-year-olds enjoy having parents perpetuating family traditions such as the house decorated for a holiday in the same way as usual or being served a traditional birthday meal. This clinging to security is not a step backward but a preliminary working through to a time of separation that will be a major milestone in reaching maturity.

Unfortunately, as another way to prove they are old enough to leave high school and enter into a more mature college or work world, older adolescents may begin to experiment with drugs or alcohol, interpreting the use of these as the mark of being an adult (Lewis & Hession, 2012).

## COMMON HEALTH PROBLEMS OF AN ADOLESCENT

A health maintenance schedule for the adolescent period and the assessments to be included at visits are shown in Table 33.2.

**TABLE 33.2 HEALTH MAINTENANCE SCHEDULE, ADOLESCENT PERIOD**

Area of Focus	Methods	Frequency
<i>Assessment</i>		
Developmental milestones	History, observation	Every visit
Growth milestones	Height, weight plotted on standard growth chart; body mass index (BMI), physical examination	Every visit
Hypertension	Blood pressure	Every visit
Nutrition	History, observation; height/weight, BMI information	Every visit
Dyslipidemia	Total cholesterol and triglycerides	At 18 years of age; earlier screening for

		children who have family members with the disorder
Parent–child relationship	History, observation	Every visit
Behavior or school problems	History, observation	Every visit
Substance use disorder	History, observation	Every visit
Vision and hearing disorders	History, observation	Every visit
	Formal Snellen or Titmus testing	At 15 and 18 years of age
	Audiometer testing	If concern or high risk is present
Dental health	History, physical examination	Every visit; recommend a yearly checkup with dental health provider
Cervical dysplasia (scoliosis)	Physical examination	Every visit at least to 16 years of age
Thyroid disease	Physical examination, history	Every visit
Tuberculosis	Purified protein derivative (PPD) test	Depending on prevalence of tuberculosis in community
Bacteriuria	Dipstick	Annually if sexually active
Anemia	Hematocrit or hemoglobin	Annually for menstruating females
Cervical or vaginal cancer	Pap test, pelvic examination	Three years after first coitus, or at age 21 years
Sexually transmitted diseases	History, observation	Every visit if sexually active

---

*Immunizations*

---

	Check history and past records; inform caregiver about any risks and side effects; administer vaccine in accordance with healthcare agency policies.	
Hepatitis A vaccine	HepA	If not previously immunized
Hepatitis B vaccine	HepB	If not previously immunized
Human papillomavirus vaccine	HPV	If not previously vaccinated
Influenza vaccine	TIV (trivalent influenza vaccine) or LAIV	Yearly
Measles, mumps, rubella vaccine	MMR	If not previously vaccinated; do not give to pregnant adolescents
Meningococcal vaccine	MPV4 (meningococcal polysaccharide vaccine)	Booster at 16 years
Pneumococcal vaccine	PCV (pneumococcal conjugate vaccine)	To high-risk groups if not previously vaccinated
Tetanus and diphtheria vaccine	Tdap	If not previously immunized
Varicella vaccine	VAR	If not previously vaccinated
<i>Anticipatory Guidance</i>		
Adolescent care including violence and nutrition counseling	Active listening and health teaching	Every visit
Expected growth and developmental milestones before next	Active listening and health teaching	Every visit

visit		
Unintentional injury prevention	Counseling about street and personal safety	Every visit
Any problems expressed by caregiver or adolescent during visit	Active listening and health teaching	Every visit

LAIIV, live attenuated influenza vaccine. From American Academy of Pediatrics. (2012). *Recommendations for preventive pediatric health care*. Evanston, IL: Author.

## Hypertension

Hypertension is present if blood pressure is above the 95th percentile, or 127/81 mmHg for 16-year-old girls and 131/81 for 16-year-old boys for two consecutive readings in different settings. (Pulse, respiration, and blood pressure value charts are available at <http://thePoint.lww.com/Flagg8e>.) Adolescents who are obese, who are Black, who eat a diet high in salt, or who have a family history of hypertension are most susceptible to developing the condition. All children older than 3 years of age should have their blood pressure routinely taken at all health assessments to detect this (Hagan, Shaw, & Duncan, 2017). This is particularly important for adolescents because new medications plus education can help to greatly reduce the incidence of cardiovascular disease as they reach adulthood (Flynn & Falkner, 2011). Prevention and management of hypertension in children and adolescents are discussed in Chapter 41.

## Poor Posture

Many adolescents, particularly those who reach adult height before their peers, demonstrate poor posture, a tendency to round shoulders and a shambling, slouchy walk to not be taller than those around them. This is also due to the imbalance of growth that arises from the skeletal system growing a little more rapidly than the muscles attached to it. Girls, especially, may slouch so as not to appear taller than boys or to diminish the appearance of their breast size if they are developing more rapidly than their friends. Yet another reason may be related to carrying backpacks that are too heavy (Kistner, Fiebert, & Roach, 2012).

Urge children of both sexes to use good posture during these rapid-growth years. Assess posture at all adolescent health appraisals to detect the difference between simple poor posture and the beginning of spinal dysplasia or scoliosis (i.e., lateral curvature of the spine) (see Chapters 34 and 51).

## Body Piercing and Tattoos

Body piercing and tattoos are a strong mark of adolescence (Stein & Jordan, 2012).

Both sexes may have ears, lips, chins, navels, and breasts pierced and filled with studs or tattoos applied to arms, legs, or their central body. Body piercings and tattoos have become a way for adolescents to make a statement of who they are and that they are different from their parents. Be certain they know the symptoms of infection at a piercing or tattoo site (e.g., redness, warmth, drainage, swelling, mild pain) and to report these to their healthcare provider if they occur because serious staphylococcal or streptococcal infections can occur at piercing sites. It is important to caution adolescents that sharing needles for piercing or tattooing carries the same risk for contacting a blood-borne disease as sharing needles for intravenous drug use.

## **Fatigue**

Because so many adolescents comment that they feel fatigued to some degree, it can be considered normal for the age group. However, fatigue may also be a beginning symptom of disease, so it is important that it is not underestimated as a concern. Always assess the diet, sleep patterns, and activity schedules of fatigued adolescents. Be aware that if the fatigue began as a short period of extreme tiredness, it suggests disease more so than a long, ill-defined report of always feeling tired.

If an adolescent's sleep and diet appear to be adequate, his or her activity schedule is reasonable, and a physical assessment suggests no illness, then the fatigue may be of emotional origin. It can be a means of avoiding school, conflict with parents (e.g., when children appear ill, parents are more sympathetic), or social situations (e.g., too tired to go to the mall). Those who are under stimulated by school may develop fatigue as a sign of boredom.

Blood tests may be indicated to rule out anemia and common infections in adolescents, such as infectious mononucleosis (see [Chapter 43](#)). Chronic fatigue syndrome, although not seen as often in this age group as in adults, may also need to be ruled out ([Lloyd, Chalder, & Rimes, 2012](#)). If tests for these categories of conditions are normal, teenagers can be assured they are healthy and should be offered guidance to solve the problem with better diet, more sleep, fewer activities, and better problem-solving techniques to relieve tension.

## **Menstrual Irregularities**

Menstrual irregularities can be a major health concern of adolescent girls as they learn to adjust to their individual body cycles. [Chapter 47](#) discusses these problems in detail.

## **Acne**

Acne is a self-limiting inflammatory disease that involves the sebaceous glands, which empty into hair shafts (the pilosebaceous unit). It is the most common skin disorder of adolescence, occurring in as many as 80% to 95% of adolescents ([Morelli & Prok, 2016](#)). It occurs slightly more frequently in boys than in girls. The peak age for the lesions occurring in girls is 14 to 17 years of age; for boys, 16 to 19 years of age.

Although not proven, genetic factors may play a part in their development.

Changes associated with puberty that cause acne to develop include:

- As androgen levels rise in both sexes, sebaceous glands become active.
- The output of sebum, which is largely composed of lipids, mainly triglycerides, increases.
- Trapped sebum causes whiteheads, or closed comedones.
- As trapped sebum darkens from accumulation of melanin and oxidation of the fatty acid component on exposure to air, blackheads, or open comedones, form. Leakage of fatty acids causes a dermal inflammatory reaction.
- Bacteria (generally, *Propionibacterium acnes*) lodge and thrive in the retained secretions and ducts.

Acne is categorized as mild (i.e., **comedones** or blocked hair follicle), moderate (i.e., papules and pustules are also present), or severe (i.e., cysts are present). The most common locations of acne lesions are the face, neck, back, upper arms, and chest (Fig. 33.6). Flare-ups are associated with emotional stress, menstrual periods, or the use of greasy hair creams or makeup that can further plug gland ducts. Lesions are less noticeable in summer months, probably because of increased exposure to the sun, which increases epidermal peeling, or because of a reduction in stress as a result of being out of school.

**Figure 33.6** Facial acne in an adolescent.

### Assessment

Always ask adolescents at health assessments if they are troubled with acne and to what extent it interferes with their self-image because this can be a major cause of stress in adolescents. Inspect for facial, chest, and back lesions on physical examination.

### Therapeutic Management

The goal of therapy for acne is threefold: (a) decrease sebum formation, (b) prevent comedones, and (c) control bacterial proliferation.

### *External Medication*

Medications that are applied externally peel away the superficial skin layer to prevent sebum plugs from forming and are sufficient if only comedones are present. A common prescription medication is tretinoin (Retin-A cream). This reduces keratin formation and plugging of ducts. Caution adolescents using a vitamin A cream to avoid prolonged sun exposure and to use a sunblock of SPF 15 or higher because the preparation makes their skin more susceptible to ultraviolet rays (Karch, 2013). Additional creams frequently prescribed contain benzoyl peroxide or azelaic acid. Caution adolescents that for the first week or two of therapy, peeling or oxidizing agents may make the complexion appear worse. If the adolescent has inflammatory lesions, topical antibiotic creams such as dapsone, tetracycline, or doxycycline may be prescribed to reduce the bacterial level on the skin. Tetracycline is not prescribed for children under age 12 years because it can cause permanent staining of teeth and may possibly interfere with growth of long bones. It is contraindicated for adolescents who are or may become pregnant as it is teratogenic (Simonart, 2012).

### *Systemic Medication*

In pustular and cystic acne, systemic (i.e., oral) antibiotics can be helpful. Systemic antibiotics have anti-inflammatory properties, and they are effective against *P. acnes*. Tetracycline (500 mg twice daily the first week and then tapered to 250 mg daily for maintenance) is effective against the anaerobic bacteria that break down sebum to form irritating acids. However, the more lipophilic antibiotics, such as doxycycline and minocycline, are generally more effective than tetracycline (Zaenglein, Pathy, Schlosser, et al., 2016). Improvement is not generally seen for 2 to 4 weeks, so you may need to support adolescents to continue to take the medication during the waiting period. Without noticeable improvement, adolescents have a tendency to continue taking the higher dose or even increase the dose, hoping to initiate a faster effect.

Food impairs the absorption of oral tetracycline so the drug should be taken on an empty stomach (2 hours before or after eating). Adolescents must be certain of the date of expiration of the drug; outdated tetracycline breaks down into an extremely toxic composition. Females taking systemic antibiotics for long periods of time become susceptible to developing candidal vaginitis and need to be instructed about the symptoms of this: a white, pruritic vaginal discharge. As yet another precaution, because antibiotic use may interfere with oral contraceptives, adolescent girls who are sexually active should use another method of birth control while taking the antibiotic. Alternative antibiotics prescribed are erythromycin or clindamycin. Although these drugs avoid the complications of tetracycline, they may not produce the same effective results.

### *Other Treatment Methods*

Estrogen, alone or in combination with progesterone, suppresses sebaceous gland

activity and, therefore, oral contraceptives are useful therapy in some girls with acne (Neuhaus, Nagler, & Orlow, 2017). Oral contraceptives taken for this reason carry the same precautions as when they are prescribed as a reproductive planning method: Estrogen tends to close epiphyseal centers of long bones, causing bone growth to halt, and long-term therapy does have potential side effects, including embolism and thrombophlebitis. A last resort is administration of isotretinoin (a retinoid or vitamin A compound) for a short time (Lyon, 1978; Rathi, 2011). Isotretinoin must be taken with caution, however, because it is extremely teratogenic and also has been linked to inflammatory bowel disease. It should not be taken at the same time as tetracycline or it can lead to brain edema. Many adolescents are left with some degree of scarring following teenage acne lesions. Laser therapy is a follow-up possibility to reduce the effect of scarring.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for low self-esteem related to the development of acne during adolescence and lack of knowledge regarding treatment possibilities

**Outcome Evaluation:** Adolescent verbalizes positive aspects of self; states acne does not affect self-image, or if patient admits to feelings of negative self-esteem, is able to discuss feelings and concerns about condition; describes ways to prevent or reduce acne outbreaks and states realistic short- and long-term goals of treatment.

It is necessary to respect how devastating acne can be to some adolescents. The actual extent of the condition often is not as important as an adolescent's feelings about it. With a face constantly covered by red marks, it may be extremely difficult for adolescents to feel good about themselves.

When carrying out interventions, remember that acne is a potentially destructive disease; if left untreated, it can cause irreparable physical and emotional scarring. Therefore, advise parents and adolescents to seek medical treatment rather than self-medicate if the condition is severe. At the same time, being overly concerned may lead to becoming unduly self-conscious, which may affect performance in school and the establishment of social relationships. Common health teaching measures for the prevention and treatment of acne are summarized in [Box 33.4](#).

### BOX 33.4

#### Nursing Care Planning Based on Family Teaching

#### **GUIDELINES FOR THE PREVENTION AND TREATMENT OF ACNE**

**Q.** Raul says to you, “I’ve had acne for the last 3 months. How can I make this go away?”

**A.** Most adolescents have some acne lesions. Try the following suggestions:

- Do not pick or squeeze acne lesions, which ruptures glands and spreads sebum into the skin, thus increasing inflammation. The times you are most likely to do this are during periods of stress, such as when you are taking a test. When you find your hand on your face, distract yourself with some other motion, such as interlocking your fingers.
- Greasy hair preparations or tight sweatbands can both plug ducts of glands and increase comedone formation, so avoid these, if possible. For girls, makeup can plug ducts; using medicated makeup both covers and helps lesions heal.
- Topical acne preparations work by unplugging glands, so you must use them consistently for them to be effective. Plan enough time in the morning before school and a time in the evening to apply these. Post a chart by your bathroom mirror to remind yourself.
- Washing daily to remove irritating fatty acids is helpful. Excessive washing is not necessary and, in fact, can actually harm healing by rupturing glands.
- Oral medications work by reducing sebum secretions or preventing bacterial invasion. Again, these work only if you take them conscientiously. Make a chart to post in your bathroom or kitchen to remind you to take these. Remember, tetracycline must be taken on an empty stomach or it is not effective.
- Both topical and oral vitamin A makes your skin very sensitive to sunlight. Avoid long exposures to sunlight, or you will sunburn readily.
- Although diet does not influence the development of acne lesions, you should eat a healthy, well-balanced diet for good general health.
- No acne medication works immediately. While you are waiting for lesions to heal, keep yourself occupied with a new activity (e.g., join a school club, try dancing lessons). When your skin is clear, these experiences will help make you an interesting person as well as one with clear skin.

**QSEN Checkpoint Question 33.3**

**PATIENT-CENTERED CARE**

Raul is prescribed both a topical cream and oral tetracycline to treat his acne. The nurse identifies that he needs additional health information from which statements (list all that apply)?

- a. “I know acne is not contagious even though all my friends seem to have it.”
- b. “My girlfriend wants to borrow my tetracycline; I don’t mind sharing it.”
- c. “I know not to take hot showers as hot water can create new lesions.”
- d. “I know not to eat chocolate because that always makes lesions worse.”

*Look in Appendix A for the best answer and rationale.*

**Obesity**

Most overweight adolescents have obese parents, suggesting that both inheritance and environment play a part in the development of adolescent obesity. Obesity can interfere with developing a sense of identity if it is difficult for adolescents to like their reflection in a mirror or if they are always excluded from groups because of their weight. Because of stress related to weight, the attempted suicide rate for obese female adolescents is higher than for non-obese adolescents (Perera, Eisen, Dennis, et al., 2016).

Some adolescents may be unaware that their food intake is excessive because they have been told they need excess nutrients for healthy adolescent growth and everyone in their family eats large portions. Health teaching with these adolescents may need to begin with a discussion of “normal” weight and standard food portions because, if they do not begin to own this problem as adolescents, they run a high risk of becoming obese adults.

If adolescents eat a diet too low in protein for any length of time, they can develop a faulty nitrogen balance, which can lead to seriously impaired growth. Therefore, a diet of fewer than 1,400 to 1,600 calories per day can rarely be tolerated by adolescents. They generally do better and will stick with a diet closer to 1,800 calories per day.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Ineffective individual coping by overeating related to stresses of the adolescent period, which has led to obesity

**Outcome Evaluation:** Adolescent identifies stressful situations that lead to overeating; describes ways to avoid those situations or methods that would help coping with them.

Adolescents who are overweight because of stress need support until their pleasure in eating diminishes and their satisfaction with themselves as a “new” person or until their friends’ satisfaction with them can sustain them. They may need to visit a healthcare facility once or twice a week for encouragement and praise for their efforts. National weight-control organizations are good to use if other adolescents also attend the meetings. They tend to be less effective if all the other members are adults because adolescents generally cannot relate to adult concerns. It’s important an adolescent’s self-esteem is maintained while losing weight or an adolescent may switch to binge eating or such severe dieting that the opposite—extreme weight loss—can occur (Sánchez-Carracedo, Neumark-Sztainer, & López-Guimerà, 2012).

In addition to reducing calories consumed, encourage activities that burn calories, such as swimming, gym classes, or walking their dog (Loprinzi, Cardinal, Loprinzi, et al., 2012). These activities are generally preferable to formal exercises, such as sit-ups and push-ups, which may be viewed as punishment.

Adolescents who use overeating as their main reaction to stress may require psychological counseling rather than diet counseling if they are to develop a more mature emotional response to stress. Behavior modification is sometimes successful with adolescents as a means of helping them lose weight, but it is rarely recommended for obesity alone (see [Chapter 35](#)).

General measures to help adolescents decrease overeating include:

- Making a detailed log of the amount they eat, the time, and the circumstances (including how they felt while they were eating) and then changing those circumstances
- Always eating in one place (the kitchen table) instead of while walking home from school or watching television
- Slowing the process of eating by counting mouthfuls and putting the fork down between bites, or being served food on small plates so helpings look larger

These measures may be of little use, however, unless they are combined with a suitable diet and adequate exercise. Despite all these interventions, weight reduction may not always be effective with adolescents. For some, a more realistic goal might be to prevent additional weight gain until they reach adulthood.

## **CONCERNS REGARDING SEXUALITY AND SEXUAL ACTIVITY**

Adolescents who engage in sexual risk behaviors can have unintended health outcomes, including unplanned pregnancies and sexually transmitted infections (STIs) such as HIV. During routine health assessments of adolescents and preadolescents, this topic should be explored.

According to a 2015 CDC survey report, 41% of U.S. high school students have had sexual intercourse, and of that number, 30% was in the previous 3 months. The survey also reported 43% did not use a condom the last time they had sex. Only 10% had ever been tested for HIV. Yet, those age 13 to 24 years accounted for an estimated 22% of all new HIV diagnoses in the United States in 2014, and within this group, 80% were gay and bisexual males. Half of the nearly 20 million new STIs reported each year were among adolescents and late adolescents age 15 to 24 years in 2014. Pregnancy in adolescence, although decreasing, is still a concern. Nearly 250,000 births were to girls ages 15 to 24 years in 2014 ([CDC, 2017d](#)).

When discussing sexuality with adolescents, the nurse should avoid assumptions about the gender of the adolescent's partner. Ask open-ended questions when providing education on health promoting behaviors. This will also help the adolescent feel more open to asking questions.

Counseling can assist adolescents improve their perspective and also learn how to say no. For adolescents who agree to have intercourse but who do not really want to, the primary reasons given are peer pressure, curiosity, and affection for their partner ([Fuzzell, Fedesco, Alexander, et al., 2016](#); [Katsufakis & Nusbaum, 2011](#)).

According to the [CDC \(2017b\)](#), most lesbian, gay, bisexual, and transgender (LGBT) youth are well adjusted during their adolescent years. The nurse should explore

the school and home environment, as adjustment can be promoted by a supportive learning environment and caring and accepting parents (CDC, 2017b). If the adolescent is not provided with this environment, they may have difficulties in their lives and possibly be at risk for violence from bullying behaviors. Bullying is described in more detail in this chapter.

Adolescents may seek a healthcare appointment for an unrelated health concern as a reason to discuss a sexual health question with a healthcare professional. During routine health visits, it is important to obtain a complete sexual health history and offer health related education appropriate to the adolescent's individualized history. General guidelines on counseling an adolescent with respect to sexual activity are summarized in Box 33.5.

### BOX 33.5

#### Nursing Care Planning Based on Family Teaching

#### HEALTH TEACHING GUIDELINES FOR ADOLESCENTS REGARDING SEXUALITY

**Q.** Raul asks you, “How will I know when I’m ready for sex?”

**A.** Here are a few common guidelines:

- It is your choice whether to participate in sexual relations. Do not be influenced by friends who may be exaggerating stories to impress you or who ask you to do something you do not want to do. When you say no, be firm and clear about your wishes.
- There is no 100% method to prevent pregnancy or a sexually transmitted infection (STI) except abstinence. Be direct with a sexual partner in discussing abstinence or reproductive and infection prevention measures.
- Sexual relations neither add to nor detract from your physical strength or general wellness.
- The mark of an adult sexual relationship is that the activity is pleasurable to both partners. If sexual partners are not interested in your enjoyment as well as their own, you should reconsider the relationship.
- There is no “normal” mode of sexual expression. Any activity that is pleasurable to both partners is “normal.”
- Learn about safer sex techniques and practice them.

Information on date rape and rape prevention should be provided as adolescents are in a high-risk age group for date rape (Makin-Byrd & Bierman, 2013) (see Chapter 55). One form of date rape occurs when flunitrazepam (Rohypnol) (i.e., the “date-rape drug”), a colorless, odorless, and flavorless benzodiazepine drug, is dropped into a drink, causing drowsiness, impaired motor skills, and amnesia for a time (Karch, 2013). Adolescents who are seen for sexual assault who appear intoxicated or have amnesia for

the event should be suspected of unknowingly ingesting flunitrazepam or another drug such as ketamine. In these instances, a urine specimen analysis will reveal the drug's metabolites or that the drug was ingested (D'Aloise & Chen, 2012).

## Stalking

**Stalking** refers to repetitive, intrusive, and unwanted actions such as constant and threatening pursuit directed at an individual to gain the individual's attention or to evoke fear. Electronic media can be used for cyberstalking, Internet harassment, and Internet bullying to embarrass, harass, or threaten adolescents (CDC, 2017c). The overall term for these methods is electronic aggression (CDC, 2017c). It can result in the same victim responses as that from aggression that is not inflicted electronically. To avoid stalking, adolescents should be aware of and avoid situations where they will be vulnerable to being alone with a stalker and, with assistance, report stalking to law enforcement.

### *QSEN Checkpoint Question 33.4*

#### **SAFETY**

Raul is depressed because his girlfriend broke up with him. Which of his statements could be interpreted as stalking?

- “I keep her photo on my bedside stand so I can kiss her goodnight.”
- “We take the same route to school every day so I often still see her.”
- “I e-mail her every night to tell her what a huge mistake she's made.”
- “I took down her photo from Facebook but wish I could put it back.”

*Look in Appendix A for the best answer and rationale.*

## CONCERNS REGARDING HAZING OR BULLYING

Bullying, which began during school age (see Chapter 32), can easily continue into adolescence and actually becomes more serious because this can be the time the bullied child has the ability to retaliate through self-destructive behavior or school violence.

Hazing, a form of organized bullying, refers to demeaning or humiliating rituals that prospective members have to undergo to join sororities, fraternities, adolescent gangs, or sports teams (Diamond, Callahan, Chain, et al., 2016). Most rituals are secret and in the past were accepted as “rites of passage.” In recent years, hazing has become so extreme the practice has moved out of the “just fun” category into activities that can cause physical and certainly psychological harm, such as being forced to wear demeaning clothing or engaging in crude or lewd skits. They can be extended to such an extreme that adolescents may be punched or kicked, sodomized, left out in the cold so long that frostbite develops, or forced to drink alcohol until they vomit, pass out, or even die from alcohol intoxication. Initiation for street gangs can require prospective members to steal or destroy property or even kill another person.

To help prevent this from happening to their child, urge parents to be aware of what clubs or organizations their adolescent joins and what the requirements for membership are. Help adolescents make sound decisions about what type of hazing their organization advocates by asking them about the subject at health assessments.

## CONCERNS REGARDING SUBSTANCE USE DISORDER

**Substance use disorder** (formerly referred to as substance abuse disorder) refers to the use of chemicals to improve a mental state or induce euphoria. This is so common among adolescents that as many as 50% of high school seniors report having experimented with some form of drug (CDC, 2012a). Use of drugs occurs in adolescence from a desire to expand consciousness, peer pressure, or a desire to feel more confident and mature; it also can be a form of adolescent rebellion related to childhood adversity or violence. Stages of drug use range from experimentation where teenagers try drugs to enhance social acceptance to regular use, where they actively seek the effect of drugs to relieve everyday stress (Benjet, Borges, Medina-Mora, et al., 2012).

### Types of Abused Substances

Because adolescents may not have a large source of money, the drugs they most frequently abuse are those they can obtain on a limited budget and through limited contacts.

### Prescription and Over-the-Counter Drugs

Adolescents may first begin drug experimentation by taking drugs prescribed for another family member or a pet such as sedatives, pain medication, ketamine (an anesthetic used in veterinary medicine), or cough syrup containing codeine or dextromethorphan (DXM). Called “pharming,” adolescents who use drugs this way can easily overdose because they are unaware of usual dosages (Storck, Black, & Liddell, 2016).

Methylphenidate (Ritalin) is a drug frequently prescribed for attention deficit hyperactivity disorder. Because methylphenidate (Ritalin) is a stimulant, when oral tablets are crushed and injected intravenously, they produce a feeling of giddiness and extreme well-being. Unfortunately, because they do not completely dissolve, the resultant small particles remaining in the bloodstream can result in complications such as pulmonary embolus or emphysema, so this is a very dangerous practice. Every house has a number of inhalants, such as oil-based cooking spray, gas, butane, or lighter fluid, which may be abused by adolescents. Inhalants can lead to cardiac failure from suffocation. Mephedrone, commonly called “bath salts,” is a stimulant that creates an enjoyable “high” and is available for purchase online and so is easily obtained by adolescents (Nguyen, O’Brien, & Schapp, 2016). The effect of using it is seen more regularly in emergency departments as the cause of reckless driving or unconsciousness

(Baumann, Partilla, & Lehner, 2013). Listed as a schedule 1 drug, it is now illegal to obtain.

## Alcohol

As many as 90% of high school seniors report having consumed alcohol, and as many as 25% of high school students report having engaged in episodic heavy or binge drinking. At least 10% of high school students report driving a car or other vehicle when they had been drinking alcohol. Nearly 30% of students report having ridden in a car or other vehicle driven by someone who had been drinking alcohol (CDC, 2012a).

Although alcohol use is correlated with motor vehicle accidents, homicide, and suicide in adolescents, it has never carried the social stigma of other drugs. Some parents are actually relieved when they learn their child's strange behavior on returning home from a party was caused by drunkenness and not illegal drugs. Alcohol use cannot be taken lightly, however, because it can cause diseases such as cirrhosis and is linked to destructive behaviors such as addiction, depression, and vulnerability to date rape.

Heredity has a definite role in the use of alcohol, but environment plays an equal part in whether an adolescent becomes a frequent user (Maimon & Browning, 2012). Remind parents they have a responsibility to set good examples for adolescents in the use of alcohol by not drinking indiscriminately.

Most adolescents will admit they use alcohol if asked two specific questions: "Do you drink alcohol?" and "When was your last drink?" Adolescents who answer yes to the first and "within the last 24 hours" to the second are candidates for further assessment.

Once adolescents admit they have come to rely on alcohol as a way to feel popular or reduce stress, an organization such as Alcoholics Anonymous can be invaluable in helping them stop drinking; innovative online programs geared especially for adolescents are also available. Encourage the remainder of their family to join Al-Anon, the organization for families of alcoholics, so both children and their families can restructure their lives to find satisfaction without the use of this drug.

Many adolescents are not the primary alcohol abuser in a family but are the children of alcoholic parents. Make an effort to identify this group of children as well, not only to prevent them from becoming users of alcohol but also to help them build self-esteem and coping abilities for the difficulties they face living in a possibly disorganized household.

### *QSEN Checkpoint Question 33.5*

#### **EVIDENCE-BASED PRACTICE**

It has long been theorized there may be a "gateway" drug or one that, when used first, leads to further and more dangerous substance use disorders. To determine whether alcohol, tobacco, or marijuana was the gateway drug, researchers obtained information on the drug use of a nationally representative sample of high school

seniors. Results of the study showed alcohol was the gateway drug, leading to tobacco, marijuana, and then other illicit substances (Barry, King, Sears, et al., 2016).

Based on the previous study, which statement by Raul would give you the most concern?

- a. “Some of my friends got hammered last weekend but I decided not to stick around.”
- b. “Some of my friends use weed; they tell me it really helps them relax.”
- c. “My parents said I could celebrate my next birthday by drinking my first beer.”
- d. “My mother eats some kind of chocolate almost every day. Is that hereditary?”

*Look in Appendix A for the best answer and rationale.*

---

## Tobacco

Although it is well documented that cigarette smoking leads to increased cardiovascular and respiratory illnesses by middle age, every day, approximately 4,000 American youth aged 12 to 17 years try their first cigarette. As many as 20% of high school students report current cigarette use, and about 14% report current cigar use. Eight percent of high school students report current smokeless tobacco use (CDC, 2012d).

Adolescents usually begin smoking because the habit conveys a stamp of maturity; those who are having difficulty demonstrating maturity in other areas may view smoking as especially desirable. Although at one time, proportionately more males than females smoked, adolescent girls now are the population most likely to begin smoking. One of the strongest determinants of whether adolescents will smoke a first cigarette is whether their friends smoke.

As cigar smoking is becoming more popular with adults, it also is becoming more popular with adolescents. “Smokeless tobacco” or chewing tobacco is also becoming more popular (Kozlowski & Sweanor, 2017). Although chewing tobacco does not have the potential dangers of smoking tobacco in relation to lung disease, it can cause gingival recession and lip and mouth cancer, and it can be just as habit forming as cigarettes.

It has been well documented that adolescents are influenced to begin smoking by advertising (Widome, Brock, Noble, et al., 2013). Most school systems have extensive programs as early as grade school to caution children not to listen to cigarette advertising. Unfortunately, the ultimate danger of illness or death in middle age is not a strong threat to young persons who are interested only in the present.

More effective campaigns, therefore, might be those that point out that cigarette smoking causes foul-smelling hair, clothes, and breath, which detracts from physical appearance (i.e., “now” concerns). Helping adolescents find other methods to demonstrate their maturity, such as allowing them opportunities for increased decision making and emphasizing that being able to *not* smoke is a sign of true maturity, needs to

be investigated. Urge adolescents who want to quit cigarette smoking to enroll in a group cigarette or online withdrawal program. Nicotine gum and nicotine patches have both been successfully used with adolescents (Harvey & Chadi, 2016).

Additionally, in recent years, the use of e-cigarettes and vaping has increased significantly among adolescents. Their use has been demonstrated to actually increase the use of cigarette consumption. This is because they become addicted to the nicotine in the e-cigarette (Gostin & Glasner, 2014). The lack of regulations regarding the sale of vaping products causes additional problems for their use among adolescents. To purchase cigarettes, all persons must show identification and be older than 18 years of age. However, less than half of the states require identification to purchase e-cigarettes (Gostin & Glasner, 2014).

Adolescents are very reluctant to follow instructions that are given from a “do as I say, not as I do” standpoint. Nurses who smoke, therefore, can have extreme difficulty launching an effective campaign against the habit with adolescents. Stopping smoking can be especially difficult during periods of stress or inactivity. Trying to introduce such an action during exam week, for example, is not good planning. During an illness is also a bad time, unless not feeling well has reduced the urge to smoke. A return visit for follow-up and health maintenance care might be a better time to introduce the topic.

### *What If . . . 33.2*

**Raul tells the nurse during a history assessment that he does not smoke, but the nurse smells cigarette smoke on his clothing. Although he says he doesn't use drugs, a number of blue-and-white capsules fall out of his shirt pocket when he unbuttons his shirt. What questions would the nurse want to ask him to determine if he is smoking cigarettes or using drugs? What would be the nurse's next action if he does admit he is not only heavily into drugs but also does not intend to stop using them?**

## Performance-Enhancing Substance Use Disorder

Anabolic steroids are derivatives of the natural hormone testosterone. Common names are stanozolol, an oral compound, and testosterone propionate, an injectable form. Adolescents take steroids (obtained illegally) to enhance lean body mass and muscular development and so improve their athletic ability or appearance. These substances have side effects of euphoria and lessened fatigue, which make them doubly appealing.

Unfortunately, steroid use can lead to early closure of the epiphyseal line of long bones, acne, elevated triglyceride levels, hypertension, aggressiveness, possibly psychosis, abnormal liver function, and perhaps liver cancer. In addition, athletes using them and paying vigorous sports can die from ventricular hypertrophy (Montisci, El Mazloun, Cecchetto, et al., 2012).

Students using anabolic steroids need to be identified so they can be cautioned that

the use of such drugs is illegal in sports competitions as well as being detrimental to their health. If needles are shared for administration, they additionally run the risk of acquiring hepatitis B or HIV infections.

Human growth hormone is a second drug used to enhance athletic performance. This increases muscle strength and stamina and is more difficult to detect than steroid use and so is also becoming a commonly abused substance in athletes ([Albertson, Chenoweth, Colby, et al., 2016](#)). It's dangerous in adolescents because side effects are joint pain and swelling and the development of diabetes.

## Marijuana

Marijuana (widely known as “pot,” “grass,” or “weed”), derived from the leaves and stems of the Indian hemp plant *Cannabis sativa*, is the most frequently abused illicit substance, next to alcohol, used by adolescents ([Kaul, 2016](#)). It is generally rolled into cigarettes (“joints” or “reefers”) and smoked, although it can also be mixed with food or sniffed. Scraping the resin from the flowering leaves produces a much stronger substance called hashish. Sinsemilla is a seedless form that is even more potent.

Breakdown products of marijuana are not readily eliminated from the body and remain in the fatty cells of the brain. This residue can create synaptic gaps that interfere with electrical brain waves and memory storage, especially for short-term memory. Physical and psychological effects of all forms of marijuana are euphoria and a sense of well-being, temporary impairment of coordination, rapid mood swings, decreased attention span, and loss of memory for recent events (up to 1 hour's time). Withdrawal symptoms include irritability, drowsiness, and cravings for high-carbohydrate snacks.

Long-term side effects can include pulmonary disorders such as sinusitis, bronchitis, emphysema, and perhaps lung cancer (which can develop after only 1 year of continual use compared with 20 years of cigarette use) as well as lack of sperm formation or subfertility in males ([Fronczak, Kim, & Barqawi, 2012](#)).

Because the drug is prescribed to relieve nausea and vomiting, adolescents may view it as harmless. Help them to realize marijuana is more than an amusing leisure activity or a way to relieve stress so they can put its long-term effects into perspective.

## Amphetamines

Amphetamines are a group of drugs used in the treatment of hyperactivity and narcolepsy, among other central nervous system disorders. They are easily manufactured in “meth labs” in people's homes and so may be readily available to adolescents. Amphetamines are called “uppers” or “speed” because they give the user a false sense of well-being, alertness, or self-esteem. A newer, stronger form that produces intense symptoms is known as “ice.” Some of the side effects of either form are aggressive or demanding behavior, paranoia, and extreme restlessness. Chronic methamphetamine abuse results in destruction of teeth enamel or blackened, crumbling teeth ([Auten, Matteucci, Gaspary, et al., 2012](#)). Amphetamines can be especially

appealing to obese adolescents as they suppress the appetite and result in weight loss.

## Cocaine

Cocaine is one of the most popular drugs of abuse for late adolescents; its use can begin in adolescents. The drug may be sniffed into the nose (snorted), smoked, or injected intravenously. Occasionally, it is combined with heroin (termed a “speedball”) and injected. Common street names for cocaine are “snow” and “white lady” because of its fine, white powder. A stronger form, called “crack,” is manufactured by heating cocaine powder with baking soda and water. This preparation process is dangerous in itself because it involves using volatile solvents that can ignite or explode. The resulting drug, often called “freebase” or “rock,” is so strong it can cause immediate cardiac and respiratory arrhythmias ([Paczynski & Gold, 2011](#)).

It is difficult to document how many adolescents use cocaine, but estimates range from 3% to 9%. After absorption, blood levels rise rapidly for the first 20 minutes, peak at 60 minutes, and then decline over the next 3 hours. Although a toxic dose of cocaine is usually considered to be 600 to 700 mg, toxicity has been reported in as low as a 20 mg dose (a single line).

Cocaine produces the physical effects of increased pulse and respiration rates, increased temperature, increased blood pressure, and decreased appetite. Psychological effects produced are euphoria, excitement and restlessness, increased sociability, and possible hallucinations.

Toxic symptoms include seizures, tachyarrhythmias, tachypnea, hypertension, nausea and vomiting, abdominal pain, headaches, chills, and fever. It can be a major cause of cardiovascular arrest in late adolescents ([Eisendrath & Lichtmacher, 2013](#)). It may be a cause of adolescent automobile accidents because it creates such a sense of well-being and safety ([Stoduto, Mann, Ialomiteanu, et al., 2012](#)).

Cocaine is rarely ingested orally, but occasionally, adolescents swallow it when trying to hide a supply from parents or school personnel. Gastric acid destroys the action of cocaine, so unless the amount is extremely large, it is potentially harmless when swallowed in this way.

Teach adolescents that although cocaine sniffing may be fascinating and offer temporary pleasure and relief from stress, it also causes psychological dependency and is potentially extremely dangerous because of its cardiac and respiratory effects. Chronic inhalation of cocaine can cause ulceration in the mucous membrane of the nose, and injection of the substance exposes an adolescent to the risk of HIV and AIDS or hepatitis B. During pregnancy, it can cause separation of the placenta with potential fetal and maternal death ([Mbah, Alio, Fombo, et al., 2012](#)).

## Hallucinogens

Examples of hallucinogenic drugs used by adolescents are lysergic acid diethylamide (LSD), dimethyltryptamine (DMT), 2,5-dimethoxy-4-methylamphetamine (STP),

phencyclidine (PCP) hydrochloride, *Salvia divinorum*, mephedrone (“bath salts”), and methaqualone (Quaalude). The use of LSD has substantially increased in popularity since the 1960s when it first became available because it is a drug that can be manufactured by an informed adolescent in a “kitchen lab.” 3,4-

Methylenedioxymethamphetamine (MDMA), also known as Molly/Ecstasy, is similar to both stimulants and hallucinogens. It gives users feelings of euphoria, pleasure, distorted time, and sensory perception. It is popular at dance clubs and “raves.” Usually, this drug is taken in tablet or capsule form; however, it can be snorted as well. MDMA affects typically last 3 to 6 hours, and side effects may include irritability, aggression, depression, anxiety, decreased appetite, and memory problems. There is still some disagreement as to whether MDMA is addictive because research results had demonstrated varying results.

All of these drugs cause bizarre mind reactions such as distortion in vision, smell, or hearing. Adolescents report seeing colors more vividly than they have ever seen them before, hearing sounds so clear they cause physical pain, or perceiving themselves as being totally impervious to harm leading to “good trips” or “bad trips.”

Recurrences or flashbacks of drug-induced experiences may, unfortunately, recur at unpredictable times and in unexpected places. Such flashbacks are not only disconcerting but also can be dangerous, especially if they occur while a person is driving a motor vehicle. They can be so frightening that some users believe they are becoming mentally deranged.

### ***QSEN Checkpoint Question 33.6***

#### **TEAMWORK & COLLABORATION**

At the conclusion of a long conversation, Raul admits he has experimented with cocaine. Which assessment finding would most strongly warrant a referral to addiction services?

- a. Raul has frown lines in his forehead.
- b. Raul has thin, fissured lips.
- c. Raul’s eyebrows appear thin.
- d. Raul lacks nasal hair.

*Look in [Appendix A](#) for the best answer and rationale.*

## Opiates

Opiates include drugs such as heroin, meperidine (Demerol), and morphine. At one time, these were not typically used by adolescents because they are expensive, but their use has increased with staggering health effects. According to the [CDC \(2017a\)](#), drug overdose involving heroin increased from 1.2 to 2.8 per 100,000 for those 15 to 24 years old between 2010 and 2015.

The American Academy of Pediatrics recommends screening adolescents for

substance use disorders. Screening, Brief Intervention, and Referral to Treatment (SBIRT) is a model used to help prevent substance use disorders and to limit the progression to riskier drugs, such as heroin (Harris, 2016). The nurse should discuss the use of opiates with the adolescent and encourage an open dialogue to identify whether they are at risk for substance use consequences.

Opiates can be extremely dangerous because of their tendency to decrease one's respiratory rate. The increase in overdose deaths has prompted the training of first responders in the use of naloxone to reverse the respiratory depression effects and to decrease the rate of deaths from overdoses. Adolescents should be encouraged to seek care for themselves or others whenever an overdose situation is apparent as prompt treatment can be lifesaving.

### Assessment of Substance Use Disorders

If adolescents form a trusting relationship with healthcare providers, they will generally disclose high-risk behaviors (Box 33.6). Increased school absences and a decrease in school achievement are important to note. Diagnosis of hepatitis B, HIV positive, or appearing to receive no benefit from usual analgesic agents are later indicators of high-risk behaviors. Physical symptoms that indicate specific substance use disorder are summarized in Table 33.3.

#### BOX 33.6

#### Nursing Care Planning Tips for Effective Communication

You talk to Raul, age 15 years, in an adolescent clinic and provide patient education on substance use.

*Tip:* Sometimes, adolescents repeat the same answer to questions even when different questions are asked in conversations. Asking them about their friends and their drug use may encourage the adolescent to respond more fully to questions.

**Nurse:** Some adolescents find it useful to read about drug use among their peers.

Here's a pamphlet about adolescents and drug use.

**Raul:** Okay, thanks.

**Nurse:** Sometimes, it's difficult to talk to parents or other adults about such things.

**Raul:** That's true.

**Nurse:** Do any of your friends use drugs?

**Raul:** Some people in my class have tried drugs. I never would because I am on the baseball team and I would be kicked off if I did any drugs.

**TABLE 33.3 SYMPTOMS TO HELP IDENTIFY SUBSTANCE USE DISORDERS**

Drugs Used	Symptoms of Use	Dangers
------------	-----------------	---------

Glue	Violence, drunken appearance, dreamy or blank expression; glue smears on clothing or fingers; tubes of glue, paper bags in possession	Lung, brain, or liver damage; death through suffocation or choking; anemia
Heroin, morphine, codeine	Stupor, drowsiness, needle marks on body, watery eyes, loss of appetite, bloodstains on shirt sleeve, runny nose; possession of needles or hypodermic syringes, cotton, tourniquet strings, burnt bottle caps or spoons, glassine envelopes	Death from overdose; addiction; liver and other infections due to unsterile needles
Cough medicines containing codeine	Drunken appearance, lack of coordination, confusion, excessive itching; possession of empty bottles of cough medicine	Addiction
Marijuana	Sleepiness, wandering mind, enlarged pupils, lack of coordination; discolored fingers, strong odor of burnt leaves; possession of small seeds in pocket lining, cigarette papers	Psychological dependence
Hallucinogens (LSD, DMT, PCP)	Severe hallucinations, feelings of detachment, incoherent speech, cold hands and feet, laughing and crying, vomiting, strong body odor; possession of cube sugar with discoloration in center	Suicidal tendencies, unpredictable behavior; chronic exposure may have neurologic effects
Stimulants (methamphetamine, cocaine)	Aggressive behavior, giggling, silliness, rapid speech, confused thinking, no appetite, extreme fatigue, black caries, dry mouth, shakiness, insomnia, absence of nasal hair; possession of pills or capsules of varying colors, possession of a glass pipe	Death from overdose; hallucinations; psychosis
Depressants (barbiturates, alcohol)	Drowsiness, stupor, dullness, slurred speech, drunken appearance, vomiting, odor of alcohol on breath; possession of pills or capsules of varying colors	Death or unconsciousness from overdose; addiction;

Steroids	Aggressive behavior, increase in muscle strength and mass	seizures from withdrawal Violent actions; possibly tumor growth
----------	---	---

LSD, lysergic acid diethylamide; DMT, dimethyltryptamine; PCP, phencyclidine.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for injury related to the use of alcohol or addictive chemical substances

**Outcome Evaluation:** Adolescent states he is not experimenting with drugs; can describe a way to respond to peers who encourage such use; shows no evidence of drug use such as lethargy, confusion, positive urine drug screen, or parental suspicion.

One of the greatest dangers of early drug experimentation is that it affects an adolescent's ability to solve problems, which creates a delay in maturity. Because adolescents may avoid adults who might detect their drug use, they remove themselves from exposure to adult role models.

Important teaching points for avoiding drug use include:

- Whether a drug is inhaled, swallowed, or injected, it still is absorbed, enters your body, and is therefore potentially harmful.
- Relying on drugs to give you courage to solve problems (or to help you forget you have problems) prevents you from learning to handle life situations and maturing.
- The bottom line of substance use disorder is that you have the final say: You are the only one who can stop chemical dependency from happening.
- Despite their social acceptability, alcohol and nicotine are drugs. A short span of daily use of either can make you addicted.

Therapeutic communities or 24-hour facilities in which adolescents can live while they recover from chemical dependency may be necessary for some adolescents. The aim of all these programs is to increase adolescents' sense of self-esteem, improve problem-solving ability, realign them with society's values, and increase their self-awareness so they can function effectively without the aid of substances of abuse. Unfortunately, campaigns against substance use disorder for adolescents have not been very successful, so the problem continues.

Adolescents who are no longer chemically dependent should be evaluated by a history and physical examination at all healthcare visits because, if the circumstances that initially caused them to become chemically dependent recur, they may return to a dependency pattern. A continuing relationship with healthcare personnel not only

allows time for this evaluation but also provides concrete role models of nonchemical, productive behavior.

## CONCERNS REGARDING DEPRESSION AND SELF-INJURY

*Self-injury* includes a range of self-destructive actions from cutting to suicide, the planned intent to end one's life. Cutting is found more frequently in girls than boys and can begin as early as grade school (Barrocas, Hankin, Young, et al., 2012).

Successful suicide occurs more frequently in males than in females, although more females apparently attempt suicide than males (a ratio of about 8:1). Adolescent suicides tend to be attempted most often in the spring or the fall, reflecting school stress at these times of year, and between 3 PM and midnight, reflecting depression that increases with the dark. Suicide is so common in adolescents it ranks in the top four causes of death in the 10- to 24-year-old age group. The top four causes of death are motor vehicle crashes (23%), other intentional injuries (17%), homicide (14%), and suicide (17%) (Kann, McManus, Harris, et al., 2016). This statistic may actually be underestimated as they may be reported as unintentional injuries. Injuries or deaths that are due to high-risk behaviors in adolescents, such as motor vehicle accidents, may mask a suicide attempt. Some degree of depression is present in most adolescents because they are losing not only their parents while they grow apart from them but also their carefree childhood (Fried, Williams, Cabral, et al., 2013). If school failure, loss of a girlfriend or boyfriend, loss of a competition with loss of self-esteem, or rejection by a peer group is superimposed on existing depression, the pressure may be great enough to cause some adolescents to attempt suicide. This makes the reasons for adolescent suicide varied: Incest, maltreatment, increased chemical dependency, marital instability in the family, and poor problem-solving ability are all reasons that may lead an adolescent to decide death may be easier than coping with overwhelming problems.

Yet, other reasons may involve anger with others, trying to get even, and manipulation (e.g., psychological blackmail) as a way of having one's needs met. Because some adolescents may be unable to believe a parent was at fault in the case of divorce, they may instead believe they somehow caused the parent to leave.

### Assessment

Adolescents need to have thorough physical examinations at health maintenance visits to assure them they are in good physical health. Assess at these visits signs of depression such as anorexia, insomnia, excessive fatigue, or weight loss (Gampetro, Wojciechowski, & Amer, 2012). In younger adolescents, depression may be manifested not so much by appearing sad, but by behavior problems such as disobedience, temper tantrums, truancy, and running away. Self-destructive behavior or injury proneness; difficulties in school; acting out with chemicals, alcohol, or sexual promiscuity; or trouble with legal authorities may be further clues.

Occasionally, depressed adolescents find it so hard to be alone that they seek constant activity as a means of escape. Others may withdraw from contact with other people and become completely isolated. Either behavior needs to be detected through assessing activity and interaction levels.

Adolescents who attempt suicide do not fall into any one category, although many tend to be loners or have difficulty expressing their feelings to others and, therefore, do not receive emotional support from friends or family. Others appear to be “perfect” students, so friends or family do not see a need to counsel them. The stress of trying to continually achieve at a high level, however, is the trigger that provokes suicide. LGBT youths appear to have higher levels of suicide than others, reflecting the level of stress they may be experiencing. Assess for LGBTs as well (Shields, Whitaker, Glassman, et al., 2012).

If another member of a family or a close friend commits suicide, the chance an adolescent will also do so is greater than usual. The anniversary of a family member’s suicide is an especially vulnerable time because wishing to join the dead family member may appear attractive. Adolescent suicide rates may actually reach epidemic proportions after a popular student’s suicide. Students who have Internet contacts may arrange a group suicide as a method of making a statement or gaining support.

Because suicide usually reflects a problem in family interaction, a family assessment is helpful. A thorough family history may reveal conflict with one or both parents or reveal how little support the adolescent receives at home. School friends may often be the ones who are first aware that an adolescent is contemplating suicide. Caution parents not to discount reports from their child’s friends who tell them they are concerned.

Close to the chosen time of suicide, some adolescents demonstrate characteristic behaviors that show they are making preparations to end their life. Teach family and friends these typical danger signs (Box 33.7).

### BOX 33.7

#### Nursing Care Planning Based on Family Teaching

##### SUICIDE WARNING SIGNS

**Q.** Raul’s father says to you, “Our neighbor’s son recently committed suicide. What are warning signs of this to look for in our son?”

**A.** The following are commonly seen clues:

- Giving away prized possessions
- Organ donation questions, such as “How do you leave your body to a medical school?”
- Sudden, unexplained elevation of mood, which may indicate the individual has reached a decision about the suicide and feels relief
- Injury proneness, carelessness, and death wishes
- Decrease in verbal communication or a statement such as “This is the last time you

will see me”

- Withdrawal from peer activities or previously enjoyed events
- Previous attempt (80% of all completed suicides have been preceded by a failed attempt)
- Preference for art, music, and literature with themes of death
- Recent increase in interpersonal conflict with significant others
- Running away from home
- Recent experience of a friend or famous person committing suicide
- Inquiring about the hereafter
- Asking for information (supposedly for a friend) about suicide prevention and intervention
- Almost any sustained deviation from the normal pattern of behavior

When caring for a child after a suicide attempt, ask enough questions on a health history so you can help to analyze whether an adolescent made a detailed suicide plan. For example, a young person who took four aspirins and left the empty aspirin container conspicuously on the kitchen counter just before his mother was due to arrive home from work is more likely to be only making a cry for help; one who took 100 aspirins and hid the container under the bed just after his mother left for 8 hours of work is much more apt to be making a serious attempt.

As you care for an adolescent in a healthcare facility, you may be the first to realize the boy or girl is not “just talking” about suicide (it is a fallacy that people who talk about suicide do not attempt it) but is someone with a definite, well-thought-out plan to accomplish it. An adolescent who has been admitted to a hospital unit after a serious suicide attempt may formulate a new plan that will be successful the next time unless some action is taken and the adolescent’s life can be changed in some way (see [Box 33.8](#) for an interprofessional care map for an adolescent with possible suicide intent).

### BOX 33.8

#### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR AN ADOLESCENT WITH POSSIBLE SUICIDE INTENT

Raul is a 15-year-old boy you meet at an adolescent clinic. His chief concern is a head cold. He has numerous acne lesions on his forehead and cheeks. His parents tell you Raul seemed depressed for a long time after his girlfriend broke up with him but now seems happy again. They are pleased to see him maturing so much; for example, he recently gave away his collection of baseball cards to a young neighbor. You mention to Raul a decongestant would probably make him feel better. He asks you how many pills it would take to kill someone and then jokes he was kidding.

**Family Assessment:** Patient lives with both parents and two younger siblings. Father manages a funeral parlor; mother works as a beautician for funeral parlor. Patient

describes finances as “All right, if you think burying people is a good way to earn money.”

**Patient Assessment:** Fifteen-year-old male with history of acne for the last 6 months. Reports washing his face approximately five or six times a day with abrasive soap and covering lesions with cocoa butter cream twice a day. He states, “Look at me. I look terrible.” Physical examination reveals scattered pustules and comedones on forehead and face. Two lesions on right cheek with large erythematous base and tender to touch. Remainder of physical examination unremarkable.

**Nursing Diagnosis:** Risk for self-injury related to disappointing appearance because of acne lesions and lack of friendships

**Outcome Criteria:** Adolescent states causes of acne; identifies measures for prevention and treatment; agrees to counseling to reestablish self-esteem.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse/nurse practitioner	Assess adolescent’s understanding of acne and its causes.	Instruct adolescent in measures to prevent and control acne.	Gentle washing removes irritating fatty acids. Omit greasy creams.	Patient states intent to follow recommendation to decrease acne symptoms.
<i>Teamwork and Collaboration</i>				
Nurse/primary healthcare provider/mental health counselor	Evaluate if patient was joking or was serious about a self-injury attempt.	Schedule consultation if patient may be contemplating self-injury.	Patient shows typical signs of self-injury behavior.	Mental health counselor meet with patient to make recommendation on patient safety.
<i>Procedures/Medications for Quality Improvement</i>				
Nurse/nurse practitioner	Assess what measures patient has been using to self-treat acne.	Discuss treatment options available.	Discussion provides the adolescent with correct information on acne therapy.	Patient describes full range of therapies available and what new measures he would be willing to try.
<i>Nutrition</i>				

Nurse/nutritionist	Assess patient's understanding of the effect of nutrition on acne.	Counsel patient to follow a well-balanced diet.	No particular food is associated with development of acne, despite old beliefs.	Patient states he understands food intake is not the major cause of acne.
--------------------	--	---	---	---

*Patient-Centered Care*

Nurse	Assess family's communication level, overall coping techniques, and abilities.	Discuss how better communication can aid in helping adolescent cope with life changes.	Better communication among family members provides support for all family members.	Parents discuss family communication pattern and make suggestions for better patterns.
-------	--	--	--	--

*Psychosocial/Spiritual/Emotional Needs*

Nurse	Assess how acne affects patient's self-esteem.	Review and reinforce with adolescent positive attributes about self.	Positive attributes provide a foundation for rebuilding self-esteem.	Patient states he knows that others value his friendship above his appearance.
-------	--	--	--	--

*Informatics for Seamless Healthcare Planning*

Nurse/nurse practitioner/mental health counselor	Assess with mental health counselor if it will be safe for patient to return home.	Give patient hotline telephone number and instruct to use as needed.	Knowing a support source is available can be as valuable as actually contacting the source.	Patient assures staff he has the hotline number available and will call if needed.
--	--	--	---	--

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for violence, self-directed, related to symptoms of depression or expressed desire to hurt oneself

**Outcome Evaluation:** Patient expresses feelings of depression to healthcare

providers or other adults; states he will contact support person should the desire to commit suicide become overwhelming.

Crisis intervention for adolescents who are contemplating suicide includes trying to alleviate their pain and depression and counseling them in an effort to help them change their perspective on the value of life. Be aware that establishing expected outcomes with adolescents who are contemplating suicide or who have made an attempt will be difficult because they are often too depressed to come up with alternative solutions to their problems (their goal was to kill themselves, not solve problems).

It is important not to underestimate adolescents' determination and capability to end their own life. In most instances, adolescents at this point need referral to a consultant who is well versed in suicide prevention to improve self-image and offer alternative solutions to problems.

As another measure, try to find out the things in the child's life that are still viewed as important; build a plan that will help view life as worth living enough to work through difficulties. Show them how no one can change everything, but everyone can make one or two changes that can make a difference. After these small changes are made, a domino effect can be created to change more and more of one's circumstances.

Because adolescents resort to suicide as a method of solving problems, helping all adolescents learn better problem-solving skills is a prime intervention strategy. Ask "what would happen if" questions such as "Suppose you did fail a course; what would be the worst that could happen?" Your help in this area is important because, generally, persons who are depressed do not have strong support people around them or do not believe anyone cares enough about them to help.

For an adolescent's safety, a period of observation on an adolescent or a psychiatric service is desirable after a suicide attempt to prevent the adolescent from inflicting personal injury again and to allow an assessment in a neutral setting, away from the stress that precipitated the attempt. Evidence for the effectiveness of selective serotonin reuptake inhibitors, as are used with adults, is limited with children; these medications have a black box warning to use with caution in persons under 25 years of age as some have been associated with elevating the mood of depressed children enough that they then are able to formulate a plan and commit suicide after taking them (Gibbons, Brown, Hur, et al., 2012).

The continuing evaluation by both history taking and physical examination should be ongoing because the young person who has attempted suicide once may attempt it again if support people and better problem-solving abilities are not available.

**Raul seems unusually happy at a clinic visit when usually he is sad because of loss of his girlfriend. The nurse knows he recently gave away his collection of baseball cards to a neighborhood boy because “I won’t need them where I’m going.” Would the nurse be concerned about him? If the nurse learned he is about to leave to be an exchange student in England, would this affect your assessment?**

## **CONCERNS OF THE ADOLESCENT AND FAMILY WITH UNIQUE NEEDS**

Homeless youth (i.e., runaways) and adolescents who are disabled have specific concerns that need special attention.

### **Homeless or Runaway Youth**

A *runaway* is commonly defined as an adolescent between the ages of 10 and 17 years who has been absent from home at least overnight without permission of a parent or guardian. Fortunately, most teenagers who run away do not go far or stay away long (under 1 week); about 1 in 20 adolescent runaways stays away as long as 1 year, and some never return home and become homeless youth. Runaway adolescents are most likely to be from either low- or high-income families. Stress factors such as family unemployment, alcoholism, sexual maltreatment, incest, attempted suicide, and poverty are frequent characteristics in their families (Moskowitz, Stein, & Lightfoot, 2012). They are slightly more likely to be male than female.

### **Assessment**

Running away is usually preceded by an argument with parents that is often the last straw after a number of long-term disagreements. Other reasons may be personal concerns such as loneliness; pregnancy; and problems with friends, school, or the police. A school history often reveals frequent truancy, failing grades, possible drug use, and runaway behavior by friends. It is a sad fact that some adolescents are “throwaways” or cannot remain at home because they have been rejected by their families.

Common health reasons for which runaway adolescents are seen at healthcare facilities are sexually transmitted diseases, including HIV and AIDS, rape, pregnancy, substance use disorders, hepatitis, and vaginitis. They also have a high incidence of suicide attempts (Palepu, Hubley, Russell, et al., 2012).

When caring for adolescents with these concerns, be certain to secure a thorough history so the fact that they are no longer living at home will not be overlooked. Do not reveal you are shocked by a report such as an adolescent has been sleeping on a park bench for 2 months, has been robbed, or steals to obtain money because this could prevent you from learning even greater concerns, such as having a sexually transmitted

disease, being pregnant, or using drugs.

As they lack references for jobs and do not necessarily qualify for public assistance programs, homeless adolescents generally have no secure source of income. This can cause both males and females to resort to stealing or prostitution to support themselves. Legally, they are considered to be juvenile delinquents, so police are required to return them to their homes if discovered.

Because many adolescents who run away are not good problem solvers, setting goals with them may be difficult. A short-term goal to stay home through a holiday rather than a long-term one of finishing high school may be all you can achieve. Try to imagine yourself in the adolescent's circumstances to determine whether your health instructions or goals will be sensible for their lifestyle. As they have no money for food, giving them an instruction to eat iron-rich foods to prevent anemia, for example, may be ludicrous. If they do not have a source of running water, telling them to soak a lesion or change a dressing may be impossible. If they don't have a means of transportation, they may be unable to return to the healthcare facility for frequent follow-up visits so try to meet as many of the runaway's needs as possible at one visit. Remember that many runaways have associated school failure and so have poor health literacy; discuss the information with them as well as give them a pamphlet or written instructions.

Be certain, also, to ask if an adolescent wants to return home. Even though being homeless is high stress, and many adolescent runaways want to take the first step back toward their parents, they may not know how to begin the process or be certain they will be welcomed back at home. Check if they are familiar with the National Youth Crisis Hotline, which they can telephone day or night when they want to return home (1-800-448-4663 [1-800-HIT HOME]). Remember also they are runaways because, for some reason, their home was intolerable. Although they agree to return home, they may not remain there unless circumstances have been or can be changed.

### **A Physically Challenged or Chronically Ill Adolescent**

Achieving a sense of identity may be difficult for adolescents who have a chronic illness or other challenges. It is vital, however, for such individuals to learn to look past their particular condition to their real selves. For example, a 16-year-old girl in a wheelchair must learn to perceive herself as a teenager who is intelligent, is a good conversationalist, has a good sense of humor, enjoys watching football, and only incidentally uses a wheelchair to ambulate.

Some of the biggest problems of chronically ill adolescents are likely to be difficulties in being as independent as they would like to be, achieving in school, and establishing intimate relationships. Those who cannot learn to drive when their friends are learning to do so, who are not invited to dances and parties because of a unique concern, or who are too hesitant to ask someone to go with them may feel acute loneliness and loss of self-esteem. Moreover, the loss of many hours of school due to illness or frequent hospitalization may result in the inability to pursue a desired career, at least a delay in doing so. Adolescence may be the first time these individuals realize

certain occupations or opportunities, such as a military career, may be closed to them. As they prepare to leave the security of a familiar school system, it may be the first time they examine just how they will be able to function on their own. Some may come to realize they will never be able to do so with complete independence.

Chronic hospitalization or the realization they will never be free of symptoms can cause depression in such adolescents, placing them at high risk for substance use disorders or self-injury. Helping these adolescents realize that even completely well people must compromise life decisions for other reasons such as lack of money, lack of qualifications, or other personal responsibilities helps them feel they are not so different from others. The fact an adult is willing to make a time commitment to discuss their future with them can be enough to give these adolescents the self-esteem they need to alter aspirations and plans and find a future role consistent with their capabilities. Nursing actions to encourage a sense of identity in an adolescent with a long-term illness or who is physically challenged are summarized in [Table 33.4](#).

**TABLE 33.4 NURSING ACTIONS THAT ENCOURAGE A SENSE OF IDENTITY IN THE PHYSICALLY CHALLENGED OR CHRONICALLY ILL ADOLESCENT**

Category	Actions
Nutrition	If adolescent is on special diet, discuss role of food preferences with dietitian (e.g., hot dogs, pizza). Respect food preferences in all ways possible.
Dressing change	Allow adolescent to order supplies. Ask for suggestions as to final appearance of dressing. If soaks are included, have adolescent time the treatment. Allow adolescent to choose time for dressing change.
Medicine	Offer the adolescent a choice of site for injection or intravenous insertion to encourage a sense of control. Teach name, action, and possible side effects of medicine.
Rest	Contract with adolescent for time and length of rest periods.
Hygiene	Respect modesty as you would with an adult. Contract with adolescent for extent of self-care (e.g., will give own bath and make bed, not medicate self).
Pain	Encourage adolescent to express pain and teach distraction technique for sharp pain, such as deep breathing and counting backward from 100. Encourage adolescent to ask for analgesics as needed.
Stimulation	Provide favorite music with earphones. Provide a radio to listen to talk shows to foster active involvement. Encourage schoolwork (you may need to help adolescents divide up school assignments so they do not become overly fatigued and

frustrated).

Provide crossword puzzles or card games to increase socialization (make or have the adolescent make a card deck from pieces of paper if one is not available).

Encourage adolescents to network with one another.

Encourage adolescents to keep in contact with friends through texting, e-mail, or writing notes.

## Nutrition and the Chronically Ill Adolescent

Adolescents who are not fully mobile must be cautious of their total calorie intake because, as growth needs decline at the end of adolescence, they may become obese. They should also be knowledgeable about good nutrition, so they can participate in meal planning, an action that can help them feel a sense of control over this area of their life. Assess how often they have a chance to eat at fast-food restaurants; although this is not a source of excellent nutrition, eating there occasionally can provide an important social experience and a chance to be like their peers.

### What If . . . 33.4

**The nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to adolescent growth and development (see [Box 33.1](#)). What would be a possible research topic to explore that is pertinent to this goal that would be applicable to Raul's family and that would also advance evidence-based practice?**

## KEY POINTS FOR REVIEW

- The major milestones of development in the adolescent period are the onset of puberty and the cessation of body growth. Between these milestones, physical growth is rapid, although the development of adult coordination and thought processes is slow.
- The development of secondary sex characteristics is completed during adolescence. These are rated according to Tanner stages.
- The developmental task of an adolescent according to Erikson ([Dunkel & Harbke, 2017](#)) is to establish independence from parents by gaining a sense of identity versus role confusion. Therefore, adolescents usually respond best to healthcare personnel who respect their attempts at independence and who allow them as many choices as possible in care.
- Adolescents reach a point of cognitive development termed *formal operational thought*. With this gained, they are able to think in abstract terms and use rational thinking to arrive at conclusions.
- Adolescents need to consume adequate calories and especially protein, iron, calcium,

and zinc to meet their increased growth needs, but at the same time, be certain they don't become overweight.

- Being an adolescent is difficult in today's world. Be aware that to reduce stress, some adolescents may begin to abuse substances. Asking about an adolescent's drug experiences during a health assessment is not intruding on privacy. Rather, it is a method of safe health interviewing and helps in planning nursing care that not only meets QSEN competencies but also best meets a family's total needs.
- Promoting adolescent safety is an important nursing role. Motor vehicle accidents, homicide, and suicide are leading causes of death in this age group.
- Common health problems in an adolescent are sometimes minor and include poor posture, fatigue, or acne; they can also be serious, such as beginning hypertension, substance use disorders, and scoliosis. Identifying these problems and referring an adolescent for help are important nursing actions.

### CRITICAL THINKING CARE STUDY

Genève is a 14-year-old who lives with her parents and an 8-year-old brother. They take a vacation for 2 weeks every summer at the beach.

1. Genève has asked her parents if she can bring her best friend, a 24-year-old neighbor, with her on vacation. Her parents ask you whether that would be a good idea. How would you respond?
2. Genève was stopped by security at a department store for shoplifting a red sweater she said she needed to wear to a party that evening. Her father paid for the sweater so she was not charged with shoplifting. Would you suggest her parents let her wear the sweater to the party?
3. Genève has her own television in her bedroom. Her parents tell you she often stays awake until 2 in the morning watching programs. Her parents ask you if they should monitor what she watches or if she is old enough to do this for herself.

# 34

## Child Health Assessment

*Keoto Wiser is a 13-year-old you meet in an ambulatory clinic. Her father has brought both her and her 2-year-old sister, Candy, for health assessment before Keoto begins seventh grade. He knows they both need an immunization update. Her father is worried Keoto doesn't see well because she always sits close to the television set. He's concerned that if glasses are prescribed, his daughter won't be able to play on her school's soccer team.*

*Previous chapters described the normal growth and development of children. This chapter adds information about techniques for assessing the health of children, including history taking; physical examination; related screening procedures for hearing, vision, and development; and recommended immunizations. This information builds a base for care and health teaching for differing age groups throughout childhood.*

**What questions would you want to ask Keoto? What screening tests for vision would be best for this 13-year-old? What could you do to help her adjust to wearing glasses if they are prescribed?**

varicocele

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe the purposes and techniques of health assessment in children of all ages.
2. Identify 2020 National Health Goals related to health assessment of children that nurses can help the nation achieve.
3. Assess a child and family by health interview, physical examination, and developmental screening.
4. Formulate nursing diagnoses based on health assessment findings.
5. Identify expected outcomes based on health assessment findings as well as help parents manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care, such as conducting an age-appropriate health interview or physical examination by modifying techniques based on the child's age.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of health assessment with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

---

A nursing assessment is not only the first step in the nursing process but also the fundamental means by which healthcare personnel establish and maintain contact with children and their families throughout childhood. Child health assessment is especially important as an opportunity to provide families with information about health promotion, signs of health and illness, and expected developmental progress in children. This anticipatory guidance can have a long-lasting and positive impact on the health of children and their families (Cameron, Rice, Sparkman, et al., 2013).

An effective assessment for the maternal–child population first requires you to be familiar with health maintenance standards and usual findings because this knowledge is essential to the ability to recognize illness. Most health screening procedures are performed in ambulatory settings such as pediatric clinics, healthcare offices, community clinics, and schools, but they can be used to evaluate children in all settings, including during hospitalizations.

Sometimes, it is necessary to complete just a partial history or a partial physical examination, such as when a child is referred for a vision examination. This chapter, however, covers all aspects of physical examination, so when necessary, a complete examination can be performed. Assessment procedures specific to particular illnesses are discussed in later chapters with the illness they detect. Box 34.1 lists 2020 National Health Goals related to health assessment in children.

#### BOX 34.1

#### Nursing Care Planning Based on 2020 National Health Goals

A number of 2020 National Health Goals directly relate to health assessment of children:

- Developmental: Increase the proportion of children with a diagnosed condition identified through newborn screening who have an annual assessment of services needed and received.
- Increase the proportion of children and youth, 17 years of age and younger, who have a specific source of ongoing care from a baseline of 94.3% to a target of 100%.
- Increase the proportion of adolescents aged 12 to 19 years who have had a hearing examination in the past 5 years from a baseline of 79.3% to 87.2%.
- Increase the proportion of preschool children aged 5 years and under who receive vision screening from a baseline of 40.1% to a target of 44.1%.
- Achieve and maintain effective vaccination coverage levels for universally recommended vaccines among young children from baselines of 85% (DTaP), 94% (hepatitis B), 57% (*Haemophilus influenzae* type b), 94% (poliomyelitis), 91% (varicella), and 92% (MMR) to a target level of 90% (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by actively participating in health assessment, including vision and hearing, and conscientiously screening for and administering vaccines.

### *Nursing Process Overview*

## FOR HEALTH ASSESSMENT OF THE CHILD AND FAMILY

### **ASSESSMENT**

Health assessment can be a positive, educational experience for the child and family if time is taken to listen carefully to the family's concerns and responses to questions. Never rush either an interview or a physical examination. Be sure children have time to familiarize themselves with the environment and the equipment that will be used. The recommendations for standard preventive child health care for the United States are available at <http://thePoint.lww.com/Flagg8e>.

### **NURSING DIAGNOSIS**

Nursing diagnoses related to health assessment most commonly speak to a health concern identified at the time of the assessment. When establishing nursing diagnoses, however, be certain not to overlook diagnoses that accentuate the healthy functioning of a child and family in addition to addressing any specific problems that have been identified. These wellness diagnoses are crucial components of the entire assessment picture. For instance, the nursing diagnosis of "Impaired social interaction related to lack of self-esteem secondary to disability" would be appropriate for a 4-year-old child who ambulates by wheelchair who, according to the parents, feels uncomfortable around other children. If the parents have difficulty adapting to their child's disability but are eager to accept advice from healthcare experts on how to provide the most stimulating environment for their child, the diagnosis "Readiness for enhanced family coping" would also be appropriate. Using both these diagnoses allows the development of a plan of care that takes advantage in the best way of this family's strengths.

### **OUTCOME IDENTIFICATION AND PLANNING**

Health promotion and illness prevention are vital parts of outcome identification following a health assessment. Helping parents plan for their child's next developmental stage or keeping them aware of important safety measures is also important. Remind parents about future immunizations that will be needed and be certain they know when to schedule the next healthcare visit. Refer parents to helpful websites and other resources when appropriate (see [Chapter 28](#)).

### **IMPLEMENTATION**

Health interviewing and physical examination both require a great deal of skill—skills that can only be perfected through practice. To perfect skills and judgment with children of different ages, take advantage of every opportunity by practicing

interviewing and physical examination techniques with them.

### **OUTCOME EVALUATION**

Health assessment of children is an ongoing process that does not end when the first database is created. Because children change so much, data must be added at all future interactions so the database remains current and meaningful. Examples suggesting expected outcomes have been achieved include:

- After a health examination, parents state they are satisfied with their child's motor development.
- After Snellen test, the child states she is aware her vision needs correction.
- The parents state they will continue to assess their child's growth by weighing the child weekly.

## **Health History: Establishing a Database**

The assessment of a young child begins with an interview of the child's parents. An adolescent or preadolescent may choose to be interviewed without the parents present, although many preadolescents and adolescents still prefer to have a parent with them for support.

The purpose of a health interview is to gather information that will direct physical or laboratory examinations to complete a thorough health evaluation. An extensive interview not only elicits facts such as parental problems in childrearing or detection of future health problems but also lays a foundation for health education and health promotion. Important principles of child health interviewing include establishing a conducive interview setting, formulating the right types of questions to ask, and organizing the information collected.

### **INTERVIEW SETTING**

An interview is best conducted in a private room with all parties seated comfortably (Fig. 34.1); if not seated, a healthcare provider can appear rushed and is also unable to interact at eye level. During the interview, be certain to call the parents by their names. This lets them know that their input and opinions about how their child is developing are valued. A question such as "Does Candy speak in sentences yet, Mr. Wisser?" is far more personal and a better form than "Does baby sit up yet?" As children grow, they are able to answer questions themselves.

**Figure 34.1** Maintaining good eye contact and allowing children to play as active a part as possible in the assessment process are important for good health interviewing.

## TYPES OF QUESTIONS ASKED

The phrasing of questions varies depending on the type of answer desired. Closed-ended and open-ended questions are two types of effective questions; compound, expansive, and leading questions, in contrast, are three types of questions to avoid.

### Closed-Ended Questions

This simplest form of question directly asks for a fact, such as “Did you take Candy’s temperature?” This is an effective type of question if a particular point is being sought. It is limited in scope, however, because the response usually will be a “yes” or a “no,” with no further elaboration.

### Open-Ended Questions

An open-ended question allows for elaboration. In contrast to the closed-ended question, “What did you do for Candy?” is open ended. The parent will answer with a list of all the things he did, such as he took Candy’s temperature, had her lie on the couch, gave her extra fluid, and so on. It is important to ask open-ended questions with school-age children and adolescents so they are encouraged to fully describe a problem (Box 34.2).

#### BOX 34.2

#### Nursing Care Planning Tips for Effective Communication

A second reason Keoto’s father has brought her to your ambulatory clinic is because she has noticed frequency and burning on urination.

*Tip:* At about 10 years of age, children are able to supply much of a health history by themselves. As children become teenagers, it is increasingly important for them to

do this because they may not have shared a total history with a parent. If a parent provides initial intake information, ask follow-up questions and make sure children have the opportunity to give a history in their own words.

In this scenario, when asked directly for information, Keoto's father responds before Keoto can respond. Some urinary tract infections occur in girls following sexual intercourse, making it important to ask if she is sexually active. If she is sexually active, it is also critical to provide anticipatory guidance regarding pregnancy prevention and safer sex practices.

**Nurse:** Hello, Keoto. What's the reason you've come into clinic today?

**Mr. Wiser:** It hurts when she urinates.

**Nurse:** I am going to ask Keoto more questions about this. Some of these questions may be of a personal nature and possibly embarrassing for her to share. Mr. Wiser, would you like to share any additional information before I ask you to have a seat in the waiting room while Keoto and I talk privately? I will come get you when we are finished.

**Mr. Wiser:** Oh, I didn't think of that. Sure. She is old enough to answer questions.

**Nurse:** [turning to Keoto after Mr. Wiser leaves] Anything we discuss now is confidential, and I would ask your permission before sharing with your parent. Can you tell me more about your symptoms?

**Keoto:** It hurts when I go to the bathroom.

**Nurse:** When did you first notice that?

**Keoto:** About an hour after I came in from my date last night.

**Nurse:** I'm going to ask you some questions of a personal nature because it will help guide me to the source of the problem. We'll also do some tests such as a urine test.

## Compound Questions

Compound questions should be avoided if all possible because the information they elicit is often inaccurate and must be followed by a clarifying question. An example is "Did Candy have nausea and vomiting?" The parent answers "yes," but it remains unknown whether Candy had vomiting and nausea, just vomiting, or just nausea because the question included multiple possibilities.

## Expansive Questions

Expansive questions are open-ended questions gone wrong because the question being asked is too vague to answer. "What can you tell me about Candy?" leaves a parent wondering where to start. "How has Candy been since her last visit?" limits the question and makes it answerable.

## Leading Questions

Leading questions supply their own answers and so they should also be avoided. “Candy has had all her immunizations, hasn’t she?” implies that Candy should have had them and perhaps implies that the parent is a poor caregiver if he responds with anything other than “yes.” The result of such an exchange could be a child left vulnerable to disease.

## **CONTENTS OF A HEALTH INTERVIEW**

Data gathering for an initial health assessment can be divided into nine sections:

1. Introduction and explanation
2. Demographic data
3. Chief concern
4. History of chief concern
5. Health and family profile
6. Day history
7. Past health history, including pregnancy history
8. Family health history
9. Review of systems

At return visits, the categories used generally include only introduction and explanation, chief concern, health and family profile, interval history, and day history.

### **Using Transition Statements**

While conducting a health interview, be certain to make a transition statement before shifting from one section of an interview to another because, without a transition, a parent can possibly misinterpret a question’s significance. For instance, if a parent has been providing information on the family’s hospital insurance policy and, without a transition, is asked whether the child has been vomiting, a parent may think the interviewer believes the child needs hospitalization when that is not the intent at all. A statement such as “Before we talk about Keoto’s current symptoms, let me ask you some general questions about your family so I can get to know you better” is an example of a good transition statement.

### **Introductions and Explanations**

As a matter of courtesy, you should introduce yourself to parents and children and introduce what topics you will be discussing. “Hello, Mr. Wiser, I’m Janet Dickson, a nurse here in the One-Day Surgery Department. I’d like to ask you some questions about Candy” is an example of a suitable introduction. Because some families have never had the benefit of in-depth health care, it is also helpful to include a statement about the subjects that will be discussed during the interview. For example, “So I can get a picture of Candy’s overall health, I’d like to ask you questions about not just why you’ve brought her here today but also her birth history and any past concerns you’ve had” would be appropriate. Hearing that, parents begin to concentrate on those areas

because they realize healthcare providers in this setting are interested not just in Candy's health on this particular day but also in her total health.

## Demographic Data

Demographic data refers to data such as a child's name, address, gender, social security number, and the name of the person who will be providing information. To provide culturally competent care and make provisions for special needs, a child's culture, ethnicity, place of birth, religious or spiritual practices, and primary and secondary language should also be identified (Box 34.3).

BOX 34.3

### Nursing Care Planning to Respect Cultural Diversity

Health assessment findings in children differ depending on racial and ethnic characteristics. Whether people establish eye contact with an interviewer, for example, is a characteristic that is may be culturally related. In Vietnam, touching the head of a child during a physical assessment is thought to be harmful because the head is considered to be the seat of the soul. Asking the parent and/or child permission before examining any part of the body that may elicit a negative response is helpful.

Because height and weight charts are standardized on middle-class White children, measurements of children who do not fit this description may not plot well on these charts.

To establish rapport with children and their families and to make a health assessment more thorough and meaningful, it is important to recognize that people may hold different cultural expectations and have different characteristics.

Some cultures advocate for all children to be immunized against childhood communicable disease. In other cultures, even if awareness about the danger of disease exists, it does not mean all people in a community are conscientious about having their children immunized or agree that it is important. Other factors, such as cost and convenience, religious beliefs, and safety concerns, are also important. The Amish is an example of a group who do not encourage immunization. Being aware immunization rates are not consistent from place to place aids in understanding the importance of planning health education and health surveillance based on findings gained from health assessment.

Be certain to identify the child's primary caregiver. If the parents are divorced or deceased, it is especially important to identify who has custody of the child or who has the right to sign a consent for healthcare treatment.

## Chief Concerns

The first topic parents want to talk about is the reason they have brought their child to the healthcare agency on this day or the **chief concern**. An effective way to elicit this information is to ask directly “Why did you bring Candy to the clinic today, Mr. Wiser?” Such an opening allows the parent freedom to answer in a number of areas of concern: physical, emotional, nutritional, or developmental. If asked “How is Candy feeling today?” or “Is Candy ill?” a parent is left to think about only physical aspects and may not voice the biggest concern: Candy’s teething difficulty or frequent temper tantrums. Record the chief concern in the child’s electronic record exactly as it is stated (“She has constant headaches,” not, “Headache”) because the parent’s description often not only reveals information about a disease condition but also the depth of the parent’s concern about the symptom (Levine, 2011).

### History of Chief Concerns

Once a parent has voiced a chief concern, ask him or her to describe at least six aspects of the problem, including:

1. Duration
2. Intensity
3. Frequency
4. Description
5. Associated symptoms
6. Actions taken

Duration refers to the length of time a specific symptom such as vomiting or the parent’s concern about the child’s symptom has been present. The intensity, in this example, refers to the kind of vomiting the child is having (e.g., drooling, spitting up, actual vomiting). The description is the amount (e.g., a cupful, a mouthful) and color (e.g., whether it contains blood, bile, mucus). Associated symptoms might include fever, abdominal pain, difficulty eating, or signs of respiratory illness. A good question to use to obtain associated symptoms is “Is Candy ill in any other way?”

Knowing the parent’s actions helps to establish ineffective actions or whether anything a parent has been doing, such as offering a great deal of fluid to replace that which was vomited, has actually made the illness worse. This information also reveals the parent’s response to caring for an ill child. The parent who says, “I tucked her into bed and gave her a little tea to drink” is different from one who replies, “Nothing. I fall apart when my child is ill.” If the child is going to return home under the parents’ care, the parents in the second example need more instructions and support before they leave the healthcare setting than the first parents.

During this phase of the interview, it is also important to gather information to see if a parent has other related or additional health concerns. “Is there anything else that worries you about Candy?” is a good way to elicit this information. Unless asked about a second concern this way (e.g., the parent is also concerned about frequent temper tantrums; as soon as he arrives home and he knows Candy will begin stomping her feet in the car, unwilling to go into the house), the parent will feel that the health care Candy

received was less than adequate because he did not receive help with this concern.

Do not assume parents will always reveal their most important concern in the initial minute of an interview; discussing certain symptoms such as constipation can be embarrassing for parents. It also can be frightening to put a fear that their child has a serious illness into words. As long as a concern hangs as a nebulous thought in the mind, it is easy to tell oneself it may not be true. Only when a parent voices the thought (“Do you think Candy is mentally handicapped?” “Do you think this is leukemia?” “Could this be inherited?”) does the fear become real. Before parents dare to speak openly this way, they must trust healthcare providers not to treat their statement lightly. For this reason, it is helpful to repeat the question about a second concern once more at the very end of the interview to be certain other concerns were not missed.

## **Health and Family Profiles**

A family profile includes documentation of the circumstances in which the child lives. A good introduction to a health and family profile is a sentence such as “Before we talk about any past illnesses or happenings with Candy, let me ask you some questions about your family as a whole.”

Important information concerning the family includes:

- Is the parent married, single, or divorced? If divorced, who has legal custody?
- What is the family type (e.g., nuclear, extended, blended)?
- How many children are in the family?
- What are the family’s living arrangements?
- What are the parents’ occupations? (This helps establish the family’s socioeconomic level and time available for childcare.)
- If both parents work outside the home, how do they manage childcare?

Obtaining a family profile is sometimes delayed by medical interviewers until the end of the interview, when, theoretically, a parent or child is more comfortable and will answer these personal questions more readily. However, by following a nursing model and obtaining the information earlier in the interview, you can better assess the child and evaluate data.

## **Day Histories**

The child’s current skills, sleep patterns, hygiene practices, eating habits, and interactions with the family can all be elicited by asking a parent to describe a typical day. Day histories are fun to obtain because most parents are eager to describe their day with their child and information gained this way is surprisingly rich and pertinent, much more so than if parents are just asked how their child sleeps, eats, or plays.

Begin by asking, “Was yesterday a fairly typical day?” (The parent says, “Yes, it was.”) “Describe for me everything Candy did yesterday, beginning with when she first woke up.” Some parents offer this information in great detail; with others, it is necessary to backtrack for particular details, such as “What did she eat for breakfast?”

Does she use a fork and spoon? Does she sit in a high chair or on your lap?"

## Play

Play is the work of children and so reveals a great deal about a child's development and overall well-being. Important questions to ask about play include:

- Is the child kept in a playpen or given room to run?
- What is the child's favorite toy?
- Does she play active, chasing games or engage in quiet, pretending types of activities?
- Is she able to sit and play quietly or does she act as if driven by a motor?
- Do you (the parent) read to the child?
- Do you (the parent) play with the child or let the child play alone? (This allows for an estimation of the quality of interaction during the day.)

## Sleep

Every child needs adequate rest for healthy growth and development. Poor sleep patterns can often reveal a psychosocial or physical health problem. Important questions regarding sleep include:

- What time does the child go to sleep at night?
- How long does the child sleep at night?
- What time does the child wake up?
- Does the child wake independently or do you need to wake the child?
- How long does the child nap (if appropriate for age)?
- Does the child share a room? With whom? Does the child share a bed? Is falling asleep a problem?
- Where does the child sleep? Does the child have night terrors or nightmares?
- Does the child sleepwalk?
- Does the child wet the bed (if the child is toilet trained)?

## Hygiene

Good hygiene practices promote healthy teeth, gums, and skin; prevent infections; and improve self-esteem. Poor hygiene may reflect neglect, depression, substance abuse, or inability of the household to have hot water. Important questions regarding hygiene include:

- How much self-care does the child do?
- Can the child shower or bathe independently?
- Does the child brush her teeth? How often? Does she floss regularly? (Responses depend on the age of the child.)
- Does the child wash her hands before snacks and meals?
- Has there been a recent change in hygiene practices?

## Nutrition

Nutritional assessment is an important portion of a health assessment because it strongly influences health (Whitney & Rolfes, 2015). Characteristics of a nutritionally healthy child that can be revealed by assessment are summarized in Table 34.1. Food and nutrient intake risk factors are summarized in Box 34.4.

**TABLE 34.1 PHYSICAL SIGNS OF ADEQUATE NUTRITION**

Assessment	Finding
Overall impression	Alert, with good energy level; positive mood
Hair	Shiny, strong, with good body
Eyes	Good eyesight, particularly at night; conjunctiva moist and not pale
Mouth	No cavities in teeth; no swollen or inflamed gingivae; no cracks or fissures at corners of mouth; mucous membrane moist and pink; tongue smooth and nontender
Neck	Normal contour of thyroid gland
Skin	Smooth; normal color and turgor; no ecchymotic or petechial areas present
Extremities	Normal muscle mass and circumference; normal strength and mobility; normal reflexes; legs not bowed; no tender joints or edema present
Gastrointestinal	No diarrhea or constipation present
Finger and toenails	Smooth, pink; not cracked or broken
Height and weight	Within normal limits on growth chart and body mass index (BMI)
Blood pressure	Normal for age

### BOX 34.4

#### Food and Nutrient Intake Risk Factors

History or evidence of any of the following may pose a potential nutritional risk:

- Intake less or greater than standard for age, for calories, protein, vitamins, or minerals
- Unusual food habits, such as pica, faddism, and meal skipping
- Inappropriate use of supplements (excessive vitamins, minerals, fortified food products)
- A healthcare provider's prescription for nothing by mouth (NPO) or a clear liquid diet for more than 3 days without enteral or parenteral nutrition
- Minimal or no intake from a major food group

- Fluid intake less than output
- Eating disorders such as bulimia
- Food allergies
- Restricted diet, such as a restricted potassium diet for kidney disease

Taking a history of a child's food intake can help determine whether there are any foods missing in a typical meal plan or if any quantities seem inadequate or excessive. Be certain to assess not only the quantity of food taken but also the quality; for example, for an infant, cereal should be iron-fortified.

Food intake is best obtained by including this as part of a typical day (24-hour recall) history, listing what the child ate for each meal and between meals as well. With an older child, the 24-hour recall can be a joint parent–child venture. Providing this history can be difficult for parents if the child consumes some meals at home and others at day care or school. It may be necessary to ask for a weekend history to get a complete picture.

When assessing an adolescent, take a 24-hour recall nutritional history without a parent present, if possible. In front of a parent, adolescents may add nutritional foods to a food intake history or leave out foods they have eaten such as milkshakes, potato chips, or pizza to avoid a lecture later; however, they may also leave out healthy items or add less desirable ones because they may enjoy the obvious parental disapproval, indicative of their rebellion against adult authority.

After taking a history of a child's food intake, determine whether the child is receiving foods that comply with the MyPlate recommendations ([U.S. Department of Agriculture, 2015](#); [www.ChooseMyPlate.gov](http://www.ChooseMyPlate.gov)). If whole food groups are absent or grossly inadequate, a follow-up evaluation should include a food frequency record as a verification to see if the 24-hour recall was truly representative of a usual day. Remember, children do not have to eat food from all groups at every meal as long as they eat from them every day. If parents think in terms of days rather than meals, it allows them to exert less pressure regarding what the child eats at each meal.

Be certain to consider the role of food preferences and cultural, lifestyle, religious, and financial variations when assessing food intake as well as the number of meals eaten at home versus outside the home, how traditional meals are cooked, and the pattern of meals. Do not appear critical of a child's diet as you record a history. If you convey dismay at erratic eating habits, parents or older children (especially adolescents) may begin to fabricate a food history to make it seem more acceptable to you.

### **Past Health Histories**

For a past health history, ask whether a child has ever had any serious illnesses. Parents do not generally think of childhood diseases such as measles, chickenpox, and mumps as serious illnesses; inquire about these separately. Also, inquire about the child's immunization history and whether immunizations are up to date for the child's age (see

the discussion of immunizations later in this chapter). Has a child had any accidents (unintentional injuries)? Any surgery? Parents may not think of a tonsillectomy as surgery because there were no stitches; ask about that separately. Did a child ever ingest anything inedible or harmful? Has a child been hospitalized for any reason? If so, for how long? How many times has a child been seen in an emergency room? What was the child seen for? These last questions provide information about the degree of adult supervision and possibly clues to maltreatment (Khan, McCormack, Bolger, et al., 2015). Information about the outcomes of past illnesses is as important to obtain as information about the illnesses themselves. If the child had otitis media (i.e., middle ear infection) at age 2 years and recovered without complications, the parent has every reason to be confident the child will also get better from a present illness because there is confidence in healthcare personnel. If the child was left with a hearing difficulty from the previous illness, parents may not be as trustful of the care being given to their child now; they may need extra support to follow instructions. A child who had had frequent ear infections may need referral to an audiologist or an ear, nose, and throat (ENT) specialist. This is important information to gain before planning care.

### ***QSEN Checkpoint Question 34.1***

#### **EVIDENCE-BASED PRACTICE**

Over 300 children (from birth through age 19 years) in the United States are seen in the emergency room due to ingestion of poisonous substances. Substances include common household products and medications. It is important to provide guidance and injury prevention information to parents to prevent unintentional ingestions by children (CDC, 2016c). Based on this information, which would be the most important question to ask Candy's father?

- a. "Has Candy tried to drink something that you're drinking?"
- b. "Do you keep all your prescription drugs securely locked?"
- c. "What do you keep in the cupboards below your sinks?"
- d. "Where do you store the alcoholic beverages in your house?"

*Look in Appendix A for the best answer and rationale.*

### **Pregnancy Histories**

The health of children is affected by their mother's health during pregnancy. For children younger than 5 years of age, therefore, a pregnancy history is usually obtained. Document which pregnancy this was for the mother. Were there complications in any of her pregnancies? Induced abortions or miscarriages? Stillbirths? Children born prematurely?

A history of the pregnancy of the child being assessed can begin with a question such as "How was your pregnancy with Candy?" This allows the mother to answer in both physical and emotional areas. After exploring details mentioned by the mother, ask

about specific events that are known to occur with pregnancy that may have had an effect on a fetus, such as:

- Did the mother have any complications such as bleeding, falls, swelling of hands and feet, high blood pressure, or unusual weight gain or loss?
- Did she take any medication?
- Were any X-ray films or sonograms taken other than a routine one to date the pregnancy?
- Did she smoke cigarettes, drink alcohol, or use recreational drugs while she was pregnant?
- Did the pregnancy end early or late?

Because life contingencies such as loss of finances or illness in the family during a pregnancy may affect a parent's ability to form a bond with a child, the emotional experiences of a woman during pregnancy are also important to obtain. Ask if the pregnancy was intentional. A question such as "A lot of pregnancies come as a sort of surprise. Is that how it was with Candy?" or "Some women want to have children and some don't. How was it with you?" lets parents know you will nonjudgmentally accept any answer they give.

Next, review the labor and birth by including such questions as:

- How long was labor? Was it spontaneous or induced? Did it go according to expectations?
- Were there any complications? Was the birth vaginal or cesarean?
- Was anesthesia used for birth?
- Was the baby born vertex (i.e., head first) or breech?

Then, ask about the health of the child immediately after birth, including:

- Did the baby cry right away?
- Did the infant room in or need care in a special nursery?
- Did the infant need special procedures or equipment?
- Was there cyanosis or jaundice?
- Was the infant discharged from the birth setting with the mother?
- How did the parents feel about having a boy or a girl?
- How did it feel for them to be new parents?
- Was the infant breastfed or formula fed?

## **Family Health Histories**

Because some diseases are inherited or familial, it is important to know which ones tend to occur in a family. Ask if any family member has a condition, such as cardiac disease (childhood or adult type), kidney disease, congenital anomalies, seizures, diabetes (type 1 or 2), tuberculosis, cancer, hypertension, a sexually transmitted infection (STI), allergies, or mental health issues, or is cognitively challenged.

## **Review of Systems**

The last step in a health interview is a summary of body symptoms or a **review of systems**. Once more, make certain to introduce this part of the history with a transition statement. Otherwise, parents may think the local problem they were describing (e.g., vomiting) has spread to other body systems. A statement such as “I’d like to ask about different parts of Candy’s body, from her head down to her toes, just to be certain I didn’t miss anything” provides such a transition.

Although the important items to be covered in a review of systems differ according to the age of the child, a basic list is shown in [Box 34.5](#).

## BOX 34.5

### Review of Systems

The following questions provide a guide when completing a review of systems:

- |                                  |   |
|----------------------------------|---|
| <i>Overall health</i>            | <ul style="list-style-type: none"> <li>• <i>What is the general state of health?</i></li> <li>• Is the child taking any prescription medications? Over-the-counter medications? Home or folk remedies, such as herbal remedies?</li> </ul>  |
| <i>Neuropsychiatric symptoms</i> | <ul style="list-style-type: none"> <li>• Has the child ever had a head injury? Seizures?</li> <li>• Attention problems?</li> <li>• Depression?</li> <li>• Aggressive behavior?</li> <li>• Has the parent ever had such difficulty rousing the child that the parent believed the child was unconscious?</li> <li>• Is there any concern about suspected substance abuse?</li> </ul> |
| <i>Eye</i>                       | <ul style="list-style-type: none"> <li>• Has the child ever had difficulty with eyes not focusing?</li> <li>• Eye infection?</li> <li>• Does the parent have any reason to believe the child does not see well?</li> <li>• Does the child wear eyeglasses or contact lenses?</li> </ul>   |
| <i>Ears</i>                      | <ul style="list-style-type: none"> <li>• Ear infections?</li> <li>• Drainage from the ears?</li> <li>• Ear aches?</li> <li>• Tubes in ears?</li> <li>• Any infection from piercing?</li> <li>• Reason to believe the child does not hear well?</li> </ul>   |
| <i>Nose</i>                      | <ul style="list-style-type: none"> <li>• Frequent drainage or cold symptoms?</li> <li>• Difficulty breathing?</li> <li>• Nosebleeds?</li> </ul>   |
| <i>Mouth</i>                     | <ul style="list-style-type: none"> <li>• Difficulty with teeth or teething?</li> <li>• Mouth infections?</li> <li>• Has the child seen a dentist (if older than 2 years of age)?</li> </ul>   |

<i>Throat</i>	<ul style="list-style-type: none"> <li>• Does the child chew tobacco?</li> <li>• Throat infections?</li> <li>• Difficulty swallowing?</li> </ul>
<i>Neck</i>	<ul style="list-style-type: none"> <li>• Masses or swelling?</li> <li>• Stiffness?</li> <li>• Does the child hold the head and neck straight? (Torticollis or wry neck will make a child hold the head crookedly; children with poor vision also may cock their heads to the side to try to see better.)</li> </ul>
<i>Chest</i>	<ul style="list-style-type: none"> <li>• Is breast development in girls appropriate for age?</li> <li>• Any pain in breasts?</li> </ul>
<i>Lungs</i>	<ul style="list-style-type: none"> <li>• Breathing problems?</li> <li>• Infections?</li> <li>• Pneumonia?</li> <li>• Asthma?</li> <li>• Does the child smoke any substance?</li> </ul>
<i>Heart</i>	<ul style="list-style-type: none"> <li>• Has a healthcare provider ever said there was difficulty? What exactly was said?</li> </ul>
<i>Gastrointestinal system</i>	<ul style="list-style-type: none"> <li>• Has there been an eating problem?</li> <li>• Frequent nausea?</li> <li>• Vomiting?</li> <li>• Diarrhea?</li> <li>• Constipation?</li> <li>• Is the child toilet trained? Any difficulty with this?</li> </ul>
<i>Genitourinary system</i>	<ul style="list-style-type: none"> <li>• Pain or burning on urination? Blood in urine? Does the child have a good urine stream?</li> <li>• If a girl is age 10 years or older, has she started menstruation? Any concerns with menstruation?</li> <li>• If an adolescent male, has he begun testicular self-examination?</li> <li>• If an adolescent, is the child sexually active? Knows safer sex practices? Uses contraception? Wants more information on contraception? Ever had a sexually transmitted infection (STI)? (To protect privacy, it is essential to ask the adolescent, not the parents, questions regarding sexuality.)</li> </ul>
<i>Extremities</i>	<ul style="list-style-type: none"> <li>• Painful or swollen joints?</li> <li>• Broken bones?</li> <li>• Muscle sprains?</li> <li>• Is the parent pleased with the child's coordination?</li> </ul>
<i>Skin</i>	<ul style="list-style-type: none"> <li>• Rashes?</li> <li>• Lesions such as warts?</li> </ul>
<i>Immunizations</i>	<ul style="list-style-type: none"> <li>• What immunizations has the child received to date? Are they up</li> </ul>

to date?

A review of systems covers a lot of ground, but it generally takes no more than 5 minutes. However, do not rush through the questions so quickly that a parent does not have time to answer or begins to believe this part of the interview is only an unimportant exercise (“Has Candy ever had nausea/vomiting/diarrhea/painful joints/broken bones?”) Each question is important. If a child has any of the symptoms described, an entirely new area of the child’s health needs to be explored.

## Conclusion

A quick review of the information you have gathered during the health history will help clarify any misunderstandings or fill in areas forgotten by the patient. It should close with one last open-ended question: “Is there anything more we should know?” or “Is there anything I didn’t mention you want to ask about?” A parent may have been reluctant to bring up something earlier. Asking this final question gives a parent a final opportunity to reveal a concern.

### *QSEN Checkpoint Question 34.2*

#### QUALITY IMPROVEMENT

With the participation of her father, the nurse obtains a health history from Keoto. What question should the nurse ask at the end of this and every interview?

- a. “Where do you think we should go from here?”
- b. “Is there anything else you’d like to discuss?”
- c. “Are you still feeling okay?”
- d. “Am I a good interviewer? I’m trying hard.”

*Look in Appendix A for the best answer and rationale.*

## Physical Assessment

Mastery of physical examination technique is essential to incorporating physical assessment data into the assessment step of the nursing process, so a physical assessment, along with health interviewing, is one of the most frequently practiced skills of a nurse. The scope and extent of a pediatric physical assessment will vary, like health interviewing, depending on the circumstances of each health contact. At a first healthcare encounter, for example, children usually receive a complete physical examination. Later on, only a single focus may be required to obtain the information needed. If a child has a gastrointestinal disorder, for example, an assessment might be only a brief, multisystem examination followed by concentration on the gastrointestinal system (i.e., mouth, abdomen, rectum, fluid status).

## PURPOSE AND TECHNIQUES

The actual process of a physical examination involves four separate techniques:

1. Inspection
2. Palpation
3. Percussion
4. Auscultation

These techniques are usually carried out in the listed order in each area of the body except the abdomen. **Auscultation** (a stethoscope examination) should follow **inspection** (a visual examination) and precede **palpation** (a hands-on examination) of the abdomen because handling the abdomen may obliterate bowel sounds. The findings from these techniques strengthen or validate history findings and help determine whether a concern requires immediate action ([Box 34.6](#)).

### BOX 34.6

#### Techniques of Physical Examination

Inspection:	Examining a child or adolescent initially with your eyes or nose and being alert to visual indications or odors that may point to a health problem.
Palpation:	Examining by touch, either light or deep. Use light palpation before deep palpation so the child or adolescent does not tense muscles and make light palpation difficult. The tips of your fingers are most sensitive to texture, vibration, consistency, and contour; the back of your hand is most sensitive to warmth. <i>If a child has a sensitive or painful body part, palpate that area last.</i> Otherwise, the child may be unwilling to allow you to touch other parts for fear of additional pain.
Percussion:	The assessment of a body structure by determining the sound you hear in response to striking the part with an examining finger and then interpreting the sound. Dense body areas such as bone have a dull, flat sound; those filled with air, such as lungs, are resonant. If an organ is stretched (e.g., a distended bladder), it has a hyperresonant or low and hollow sound. An organ stretched to an even greater point of distention has a tympanic or extremely hollow, ringing sound.
Auscultation:	Listening to sounds that are either discernible to the ear (e.g., wheezing or heavy breathing) or, as in most instances, made louder by means of a stethoscope. Always listen for four qualities of sound: duration, frequency, intensity (i.e., loudness), and pitch (i.e., high or low).

Effective use of physical assessment skills takes practice. Palpating an abdomen, for example, is a simple procedure; recognizing abdominal pathology through palpation is a more complicated skill. It is difficult to distinguish between normal liver tissue and a

distended liver, for example, until both these conditions have been felt many times.

## **EQUIPMENT, SETTING, AND APPROACH**

When performing a complete physical assessment, you'll need the following equipment: a thermometer, a stethoscope, a tongue depressor, an ophthalmoscope, an otoscope, disposable otoscope covers, a sphygmomanometer, a tape measure, a tuning fork, a reflex (**percussion**) hammer, examination gloves, and perhaps a patient drape or gown. Nurses who work in community settings or patients' homes must be sure to carry with them any equipment that may be needed.

Be certain to provide privacy and that the temperature in an examining room is comfortable. Change paper table covers between children to avoid possible spread of illness. During a complete physical examination, every part of the child's body should be exposed for inspection. To protect against chilling and to provide for modesty, expose body parts individually and only for the amount of time necessary for the examination. Because examining body parts such as the mouth or an open lesion exposes your hands to body fluids, as part of infection control precautions, wear gloves as appropriate during an examination.

People have the right not to have another person touch their body unless they permit them to do so. It is essential, therefore, to inform children that it is necessary to touch them for a physical examination and tell them what is happening at each step during the examination so they know when they will be touched. For instance, say "Next I want to look at your throat" to prevent surprises. Giving the child an option of what to examine first allows the child to feel in control. Never ask permission to exam a body part. If you proceed with the examination anyway, you will lose trust if the child had said "no." If some action will cause discomfort, such as deep palpation of the abdomen, offer fair warning such as "You'll feel pressure for a minute."

Assume that adolescents will cooperate in placing themselves in whatever position is required to inspect body parts unless they are short of breath or in some other way unable to cooperate. Small children may not cooperate readily and so may need to be restrained during an examination of such body parts as the nose, throat, and ears. Proper restraint enables an examiner to see well and also to ensure an instrument such as an otoscope will not accidentally cause injury. As a rule, do not ask parents to restrain during any procedure in which the child will feel threatened or feel pain; parents are best used as protectors and comforters after the procedure. If a parent does volunteer to restrain a child, urge them to do this with a positive approach such as "I'll help you keep your head still."

## **VARIATIONS FOR AGE AND DEVELOPMENTAL STAGE**

Techniques of physical examination need to be tailored to the age and developmental stage of the individual child being assessed. Expected findings also depend on the child's age and developmental stage.

## The Newborn

All newborns receive a physical examination immediately after birth and again after the first 24 hours of life. When examining newborns, cover body areas that are not being directly examined or perform the exam under a radiant heat warmer because maintaining body temperature is difficult for the newborn (Gupta, Patel, Murty, et al., 2015). Take axillary or tympanic temperatures to prevent rupture of rectal mucosa. Assess the heart rate apically because peripheral pulses may be too faint to be counted accurately. Be certain to obtain femoral pulses in newborns to rule out coarctation of the aorta. Include newborn reflexes, head circumference, and an assessment of gestational age (see Chapter 18) as routine parts of the examination. Taking blood pressure is not necessary because this value is unreliable in newborns. If possible, examine newborns with the parents present and use this assessment time to teach them about normal appearance and development.

## The Infant

Infants are usually examined most effectively if a parent holds them during most of the examination. Use an “Isn’t this fun?” or “This is a game” approach with the infant. As a rule, assess heart and lung function first; do intrusive procedures such as ear and throat assessment last so an infant does not cry and complicate the remainder of the examination. Blood pressure is still not taken routinely. Temperatures can be taken temporally. Include assessment of newborn reflexes until 6 months of age; continue to take the heart rate apically and the temperature in the axilla or by tympanic membrane. Measure head circumference for a full 24 months.

Between 7 and 12 months, children become fearful of strangers. Taking an extra minute to become well acquainted with an infant at the beginning of an examination can help to counteract this problem. Remember, infants calm to the tone of your voice as much as they do to what you actually say. They can be distracted by brightly colored toys while you listen to their heart or lungs. Offering a bottle of water or pacifier may be necessary during a heart assessment.

## The Toddler and Preschooler

Ask parents to remove clothing or allow a toddler or preschooler to do this independently so it is less threatening. Children this age may be very afraid of examining equipment. To alleviate their fears, allow them to sit on their parent’s lap for most of the exam and let them handle items such as stethoscopes, otoscopes, and blood pressure cuffs before the examination (Fig. 34.2). Leave intrusive procedures such as assessment of the genitalia, ears, and throat until last. Give generous praise for cooperation (anything short of hysterical screaming or kicking is good cooperation for intrusive procedures in this age group). Box 34.7 describes ways parents can prepare children of this age for assessment.

**Figure 34.2** Children need the opportunity to play with examining equipment so they become more familiar with and less frightened by it. (© [Fotosearch.com](https://www.fotosearch.com))

#### BOX 34.7

### Nursing Care Planning to Empower a Family

#### SUGGESTIONS FOR PREPARING A CHILD FOR A HEALTH ASSESSMENT

**Q.** Candy's father asks you, "How can I best prepare my 2-year-old for a preschool health exam?"

**A.** Here are some suggestions to help prepare a child for a health assessment:

- Promote the attitude that a health visit will be a positive experience.
- Bring a comfort item from home (e.g., a favorite doll or toy).
- Never threaten the child that if she is not good, a healthcare provider will punish her.
- Review with your daughter what she can expect during an assessment, such as a healthcare provider will ask questions of her parent; she or he will then look at the child's head, hands, etc.
- If she has been taught not to let strangers touch her body (as she should have been taught), reassure her it is all right for the healthcare provider to examine her.
- Dress your daughter in clothing that is easy to remove and replace so you can dress her quickly after an examination to rapidly assure her that the examination is over.

Begin to include blood pressure as part of routine assessment at 3 years of age; take a temporal temperature by an electronic thermometer rather than a tympanic temperature. Children up to school age often need to be restrained for ear and throat examinations because they grow fearful about procedures performed on a part of the body they cannot see (e.g., ears) or about a throat examination that may be

uncomfortable. Before beginning an examination, establish a good rapport with the child's parents because children this age sense parental trust or suspicion.

### The School-Age Child and Adolescent

Some children of this age may still be unaware of what a physical examination includes and whether it will cause discomfort. Offer good explanations so they are not frightened by the unknown. Provide older children with a choice about having a parent with them during the examination. Comment on body parts as you examine them to teach about good health such as "Your heart sounds good. And your ears look fine." Sometimes, adolescents are so concerned with a part of their body (e.g., a supernumerary nipple) that they are unable to voice this concern. A comment such as "This is a supernumerary (extra) nipple. Does it ever worry you that you have that?" may help an adolescent talk about what has indeed been a concern for years. Use a head-to-toe procedure; leave genitalia for last. Be certain to assess height and weight because more children in this age group are obese than ever before.

It is increasingly important to take blood pressure beginning in early school age also because as more children are overweight, more have elevated blood pressure (Spagnolo, Giussani, Ambruzzi, et al., 2013). Because obesity in school-age children and adolescents is associated with the development of type 2 diabetes mellitus and future cardiovascular disorders (Ayers, Charakidah, Deanfield, et al., 2015) and because there is also an association between being overweight and self-harm (Perera, Eisen, Bawor, et al., 2015), signs of these conditions need to be assessed as well.

School-age children and adolescents are particularly modest. Respect this by using gowns or drapes. Include a breast exam for adolescent girls and testicular exam for boys and teach testicular self-examination for boys beginning at about age 13 years.

### QSEN Checkpoint Question 34.3

#### PATIENT-CENTERED CARE

Keoto's sister is 2 years old and appears fearful of medical equipment. To preserve her comfort, the nurse can exclude blood pressure measurement from assessment until what age?

- a. 2.5 years
- b. 3 years
- c. 5 years
- d. 7 years

*Look in Appendix A for the best answer and rationale.*

## COMPONENTS OF PHYSICAL EXAMINATIONS

Presented here are the components of routine or general physical assessment. It is important to recognize what a "general" physical examination entails so you can

interpret the extent of the assessment a child has received when the parent states, “He had a routine physical.” The physical examination may be done in any order, but traditionally, the order proceeds from head to toe, examining each body part thoroughly before moving on to the next. Infants and young children are the exception, however, because if the infant cries, findings in a specific area become difficult to assess.

If abnormalities are discovered during an examination, a further assessment will be necessary. A complete neurologic examination, for example, is not routine and so is not included here (see [Chapter 49](#) for details of a complete neurologic examination).

## Vital Signs Assessment

Vital signs refer to temperature, pulse, respiration, blood pressure, and whether the child has pain (i.e., the state of vital bodily functions including heart and lung function, metabolic rate, and comfort level). Temperature is an important assessment in children because it can reveal a subtle infection not as obvious yet by other signs. Because of the important information these provide, measurements of vital signs are recorded not only with complete physical examinations but also in many other instances of care.

Techniques of these measurements and the nursing responsibilities that accompany them are discussed in [Chapter 37](#). Remember, blood pressure in children can be elevated if they are anxious in a medical setting, the same as happens to adults and so needs to be evaluated in light of that ([Spagnolo et al., 2013](#)).

## General Appearance

General appearance establishes an overall impression of a child’s health as well as reveals specific body areas that will need a detailed assessment ([Fig. 34.3](#) and [Box 34.8](#)). Be certain to include such areas as:

- Does the child appear well or ill overall?
- Is the child’s height and weight proportional?
- Does the child appear well nourished? Appear underweight or overweight?
- What is the child’s color? Pale? Yellow (jaundiced)? Cyanotic (blue)?
- Is posture normal? (Children who are in pain often assume an abnormal posture for relief.)
- What is the child’s hygiene level? (Fatigue or illness can cause poor hygiene.)
- Is the child dressed appropriately for temperature and climate?
- Are lesions or symptoms of a specific illness present?
- Are there any significant body odors ([Table 34.2](#))?
- Does the child appear relaxed or distressed? Lethargic or active?
- Is breathing easy or distressed?

**Figure 34.3** A general appearance assessment reveals that this child is well proportioned and active.

### Nursing Care Planning Using Assessment

#### ASSESSING THE CHILD FOR GENERAL WELL HEALTH

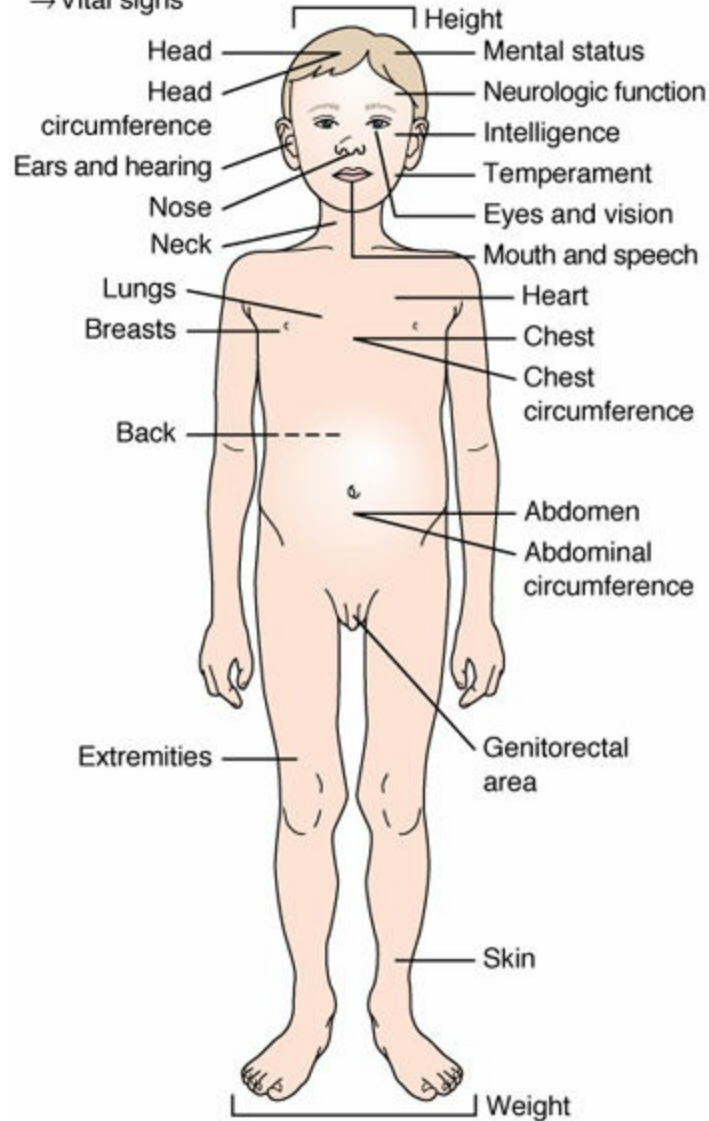

**History**

- Demographic data
- Chief concern
- History of chief concern
- Health and family profile
- Past health history
- Family health history
- Review of systems

**Physical examination**

- General appearance
- Vital signs

**TABLE 34.2 SIGNIFICANT BODY ODORS**

Source of Odor	Possible Cause
<i>Breath</i>	
Alcohol	Possible recent ingestion (important if coma or neurologic symptoms are present as cause of abnormal functioning)
Camphor	Mothball ingestion
Halitosis (bad breath)	Poor dental hygiene, lung infection; foreign body in respiratory

	tract
Burnt rope	Marijuana use
Sweet	Acidosis (seen in a child in diabetic coma)
<i>Body</i>	
Stale urine	Incontinence; poor kidney function leading to uremia; infrequently changed diapers; neglect
Sweat	May imply child is too fatigued or stressed to maintain hygiene
“Spoiled fruit”	Wound infection
Sweet	<i>Pseudomonas</i> infection
<i>Urine</i>	
Maple syrup	Protein metabolic condition
Musty or mousy	Phenylketonuria or a protein metabolism disorder
Ammonia	Urinary tract infection or poor hydration leading to concentrated urine
<i>Stool</i>	
Putrid	Fat in stool from inadequate absorption

If the child appears to have pain, ask the child to rate it on a child-appropriate pain scale, such as the Faces scale, to better determine the degree of pain (Ely, Chen-Lim, Zarnowsky, et al., 2012).

### Mental Status Assessment

A mental status assessment is also made early in an examination as a complement to general appearance. As with general appearance, additional information is gained on mental status throughout the entire examination.

Begin by assessing a child’s level of consciousness: Is the child alert? Next, assess orientation, or if the child is aware of person, place, and time (i.e., awareness of who they are, where they are, and the date) if the child is over preschool age. If an infant, does the child “attune” or look aware of surroundings? Assess the appropriateness of behavior and mood (e.g., Is a child hostile, frightened, shy, relaxed?). At some point in the examination of children older than preschool age, ask questions that test recent memory (e.g., what they ate for breakfast) and distant memory (e.g., the name of their first-grade teacher).

### Body Measurements

Body measurements are important determinants of health in children because, with chronic illness, the body expends so many nutrients combating the destructive process

of the disease that normal height and weight cannot be maintained. Conversely, being overweight (i.e., obesity) needs to be documented because this can lead to illnesses such as heart, endocrine, and lung disease later in life.

## Weight

Until they can stand well, infants are weighed nude lying or sitting on an infant scale (diapers can be heavy in proportion to total body weight). Always keep a protective hand over an infant on an infant scale (hovering but not touching) because infants squirm readily and there is danger of them falling ([Fig. 34.4A,B](#)). Cover both infant scales and adult scales with scale paper before weighing to prevent the spread of infection from one child to another.

**Figure 34.4** (A,B) Weighing an infant. Note the protective hand to ensure the infant's safety. (C) Weighing an older child.

Children older than 2 years of age are weighed on standing scales, in street clothes (no shoes), or, if in a hospital, in a gown or pajamas (Fig. 34.4C). If children are going to have serial weights (i.e., weighed every day), be sure they wear the same clothing every time they are weighed so any discrepancy in weight is truly a difference in body weight and not due to more or less clothing. Also, take serial weights at the same time each day (preferably before breakfast) on the same scale for greatest accuracy.

Most children and their parents want to know their weight. To convert from kilograms to pounds, multiply the kilogram amount by 2.2 ( $50 \text{ kg} \times 2.2 = 110 \text{ lb}$ ). To assess whether weight is average for height, compare the child's weight with a standardized height/weight graph (available at <http://thePoint.lww.com/Flagg8e>). On these standardized graphs, all weights between the 10th and 90th percentiles are considered normal (statistically, a range of weights that includes two standard deviations from the mean or the 50th percentile). All children with weight below the 25th or above the 75th percentiles need close examination because they are moving close to the end points of the usual weight continuum. There are also specific graphs for premature infants and those with Trisomy 21. (These graphs are available at [www.ncbi.nlm.nih.com](http://www.ncbi.nlm.nih.com).)

As important as it is for children's weight to fall between the 10th and 90th percentile on growth charts, it is also important that, over time, the weight follows one of the percentile curves; in other words, children should not be at the 70th percentile the first time they are weighed, and a month later, at the 80th or 40th percentile. Although both readings are within the normal range, they reflect a weight change that would need investigation. A child is defined as "failing to thrive" if height or weight drops below the third percentile on a standardized growth chart (Jaffe, 2011). Any height or weight in this category definitely needs to be reported so its cause can be investigated. Identifying that one is overweight is equally important because this can lead to so many illnesses later on in life (Ward, Welker, Choate, et al., 2017).

U.S. growth charts were compiled by the Centers for Disease Control and Prevention (CDC) in the 1960s when almost all infants were formula fed, not breastfed, so breastfed infants tend to score lower on these charts than might be expected (often at the 25th percentile). The World Health Organization (WHO) has published growth charts that better reflect the weight of breastfed infants. It can be helpful to plot infant weight on these alternative growth charts to reassure parents that their breastfed infant is thriving (de Onis, 2015).

Another method to determine whether a child's weight is consistent with height is to compute his or her body mass index (BMI) by using a website such as [www.cdc.gov](http://www.cdc.gov). Many electronic medical records now record and graph BMI.

## Height

In children, height is as good a determinant of health and normal nutrition as is weight. For tips on accurately measuring the height of infants and older children, see Box 34.9.

**MEASURING A CHILD'S HEIGHT****Purpose:** To assess for optimal growth

Procedure	Principle
<i>Infant</i>	
1. Until they can stand securely (at approximately age 2 years), measure infants lying down on a measuring frame or an examining table.	1. Promotes accuracy
2. Align the infant's head snugly against the top bar of the measuring frame and ask an assistant to secure it there. Parents can help you restrain infants for height measurements because it is a painless procedure.	2. Provides a starting point for measurement
3. Straighten the infant's body (Fig. A).	3. Knees are difficult to straighten in infants because they usually keep them flexed.
	
4. Hold the infant's feet in a vertical position. Bring the foot board up snugly against the bottom of the foot.	4. Completes measurement
5. If an examining table is used instead of a measuring frame, mark the spots at the top of the child's head and bottom of the feet on the table paper	5. Provides for an alternative approach

and then measure between the marks with a tape measure.

6. Plot height measurements on a standard graph.

6. Allows for interpretation of findings

---

*Older Child*

---

1. Have the child remove shoes and step onto the scale.

1. Promotes accuracy

2. Ask the child to stand straight with head held level.

2. Puts the child in the proper position for accurate measurement

3. Align the measuring bar of a standing scale with the top of the child's head.

3. Determines the measurement

4. If a scale with a measuring bar is not available, place a flat object such as a clipboard on the child's head in a horizontal position and read the height at the point at which the object touches a measuring tape on the back of the scale or a flat wall surface (Fig. B).

4. Provides for an alternative approach

5. Plot height measurement on a standard graph.

5. Allows for interpretation of findings

B

---

Following a measurement, plot the height of children on a standard graph, the same as for weight. Height and weight should follow the same percentiles. Remember that height/weight charts have been standardized for middle-class White American children, so there will be variations among children from different ethnic and socioeconomic backgrounds. The important thing to look for is consistency in measurements over time (i.e., always at the same percentile).

### *What If... 34.1*

**Keoto, 13 years old, weighs 93 lb. Would the nurse be concerned? What if 6 months earlier she weighed 110 lb and a year earlier she weighed 105 lb?**

---

## Head Circumference

Head circumference is measured at birth and routinely on physical assessment until 1 or 2 years of age. Head growth occurs because the brain is growing, so head circumference reflects brain growth and potential neurologic function. The measurement is made by placing a tape measure around the infant's head just above the eyebrows and around the most prominent portion of the back of the head (i.e., the occipital prominence) (Fig. 34.5). Babies generally push any object away from their head, so it may be more difficult than it seems to carry out this simple procedure. Plot measurements on a standardized graph (see "Growth Charts" available at <http://thePoint.lww.com/Flagg8e>). Head circumference should correlate with the child's length; that is, if length is in the 40th percentile, head circumference also should be. If measurements of head circumference plot at different percentiles over time, this should be reported because it implies brain or skull growth is in some way abnormal and needs to be investigated.

**Figure 34.5** Measuring head circumference. The measuring tape passes just above the eyebrows and around the prominent posterior aspect of the head.

### Chest and Abdominal Circumference

Measurements of chest and abdominal circumference are not done routinely but rather only when specific pathology warrants. Chest circumference is measured at the nipple line, and the abdominal circumference is measured at the level of the umbilicus.

### Skin

Skin is assessed in conjunction with the examination of each body region. Always assess temperature, color, dryness, texture, **turgor** (i.e., amount of fluid in body tissue), and the presence of any lesions such as a rash that might reveal a communicable illness. [Table 34.3](#) summarizes various findings that may be detected on skin examination. Be certain there is adequate lighting, especially when assessing dark-skinned children. Also, be certain to examine a child's total skin surface at some point during an examination. If necessary, remove and replace adhesive bandages or other dressings that could hide important findings (e.g., possible maltreatment).

**TABLE 34.3 SKIN FINDINGS IN CHILDREN THAT SUGGEST ILLNESS**

Finding	Indication
Central bluish color	Cyanosis from decreased respiratory function or cyanotic heart disease; acrocyanosis (blue hands and feet) is normal in newborns for first 48 hours.

White color	Edema (accumulated subcutaneous fluid is stretching the skin)
Pale color	Anemia or decreased circulation to a body part
Reddened area	Local inflammation or increased systemic temperature
Linear abrasion	Scratch marks from local irritation from an insect bite or allergic reaction
Ecchymoses (black and blue marks)	Recent injury to skin
Petechiae (pinpoint blood marks)	Blood dyscrasia (poor clotting ability)
Yellow color	Jaundice from increased bilirubin in subcutaneous tissue; carotenemia (excess carotene in skin)
Moistness	Excess perspiration from elevated temperature
Localized cold temperature	Decreased circulation to particular body part
Warm temperature	Local irritation or elevated systemic temperature
Poor turgor	Dehydration
Rash	Infectious childhood illness, excessive heat, or allergy

### The Newborn and Infant

Newborns may appear ruddy because, as their layer of subcutaneous fat is thin, the intense redness of their blood circulation is visible. Erythema toxicum (i.e., newborn rash) or birthmarks (e.g., hemangiomas, Mongolian spots, nevi) may be present (see [Chapter 18](#)). After the first few days of life, a diaper rash may be present.

### The Toddler, Preschooler, and School-Age Child

Many children this age have minor lesions from mosquito bites or from fleabites if they own a pet. They also typically have a number of ecchymotic spots on their lower extremities from bumping into objects during active play. Ecchymotic spots on upper extremities are less common and may suggest a blood coagulation problem or maltreatment ([Chiesa & Sirotnak, 2014](#)). Lesions, scratch marks, or excessive dryness can reveal atopic dermatitis, a common childhood disorder ([Spiewak, 2012](#)). Ecchymotic areas on lower or upper extremities not typical of a fall should be assessed for coagulation disorders or abuse.

### The Adolescent

At least a few acne lesions on the face or back are usually present in an adolescent. Lesions or rashes caused by allergies to cosmetics also may be seen. If a child has a

tattoo or a body piercing, assess the site for inflammation to be certain an infection is not present. Look carefully for moles that are very dark, have uneven borders, or have recently changed shape because these are signs of melanoma or skin cancer (de Maleissye, Beauchet, Saiag, et al., 2013).

## The Head

To examine a child's head, slide a hand over the skull, assessing for irregular configurations or tenderness. Most children have a prominent occipital outgrowth; do not mistake this natural head contour for an abnormality. Assess the texture and cleanliness of hair. Children who are well nourished usually have hair of good texture; poorly nourished children tend to have dry, brittle, or limp hair. If hair is exceptionally oily, it may suggest a lack of adequate hygiene, possibly from fatigue due to an unidentified illness. If a serious protein deficiency such as **kwashiorkor** is present, the hair becomes striped with dark and light color because dark hair forms during periods of good protein intake and the light color forms during periods of protein deficiency. Patches of hair loss (i.e., alopecia) suggest a fungal infection (e.g., tinea capitis), child maltreatment, or a possible drug reaction (chemotherapy will cause total hair loss, not patches).

## The Newborn and Infant

In a newborn, the head usually shows molding (i.e., an elongated shape due to pressure against the cervix before birth). A caput succedaneum or cephalohematoma from the pressure of birth may be present (see [Chapter 18](#)). Skull suture lines are palpable. In both newborns and infants, sit the child upright and palpate the skull for the presence of fontanelles (i.e., the places where the skull bones fuse). The anterior fontanelle is diamond-shaped and measures 2 to 3 cm (0.8 to 1.2 in.) in width and 3 to 4 cm (1.2 to 1.6 in.) in length. The posterior fontanelle is triangular and measures approximately 1 cm (0.5 in.) in length (see [Chapter 15, Fig. 15.2](#)).

With the infant sitting, fontanelles should be felt as soft spots but should not appear indented (a sign of dehydration) or bulging (a sign of increased intracranial pressure). When an infant cries, cerebral pressure increases, so with crying, the fontanelles may feel tense, and sometimes, the fluctuation of a pulse can even be observed. The anterior fontanelle normally closes at 12 to 18 months and the posterior fontanelle by the end of 2 months so should not be palpable after these times. The closing of fontanelles too early or too late can indicate decreased or increased brain or ventricle growth and is, therefore, a serious finding.

Because of the campaign to encourage “back” sleeping for infants, many infants have a flat occiput “plagiocephaly.” Infants should start with “tummy time” when they are discharged from the hospital. By 3 to 4 months, they should be getting 20 minutes of tummy time per day. A scalp problem commonly encountered in infants is seborrhea (i.e., scaling, greasy-appearing, salmon-colored patches) or “cradle cap.” You can

advise parents that increasing the frequency of hair washing to once a day and applying baby oil to the scalp typically reduces this problem.

### The Toddler, Preschooler, and School-Age Child

Examine the hair of children who attend school or day care carefully for small white-yellow, sand-sized particles attached to hair strands, which are the eggs (i.e., nits) of pediculi (i.e., head lice). Pediculi can spread easily in school-age children due to sharing of combs and towels in school. Nits cling and cannot be readily removed from the hair by running fingers the length of the hair (Devore & Schutze, 2015). The child may have recent scratch marks on the scalp or state that the scalp feels itchy.

Also examine the scalp carefully for round circular areas (perhaps weeping in the center, crusting and scaling on the edges) that would suggest tinea capitis (i.e., ringworm, which is a fungal infection). Like pediculi, fungal infections can easily spread among school-age children; a prescription medication is necessary to best cure tinea capitis (see Chapter 43). Both over-the-counter and prescription medications are available for pediculosis.

### The Adolescent

Adolescents may streak their hair with dye or arrange it in a way that requires gel, hair extensions, or use of a curling iron. Inspect to see that their scalp and hair are healthy underneath the styling. Tight cornrows and weaves can cause hair to break, resulting in areas of baldness.

### The Eyes

Observe eyes for symmetry and signs of redness (i.e., erythema), frequent blinking, crusting, squinting, or rubbing because these are signs of **conjunctivitis**, an infection of the thin conjunctiva covering the eye globe (Braverman, 2016). Also, observe lids and lashes for redness or abnormalities to detect a **hordeolum** or sty (i.e., an infection of the gland that lubricates an eyelash). Both conditions require an antibiotic for therapy (see Chapter 50).

Assess the location of eyes in relation to the nose (i.e., not unusually wide or narrow spaced) and the relationship of the globe to the socket (i.e., neither sunken nor protruding from the socket [exophthalmos]). Abnormalities in these areas occur in chromosomal or metabolic illnesses such as hyperthyroidism. Inspect the sclera of the eye for spots of hemorrhage (i.e., subconjunctival hemorrhage) or yellowing. Black children often have a slight yellowing of the sclera and small black spots on the sclera; do not mistake these for abnormal findings. Assess that no sclera shows above the pupil (if it does, this is termed a *sunset sign*, a possible indication of increased intracranial pressure or trisomy 21).

Palpate each eye globe with the eyelid closed to assess for tenseness, a finding suggesting glaucoma (although this is rare in children). Determine whether the eyelids

completely close; edema or neurologic illnesses may shorten eyelids so they cannot close. Lastly, determine whether the lids retract far enough so they do not obscure vision when the child opens his or her eyes. When a lid obscures vision (**ptosis**), it generally denotes neurologic involvement. The difference in Western and Eastern eye creases is shown in [Figure 34.6](#).

**Figure 34.6** Differences in eye formation. **(A)** Western. **(B)** Eastern. The extra inner fold of tissue is an epicanthal fold.

Examine the inner lining of the lower eyelid (i.e., the conjunctiva) by pulling the lid down slightly with your fingertip. Here, the mucous membrane should appear moist and not pale. In children with anemia, it often appears pale; for a child with an allergy or infection, it may appear unusually red and irritated. Do not initiate a blink reflex by touching the cornea with a wisp of cotton, as is done in adults, because this is momentarily painful and frightening for children.

In addition, observe whether the eyes appear to be in good alignment. **Strabismus** refers to eyes that are not evenly aligned. If an eye is always turning in, the condition is termed **esotropia**; if it always turns out, this is termed **exotropia**. Two screening

procedures for straight eye alignment include the Hirschberg test and the cover test. During a Hirschberg test, the light of an otoscope should reflect evenly off both pupils if they are in equal alignment (Fig. 34.7).

**Figure 34.7** Testing good eye alignment by the Hirschberg test. The child is asked to look directly at the light of the otoscope. The light reflex on the pupils of both eyes will be equal if the eyes are in straight alignment.

To perform a cover test (Fig. 34.8), perform the following steps:

- Have children look at an attractive object approximately 4 ft in front of them.
- Hold a 3 × 5 in. card over the left eye for a count of five. If any degree of strabismus is present, the eye will wander to its misaligned position while covered.
- Remove the card and observe the eye for movement.
- As the child again fixes vision on the specified object, the eye will move back into line, revealing the misalignment.
- Repeat the process with the right eye.

**Figure 34.8** The cover test. (A) The child's eyes appear to be in good alignment. (B) The left eye is covered for 5 seconds. (C) When the card is removed, the left eye is seen to move perceptibly back to good alignment. This movement indicates it "drifted" into a deviant position while covered; that is, an exophoria (misalignment) is present.

Some children, particularly preschoolers with wide epicanthic folds, may appear at a quick glance, to show misalignment. A cover test is helpful in these children because there will be no eye movement after removal of the card, demonstrating no actual misalignment, only the temporary appearance of that. Reasons for true misalignment are discussed in [Chapter 50](#).

To test the eyes for their ability to focus in all fields of vision:

- Ask the child to follow a moving light (or catch the attention of an infant with a moving light) while holding the child's chin stationary.
- Move the light out to the side, then up, and then down.
- Cross to the opposite side and move it up and down.
- Bring the light back to the midline and observe whether the child's eyes converge (follow the light in to the nose). Infants younger than 3 months of age cannot follow past the midline; the eyes of children under school age do not converge well.

If the pupil constricts (i.e., reduces in size) in response to the light, it is confirmation the third cranial nerve is intact. For this test, it is best to approach the child's eye from the forehead so the light suddenly appears on the pupil rather than advancing it toward the child slowly because this makes the pupil constrict more dramatically. When one pupil constricts in response to a bright light, this is termed *direct constriction*; constriction should also occur in the opposite eye (i.e., *consensual constriction*). Record pupils are equal in size and react to light as PERL (pupils equal, react to light). If the pupil converges (i.e., moves to follow a light in toward the nose), this is charted as PEARL or PERLA (pupils equal, react to light, accommodate).

For a final step, shine a flashlight or ophthalmoscope light into the pupil. A red reflex or the red pupil that occurs with a flash photo should appear. This is evidence the retina is intact and the lens and cornea are clear (i.e., no tumor, cataract, scarring, or infection is present).

## The Newborn and Infant

Newborns often have a small, bright-red spot on the sclera (i.e., a subconjunctival hemorrhage) because the pressure of birth ruptured a small conjunctival blood vessel. This is normal and will fade in 7 to 10 days as the blood is absorbed.

Newborns and infants can easily be tested for a red reflex, but until they are about 3 months, they cannot follow an object or light across the midline or follow a light into all six positions of gaze. Assessing for a red reflex is especially important in newborns because a congenital cataract can lead to a loss of central vision if not discovered early.

## The Toddler and Preschooler

Most young children are reluctant to let someone look into their eyes. Explaining what will happen during an eye examination is important to reduce the child's anxiety about this part of the assessment.

## The School-Age Child and Adolescent

Many older children wear contact lenses (a red reflex is visible with a contact lens in place), and others may be nervous about having their eyes examined because they know they should be wearing prescribed eyeglasses but are not wearing them because they do not like their appearance. Observe carefully for pupillary appearance and ability to constrict in adolescents to rule out drug abuse. Many adolescent girls are anemic and so have pale conjunctiva.

## The Nose

Observe the nose for flaring of the nostrils (a sign of a need for oxygen). Using an otoscope light, observe the mucous membrane of the nose for color—it should be pink; pale suggests allergies, and redness suggests infection. Note and describe any discharge. Document the septum is in the midline because a displaced septa such as those that occur after facial injuries can interfere with respiration and make nasal intubation in emergencies difficult. Gently press one nostril closed and ask the child to inhale. Repeat on the opposite side to ensure both sides of the nose are patent; that is, no choanal atresia or membrane obstructing the posterior nares exists. Sinuses do not fully develop until about 6 years. For children 6 years or older, palpate the areas over the frontal and maxillary sinuses for tenderness, which is a symptom of sinus infection. Assess the sense of smell in school-age children and adolescents by asking them to identify a familiar odor such as chocolate or an orange.

## The Newborn and Infant

Infants are obligate nose breathers. They cannot coordinate mouth breathing, so they become disturbed when the nose is temporarily blocked to check for patency; do this only momentarily to avoid discomfort. Most newborns have milia (i.e., small white papules) on the surface of the nose, which are of no consequence and disappear without treatment.

## The Older Child

Many children preschool age and older have upper respiratory infections that cause reddened nasal mucous membranes and a purulent discharge. In contrast, allergies cause a clear discharge and pale mucous membranes. Children who have dry mucosa due to dry air, which leads to cracking and nosebleeds, may be reluctant to allow inspection of their nose. Adolescents who sniff cocaine lose nasal hair and may have excoriations or

abscesses in the mucous membrane as well as holes in the septum. If the child has a nose piercing, inspect the site for redness or drainage.

## **Ears**

Observe ears for proper alignment. In the average child, a line drawn from the inner canthus of the eye to the outer canthus and then to the ear will touch the top of the pinna of the ear (Fig. 34.9). Ears set lower than this are associated with chromosomal disorders such as trisomy 13. Observe the opening to the ear canal for any discharge. Touch the pinna and watch for evidence of pain, which is a sign of external canal infections. Observe the area immediately in front of the ear for a dermal sinus or skin tag, findings that are usually innocent but may be associated with kidney abnormalities. Observe the ear lobes for redness or drainage from infected piercing sites, if applicable.

**Figure 34.9** Normal ear alignment. When a line is drawn from the inner canthus through the outer canthus of the eye to the ear, the top of the ear pinna should meet the line (A). Abnormal ear alignment (B) is associated with certain chromosomal abnormalities.

To examine the ear canal:

- Select the smallest size otoscope tip possible that will still give adequate visibility.
- Straighten the ear canal by pulling the pinna gently down and back in the child under 2 years of age and up and back in the older child.
- Insert an otoscope tip into the external canal.

- Be certain to rest the instrument on your hand, not on the child's head (Fig. 34.10). In this position, the otoscope will move with the child, avoiding the danger the plastic tip will scratch the canal if the child should move suddenly.
- Inspect the sides of the ear canal and then locate landmarks on the surface of the tympanic membrane.

**Figure 34.10** An otoscopic examination. Note how the nurse's hand rests between the otoscope and the child's head. Should the child move, no injury to the tympanic membrane will be sustained with this technique because the otoscope will move with the child's head.

The outline of the malleus of the inner ear should be visible through the translucent membrane and is a key landmark to visualize (Fig. 34.11). The color of the membrane should be pinkish gray; usually, if the tension of the membrane is normal, a cone of light (i.e., the light reflex) should be present in one of the lower corners (at either the 5 o'clock in the right ear or the 7 o'clock position in the left ear).

**Figure 34.11** A tympanic membrane as viewed with an otoscope.

Although many children have wax (i.e., cerumen) in their ear canals, which appears as a dark-brown, glistening substance or flaky amber, viewing the tympanic membrane past the wax is almost always possible.

If an ear infection is present, the tympanic membrane will appear reddened and will often bulge forward so the malleus is no longer discernible and the cone of light is absent (Yoon, Kelley, & Friedman, 2016).

If there is fluid in the middle ear, it may be possible to see bubbles of air through the membrane. With chronic middle ear disease (i.e., serous otitis media), the tympanic membrane may be retracted, the malleus will then be extremely prominent, and the cone of light will be missing. If the membrane has been torn from trauma or rupture, the jagged edge and opening to the middle ear are discernible and may have purulent discharge. Inspect also for any ulcerated areas that could be a cholesteatoma or an ingrowing tumor, most often seen on the upper part of the membrane (see Chapter 50).

Although not a routine procedure, the mobility of the eardrum can be tested by injecting a column of air into the ear canal against the drum by a pneumatic attachment on an otoscope, which looks like the bulb of a blood pressure cuff (Fig. 34.12). A normal drum is freely mobile and can be seen to move with pressure on the bulb; one with fluid behind it has decreased mobility. Before introducing air, warn the child air against the membrane will tickle. A tympanogram can also assess for fluid behind the eardrum.

**Figure 34.12** An otoscope with pneumatic attachment.

Finally, appraise hearing. Appraisal for this can be done grossly in older children by assessing their response to your questions. Distract an infant with a toy and then make a sound behind the infant's back, out of peripheral vision, and watch if there is a response. Hearing infants will show some noticeable reaction, although they have difficulty looking directly toward or locating the sound until about 4 months of age.

### The Newborn and Infant

Many newborns still have amniotic fluid or vernix caseosa in their ear canal, so inspecting the ear canal is ineffective. Be certain to assess for ear level and normal pinna contour. Assess gross hearing ability, for example, by watching the infant startle to a sudden sound or quiet to the calming effect of quiet talking.

### The Older Child

Middle ear infection (i.e., otitis media) is a common childhood illness. This causes the ear to be painful when examined. An external ear infection (often called swimmer's ear) causes any movement of the pinna to be painful. Explaining what is happening during the examination helps to allay a child's fear of having an instrument pressed into the ear. Beginning with preschool age, children may have myringotomy tubes (i.e., small circular plastic tubes placed into the tympanic membrane) to relieve chronic fluid collected in the middle ear. Inspect that the area surrounding the tube is not inflamed and the tube is not merely lying in the external canal and no longer inserted into the membrane (see [Chapter 50](#)).

### The Mouth

Assess the external appearance of the lips for symmetry and color. Ask the child to smile and frown to evaluate the mobility of facial muscles. Count the number of teeth present and assess their condition (e.g., number missing or cavities present). Inspect the gum line (i.e., gingivae) for redness, tenderness, and edema, symptoms of periodontal disease. Inspect the buccal membrane and palate for color (e.g., pink) and the presence of any lesions. Ask the child to stick out his or her tongue and assess for midline position and no fasciculations (i.e., trembling). Inspect the area under the tongue for lesions in school-age children and adolescents who smoke or chew tobacco because this is the most common first site for oral cancer.

A child's tongue is normally smooth and moist. With dehydration present, it often appears roughened and dry. **Geographic tongue** is the term for the rough-appearing tongue surface that often accompanies general symptoms of illness such as fever; it may also normally occur. If a child has a pierced tongue, inspect for redness at the site. Assess that the object is secure so there is little chance of aspiration and that it is not striking and wearing down the tooth enamel.

Use a tongue blade to press down and forward on the back of the tongue to inspect the uvula in midline (Fig. 34.13). The epiglottis can usually be observed with the tongue depressed. Observe for abnormal enlargement, palatine redness, or drainage of tonsils. Although tonsillar tissue differs greatly in size, it should not be reddened or have pus in the crypts (i.e., indentations). After initiating a gag reflex in infants to view the back of their throat, always turn their head to the side so they do not choke on any saliva that accumulated in the mouth during the throat examination because infants are less able to manage this than are adults.

**Figure 34.13** Inspecting the pharynx in a school-age child.

*Do not depress the tongue of any child who is suspected to have epiglottitis or whose glottis is inflamed.* Symptoms of this condition are a sore throat, drooling, high fever, difficulty with respiration, dysphagia, and a barking cough. If a swollen, inflamed epiglottis rises with the pressure of a tongue blade, it can obstruct the respiratory tract so completely that the child is immediately unable to breathe.

### The Newborn and Infant

Many newborns have considerable mucus in their mouths because they are less able to handle swallowing due to immature muscle coordination. If a newborn has teeth, evaluate them for stability; if teeth are loose, they may need to be removed to prevent aspiration. Assess for white patches that do not scrape away from the buccal membrane or tongue (i.e., thrush), a common but abnormal finding in infants that requires antifungal therapy (see [Chapter 43](#)). White patches that scrape away easily are usually caused by an accumulation of formula or breast milk.

### The Older Child

Tonsillar tissue in children reaches its maximum growth at early school age, making many preschool children appear to be “all tonsils.” As long as the tissue does not appear reddened or tender, you can assume it to be normal for the age. Many children with enlarged tonsils snore at night and wake feeling tired. These children should be assessed

by an ENT specialist for sleep apnea. Many children have irregular, pale-pink, and elevated projections on the posterior pharynx as a normal finding. A stream of mucopurulent discharge in the posterior pharynx, however, is not usual and suggests an upper respiratory infection and that a “postnasal” flow of secretions is present. For a child with orthodontic appliances such as braces, assess carefully for pinpoint ulcers on the gum line to be certain the wires are not causing undue discomfort or infection. Cavities appear as dark-brown areas on the tooth enamel. Many school-age children or adolescents have at least one present and will need a dental care referral.

***QSEN Checkpoint Question 34.4***

**TEAMWORK & COLLABORATION**

Pressing a tongue blade against the back of the throat causes a gag reflex. When would the nurse want the team members to know it is important *not* to elicit a gag reflex?

- a. When a child is under 5 years of age
- b. When a child has symptoms of epiglottitis
- c. When a boy has a possible inguinal hernia
- d. When a girl has a geographic tongue

*Look in Appendix A for the best answer and rationale.*

**The Neck**

Assess the neck for symmetry (the trachea should be in the midline; any deviation suggests lung or thyroid pathology). Observe the outline of the thyroid gland (barely noticeable before puberty) because it is obscured by the sternocleidomastoid muscle, on the anterior neck, to be certain it is not swollen or tender. Palpate the area in front of the ear, which is the location of the parotid gland, and smooth a hand over the location of lymph nodes at the sides of the neck and under the chin to palpate for swelling. [Figure 34.14](#) shows the location of lymph node chains of the head and neck. Because children have so many upper respiratory infections, a few nodes that are freely movable, about the size of peas, termed “shotty” nodes because they simulate the feel of buckshot under the skin, are often present. Commonly, preauricular and postauricular nodes are palpable after ear infections, and postoccipital nodes are palpable after a scalp infection. Submental nodes generally denote a tooth abscess. Palpable submaxillary, anterior, and posterior cervical nodes follow throat infections.

**Figure 34.14** The location of lymph node chains in the head and neck.

Ask the child to move the head (or move it for the child) through flexion (i.e., touch chin to chest) and extension (i.e., raise chin as high as possible) and turn it right and left (i.e., rotation) to see that a child does all of these movements easily. Pain on forward flexion is an important sign because it can be caused by neurologic (i.e., meningeal) irritation or is a sign of meningitis.

### The Newborn and Infant

With infants, always assess the ability to control the head by laying the infant supine and pulling the child to a sitting position. Babies younger than 4 months of age will let their heads lag backward as they are pulled up this way, and they will right their heads only as they reach a sitting position. After 4 months, infants should bring their head up with no head lag if their neuromuscular coordination is adequate for their age. This simple but important test yields information about overall neuromuscular control as well as neck strength.

### The Adolescent

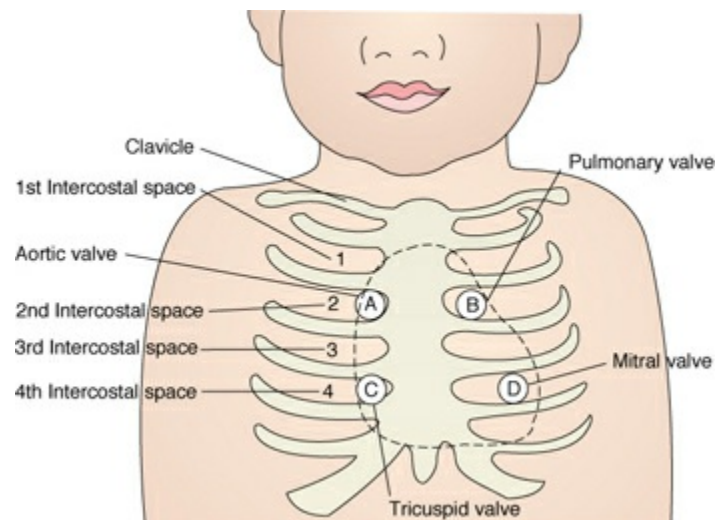

In adolescents, be certain to palpate the thyroid gland for both symmetry and possible nodes. To do this, have the adolescent tilt their head slightly forward and press on the right side of the gland, which will cause it to be more prominent on the left side. Palpate the left half to discern any irregularities (areas of hardness). Repeat on the right side. A finding of a thyroid node needs to be investigated because it may be only an innocent transient cyst or it may be the first indication of thyroid malignancy. Many adolescents have a normal increase in the size of the thyroid at puberty; this hypertrophy should not be accompanied by any nodes.

### The Chest

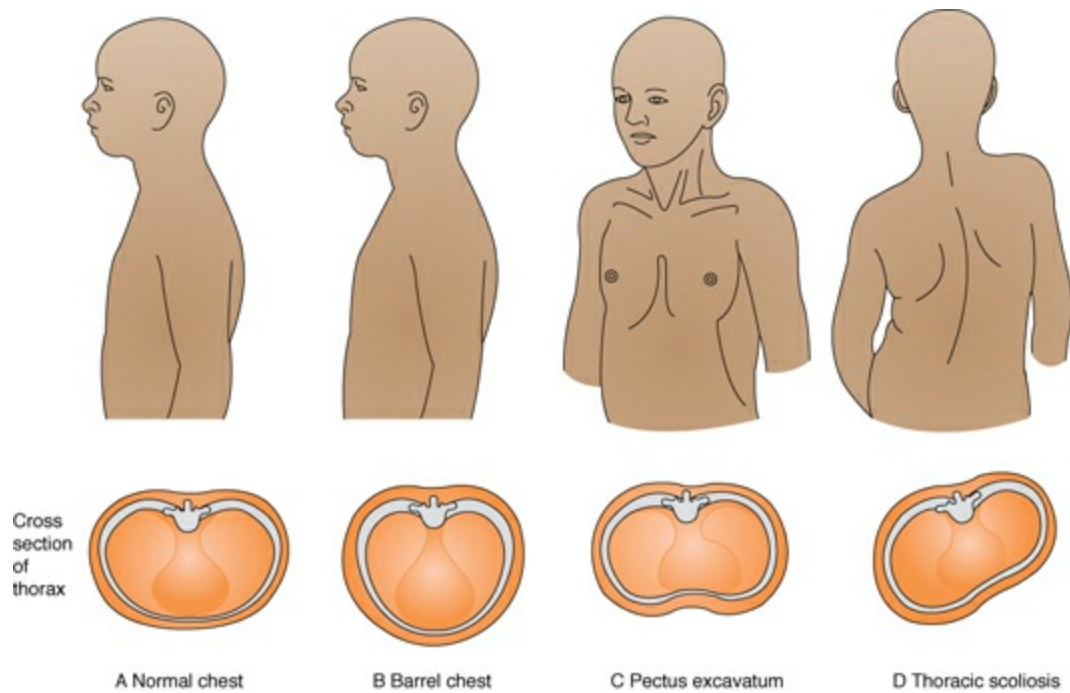

For ease in specifying the location of chest pathology, the chest is divided into sections

by imaginary lines drawn through the midclavicle, midmammary, and midsternum points on the front; the midaxilla on the side; and the midscapula on the back. Pathology is described in terms of these lines such as “abnormal lung sound heard at left midaxillary line.” Other helpful means of locating pathology is by the suprasternal notch, the ribs, and the spaces between them (**intercostal spaces**). Intercostal spaces are numbered according to the ribs immediately above them (Fig. 34.15). Inspect both front and back surfaces of the chest for symmetry of appearance and motion. Inspect for **retractions** or indentation of intercostal spaces or the suprasternal and substernal areas reflect in difficult respirations. Assess the proportion of the anteroposterior to the lateral diameter (normally 1:2). Children with chronic lung disease develop a broad (i.e., barrel) chest or a chest more rounded than usual. This and other chest abnormalities are shown in Figure 34.16. An infant with a diaphragmatic hernia (i.e., intestine herniated into the chest cavity) may have a chest enlarged on that side. An infant with atelectasis (i.e., collapsed lung) may have a chest smaller on the affected side. If a child has an enlarged heart, the left side of the chest may appear larger.

**Figure 34.15** Intercostal (between rib) spaces are numbered according to the ribs immediately above them. The points (A, B, C, D) are the locations where the sounds of the heart valves radiate or where they can be heard best.

**Figure 34.16** Chest contours that can be assessed by inspection. **(A)** Normal chest. **(B)** Barrel chest. **(C)** Funnel chest (pectus excavatum). **(D)** Thoracic kyphoscoliosis.

## The Breasts

The degree of breast assessment depends on the child's age and development. As part of a usual breast assessment, inspect and palpate the breasts of all children to detect any abnormalities.

### The Newborn

Both male and female newborns may have breast edema from the influence of maternal hormones. A few drops of clear fluid may be present from the nipples. This is normal and will fade in a few days' time. Do not squeeze the nipple to remove the fluid. Document if a supernumerary nipple is present for baseline data.

### The School-Age Child and Adolescent

Do a breast examination on all girls past puberty. If a girl younger than 8 years is beginning breast development, precocious puberty (see [Chapter 48](#)) should be suspected. Often, one breast starts to develop before the other. Young girls who are starting to develop breast tissue may complain of discomfort in the developing breast. Many preadolescent boys develop hypertrophy of breast tissue due to increased hormonal influences (i.e., gynecomastia); such boys may be concerned and will need reassurance that this is normal for their age and will fade as soon as androgen becomes their dominant hormone. Adolescent girls may be concerned their breast tissue is inadequate or that breast growth is uneven. They can be assured many women do not

have completely symmetric breasts.

Inspection of breast tissue is easiest if the child sits on the examining table, arms at the sides, with both breasts exposed. Inspect for symmetry. As mentioned, it is not unusual for a girl to have breasts of slightly unequal size.

Inspect next for edema, erythema (i.e., redness), wrinkling, retraction, or dimpling of the skin because all suggest a tumor may be growing in deeper layers of the breast. Edema, resulting from blockage of lymph channels, makes the skin appear not only swollen but also pitted (an orange-peel effect). Note any nipple discharge or “pulled” nipple placement as another way to detect edema.

With the girl’s arms at her sides to take pressure off breast tissue, palpate well into each axilla (breast tissue extends that far) and also to assess axillary lymph nodes. Normally, no nodes under the arm should be felt. Next, ask the girl to lie down and place a folded towel under her near shoulder. Palpate the near breast with her arm raised and placed under her head because this spreads out breast tissue; begin at the nipple and palpate outward in a circular motion. The lower edge of each breast feels hard; do not mistake this or rib prominences underneath for a tumor. Repeat on the other side. Although breast self-exams are no longer recommended, it’s good to teach adolescents breast awareness or to know what their breasts normally feel like so if a condition such as fibrocystic breast disease should develop, they will be able to recognize this and report it to their primary healthcare provider.

## The Lungs

Various findings reveal respiratory distress in children. Assess the rate of respirations and whether respirations seem easy and relaxed or stressed. Assessment related to skin tone can affect findings such as jaundice in a newborn or cyanosis in a child in respiratory distress. Assessing for cyanosis is different in dark-skinned than in fair-skinned children (the mucous membrane is the best place to detect this). Note if it’s necessary for a child to use accessory muscles to achieve effective ventilation. Palpate over the lung area for vibrations that suggest air is having difficulty moving through small air passages.

On the anterior chest, lung tissue extends from above the clavicles to the sixth or eighth rib. On the posterior chest, lung tissue extends as low as the 10th to 12th thoracic vertebrae. The right lung has three lobes; the left, only two. Attempt to evaluate all five lobes during lung assessment because lung disease can be specific for a lobe rather than involve the entire lung.

Following palpation, percuss lung tissue. Normal lung sounds are resonant in older children; in infants and younger children, sounds are hyperresonant due to the thinness of the chest wall. Overexpanded lungs will sound hyperresonant in older children, and lungs filled with fluid sound dull in older children and less resonant in younger children. The lower anterior lobe of the right lung will sound dull because the liver covers it on the anterior surface below the fourth or fifth intercostal space. The space over the heart will also percuss as dull.

**Diaphragmatic excursion** (i.e., the distance the diaphragm descends with inhalation) is an estimation of lung volume. To establish this, perform the following steps:

- Ask the child to take a deep breath and hold it.
- Percuss downward to locate the bottom of the lungs (the percussion note changes from resonant to flat at that point).
- Ask the child to expire fully and momentarily hold that position.
- Percuss upward to locate the expired or empty lung position (the percussion note changes from flat to resonant).

The difference between these two points is the diaphragmatic excursion. Children who have overexpanded lungs from obstructive disease have little diaphragmatic excursion in relation to others.

Auscultate breath sounds by listening through one full cycle at each auscultatory site with the diaphragm of a stethoscope over each lung lobe while a child inhales and exhales (preferably with the mouth open). Listen both anteriorly and posteriorly; compare the left side with the right side for equal findings. Usual breath sounds are slightly longer on inspiration than expiration. Consider whether there are any abnormal sounds. [Table 34.4](#) describes usual breath sounds and transmitted airway sounds as well as adventitious sounds that, if heard, might reflect illness.

**TABLE 34.4 BREATH SOUNDS HEARD ON AUSCULTATION**

Sound	Characteristics
Vesicular	Soft, low-pitched sound, heard over periphery of lungs; inspiration longer than expiration. Normal.
Bronchovesicular	Soft, medium-pitched sound, heard over major bronchi; inspiration equals expiration. Normal.
Bronchial	Loud, high-pitched sound, heard over trachea; expiration longer than inspiration. Normal.
Rhonchi	A snoring sound made by air moving through mucus in bronchi. Normal.
Rales (also called crackles)	Crackling or crinkling sounds (like cellophane) are created by air moving through fluid in alveoli. Abnormal.
Wheezing	Whistling on expiration made by air being pushed through narrowed bronchi. Abnormal; seen in children with asthma or foreign body obstruction.
Stridor	Crowing or rooster-like sound made by air being pulled through a constricted larynx. Abnormal; seen in children with upper respiratory obstruction.

Infants cannot breathe in and out on request. Try to listen to breath sounds early in an examination because breath sounds are difficult to hear clearly over the sound of crying.

## The Heart

Heart assessment begins with asking children if they have ever noticed any cardiac symptoms such as pain. Visual inspection to see if there is a point on the chest where the heartbeat can be observed follows this. This point represents the location of the left ventricle or the point where the apical heartbeat can be heard best. In children younger than 7 years of age, this point is generally lateral to the nipple line and at the fourth intercostal space. In children older than 4 years, it is at the nipple line or just medial to it and at the fifth intercostal space. This point is termed the **point of maximum impulse (PMI)** and is observable in approximately 50% of children.

Percuss the left side of the chest to discern the left side of the heart. Percussing in from the axilla, the sound will become dull as the heart is identified. Normally, the percussion note changes from resonant (i.e., percussing over lung) to flat (i.e., percussing over heart) midway between the midaxillary and midmammary line. A heart located further to the left than this suggests enlargement.

## Heart Sounds

To assess heart function, first listen over the heart and record the rate ([Fig. 34.17](#)). Compare this to the child's age to determine if it is normal. To hear differences in first and second heart sounds, auscultate at the four main points in the following bullets. Although these are not the anatomic locations of heart valves, they are the sites to which the sounds of the valves radiate and can be heard best in children (see [Fig. 34.15](#)).

- The mitral valve is heard best at the fourth or fifth left intercostal space at the nipple line.
- The tricuspid valve is heard best near the base of the sternum (fourth or fifth right intercostal space).
- The pulmonary valve is heard best at the second left intercostal space.
- The aortic valve is heard best at the second right intercostal space.

**Figure 34.17** Auscultating heart sounds.

Table 34.5 describes normal and abnormal heart sounds, which may be heard on auscultation. Abnormal sounds are heard best if you listen first through the diaphragm of the stethoscope, followed by the bell.

**TABLE 34.5 HEART SOUNDS HEARD ON AUSCULTATION**

Sound	Cause
S <sub>1</sub> (first heart sound)	Closure of tricuspid and mitral valves with beginning of ventricular contraction (systole)
S <sub>2</sub> (second heart sound)	Closure of pulmonary and aortic valves with beginning of atrial contraction (diastole)
S <sub>3</sub> (third heart sound)	Rapid ventricular filling
S <sub>4</sub> (fourth heart sound)	Abnormal filling of ventricles

To understand heart sounds, recall heart physiology. The first sound heard (S<sub>1</sub>) is that of the mitral and tricuspid valves closing and the ventricles contracting (described as a “lub” sound). The second sound (S<sub>2</sub>; described as a “dub” sound) is made by the closure of the aortic and pulmonary valves and atrial contraction. The first sound is generally longer and lower pitched than the second. Over the heart ventricles, it is louder but at other sites tends to be slightly quieter.

The rhythm of the heart sounds should be regular. **Sinus arrhythmia** is a normal but marked heart rate increase that occurs as a child inspires and a marked decrease in heart rate as the child expires and is frequently noted in school-age children and adolescents. Ask a child to take and hold a breath, and the rhythm of the heart should remain steady.

Another variation in heart sounds occurs because with inspiration and the resulting

increase of pressure in the lungs, the pulmonary valve closes slightly later than the aortic valve. This is termed **physiologic splitting** and is heard as a “lub d-dub” sound. As long as this is associated with inspiration, it is a normal finding. Splitting that is always present implies there is difficulty with the pulmonary valve closing and suggests pathology.

At times, a distinct third heart sound ( $S_3$ ) may be heard due to rapid filling of the ventricles. Although this is not necessarily a serious finding, further investigation is warranted. The presence of a fourth heart sound ( $S_4$ ) generally signifies heart pathology because this sound (a gallop rhythm) is caused by an abnormal filling of the ventricles, which causes increased pressure on valves.

Lastly, listen for heart murmurs. These are caused by the sound of blood flowing with difficulty or in an abnormal pathway within the heart (sounds like a swishing sound) and can be either innocent (i.e., functional) or pathogenic (i.e., organic). If a heart is pumping with abnormal force, there may be a palpable vibration, termed a *thrill*, on the chest wall. Palpate the precordium (i.e., area over the heart) for evidence of this (feels like a cat purring) or a heave (a definite outward chest movement), which also denotes a struggling heart. On hearing or palpating any accessory heart sounds or movements, describe them with reference to [Table 34.6](#).

**TABLE 34.6 DESCRIPTION OF ACCESSORY HEART SOUNDS**

Assessment Information to Be Gathered	
Location	At which listening post is the sound most distinct?
Quality	Can sound be described as blowing, rubbing, rasping, or musical?
Intensity	<p><i>Murmurs</i> are graded according to the following criteria:</p> <ul style="list-style-type: none"> <li>• Grade 6: so loud it can be heard with stethoscope not touching the chest wall; has a thrill (palpable vibration)</li> <li>• Grade 5: very loud but must touch stethoscope to chest to hear; has a thrill</li> <li>• Grade 4: loud; may or may not have a thrill</li> <li>• Grade 3: moderately loud; no thrill</li> <li>• Grade 2: quiet, but easily discernible</li> <li>• Grade 1: very quiet; difficult to hear</li> </ul>
Timing	When in relation to $S_1$ and $S_2$ , did you hear the murmur? A sound superimposed between $S_1$ and $S_2$ is a <i>systolic murmur</i> ; one between $S_2$ and the next $S_1$ is a <i>diastolic murmur</i> . Innocent murmurs (functional, denoting no pathology) are usually systolic, although there are exceptions to this. Pathologic murmurs are more likely to be diastolic.
Pitch	Can the sound be described as high pitched or low pitched?
Radiation and	Is there an accompanying thrill? Does sound radiate so it can be heard at another location, such as the back of the chest?

All unusual heart sounds need further identification and investigation as to their cause. The skills of listening to and identifying normal and abnormal heart sounds require considerable practice. Determining the cause of an abnormal heart sound requires a cardiac specialist. However, determining that an abnormal sound exists and securing proper referral is an important nursing role.

### The Newborn, Infant, and Toddler

Listen to heart sounds in young children early in an examination, before a child begins to cry, because it is almost impossible to evaluate heart sounds over the sound of crying. Allowing a parent to hold a child while listening to the heart helps reduce fear.

### The School-Age Child and Adolescent

Listen carefully for sounds of murmurs in children of school age and older. Be particularly conscientious with student athletes; it seems paradoxical that they could have heart disease, but if present, this could be fatal to them during athletic events (Harmon, Asif, Maleszewski, et al., 2016). Refer them to their primary healthcare provider for further evaluation if any abnormalities are detected. Parents are always frightened by an unusual heart sound, but unless the child has other symptoms, they can be assured that although you are referring them, most murmurs are innocent (i.e., functional) and caused only by the normal flow of blood across valves.

### *QSEN Checkpoint Question 34.5*

#### **INFORMATICS**

The nurse is using a stethoscope to auscultate the sound of Keoto's mitral heart valve closing. When determining where to listen, the nurse identifies which location as best?

- Over the anterior sternum
- The right 9th or 10th intercostal space
- The left interior rim of the left clavicle
- The fourth or fifth left intercostal space at the nipple line

*Look in Appendix A for the best answer and rationale.*

### **The Abdomen**

The abdomen is anatomically divided into four quadrants. The quadrants and the organs that lie within them are shown in Figure 34.18. To assess an abdomen, first inspect the surface for symmetry and contour. It will be slightly protuberant in infants and scaphoid in older children. Note any skin lesions or scars.

**Figure 34.18** The quadrants of the abdomen and underlying structures.

Auscultate the abdomen for bowel sounds before palpating because palpating may alter bowel action (i.e., peristalsis) and therefore disturb bowel sounds. Bowel sounds can normally be heard in all quadrants of the abdomen. They are high “pinging” sounds that occur normally at intervals of approximately 5 to 10 seconds and, because they are high-pitched sounds, are heard best with the bell of a stethoscope. If the bowel is distended, the sounds occur more frequently; if the bowel is blocked, so there is no movement of contents, sounds will be absent below the obstruction. Listen for 3 to 5 minutes before concluding that no bowel sounds are present to be certain they are not just widely spaced.

Next, listen along the middle of the abdomen over the aorta for irregular sounds. A **bruit** is a swishing or blowing sound occurring if there is an outpouching of the aorta (i.e., an aneurysm), a condition that can be congenital, although it usually occurs with aging.

Palpate the abdomen in a systematic manner (e.g., the lower left quadrant, upper left quadrant, upper right quadrant, lower right quadrant) to include all four quadrants. First, palpate lightly and then deeply. Ascertain whether any area is tender by watching the child’s face while palpating; observe for guarding or the child tensing the abdominal muscles to keep you from pressing deeply at that point. If a child indicates any portion of the abdomen is tender, begin assessment at the farthest point and work toward the tender area. If no tenderness is present, the order of palpation is unimportant as long as

it is thorough. Note any hard areas or masses. If a tender area is detected, attempt to elicit rebound tenderness to determine its cause. To do this, press on the abdomen and then lift your hand suddenly. This causes internal organs to vibrate. Although all children do not show this sign, the occurrence of more pain with the vibration than with the original pressure is one of the standard diagnostic criteria for appendicitis (Santillanes, Simms, Gausche-Hill, et al., 2012).

When palpating from the right lower quadrant to the right upper quadrant, the hand will bump against the lower edge of the liver 1 to 2 cm below the right ribs. On the left side, the lower edge of the spleen may be discernible in the same way. A liver or spleen larger than this is suggestive of disease. Lastly, palpate the umbilicus to try to identify the presence of an umbilical hernia. A fascial ring at the umbilicus of more than 2 cm in diameter in an infant denotes a ring of fascia larger than will normally close spontaneously; when this is present, the child will generally need surgery to prevent an umbilical hernia. Liver, spleen, and bladder size can all be documented further by percussion.

### The Newborn and Infant

Kidneys may be located by deep abdominal palpation in newborns and infants. The right kidney is slightly lower than the left and so is easier to locate. The optimal time to palpate the kidney of a newborn is during the first few hours of life, before the bowel begins to fill with air and obscures palpation. To palpate for kidneys, perform the following:

- Place a hand under an infant's back just below the 12th rib.
- Press upward.
- Place the other hand on that side of the abdomen just below the umbilicus.
- Press deeply with your upper hand.
- Locate the kidney, which can be felt as a firm mass approximately the size of a walnut, between the hands.

### The Preschooler and the School-Age Child

Children's abdomens at this age are often ticklish, and children may tense or guard their abdominal muscles when touched, making it difficult to palpate. Distract a child by asking a question about home or school or let a child place his or her hand under your hand to help relax (Fig. 34.19).

**Figure 34.19** Decrease ticklishness during abdominal palpation by placing the child's hand under yours.

### The Genitorectal Area

In both sexes, the rectum should be inspected for any protruding hemorrhoidal tissue (rare in children) or fissures. Fissures may signify chronic constipation, intra-abdominal pressure, or sexual maltreatment.

#### The Female Genitalia

Inspection of the external genitalia and an assessment of femoral nodes are included in every complete health assessment in girls ([American College of Obstetricians and Gynecologists, 2014](#)). An external examination consists of inspecting for the Tanner stage of pubic hair growth and configuration (i.e., an inverted triangle) and inspection of external genitalia (i.e., clitoris, labia majora, and labia minora) for normal contours. Look for signs of discharge or irritation. A vaginal discharge that suggests infection or a fourchette tear in a young child may be an indication of sexual maltreatment, and in an adolescent, this can be an indication of rape ([Peterson, Nurre, & Dunn, 2017](#)).

A pelvic examination is usually scheduled at the time the girl becomes sexually active, at 21 years of age, or at the first sign of a gynecologic disorder ([American Academy of Pediatrics \[AAP\], 2016](#)). The technique for internal pelvic examinations is discussed in [Chapter 11](#).

#### The Male Genitalia

Inspection of male genitalia consists of observing:

- The distribution and the Tanner stage of pubic hair, which has a diamond shape
- The penis, for lesions that might suggest an STI
- Appearance and placement of the urethral opening, which should be slit-like and centered at the penis tip. Note whether the boy is circumcised because boys who are uncircumcised have more urinary tract infections than those who are circumcised ([Stein, Dogan, Hoebcke, et al., 2015](#)); repeated urinary tract

infections can cause scarring of the meatal opening, making it small and round.

- The ability to retract the foreskin, if a boy is uncircumcised. *Phimosis* exists when the foreskin of a child older than 6 to 12 months is too tight to retract. Do not retract a tight foreskin over the corona of the penis.

**Hypospadias** means the urethral opening is located on the inferior or ventral (i.e., under) surface of the penis; **epispadias** denotes a urethral opening on the superior or dorsal (i.e., upper) surface. Both these conditions need to be identified. If more than a slight deviation is present, repair is usually initiated before school age because such a urethral placement may interfere with self-image if not corrected. During adulthood, it can interfere with fertility.

Inspect the scrotum for size and the presence of testes. In most boys, the left testicle is slightly lower than the right, so the scrotum does not appear truly symmetric. Palpate to check that both testes are present by placing one hand at the top of the scrotum over the inguinal ring and then palpating the testis on that side (see [Chapter 18, Fig. 18.21](#)). This hand position prevents the testis from slipping up into the inguinal ring and appearing to be absent on palpation. If the testis cannot be palpated with the boy lying supine, have him sit upright with his legs crossed while palpating. Gravity often will help the testicle fall into place. Any swelling or mass in the scrotum needs to be identified. The most likely cause of such a condition is a **hydrocele** (i.e., a fluid-filled sac), but it could represent a serious finding such as testicular cancer in adolescents. Hydroceles can be transilluminated; when a flashlight is held in back of the scrotum, the fluid-filled cyst glows. A **varicocele** (i.e., enlarged veins of the epididymis) may be palpated. These are not important findings in young boys, but they could possibly interfere with fertility later in life.

Assess the urethral meatus for any discharge that could reveal an STI, such as gonorrhea, or any lesions that would suggest herpes simplex type 2 infection or syphilis (see [Chapter 47](#)). Palpate femoral nodes (located in the groin and on the inner surface of the upper thigh) for any swelling, which suggests infection. Beginning at puberty, teach boys to do testicular palpations every month. The technique for this is described in [Box 34.10](#).

#### BOX 34.10

#### Nursing Care Planning Based on Family Teaching

#### TESTICULAR SELF-EXAMINATION

**Q.** Keoto's father asks you, "What is the best technique for testicular self-examination?"

**A.** Starting in their adolescent years, all males need to perform testicular self-examination once a month. Follow these guidelines:

- Select a certain day each month (e.g., first day, last day) to perform the examination.

- Perform the examination in or immediately after a shower because warmth makes scrotal skin relaxed.
- Gently roll each testicle between your thumb and fingers, feeling for any hard lumps or nodules, a change in consistency, or a difference in size.
- Also, feel for the epididymis found at the rear of the testes. It should feel like a strong cord.
- Remember that for most males, one testicle is slightly larger than the other and hangs a little lower in the scrotal sac.
- If you notice any changes in size, tenderness, or unusual mass, call or visit your healthcare provider.

To assess for the presence of an inguinal hernia in an infant, simply observe the groin area for any bulging, especially while the infant is crying. In the school-age child or adolescent, with the child standing, place a fingertip against the inguinal ring in the groin area and ask the child to cough. If the tendency for a hernia is present, coughing tightens the abdominal muscles and forces the abdominal contents to bulge against the finger.

### The Extremities

Observe the upper extremities for good color and warmth. Because changes in fingernails can be a sign of overall ill health, inspect them for color, contour, and shape (Chernoff & Scher, 2016). Normally, nails are pink (or deeply pigmented in darker skinned children), smooth, and convex. They should feel hard to the touch but not so brittle they break readily. Signs of bitten fingernails in the school-age child may reflect a high level of stress. A blue or purple tinge denotes cyanosis; a yellow tinge denotes jaundice. Children who have decreased respiratory function or heart disease develop clubbed fingers (Fig. 34.20); children with endocarditis often have characteristic linear hemorrhages under the nails.

**Figure 34.20** Clubbed fingers are a sign of cyanosis from heart or respiratory disease. (NMSB/Custom Medical Stock Photo.)

Iron-deficiency anemia may cause extremely concave surfaces of fingernails (spoon-shaped). Press against a fingernail, release the pressure, and time the refilling interval (should be under 5 seconds). Count the fingers and check for webbing between fingers. Examine that fingerprints are present. Distinctive dermatoglyphics are present on fingertips from the third month of intrauterine life; these are unique to every person and show patterns of circular grooves. Abnormal fingerprints may occur with chromosomal anomalies. Check also for normal palmar creases. Children with chromosomal abnormalities may have only one central palm crease (i.e., a simian line) on each hand rather than the normal three (see [Chapter 7](#)). Check the wrist, elbow, and shoulder joints for movement and for normal range of motion; palpate joints for swelling or warmth. Palpate to be certain no lymph nodes are present in the antecubital space; palpate to check a radial pulse is present.

Inspect the lower extremities for color and warmth. Count the toes and check for webbing between toes. Check the ankle, knee, and hip joints for normal range of motion. Check for developmental hip dysplasia in infants by attempting to abduct the hips fully (see [Chapter 18, Fig. 18.22](#)). Palpate to ensure no enlarged lymph nodes are present in the groin or popliteal areas and femoral pulses are present and equal bilaterally. Ask the older child to walk and observe for ease of gait, limping, or any foot displacement such as toeing in or out. Toddlers typically walk with a wide-based gait; they walk best if allowed to walk toward their parent (a safe action) rather than away. Remember many adolescents are self-conscious and slouch or amble rather than present their true, natural gait. Children who limp need a further evaluation. A limp can be due to something as simple as a blister on the foot from wearing new shoes or can be a sign of a serious hip or bone condition ([Lyons, 2015](#)).

## The Back

Inspect the back for symmetry and the spinal column for any deviation. Inspect the base of the spine for a dermal sinus (i.e., a pinpoint opening) or a tuft of hair or a hemangioma that might reveal spina bifida occulta (i.e., a defect of the bony structure of the canal). Also inspect for any dimpling that might denote a dermal cyst (i.e., pilonidal cyst). This is an innocent finding unless it becomes infected or connects to deeper tissue layers. Assess for tenderness along the spinal column by palpating each vertebra because chronic lower back pain can be present as early as school age ([Spiteri, Busutil, Aquilina, et al., 2017](#)).

A routine assessment of the school-age child beginning at 10 years of age and through adolescence should include screening for scoliosis (i.e., sideways curvature of the spine) ([Walter, 2011](#)). [Box 34.11](#) details the steps to follow for a scoliosis screening exam (see [Chapter 51](#) for more details on scoliosis).

### BOX 34.11

#### Nursing Care Planning Using Procedures

## SCOLIOSIS SCREENING

**Purpose:** To assess for scoliosis (sideways curvature of the spine)

Procedure	Principle
1. Have the child remove clothing except for undergarments. Ask the child to stand up straight, with feet together and arms at sides. Observe the child from a posterior view.	1. Promotes optimal view of back
2. To inspect for a curved spinal column (Fig. A), observe: <ul style="list-style-type: none"><li>• Is one shoulder higher than the other?</li><li>• Is one shoulder blade more prominent than the other?</li><li>• Does one hip seem higher or more prominent than the other?</li><li>• Does the child seem to lean to one side?</li><li>• Does the spinal column appear curved?</li></ul>	2. Denotes signs of spinal curvature

3. With the child's arms hanging down at his or her sides, compare the level of the elbows in relation to the iliac crests:

- Are the elbows held at the same level?
- Do the elbows fall at the level of the crest or closer to the crest on one side? (Normally, elbows fall above the iliac crest.)

4. Ask the child to bend over and touch toes while you continue to observe the back (Fig. B).

- Is there a hump in the back?
- Does the spinal column appear to curve?
- Is one shoulder blade more prominent than the other?

5. Refer the child to his or her primary healthcare provider for further examination if any of the previous

3. Helps to determine uneven posture because it will affect level of elbows

4. Provides evidence of spinal rotation. As the child bends, the rotation of the spine accompanying scoliosis becomes more prominent.

5. Provides for proper referral

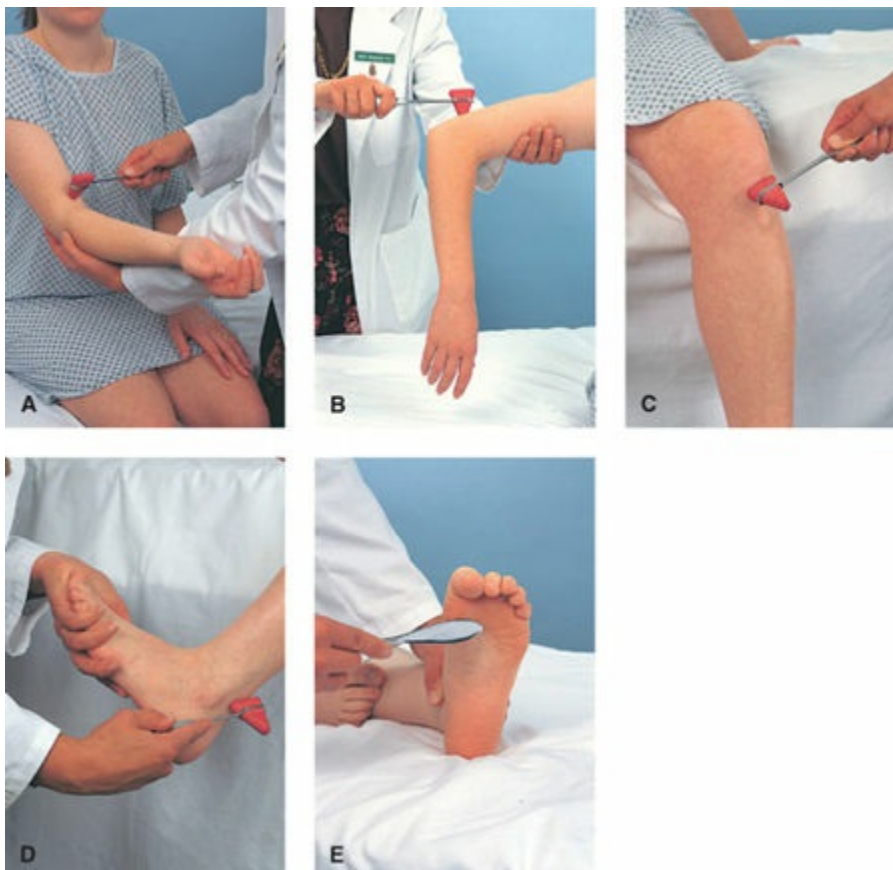

observations are noted.

6. Educate the child to inform parents or healthcare providers if signs of scoliosis, such as a skirt hanging unevenly or bra straps need to be adjusted, begin to develop.
6. Encourages health promotion

## Neurologic Function

A full neurologic examination takes at least 20 minutes to complete, so this is not included in a routine physical examination. It is important, however, to assess for **deep tendon reflexes** (such as triceps, biceps, patellar, and Achilles reflexes) to test for motor and sensory function and balance and coordination. Techniques for eliciting deep tendon reflexes are shown in [Figure 34.21](#). Grade reflexes according to the scale is shown in [Table 34.7](#). The biceps reflex tests the fifth and sixth cervical nerves; the triceps reflex tests the seventh and eighth cervical; the patellar reflex tests the second, third, and fourth lumbar; and the Achilles reflex tests the first and second sacral. Test the sole of the foot for a Babinski reflex (see [Chapter 18, Fig. 18.9](#)). Fanning of the toes will occur in an infant younger than 3 months of age; a downward reflex of the toes will occur beyond 3 months of age. (Some normal infants demonstrate a flaring Babinski response until they are 2 years of age, and in the absence of other neurologic findings, this is not significant.)

**Figure 34.21** Techniques for eliciting major reflexes. **(A)** The biceps reflex. **(B)** The triceps reflex. **(C)** The patellar reflex. **(D)** The ankle or Achilles reflex. **(E)** The Babinski response. (From Weber, J., & Kelley, J. [2003]. *Health assessment in nursing* [2nd ed.]. Philadelphia, PA: Lippincott Williams & Wilkins. Images © B. Proud.)

**TABLE 34.7 GRADING OF DEEP TENDON REFLEXES**

Grade	Interpretation
4+	Hyperactive; extremely marked reaction; abnormal
3+	Stronger than average but within normal range
2+	Average response
1+	Less than average response but within normal range
0	No response; abnormal

Test for superficial reflexes: abdominal reflexes in both sexes and a cremasteric reflex in boys. An abdominal reflex is elicited by lightly stroking each quadrant of the abdomen. Normally, the umbilicus moves perceptibly toward the stroke. Presence of the reflex indicates integrity of the 10th thoracic nerve and the first lumbar nerve of the spinal cord. A cremasteric reflex is elicited by stroking the medial aspect of the thigh in boys. With this, the testes move perceptibly upward. The presence of this reflex indicates integrity of the first and second lumbar nerves.

### Motor and Sensory Function

Test general facial nerve function by asking a child to make a face. The child's ability to grasp with the hands and push against a surface with the feet establishes general motor ability. Recall whether the child's gait was adequate when observed walking to assess for balance and coordination.

To test sensory function, ask children to close their eyes and identify the location where you touch them at (at least) six points on different body parts.

#### *What If . . . 34.2*

**Although the nurse knows children should be completely undressed for physical examinations so all body surfaces can be inspected, Candy's father says he doesn't want Candy undressed because the exam room is too cold. How would the nurse best respond if not wanting to remove a Band-Aid from Candy's back?**

## Vision Assessment

Assessing vision is an important part of a physical assessment because good vision is so important to childhood development. The extent and type of testing depends on the age of the child.

Any child with congenital anomalies, low birth weight, or fetal alcohol syndrome is at risk for eye abnormalities, as is a child who received oxygen at birth. During an assessment, if you notice an unreported eye injury or infection or signs of neglected vision, make a special note. Because the average parent is careful of a child's eyes, these findings may be indicative of child neglect.

### VISION SCREENING

Routine vision screening can begin as early as 6 to 12 months of age. Parents can provide important clues to possible problems; therefore, listen carefully any time a parent expresses concern about or questions a child's ability to see well. Common vision screening, indicators, and techniques for children of different ages are summarized in [Table 34.8](#).

**TABLE 34.8** Common Vision Screening Indicators and Procedures

Age	Common Test
Newborn	General appearance* Ability to follow moving object to midline; focus steadily on an object at 10–12 in.
Infant and toddler	General appearance* Ability to follow light past midline
Age 3 years to school age	General appearance* Random dot E for stereopsis (depth perception) Allen cards or preschool E chart for visual acuity Ishihara's plates for color awareness
School age to adult	General appearance* Snellen test for visual acuity

\*Note redness, blinking, squinting, crusting of eyes, or tilting of head.

### Newborn and Infant

Newborns should be able to focus on a moving object such as a finger and follow it to the midline. Infants see black and white objects better than they do colored objects. They seem to see objects that are at a distance of about 19 cm [8 to 10 in.] best. Ask parents if an infant's eyes follow them as they move around the room. Does an infant who is older than 6 weeks return their smile? Do the parents have any reason to think their child has difficulty seeing?

## The Toddler and Preschooler

Ask parents if their children do any of the following, which may be signs of vision problems:

- Rub their eyes, blink frequently, squint, or frown
- Cover one eye to look at objects
- Tilt the head to see things better
- Stumble over objects in their path
- Hold books and toys extremely close or extremely far away to look at them

Asking whether children sit close to a television set is meaningless because almost all children sit closer than necessary if allowed.

## The School-Age Child and Adolescent

Ask if the child or adolescent:

- Reports difficulty seeing
- Reports frequent headaches
- Does poorly with class work
- Avoids sports that require long-distance vision, such as baseball or softball
- Avoids watching movies
- Skips over words when reading aloud
- Reports blurriness or double vision
- Has reddened conjunctivae or drainage from the eyes
- Blinks at bright light

## Techniques of Vision Testing

Vision is tested by asking a child to read a standardized eye chart. All children need good orientation to such testing so they can appreciate that this is not a test in the usual sense of the word; otherwise, they may be unusually anxious or try to “pass” it by cheating. Vision testing needs to be started in the preschool period, so children with amblyopia (i.e., lazy eye; see [Chapter 50](#)), a potentially serious vision disorder, can be identified while the condition is still correctable ([Taylor & Elliot, 2014](#)). In addition to usual testing, a digital photo of the child’s face can be used to help identify strabismus (i.e., uneven gaze or eyes not symmetrically aligned).

### The Snellen Chart

As soon as children can identify letters of the alphabet (i.e., early school age), their vision can be tested by use of a Snellen eye chart. Because this chart is standardized, set procedures must be followed when using it to test vision ([Box 34.12](#)).

BOX 34.12

Nursing Care Planning Using Procedures

## SNELLEN EYE CHART ASSESSMENT

**Purpose:** To assess vision

### Procedure

1. Hang the chart so the 20-ft line is at the child's eye level.
2. Provide a good light for the chart and place it so there is no glare. A light intensity of 20-ft candles is recommended.
3. Measure a distance of 20 ft from the chart. Mark the floor at this point with a piece of masking tape or other similar mark. For younger children, it is helpful to cut out paper footprints and paste them to the floor with the heels of the footprints touching the 20-ft line. If the child sits in a chair, the back legs of the chair should touch the 20-ft line.
4. Provide the child being examined with a 3 × 5 in. card to cover the eye

### Principle

1. The child who has to look up or down must look farther than the child who is looking straight across at the chart. A possible solution to avoid moving the chart is to have smaller children stand and taller children sit. To accommodate children in wheelchairs, the chart needs to be lowered (or have all children sit for the test).
2. Appropriate lighting provides for optimal test conditions.
3. Twenty feet is the optimal distance from the chart for testing.
4. Covering the other eye allows for one eye to be tested at a time.

not being tested.

5. If the child wears glasses, screen first with the glasses in place. Do not screen the child first without glasses and then with them because this forces the child to strain to read the chart.
  6. To begin testing, tell the child to stand with shoes on the footprints (heels against the line), keep both eyes open and cover the left eye with the occluding card. Be certain the child does not press the card against the eye (instead, the edge of the card should rest across the child's nose).
  7. Begin at the 40-ft line of the chart and, using a pointer or pencil, point to each symbol on the line from left to right (the order in which children are taught to read). If the child reads the majority of symbols in a line, the line is passed satisfactorily.
  8. If the child "passes" the 40-ft line, have the child read the 30- and 20-ft lines or the last line the child can read. Record the last line read. If the child fails to read the 40-ft line satisfactorily, then begin at the top of the chart and move downward to identify the last line the child can read. Record this reading. Because the 200-ft, 100-ft, and 70-ft lines have so few symbols, the child must read all the symbols on them to have read them satisfactorily.
  9. Visual acuity is always stated as a fraction. The top number is the distance in feet the child stands from the chart (always 20). The bottom of
5. Testing with corrective lenses screens for corrected eyesight. After squinting, a child may have difficulty readjusting to reading with glasses, and this makes the prescription appear too weak or too strong.
  6. Covering the eye not being tested provides one eye to be tested at a time. Pressure will cause blurred vision when the child removes the card to test that eye.
  7. Starting at the 40-ft line is the standardized testing procedure.
  8. Moving to the 30-ft line or less reflects use of the standardized testing procedure.
  9. Using a fraction for visual acuity is the standardized reporting procedure.

the fraction represents the last line the child read correctly. The adult with good (average) vision can read the 20-ft line from 20 ft away and thus is said to have 20/20 vision.

10. It is important to test the eyes separately and then together. For example, suppose Keoto reads all the symbols on the 40-ft line with her right eye but she misses three out of four on the 30-ft line. Her visual acuity for her right eye is 20/40 (the distance from the chart/the last line she read correctly). With her left eye, she reads the 40-ft, 30-ft, and 20-ft lines correctly. Her vision in that eye is 20/20. With both eyes, Keoto reads the 40-ft, 30-ft, and 20-ft lines correctly. Her visual acuity for both eyes is therefore 20/20.
  11. Observe children for straining or squinting as they read the chart.
10. If only this last reading were taken, the right eye weakness (a symptom of amblyopia or “lazy eye”) would be missed.
  11. By squinting and changing the shape of the eyeball, children can improve vision and will score higher; therefore, children will appear to see better than they actually do in everyday situations.

## The Preschool E Chart

Between 3 years of age and the age when children can read the alphabet, they can be tested by use of a preschool E chart (Fig. 34.22). This chart is also helpful to test children who are cognitively challenged or those who do not speak fluent English. The procedure is similar to that of the standard Snellen chart:

1. The child stands 20 ft from the chart and reads first with the right eye, then with the left, and then with both eyes. Young children do not understand the importance of not pressing the card against their eye and of not peeking, so a second person is often needed to hold the occluder card for children of this age.
2. Compare the E on the chart with a table with three legs and ask the child which way the legs of the table point. By 3 years of age, children are familiar with tables, but the letter E may still be a strange symbol. Tell the child to point with the entire arm and hand in the direction the legs point so you do not confuse the hand motion.

3. Ask the child to begin by looking at the 40-ft line, as with a standard Snellen chart, and work downward until the child passes all lines or cannot read the majority of symbols on a line. Record the distance from the chart and the last line read correctly (20 over the last correct line).

**Figure 34.22** An astigmatic and preschool E chart. (American Optical Company August 1935 Catalog. “Ophthalmological Instruments and Equipment.” Courtesy of the Optical Heritage Museum.)

### The National Society for the Prevention of Blindness Home Test

A home eye test is available from the National Society for the Prevention of Blindness for parents to test children ages 3 to 6 years at home. It is similar to the preschool E chart except it is smaller and the child stands only 10 ft away. The test can help alert parents that a child needs a professional eye examination. Home tests can be given or suggested to parents whose child is tired or who, for some other reason, does not test well in a healthcare facility ([Prevent Blindness America \[PBA\], 2016](#)).

### Allen Cards

Allen cards consist of pictures of common objects such as a horse and rider, a car, a house, and a birthday cake. The cards are shown to the child at a 15-ft distance, and the child is asked to identify the pictures (proof the child sees them). Be certain children have time to examine the cards before the test so you’re sure they know the names of the objects.

### STYCAR Cards

For this test, a child is given cards with nine letters: H, C, O, L, U, T, X, V, and A. The child holds up the card that matches the one you point to on a STYCAR chart.

### Titmus Vision Tester

Another useful method for testing the vision of children is the Titmus Vision Tester, the same instrument used by many motor vehicle licensing offices. As the child looks into

the eyepieces of the machine, alphabet letters, or preschool Es are projected onto a screen for the child to identify. Closed vision testers such as the Titmus have an advantage over wall charts in that a child is less easily distracted during testing. Also, because children cannot see the vision chart beforehand, they cannot memorize the letters while waiting to be tested.

## Vision Color Awareness Testing

The inability to discern colors is a sex-linked recessive characteristic that occurs in males rather than in females, although females carry the recessive gene for the disorder. All male children should be screened once for the disorder during their early school years.

To test a child for color awareness, ask the child to identify the colored stripes at the top of a Snellen eye chart or show the child a series of colored diagrams (i.e., Ishihara plates). With the latter, a person with color vision is able to see hidden figures such as butterflies, but people with red-green or yellow-blue color vision deficits cannot. Detecting a color vision deficit in children is important because many educational materials and some occupations depend on the ability to identify color. Even such a simple childhood pleasure as riding a bicycle safely on city streets depends on being able to distinguish colors, such as deciphering red from green on a traffic light.

## Vision Referrals

Always screen children twice before referring them to their primary care provider. Some children do not perform well on eye tests because they are too easily distracted or do not know their alphabet as well as they pretend (e.g., they may say they do not see a letter when they really mean they do not know or remember its name). Testing twice helps eliminate or identify this type of misleading result.

After a second screening, the following children generally require a vision referral:

- Preschool children (3 to 5 years of age) who have 20/50 vision or less in one or both eyes
- Children 6 years of age or older who have 20/40 vision or less in one or both eyes
- Any child with a two-line difference between the eyes, as this might be a beginning of amblyopia
- Any child who states or shows other symptoms of visual difficulty (PBA, 2016)

### *What If . . . 34.3*

**Keoto's father expresses concern she may have a vision problem because she always sits very close to a television set. Keoto doesn't want to be tested because she "will never wear glasses." What questions would the nurse identify as important to ask her on history? What type of eye chart would the nurse use**

## Hearing Assessment

A thorough health assessment should also include an evaluation of hearing, including both history and observation, because good hearing is so important for the development of age-appropriate skills. Parents and grandparents are usually attuned to hearing difficulty in children and may be suspicious of it in advance of its official detection. When taking an auditory history, therefore, be certain to ask the accompanying adult or parent an overall question such as “Do you have any reason to believe your child doesn’t hear as well as other children?”

### AUDITORY SCREENING

Routine screening for adequate hearing levels is usually begun at 3 years of age. Testing requires knowledge of the technique, use of an audiometer, and a quiet, undistracted setting.

#### Newborn and Infant

All infants should be screened at birth. Those most apt to be born with a hearing difficulty are those with:

- A history of childhood hearing impairment in the family
- Perinatal infection, such as cytomegalovirus, rubella, herpes, toxoplasmosis, or syphilis
- Anatomic malformations involving the head or neck
- Birth weight less than 1,500 g
- Hyperbilirubinemia at a level exceeding indication for exchange transfusion
- Bacterial meningitis, especially when caused by *Haemophilus influenzae*
- Severe birth asphyxia: infants with an Apgar score of 0 to 3, those who failed to breathe spontaneously within 10 minutes of birth, or those with hypotonia persisting to 2 hours of age

A newborn’s hearing is assessed through simple response testing—observing whether an infant stirs or responds to a sound delivered to the child with a commercial sound device (CDC, 2012).

It can also be done by brain stem auditory-evoked response (BAER) testing. For this method, an earphone is placed on the infant and an electrode is attached to the scalp. When sound is transmitted to the child’s ear through the earphone, the electrical potential created as the sound is processed by the brain stem is read by the scalp electrode, processed by a microcomputer, and plotted on a graph. This type of testing may be used at any age and is successful even in children who are comatose or anesthetized. Smaller units using transient evoked otoacoustic emissions (TEOAEs) are also available. With these, a click stimulus delivered to a normal ear produces an echo

from the cochlea. This can be detected by a miniature microphone to reveal the presence of even minor hearing loss. Although newborn hearing screening can lead to false-positive results because many infants of this age are still sleepy from birth analgesia and may have fluid- or vernix-filled ear canals, a repeat test usually decreases the incidence of false-positive results.

### **The Older Child**

Older children who are at risk for hearing loss are those who have been exposed to loud noises such as an explosion or loud music, were of low birth weight, have congenital anomalies, have a repaired cleft palate, or have had repeated ear infections. During history taking, ask children if they ever worry if they have difficulty hearing. Be certain not to confuse difficulty hearing with shyness or recalcitrance in answering. Also, ask them how they are doing in school. Some children with a minimal hearing impairment are considered to have behavioral problems in school because they do not follow directions well, when in fact, they may be unable to hear the instruction. Children with an ear infection (i.e., otitis media) or allergies should be tested after the fluid in their ears clears because their hearing may be temporarily affected by these conditions. Almost all children have some cerumen (i.e., ear wax) in their ear canals; only when this becomes impacted it is a cause of hearing loss (Krug, Cieza, Chadha, et al., 2016).

### **Principles of Audiometric Assessment**

With proper instruction in technique, nurses conduct audiometric testing in schools and other ambulatory settings.

#### **Frequency**

Sound is the result of vibration; the frequency of sound is the number of vibrations a sound creates per second. When frequency is increased, the pitch of the sound increases. For audiometric testing, frequency is measured in hertz units. Normal speech sounds fall into a narrow range of 500 to 2,000 Hz; so, to function adequately and speak effectively, a child must be able to hear in this range. Children are tested for a wider frequency range than this, however, from 500 to 6,000 Hz, on a routine screening assessment.

#### **Loudness**

Decibels are an expression of the intensity or loudness of a sound (or vigor of the vibrations). A decibel level of 0 dB is the softest sound that can be heard. Normal conversation is held at approximately 50 to 60 dB. The sound level at which inner ear damage can occur is about 90 dB. Sound levels of 140 dB are so intense they actually cause pain. Screening audiometry is done at 25 dB.

#### **Hearing Loss**

Table 34.9 lists levels of hearing loss and the effect of hearing loss on conversation and speech. If children can hear all frequencies at the 25-dB level, they have passed an audiometric screening check. If a child fails to hear two or more frequencies at 25 dB, in either or both ears, the child has failed and should be referred to the primary care provider or an otologist. An **audiogram** is a record of audiometric testing. Figure 34.23 shows an audiogram of a child with normal hearing in the right ear (the child heard all frequencies at the 20-dB level), but with an inability to hear sounds softer than 45 dB in the left ear at frequencies of 1,000, 2,000, and 4,000 Hz.

**TABLE 34.9 Levels of Hearing Loss**

Hearing Loss (dB Level)	Hearing Level Present
Slight (less than 30 dB)	Inability to hear whispered words or faint speech No speech challenge present Possible lack of awareness of hearing difficulty Achievement in school and home is attained by leaning forward, speaking loudly
Mild (30–50 dB)	Beginning speech challenge may be present Difficulty hearing if not facing speaker; some difficulty with hearing normal conversation
Moderate (55–70 dB)	Speech challenge present, possibly requiring speech therapy Difficulty hearing normal conversation
Severe (70–90 dB)	Difficulty hearing any but nearby loud voice Vowels easier to hear than consonants Speech therapy required for clear speech Possible ability to still hear loud sounds such as jets or whistle of train
Profound (more than 90 dB)	Almost no sound heard

**Figure 34.23** An audiogram done as a screening procedure. Notice that hearing is normal in the right ear (all frequencies are heard at the 20-dB level). In the left ear, there is hearing loss (the frequencies 1,000, 2,000, and 4,000 Hz are heard only at the 45-dB level). (Courtesy of Dr. H. Schill, Speech Pathology and Audiology Department, Boston University.)

### Acoustic Impedance Testing

Acoustic impedance testing is based on the principle that sound entering the ear canal meets resistance at the tympanic membrane. If the middle ear is functioning normally, there will be a symmetric pattern of resistance on a tympanogram printout. If the middle ear is not functioning normally, the level of resistance will be greater or less, and so the pattern will be abnormal.

Acoustic impedance testing is performed by audiologists. For the assessment, the ear to be tested is plugged with a rubber disc. Sound is then administered to the ear through the center of the disc. The resistance met at the eardrum is registered and recorded as a graph. Tympanograms are inaccurate in children younger than 7 months of age because the tympanic membrane is too compliant under that age to register normal impedance.

## Conduction Loss Testing

Both the Rinne and the Weber tests are used to perform assessments that can be used to identify conduction loss in older children ([Box 34.13](#)).

### BOX 34.13

#### Rinne and Weber Tests

Rinne and Weber tests are assessments for air and bone conduction.

##### RINNE TEST

Strike a 500-Hz tuning fork and hold the stem of it against the child's mastoid bone. Ask the child to say when the tuning fork's ringing sound can no longer be heard. When the child says it is no longer audible, move the fork forward so it is at the auditory meatus ([Fig. A](#)). Because air conduction is normally better than bone conduction, the child should hear it when it is held in front of the meatus, although it can no longer be heard when it was held against the bone. If the child does not hear it when it is brought forward, then the child's air conduction is probably reduced.

##### WEBER TEST

Strike a 500-Hz tuning fork and hold the stem of it against the top of the child's head ([Fig. B](#)). The child with normal hearing in both ears will hear the sound equally well with both ears. If the child has an air conduction loss in one ear, the child will hear the sound better in that ear than in the good ear. The test must be used in conjunction with other evaluation tools because if the sound is intensified in one ear, it may mean that there is no hearing perception (i.e., there is nerve loss) in the opposite ear.

## Speech Assessment

Speech problems are directly related to hearing problems: Infants who do not hear will make preliminary babbling sounds but then will not develop intelligible speech because they cannot hear speech sounds to repeat. Speech difficulties may also be related to:

- Motor development, such as when a child does not have enough control of tongue and facial muscles to be able to form words properly
- Cognitive development, such as when a cognitively challenged child cannot grasp the concept of speech or word use until later than usual, or possibly not at all
- Cultural influences, such as when parents speak two languages, making it difficult for a child to accurately learn and articulate either language or if parents spoke “baby talk” for so long that the child mimicked that instead of pronouncing words clearly

Speech screening begins by asking children a few simple questions to determine their language pattern. Also, ask parents if they have noticed any difficulties with their child’s pronunciation or comprehension. Standardized tests, such as the Denver Articulation Screening Examination (DASE), may also be administered.

### DENVER ARTICULATION SCREENING EXAMINATION

The DASE is designed to detect significant developmental delays as well as normal variations in the acquisition of speech sounds. Because it is a standardized test, its

directions must be followed precisely. The test is only standardized for use with English-speaking children.

### Administration

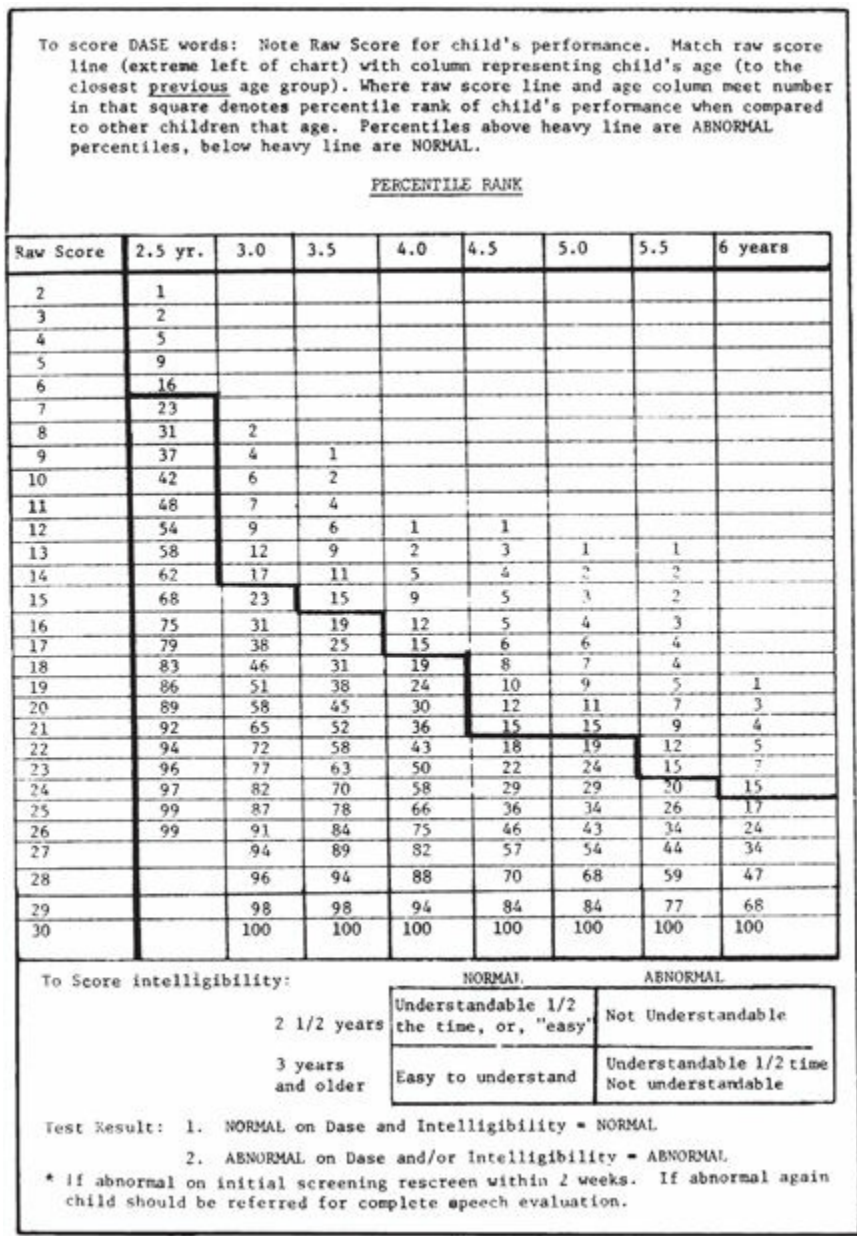

Before the test, explain that the child will need to repeat the words he or she hears you speak. Give enough examples so you are certain the child understands what he or she is to do: “When I say ‘boat,’ then you say ‘boat.’” When you are certain the child understands the directions, say each of the 22 words shown on the DASE form (Fig. 34.24A). Convey the impression there are no right or wrong answers. Give the child approval for responding and following directions correctly, no matter how inaccurately the child repeats the word.

**A**

<b>DENVER ARTICULATION SCREENING EXAM</b> for children 2 1/2 to 6 years of age  Instructions: Have child repeat each word after you. Circle the underlined sounds that he pronounces correctly. **Figure 34.24** The Denver Articulation Screening Exam (DASE). (A) The test form. (continued)

B

Figure 34.24 (continued) (B) The percentile rank form. (Reprinted by permission. Denver Developmental Materials, Inc.)

**Scoring**

The DASE is designed for use with children between the ages of 2.5 and 6 years. In scoring, consider the child's age to be the closest previous age shown on the percentile rank chart (Fig. 34.24B). Score the child's pronunciation of the underlined sounds or blends in each word on the test form. A perfect raw score is 30 correctly articulated sounds. Match this raw score on the percentile rank chart with the column representing the child's age. The number at which the raw score line and the age column meet is the percentile rank of the child (how the child compares with other children of that age). Percentiles shown above the heavy line are abnormal; those below the line are normal. For example, a 3-year-old who says only 12 sounds correctly ranks in the ninth

percentile (abnormal ranking); a 3-year-old who scores 20 sounds correctly ranks in the 58th percentile (normal ranking).

In addition to determining the percentile ranking, rate the child's spontaneous speech in terms of intelligibility as 1, easy to understand; 2, understandable half the time; 3, not understandable; or 4, cannot evaluate (e.g., maybe the child did not speak in sentences or phrases during your contact time). Score intelligibility according to the chart in [Figure 34.24B](#). For a final score, rate the child's total test result (e.g., normal or abnormal on the DASE or intelligibility).

Children who score abnormally on this screening test should be retested in about 2 weeks. If they still score abnormally, they should be referred for a complete speech evaluation.

## Developmental Appraisal

It would be ideal if children demonstrated all the developmental skills they are capable of every time they are asked to demonstrate them. Rarely, however, do they accomplish this. Infants become hungry, sleepy, or upset during testing. Older children may become shy. Therefore, a portion of developmental information, especially developmental milestones, on almost all health assessment must be elicited by history taking.

### DEVELOPMENTAL HISTORIES

Many parents keep careful records of their first child's development, a less careful record of their second, a scanty record of the third, and so on. Information, therefore, generally depends on parents' memories.

If parents cannot recall the month during which a skill was first demonstrated, ask them to try to remember in terms of holidays or seasons when they first saw the child performing the skill. They may not recall, for example, at which month their infant first used a pincer grasp (grasped cleanly with index finger and thumb) but do recall the child pinched the ear of the family dog at a summer picnic.

If parents seem to have no recall at all of developmental milestones and these are important to the child's present evaluation, suggest they ask other family members or look through family photographs to jog their memories and to call back with as much information as they can gather.

The CDC has developmental norms listed on their website ([www.cdc.gov](http://www.cdc.gov)) that parents can use to compare their child's progress (CDC, 2016a). In addition to getting the parents' descriptions of whether their child has mastered these skills, it is helpful to watch a child perform skills and rate them according to standard criteria.

### Denver II Developmental Screening Test

The Denver II Developmental Screening Test (available at <http://thePoint.lww.com/Flagg8e>) is the most widely used tool to assess early childhood

development (Frankenburg, 1994). Four categories are rated:

1. Personal–social
2. Fine motor–adaptive
3. Language
4. Gross motor skills

## Administration

The Denver II should ideally be administered when a child is approximately 3 or 4 months of age, again at about 10 months, and again at 3 years. It is a supplement to the developmental evaluation by history that should be a part of every well-child assessment.

The materials to administer the test must be purchased as a kit. They include a skein of red wool, a box of raisins, a small bottle, a bell, a rattle with a narrow handle, a tennis ball, ten 1-in. brightly colored blocks, a small plastic doll, a toy baby bottle, a plastic cup, and a pencil.

Although administration of the Denver II is not difficult, it should not be attempted except by healthcare providers trained specifically in its procedures and interpretation. This precaution is necessary to ensure the validity of its developmental norms. Periodic retraining and proficiency testing are recommended, so administrators sustain a high degree of accuracy in administration.

Caution a parent before administration that this is not a test of intelligence but of the child's level of development or ability to perform age-appropriate tasks.

The child's inability to perform a task most children of the same age can accomplish indicates a delay in that area. Further evaluation is then needed to determine the reason for this delay.

## Scoring

The child is scored P (passed), F (failed), R (refused), or N.O. (no opportunity) on each item according to guidelines in the instruction manual. Each item is represented on the Denver II test form by a bar showing the ages by which 25%, 50%, 75%, and 90% of children normally have mastered that item. For example, on the form, 25% of children are expected to demonstrate the task "plays pat-a-cake" at 7 months, 50% perform this between 9 and 10 months, 75% between 10 and 11 months, and 90% by ages 11 to 12 months. A description of each task and an interpretation of performance are detailed in the manual.

## Prescreening Test

A Revised Denver Prescreening Developmental Questionnaire (R-PDQII) is available in addition to the Denver II. The PDQII is a questionnaire completed by the parents addressing 10 developmental items. A child who scores 8 out of 10 or fewer should be retested in approximately 2 weeks. If the initial score is under 6 or the retest score is 8

or below, the child should be referred for Denver II testing. Encouraging parents to complete a questionnaire this way is helpful because it can detect developmental delays otherwise missed in a busy office or clinic.

## Intelligence

Children must learn many important concepts or ideas such as near and far, number sequences, how to judge time intervals, how to reason and solve problems, and how to judge weight before they can function effectively in the world.

This type of learning—gaining concepts—is cognitive learning and is measured by intelligence tests. **Intelligence** can be defined as the ability to think abstractly, to adjust to new situations, and to profit from experience. Almost everyone has their IQ rated at some point in a school career. Although intelligence tests are not part of routine health appraisals, it is helpful to be familiar with those that are used for childhood measurements because these findings can help predict a child's school success.

The IQ is the ratio of mental age as measured by an intelligence test to chronologic age. To determine IQ, the formula is

$$(\text{mental age} \div \text{chronologic age}) \times 100$$

A child aged 9 years old (i.e., chronologic age) who passes all the items on an intelligence test that an average 9-year-old child is expected to pass would be

$$(9 [\text{mental age}] \div 9 [\text{chronologic age}]) \times 100 = 100 (\text{child's IQ})$$

If a child passes no more items than the average 5-year-old child would pass, the IQ would be

$$(5 [\text{mental age}] \div 9 [\text{chronologic age}]) \times 100 = 55$$

If a child passed all the items that a 12-year-old child normally passes, the IQ would be

$$(12 [\text{mental age}] \div 9 [\text{chronologic age}]) \times 100 = 133$$

Intelligence scores are not always accurate; for instance, children may score poorly because of test anxiety. Cultural bias and past experience can also affect scores. Labeling children by IQ and classifying them into divisions based on IQ is no longer used as extensively as in the past. It must be done with considerable thought and study.

It is difficult to test very young children with any degree of accuracy because they lack the ability to complete tasks in the areas used for scoring intelligence tests, including comprehension, imagination, reasoning, memory, and vocabulary. The most common tests used with infants include the Cattell Infant Intelligence Scale, the Bayley Mental Scale, and the Gesell Developmental Schedule. These tests rely heavily on perceptual and motor skills as rating devices.

The two most frequently used tests for older children are the Wechsler Intelligence Scale for Children and the Stanford–Binet test. The results of these can be made

available, with parental permission, to child healthcare teams if they can demonstrate to school officials that such information is necessary for total health care or planning. If the information is unavailable, the child can be referred to a psychologist or a psychological testing clinic for assessment at the time of a disease diagnosis.

## GOODENOUGH-HARRIS DRAWING TEST

A Goodenough-Harris Drawing Test is a quick intelligence measurement that can be administered without special training to children between 3 and 10 years of age (Goodenough, 1926). To administer this, give a child a pencil and paper and tell the child to draw a person. Urge the child to draw carefully and take enough time to do it well.

The child receives 1 point for each of the items listed in Box 34.14 that are demonstrated in the drawing. For each 4 points scored, 1 year is added to a base age of 3 years to calculate the child's mental age. The picture shown in Figure 34.25, for example, was drawn by a 4.5-year-old: It received 8 points. The child's IQ level is therefore

$$(5.0 \text{ [mental age]} \div 4.5 \text{ [chronologic age]}) \times 100 = 111$$

### BOX 34.14

#### Goodenough-Harris Drawing Test

Score 1 point for each characteristic listed as follows that is present on the drawing. For every 4 points scored, add 1 year to a base mental age of 3 years.

1. Head present
2. Legs present
3. Arms present
- 4a. Trunk present
- 4b. Length of trunk greater than breadth
- 4c. Shoulders indicated
- 5a. Both arms and legs attached to trunk
- 5b. Legs attached to trunk; arms attached to trunk at correct point
- 6a. Neck present
- 6b. Neck outline continuous with head, trunk, or both
- 7a. Eyes present
- 7b. Nose present
- 7c. Mouth present
- 7d. Nose and mouth in two dimensions; two lips shown
- 7e. Nostrils indicated
- 8a. Hair shown
- 8b. Hair nontransparent, over more than circumference
- 9a. Clothing present

- 9b. Two articles of clothing nontransparent
- 9c. No transparencies, both sleeves and trousers shown
- 9d. Four or more articles of clothing definitely indicated
- 9e. Costume complete, without incongruities
- 10a. Fingers shown
- 10b. Correct number of fingers shown
- 10c. Fingers in two dimensions; length greater than breadth, angle less than 180°
- 10d. Opposition of thumb shown
- 10e. Hand shown distinct from fingers or arms
- 11a. Arm joint shown, either elbow, shoulder, or both
- 11b. Leg joint shown, either knee, hip, or both
- 12a. Head in proportion
- 12b. Arms in proportion
- 12c. Legs in proportion
- 12d. Feet in proportion
- 12e. Both arms and legs in two dimensions
- 13. Heel shown
- 14a. Firm lines without overlapping at junctions
- 14b. Firm lines with correct joining
- 14c. Head outline more than circle
- 14d. Trunk outline more than circle
- 14e. Outline of arms and legs without narrowing at point of junction with body
- 14f. Features symmetric, correct position
- 15a. Ears present
- 15b. Ears in correct position and proportion
- 16a. Eye detail: brow and lashes shown
- 16b. Eye detail: pupil shown
- 16c. Eye detail: proportion correct
- 16d. Eye detail: glance directed to front in profile drawing
- 17a. Both chin and forehead present
- 17b. Projection of chin shown

**Figure 34.25** An 8-point drawing, as scored on the Goodenough-

## Harris Drawing Test.

Scores on the test are reasonably reliable, correlating well with a Stanford–Binet test, although results may not be as reliable with children who are mentally ill. A child who scores significantly lower than chronologic age (after allowing for fatigue, illness, strange surroundings, nervousness, physical ability to use a pencil, and previous practice using a pencil and paper) should be referred for more refined testing.

## Temperament

**Temperament** refers to a child’s innate behavioral characteristics, such as activity level, rhythmicity, tendency to approach or withdraw, and adaptability to situations (see [Chapter 28](#)). A child with an “easy” temperament is generally adaptable and easy to care for; in contrast, a child with a “difficult” temperament will almost invariably create childrearing concerns. Helping parents assess their child’s temperament helps them, in turn, recognize their child’s uniqueness and so anticipate and ideally prevent personality conflicts as a child grows older and expresses identified reactions to situations. If a behavior or parent–child interaction problem is already present, a nursing assessment can be useful to determine whether temperament is a factor in the problem and to assist parents with constructive solutions ([Thomas & Chess, 1977](#)).

## Immunizations

One of the most important health assessment and promotion measures for children is to verify their immunization status is up to date (see “Recommended Childhood and Adolescent Immunization Schedule” available at <http://thePoint.lww.com/Flagg8e>).

Teach parents about the importance of having their children immunized and the need to be able to describe the number and type of immunizations a child has received. If gaps are present in a child’s number of immunizations, remind the child’s primary care provider about this lack in protection and prepare to administer the necessary vaccines.

Help parents understand that although diseases such as measles and mumps are referred to as common childhood illnesses, they are potentially serious and possibly lead to complications such as pneumonia and encephalitis (see [Chapter 43](#)).

### TYPES OF IMMUNIZATIONS

Vaccines are the solutions used to immunize children in order to provide artificially acquired active or passive immunity ([Box 34.15](#)) for the definition of active and passive immunity).

BOX 34.15

Active Versus Passive Immunity

Immunity, the ability to combat a particular antigen, may be either active or passive.

**Active Immunity.** When a child produces antibodies after the natural invasion of a pathogen (e.g., the child has measles), the child develops *naturally acquired active immunity*. Active antibodies (or the child's ability to produce antibodies rapidly should the specific antigen [measles] invade again) last a lifetime. When pathogens are artificially injected into the child by immunization, the child receives *artificially acquired active immunity*. If the specific antigen should enter again, antibodies will be produced against the pathogen that are just as lasting as those produced in naturally acquired active immunity.

**Passive Immunity.** Immunoglobulin G (IgG) antibodies a woman possesses either through immunization or through having had a disease are transferred across the placenta to a fetus in utero. Because the fetus does not make these antibodies but merely receives them, this is termed *naturally acquired passive immunity*. Passive immunity usually lasts only a few months, although some antibodies transferred across the placenta, such as those for measles, have been isolated up to age 1 year (which is why measles immunization must be delayed until 15 months of age).

When children are exposed to a disease against which they have no antibodies, antibodies made synthetically or obtained from animal serum may be injected into the child to give rapid immunity (*artificially acquired passive immunity*). Like naturally acquired passive antibodies, these last only approximately 6 weeks. A child who is susceptible to tetanus, for example, would receive tetanus antibodies after a stab wound to ensure she has protection against the tetanus virus.

Vaccines are prepared in a number of forms. Attenuated vaccines are made from live organisms reduced in virulence to a point where they will not cause active disease but will ensure a good antibody response. Because they are strong solutions, a single dose usually provides a good degree of active immunity.

Because some bacteria, such as diphtheria, cause disease by producing a toxin, the vaccine against such a disease, a **toxoid**, is actually an extract of the toxin with reduced virulence. The antibodies produced against toxin-producing bacteria are called **antitoxins**.

**Gamma globulin** is serum obtained from the pooled blood of many people. Because it combines the serum of many people, it probably has antibody protection against measles, rubella, poliomyelitis, varicella, and hepatitis B, among many other infectious diseases. When administered, it offers artificially acquired passive immunity.

Immune serums are serums available against specific diseases such as diphtheria, tetanus, the pit viper snake, the black widow spider, and respiratory syncytial virus. Like general immune globulin, these provide passive immunity.

## CHILDHOOD IMMUNIZATIONS

The AAP and the CDC both issue specific recommendations for childhood

immunization (available at <http://thePoint.lww.com/Flagg8e>).

### **The Diphtheria, Tetanus, and Pertussis Vaccine**

Diphtheria, tetanus toxoid, and acellular pertussis (i.e., whooping cough) (DTaP) vaccines are supplied in a single vial as DTaP and given in one intramuscular injection. It is recommended that children receive a primary series of four immunizations with the vaccine (at 2, 4, 6, and 15 to 18 months of age). A booster is then given between 4 and 6 years of age or before entry into school. Because whooping cough outbreaks have occurred in the teenage and late adolescent population, a combined injection of the DTaP vaccine is recommended at 11 to 12 years of age. Teenagers who did not receive the booster at 11 to 12 years of age or who received only a diphtheria/tetanus (Td) injection at that time are encouraged to receive one dose of DTaP 5 years after the last Td/DTaP dose. It is recommended that late adolescents continue with tetanus prophylaxis every 10 years throughout life to keep their tetanus immunizations current.

Side effects to these vaccines include drowsiness, fretfulness, low-grade fever, and redness and pain at the injection site. A pertussis vaccination may not be recommended for children who have a progressive or unstable neurologic disorder. A Td vaccine can be substituted for these children.

### **The Polio Vaccine**

Inactivated polio vaccine (IPV) contains all three strains of poliovirus and is the preferred type for routine immunization. It is administered in a primary series of three doses and given along with DTaP at 2, 4, and 6 to 18 months of age with a fourth booster dose given between the ages of 4 and 6 years or before school entry ([CDC, 2016b](#)).

### **The Measles, Mumps, and Rubella Vaccine**

The measles, mumps, and rubella (MMR) vaccine is furnished in one injection and routinely administered between 12 and 15 months of age. A second dose of MMR is generally given between the ages of 4 and 6 years, or if the child did not receive this dose at 4 to 6 years of age, it is given at 11 to 12 years of age. The first dose is delayed until the end of the first year because children receive a great deal of passive immunity to measles from their mothers while they are in utero. Until this passive immunity has faded, the injected vaccine would be neutralized by passive antibodies and no immunity would result. For the same reason, children who have recently received immune globulin or other blood products that contain antibodies should not receive an MMR vaccination for about 3 months because the passively acquired antibodies could interfere with the child's immune response to the vaccine.

Side effects to the vaccine include transient rash and a fever, which may begin 5 to 12 days after vaccination and last several days. Adverse reactions include joint pain, low-grade fever, rash, and lymphadenopathy 5 to 12 days after vaccination.

Before the vaccine is administered, children who are at risk should be skin tested for tuberculosis because the measles virus can cause tuberculosis to become systemic. Tuberculosis skin tests also may show false-negative reactions if given shortly after a measles immunization (i.e., a child who has active tuberculosis would be wrongly identified as not having the illness).

Formerly, there was a concern the administration of the MMR vaccine was associated with the development of autism in children, as symptoms of autism often begin to be apparent during the second year or close to the time of MMR vaccine administration. Further research has shown there to be no causal relationship between the vaccine and autism (Uno, Uchiyama, Kurosawa, et al., 2015). Parents may ask about this association, however, or may refuse to have their child immunized against MMR for this reason (Salmon, Dudley, Glanz, et al., 2015).

### **The Hepatitis B Vaccine**

The vaccine for hepatitis B virus (HBV) is recommended for all infants in the United States because hepatitis B is associated with liver cancer later in life. Three doses are required. Those infants born to hepatitis B surface antigen (HBsAg)-negative mothers should receive the first dose in the newborn period before hospital discharge, a second dose at 1 or 2 months, and a third dose at 6 or 18 months. Those born to HBsAg-positive mothers should receive hepatitis B immune globulin within 12 hours of birth plus HBV vaccine. A second dose of HBV vaccine is then recommended at 1 to 2 months of age and a third dose at 6 months.

If the mother's HBsAg status is unknown, infants should receive the vaccine within 12 hours of birth, the second dose at 1 month of age, and the third dose at 6 months of age. Children who did not receive the vaccine at birth may begin a two- or three-injection series, depending on the vaccine used at any well-child visit.

In addition, the HBV immunization is recommended for populations at increased risk for contracting hepatitis B infection, including healthcare providers with significant exposure to blood, patients receiving hemodialysis, those with hemophilia or who receive clotting factor concentrates, those who take illicit injectable drugs, and sexually active individuals with multiple sexual partners.

### **The Hepatitis A Vaccine**

Two doses of hepatitis A vaccine, administered 6 months apart, are recommended for all children between 1 and 2 years of age. Children who did not receive this as toddlers can be vaccinated against hepatitis A at any time.

### **The Rotavirus Vaccine**

Rotaviruses are responsible for the majority of severe gastrointestinal disease in infants, so immunization against these viruses is important for preventing outbreaks of diarrhea in infants, particularly those who attend a day care setting. The vaccine is given at 2, 4,

and 6 months of age. No doses should be given after children reach 32 weeks of age.

### ***Haemophilus influenzae* Type B Vaccine**

*Haemophilus influenzae* type B conjugate vaccine (Hib) protects against *H. influenzae* bacteria, a major cause of meningitis in children. You may need to explain the difference between *H. influenzae* (a bacteria) and the influenza virus so that parents do not think a “flu shot” protects against this. Several formulations of this vaccine are available; depending on the individual vaccine, they are administered in a two-dose (at age 2 and 4 months of age) or a three-dose regimen (at 2, 4, and 6 months of age, with an additional booster at 12 months of age). Local reactions include tenderness at the injection site. Reactions such as crying and fever may occur (CDC, 2016b).

### **The Varicella Vaccine**

The varicella (i.e., chickenpox) vaccine was a difficult vaccine to develop because of the complex structure of the herpes zoster virus. It’s an important vaccine because once a generation of children has been successfully immunized, it should mark the end of an epidemic childhood illness. Infants may receive varicella vaccine at any visit after their first birthday (usually scheduled at 12 to 18 months of age) and again at 4 to 6 years of age. Those who did not receive the vaccine as infants and who lack a reliable history of chickenpox should be immunized during adolescence with two doses of vaccine administered at least 1 month apart.

### **The Pneumococcal Pneumonia Vaccine**

The pneumococcal vaccine is recommended for all children between 2 and 23 months of age. The vaccine is administered at 2, 4, 6, and 12 months of age and provides protection for 6 to 10 years (AAP, 2013). It is especially recommended for children (and adults) who would be prone to a pneumococcal infection (e.g., those with pulmonary or cardiac disease, those without a spleen, those who are immunosuppressed).

### **The Human Papillomavirus Vaccine**

The human papillomavirus (HPV) is associated with the development of cervical cancer in women. It is recommended that all preteens (male and female) receive three injections of this vaccine beginning at 11 to 12 years of age. The second dose should be administered 2 months after the first dose, and the third dose should be given 6 months after the first dose. Those who did not receive the vaccine in early adolescence can receive it at any time, with the proper monthly intervals for administration. Some teenagers who have taken abstinence pledges not to have sexual relations until they are married may state they do not need the vaccine. Counseling them about the safety of being immunized in case they change their mind about abstinence or to be protected when they become sexually active may be necessary.

## The Meningococcal Vaccine

Children who have immunologic deficiencies or have had their spleen removed due to trauma or those receiving therapy for a blood dyscrasia are prone to develop meningitis caused by meningococcal bacteria. Children in these high-risk groups are, therefore, advised to receive a meningococcal vaccine between 2 and 10 years of age. Administer a single dose of meningococcal vaccine at age 11 through 12 years, with a booster dose at age 16 years. If the first dose of meningococcal vaccine is administered at age 16 years or older, a booster dose is not needed.

## The Lyme Disease Vaccine

Lyme disease is a serious and debilitating infection caused by *Borrelia burgdorferi* and transmitted by the bite of a deer tick. A vaccine to guard against it is no longer available. Children who contract the disease can be successfully treated with antibiotics to minimize the disease. Tips for preventing Lyme disease are shown in [Chapter 43](#).

## The Influenza Vaccine

Influenza is caused by A, B, or C retroviruses, which mutate so easily that it has been impossible to design a vaccine that is effective for more than 1 year. All children—infants 6 months of age through adolescents—and particularly those who have chronic pulmonary or cardiovascular disorders or are immunosuppressed should receive a yearly injection of the vaccine ([CDC, 2016b](#)). For most healthy children age 2 years and older, the live attenuated influenza vaccine (LAIV) can be administered. Children 6 months through 8 years who have never received the influenza vaccine before will require two doses at least 1 month apart.

## The Anthrax and Smallpox Vaccines

Anthrax is a potentially fatal disease caused by a gram-positive, spore-forming *Bacillus anthracis* and spread by farm animal feces. It is extremely rare, but parents may ask about a vaccine for it because of the threat of biologic warfare associated with terrorism. A vaccine is available for people in high-risk occupations, such as hunters, taxidermists, or veterinarians, but it is not recommended for children.

Smallpox is an extremely infectious disease caused by the smallpox virus and transmitted by direct or indirect contact. Smallpox vaccination has not been required in the United States for over 30 years because the disease is theoretically extinct across the world. As with anthrax, parents may ask about a smallpox vaccination because it is a disease associated with biologic warfare and terrorism. Both a vaccine (active artificial immunity) and passive artificial immunity are available should a child be exposed to the virus. In some high-risk communities, healthcare providers are asked to be immunized to be certain they will not contract the virus if a terrorist attack should occur ([Frey, Winokur, Salata, et al., 2013](#)).

## ADMINISTRATION OF IMMUNIZATIONS

Current immunization recommendations are available at <http://thePoint.lww.com/Flagg8e>. Assess both well children at health maintenance visits and ill children at clinic or hospital admission to identify those who need their immunizations updated according to this schedule. Children who are seriously ill should not receive immunizations, but a slight upper respiratory tract infection (e.g., a stuffy nose with no fever) is not a contraindication. So many infants and preschoolers have common cold symptoms (the average toddler has 10 to 12 colds a year); if children were not immunized at health maintenance visits when they have slight cold symptoms, many would never receive basic immunizations. Catch-up schedules for children who did not receive primary immunizations or who are behind in an immunization schedule are also available at <http://thePoint.lww.com/Flagg8e>. Because these schedules change yearly based on the introduction of new vaccines or new potential health threats, consult the AAP website ([www.aap.org](http://www.aap.org)) or the CDC website ([www.cdc.gov](http://www.cdc.gov)) for up-to-date information before immunizing a specific child.

When preparing to administer an immunization, be certain to follow the manufacturer's recommendations for storage and handling of vaccines, such as whether the vaccine should not be exposed to light or whether it needs refrigeration. Failure to follow these precautions may significantly reduce the potency and effectiveness of vaccines.

## CHILDREN WITH UNIQUE NEEDS

Children with chronic illnesses may be hospitalized at the time an immunization is due and so fall behind schedule. Children who miss the scheduled time for an immunization do not need to have the series started over but rather should simply continue at the point they left off. Primary care providers may choose to alter the sequence of immunization schedules if specific infections are prevalent at the time. For example, the measles vaccine might be given on a first health maintenance visit (providing a child is older than 12 months of age) if an epidemic was underway in the community at the time.

Children who are immunosuppressed, receiving corticosteroids, or receiving chemotherapy or radiation therapy should not receive live virus vaccines. The live attenuated viruses such as measles, rubella, oral polio vaccine (OPV), and mumps must not be given to girls who are pregnant because these vaccines could cross the placenta, thus causing disease in the fetus. Before traveling internationally, parents should consult their local public health service to see what additional vaccines are required for children for overseas travel.

Although MMR vaccines are prepared from chick embryo cultures, egg sensitivities are not likely to occur because egg albumin and yolk components of the egg are absent from the culture. The minute quantity of egg proteins contained in the MMR vaccine seems to be insufficient to cause an allergic reaction in egg-allergic people. Therefore, no allergy testing needs to be completed prior to the administration of the vaccine.

## PARENTAL EDUCATION

A major reason parents do not bring children for routine immunizations is they do not know what is required or have misconceptions about immunity. Fully inform parents and, when old enough, children about what immunizations are recommended. When vaccines are given, be certain parents know what is being given and what side effects may be expected. Because children may develop a low-grade fever after any immunization, counsel parents that they may need to give acetaminophen (Tylenol) or children's ibuprofen for a fever higher than 101°F (38.4°C).

Unfavorable reactions are most likely to occur within a few hours or days of administration. With live attenuated virus vaccines, viruses can multiply, so reactions may occur up to 30 days later. With the rubella vaccine, a reaction (serum sickness) may occur up to 60 days later. Ask parents to report any untoward symptoms of immunization.

When giving a vaccine, record the date, type of vaccine, vaccine manufacturer, lot number, and name and address of the vaccine provider so that if a vaccine reaction should occur, the instance can be investigated. Make a copy of the child's immunization record for the parents and urge them to keep good track of such a record. They will need this information to admit their child to school and to feel safe in the event an epidemic of a particular disease occurs. They will need to know their child's record of tetanus immunizations if the child should receive a puncture wound so that the correct therapy can be given for this.

### *QSEN Checkpoint Question 34.6*

#### **SAFETY**

Keoto's father wants to be sure Keoto's immunizations are up to date. The nurse determines the immunization for HPV is recommended by which age?

- At 12 to 18 months of age
- Before kindergarten entrance
- At 16 years of age
- At 11 to 12 years of age

*Look in Appendix A for the best answer and rationale.*

## Concluding a Health Assessment

At every health maintenance visit, inform parents and the child (or ask the child's primary care provider to inform them, depending on agency policy) of any available results of screening procedures performed. After learning the results, some parents may require counseling to assist them with health or behavior concerns. [Box 34.16](#) shows an interprofessional care map illustrating both nursing and team planning for a child in need of a pre-sports health assessment. Ask parents if they have any other remaining

questions. If the health assessment revealed some health concerns and follow-up procedures are planned, be certain parents understand the reason for the upcoming tests. Suggest to parents that follow-up phone calls are welcome after they return home from a health assessment so additional questions can be answered. Provide parents with the best hours to call so someone will be available to answer questions for them. Many providers now have patient portals families can use to ask additional questions or download physical forms and immunization records.

BOX 34.16

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR A CHILD IN NEED OF A PRE-SPORTS HEALTH ASSESSMENT

Keoto Wiser is a 13-year-old you meet in an ambulatory clinic. Her father has brought her for health assessment before Keoto begins seventh grade.

**Family Assessment:** Child lives with two parents and 2-year-old sister, Candy. Father works as a paramedic for the fire department; mother is a notary public employed by a bank. Father rates finances as “good.”

**Child Assessment:** Keoto was born with a lung cyst that required removal not only of the cyst but also a portion of her left upper lung lobe at 6 months of age. Her father is concerned her lessened lung size may make her ineligible for competitive sports participation. He asks if carbohydrate loading would give her enough energy to make up for any decreased lung function. He’s also concerned she may need eyeglasses because she always sits close to the television set. He asks you if wearing glasses could decrease her chance of being chosen for a sports team.

**Nursing Diagnosis:** Anxiety related to ability to participate in school sports program

**Outcome Criteria:** Patient participates in school sports program to the degree dictated by physical findings.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
-------------------------	------------	--------------	-----------	------------------

#### *Activities of Daily Living, Including Safety*

Nurse	Assess child’s development by taking a 24-hour day history.	Discuss with parent and child any areas that cause concern.	Parents can “get behind” in expectations of child, as preteenage children grow and develop	Parent or child gives day history and discusses any areas seen as problematic.
-------	---	---	--	--

rapidly.

*Teamwork and Collaboration*

Nurse/primary healthcare provider	Determine name of healthcare provider who determines eligibility for sports teams at child's school.	Consult with identified healthcare provider to determine eligibility rules for sports.	Schools may have restrictions on children who do not have both pairs of duplicate organs such as lungs.	Qualifications for sports participation are obtained and outlined for parents and child.
-----------------------------------	--	--	---	--

*Procedures/Medications for Quality Improvement*

Nurse/primary healthcare provider	Obtain health assessment, particularly with regard to stamina and past ability to participate in sports activities.	Perform complete physical examination focusing on heart, lung, and muscle status.	Physical examination can reveal additional findings regarding lung capacity and stamina.	A physical examination yields information on child's overall health.
Nurse	Assess whether child is familiar with Snellen vision testing.	Assess child's eyesight using a Snellen eye chart.	A Snellen eye chart is a standardized test for vision appraisal.	Child completes eye exam and is told results.

*Nutrition*

Nurse/nutritionist	Assess what parents and child know about carbohydrate loading.	Counsel regarding disadvantages of carbohydrate loading for children.	Children and parents who are well informed can make better choices for nutrition practices.	Parent and child state they understand carbohydrate loading is not recommended for children.
--------------------	--	---	---	--

*Patient-Centered Care*

Nurse	Assess past health history	Review with parents and child	Parents are often	Parents and child agree to
-------	----------------------------	-------------------------------	-------------------	----------------------------

	and recommended immunizations.	the child's current immunization status and any immunizations needed.	unfamiliar with required immunizations and so need to be reminded of recommended schedules.	any immunization necessary before child returns to school.
--	--------------------------------	---	---	--

*Psychosocial/Spiritual/Emotional Needs*

Nurse	Assess what will be child's likely reaction if she cannot participate in her school's sports program or needs to wear eyeglasses.	If child is unable to participate in school sports, review with child other options: joining a club, petition school sports committee, etc. Discuss advantage of clear vision.	Planning ahead can help child adjust to less-than-desired results if these occur.	Child lists alternate ways to participate with other children at school, if sports are not an option, or describes a sensible plan for petitioning for an exception to rules.
-------	---	--	---	---

*Informatics for Seamless Healthcare Planning*

Nurse	Assess if parents or child have had questions answered during the health assessment.	Answer remaining questions, if any; schedule a return visit as needed.	If questions remain unanswered at the health assessment, needs haven't been fully met.	Parents and child state they have no further questions; describe plans for next action.
-------	--	--	--	---

*What If... 34.4*

**The nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to health assessment (see [Box 34.1](#)). What would be a possible research topic to explore that is pertinent to this goal, applicable to Keoto's family, and that would also advance evidence-based practice?**

## Unfolding Patient Stories: Eva Madison • Part 1

**Eva Madison**, a 5-year-old female, is at the clinic with her mother for a routine checkup. How can the nurse create an environment that is conducive to obtaining health information? How can the nurse prepare the child and the mother for the physical exam? What key areas of the health history and physical assessment should the nurse evaluate in this 5-year-old female? (Eva Madison's story continues in [Chapter 36](#).)

Care for Eva and other patients in a realistic virtual environment: *vSim for Nursing* ([thepoint.lww.com/vSimMaternityPed](http://thepoint.lww.com/vSimMaternityPed)). Practice documenting these patients' care in DocuCare ([thepoint.lww.com/DocuCareEHR](http://thepoint.lww.com/DocuCareEHR)).

### KEY POINTS FOR REVIEW

- Health assessment always causes some degree of apprehension for both parents and children because of the worry that an illness will be detected. Giving reassurance of wellness during examinations helps to alleviate this worry.
- A health history is an important part of an assessment. The purpose is to gather information that will supplement physical or laboratory examinations to provide a more thorough health evaluation.
- A health history includes an introduction, chief concern, family profile, history of past illnesses, day history, family health history, and review of systems.
- A physical examination involves four techniques: inspection, palpation, percussion, and auscultation. Techniques and approaches must be varied according to the child's age.
- Be certain to use examining instruments safely, such as supporting an otoscope base so that if a child moves, the otoscope moves with the child. Be certain young children are not left unsupervised on an examining table because this could cause a fall.
- The components of a physical examination include vital sign assessment, general appearance, mental status assessment, body measurements, and an assessment from head to toes.
- Adolescent boys can be taught testicular self-examination at the time of a health appraisal. Breast self-examinations for females should be done by the examiner but is no longer thought to reveal enough information to be practical as a preventive measure.
- A vision assessment consists of asking children to read a standardized chart such as a Snellen or preschool E chart, cover testing, or color discrimination assessment.
- A hearing assessment consists of such assessments as audiometric testing and Rinne and Weber tests.
- Determining a child's development is an important part of total assessment. The Denver II Developmental Screening Test and the DASE are specific development

tests used.

- The Goodenough-Harris Drawing Test correlates well with IQ and is an easy test to administer to children between the ages of 3 and 10 years to assess intelligence.
- An assessment of immunization status is included as part of a health assessment. Childhood immunizations are a major safeguard for children against common childhood illnesses; being certain they receive what is needed at each healthcare visit not only helps in planning nursing care that meets QSEN guidelines but also helps to keep a child safe.

### CRITICAL THINKING CARE STUDY

Suzanne is a 6-year-old you meet at a school-based clinic. You notice from her attendance record that she misses about 4 days of school every month for “constipation.” As she walks down the hallway, you notice she walks on her tiptoes.

1. Suzanne’s mother tells you Suzanne walks on her tiptoes because she learned to do that so her father, who works nights, won’t be awakened during the day. Would you want to examine Suzanne’s gait any further?
2. Suzanne’s mother confirms Suzanne has almost “constant constipation.” Her mother explains it is because Suzanne never eats vegetables. On examination, you locate a hard mass in her upper right quadrant. Would you want to ask more questions about Suzanne’s constipation?
3. Suzanne tells you she often doesn’t eat lunch at school because she forgets her lunch money. Would you want to assess Suzanne’s short-term or long-term memory?

## Communication and Teaching With Children and Families

*You meet two patients of very different ages in an outpatient clinic. Wolf Whitefeather is a 3-year-old boy who is scheduled for repair of syndactyly (webbed fingers) next week. His mother tells you his favorite activity is coloring. She is concerned he will be hard to entertain after surgery because the large pressure bandage he will have afterward will prevent him from using that hand. “I don’t even want to begin to talk to him about surgery,” she tells you.*

*Barry Sandoz is a 16-year-old with a recurring peptic ulcer. His mother tells you health teaching with Barry will be ineffective because he never listens to a thing adults say.*

*Previous chapters discussed normal growth and development and how children’s understanding increases with age. This chapter adds information about techniques for effective communication and health teaching with children and adolescents. This type of information is what builds a successful base for disease prevention and health promotion as well as increases health literacy.*

**What would be a good strategy for teaching 3-year-old Wolf about his surgery? Would you try to teach Barry more about his condition, or not? How would your communication with these children vary because of their age difference?**

### KEY TERMS

**affective learning**  
**behavioral therapy**  
**clarifying**  
**cognitive learning**  
**communication**  
**demonstration**  
**empathy**  
**feedback**  
**focusing**  
**health literacy**

nontherapeutic communication  
paraphrasing  
perception checking  
positive reinforcement  
psychomotor learning  
redemonstration  
reflecting  
therapeutic communication

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe principles of effective communication as well as teaching and learning as they relate to health teaching with children.
2. Identify 2020 National Health Goals related to communication and teaching with children that nurses can help the nation achieve.
3. Assess children for their ability to communicate and their readiness to learn.
4. Formulate nursing diagnoses related to communication and health teaching with children.
5. Identify expected outcomes for a specific child based on the child's age, developmental maturity, emotional needs, and communication or learning style to better enable parents to manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement health teaching, such as creating a puppet show, using principles of effective communication and teaching and learning.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of communication and teaching with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

---

**Health literacy** is an individual's ability to read, understand, and use healthcare information to make decisions and follow instructions (Taylor, Nicolle, & Maguire, 2013). Both communication and health teaching are independent nursing actions that are important for increasing health literacy, helping children learn more about their illness, and providing better measures to use to stay well. Increasing health literacy is especially important when preparing a child for surgery or some other healthcare procedure.

Communication is fundamental to social interaction and is one of the first and most important skills children learn (Cruz, Quittner, Marker, et al., 2013). It can be either a formal or an informal exchange. Health teaching can also be both formal, such as teaching a group of preschoolers about hospitalization, or informal, such as assuring a parent a child is getting enough nutrition even though the child snacks rather than sits down to regular meals. It may be offered to an individual child or to a group of children with similar learning needs. Health teaching is so important that a number of 2020 National Health Goals speak to it (Box 35.1).

### BOX 35.1

#### Nursing Care Planning Based on 2020 National Health Goals

A number of 2020 National Health Goals address good communication and health teaching because it is such an important mechanism of preventive health care.

- Increase the proportion of schools that provide school health education from a baseline of 35.2% to 38.7% for elementary school, from 56.9% to 62.2% for middle school, and from 76.8% to 84.5% for high school.
- Increase the health literacy of the population by increasing the proportion of persons who report their healthcare provider always gave them easy-to-understand instructions about what to do to take care of their illness or health condition (developmental).
- Increase the proportion of persons who report their healthcare providers have satisfactory communication skills by increasing the proportion of persons who report their healthcare provider always explained things so they could understand them from 60% to 66%.
- Increase the proportion of local health departments that have established culturally appropriate and linguistically competent community health-promotion and disease-prevention programs (developmental) (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by consulting with schools and healthcare organizations to develop what health teaching programs are needed, and then teaching in such programs.

### *Nursing Process Overview*

#### FOR HEALTH TEACHING WITH CHILDREN

##### **ASSESSMENT**

Communication and health teaching are best accomplished when they are placed within the context of the nursing process. Learner needs and characteristics, teacher characteristics, available support people, and the level of content are all factors that affect learning and whether communication will be received. Assessing these allows

for nursing diagnoses that clearly state the specific health needs to be formulated.

### **NURSING DIAGNOSIS**

Common examples of nursing diagnoses related to communication or health teaching include:

- Risk for impaired verbal communication related to use of Russian as primary language
- Deficient knowledge related to importance of taking medicine daily
- Health-seeking behaviors related to ways to improve the child's nutritional intake
- Impaired verbal communication related to placement of endotracheal tube
- Anxiety related to perceived amount of material needed to be learned for home care of child

### **OUTCOME IDENTIFICATION AND PLANNING**

After formulating a nursing diagnosis, an individualized plan for communication or teaching should be constructed. The plan should detail not only what is to be communicated or learned but also methods to accomplish this and how it can be evaluated. The most effective way to ensure expected outcomes are achieved is to ask a child or family to join in the planning. Be certain outcomes are concrete and measurable (not "Child will discuss general aspects of his disease" but "Child will list three steps to help prevent disease reoccurrence"). Refer families to helpful websites and other resources when appropriate (see [Chapter 28](#)).

### **IMPLEMENTATION**

The step of implementation involves the actual carrying out of the communication or teaching. Teaching children is not always easy and requires practice and knowledge of each child's particular developmental level and needs.

### **OUTCOME EVALUATION**

As a final step of communication or teaching, what was communicated or learned must be evaluated to be certain learning occurred. A new plan may need to be developed and teaching continued if communication or learning proves to be less than optimal. Examples of outcome criteria include:

- Child demonstrates good technique for self-injection of insulin.
- Child demonstrates anger using language rather than punching wall.
- Child lists five foods to include in a high-protein diet.
- Family demonstrates improved family communication techniques by next clinic visit.
- Parents/guardians demonstrate effective cardiopulmonary resuscitation technique at home visit.

## **Communication**

**Communication** is the exchange of ideas between two or more persons. It can be verbal (i.e., using words) or nonverbal (i.e., using actions, such as touch or eye contact, or a remote system, such as mail or e-mail). Communication is important in the care of children because it can make or break an effective relationship. As a process, communication is divided into two major categories: *nontherapeutic* (i.e., casual, everyday conversation) and *therapeutic* (i.e., helpful, constructive interchanges).

## **NONTHERAPEUTIC COMMUNICATION**

**Nontherapeutic communication** is identified by its lack of structure or planning; that is, it lacks deliberate purpose other than socializing. Dinner conversation is an example of nontherapeutic communication.

## **THERAPEUTIC COMMUNICATION**

**Therapeutic communication** is a face-to-face process of interaction focusing on advancing the physical and emotional well-being of patients. It is an interaction between two people that is planned (e.g., you deliberately intend to determine how a child truly feels), has structure (e.g., you use specific wording techniques that will encourage a truthful response), and is helpful and constructive (e.g., at the end of the exchange you will know more about the child than you did at the beginning, and ideally, the child will know more about a particular problem or concern) (Roberts, Fenton, & Barnard, 2015).

In some instances, there is no cure for a child you care for—no surgery, no medication, and no pain relief. If you practice therapeutic communication, however, you still have something to offer this child and family: support by your words or nonverbal communication such as touch. In perspective, this is often the most valued, most appreciated, and most helpful aspect of care (Leathers & Eaves, 2015).

## **COMPONENTS OF GOOD COMMUNICATION**

Communication can be broken down and diagrammed according to its essential components: the encoder, the code, the decoder, and response or feedback (Arnold, 2015) (Fig. 35.1).

**Figure 35.1** Health teaching is an interactive process, in which both a teacher and a learner share in the learning experience.

### **The Encoder**

The encoder is a person who desires to share a thought or feeling with someone else and so originates a message. This person molds this thought into a form suitable for transferring to another person (i.e., a code). Communication can be ineffective if a person omits cognitive processing or speaks without thinking; chooses the wrong words for the message; or accompanies the spoken words with a facial expression, tone of voice, or gesture that is inappropriate for the message.

### **The Code**

The code is the message conveyed and includes the medium or system used to convey it. Although this usually involves a simple spoken system, messages can also be conveyed by such methods as a painting, writing a poem or novel, Morse code, Braille, by electronic devices such as through text messaging, a movie projector, or over the telephone. Communication can be ineffective when a person chooses the wrong medium for a message; for instance, delivering a lecture with many technical words when a drawing would have made the message much clearer, or e-mailing when confronting a person directly would have had more impact.

## The Decoder

The receiver (decoder) is the person who not only receives the message (i.e., hears it, reads it, views it) but also interprets or decodes its meaning (i.e., cognitive processing). Messages are interpreted in light of the receiver's previous knowledge. They may be misinterpreted if a receiver's store of knowledge is too different from that of the sender or if the receiver misses part of the transmission, such as a wink accompanying the spoken words that would have let the receiver know the sender was joking. Under stress, children tend to narrow their ability to receive information to a small area of concern (i.e., they center). Children who are extremely anxious, therefore, may not receive or be unable to interpret a message because of anxiety, even though both the sender and the message components of the communication were adequate.

## Feedback or Response

**Feedback** is the reply the decoder returns to the sender to acknowledge the message has been received and interpreted. This could be a spoken statement, a nod of the head, a facial grimace or smile, a hand gesture, a return e-mail, or the sudden slamming of a telephone receiver. With feedback, the roles of sender and receiver become reversed and another communication cycle is begun. Communication can be ineffective if children do not offer feedback (i.e., the message was neither received nor understood) or if they offer feedback before the message is fully interpreted (i.e., acting before thinking). When you are caring for children with sensory challenges such as vision or hearing, you may need to change your usual feedback mechanisms in order to be understood because a nod of the head or quiet response may not be received. When a child is from a culture different than yours, it may require sensitive adaptation to be fully heard or to hear and understand.

## THE DEVELOPMENT OF LANGUAGE

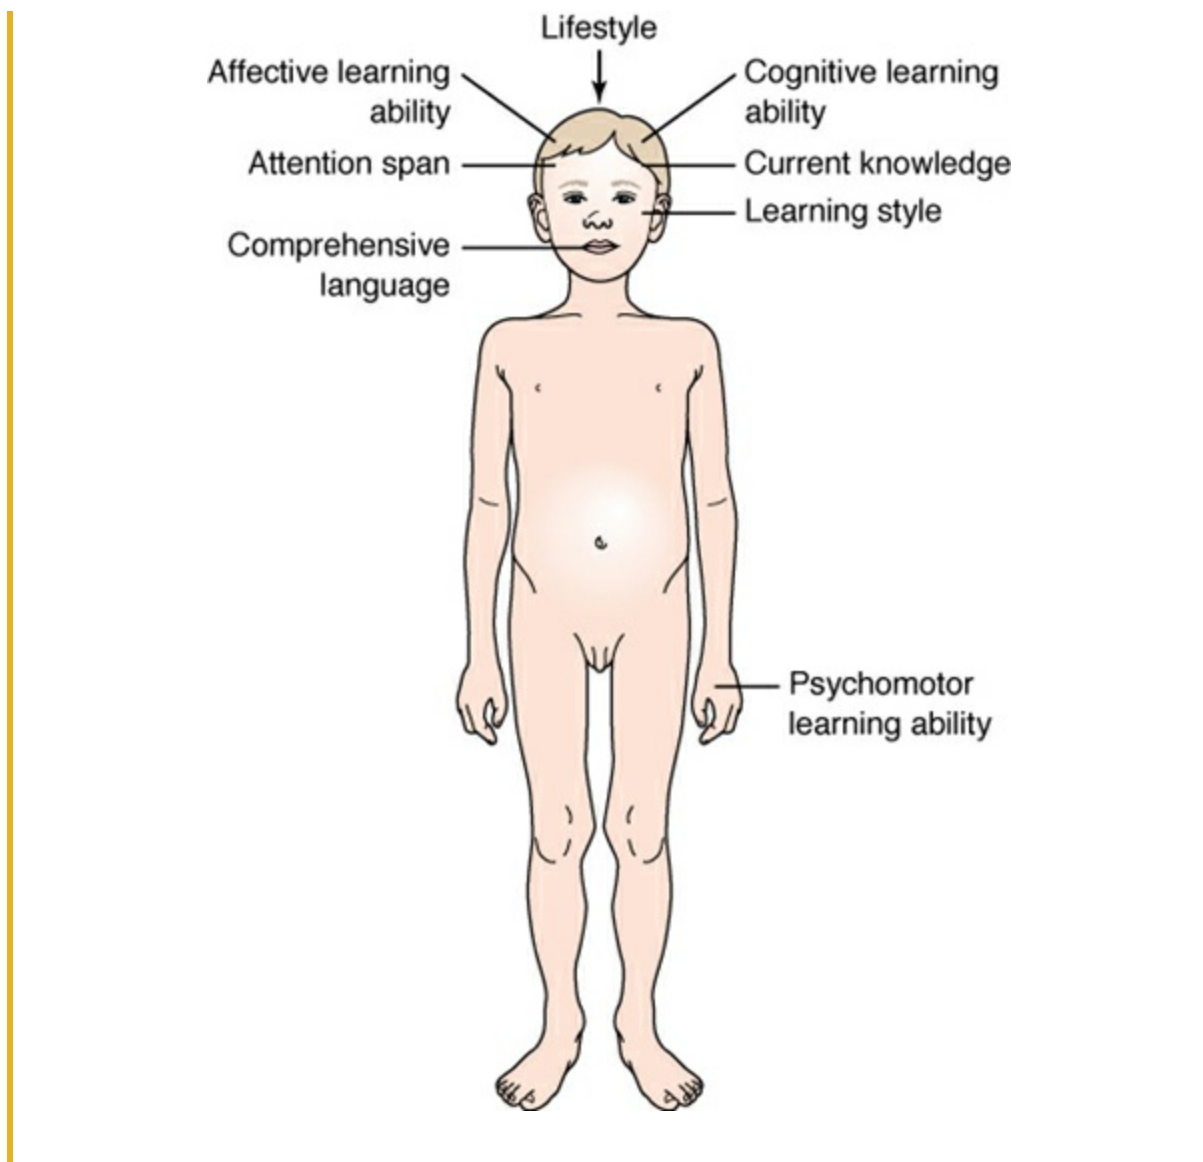

The development of language involves not only physically being able to form and voice words but also the comprehension of what they mean and how they are used (Box 35.2). One of the first responses an infant makes at birth is to cry. This first cry is important because it both signals that the infant is breathing well and also announces to the parents the birth is real, therefore stimulating the beginning of parent-child interactions.

BOX 35.2

Nursing Care Planning Using Assessment

**ASSESSING THE CHILD'S LEARNING AND COMMUNICATION CAPABILITIES**

By 2 years of age, children have mastered language well enough to be able to put two-word sentences (a noun and a verb) together. By preschool age, they not only have a vocabulary of about 900 words but also can code them into simple jokes or stories (Levine, 2014). Even children with cognitive challenges, although they may interpret jokes differently, still appreciate them (Briggs, Schuitema, & Vorhaus, 2016).

School-age children enlarge their ability to communicate from oral exchanges to use of the telephone and various electronic devices. They can write poetry and, by the end of the period, show an adult sense of humor by the jokes they create. Adolescents progress to a new phase in which they originate new words for objects or feelings (“cool” and “whatever” as responses). This form of communication helps them separate their world from adults and keep their adolescent culture separate.

## LEVELS OF COMMUNICATION

Not every conversation you engage in has the same depth level, nor should it.

Throughout the day, a person may use as many as five levels, from clichés to peak communication.

### **The First Level: Cliché Conversation**

Cliché conversation is pleasant chatting or comments such as “Have a nice day” between people who do not intend for their relationship to extend beyond a superficial level. It is important when meeting a child for the first time that you introduce yourself not only with your name but also with your position and function (e.g., “I’m a student nurse who is going to take care of you”; “I’m a nurse who will be visiting you in your home”). This information leads the family to move the conversation from the cliché level to a more meaningful one.

### **The Second Level: Fact Reporting**

Fact reporting is simply stating facts about oneself (a child says, “I’m 12; I’m in sixth grade”). Fact reporting is necessary for you to understand children, but it does not tell you anything about their feelings or needs. Children can move from this level to a higher level of communication only when they feel they can trust you with more information.

### **The Third Level: Shared Personal Ideas and Judgments**

When children know you well, they are able to share ideas such as “I always wanted to be an astronaut” and judgments such as “This is too hard for me.” This level of communication exposes them to a loss of self-esteem if their views are not respected. It is the level that is the beginning of therapeutic interactions.

### **The Fourth Level: Shared Feelings**

It is difficult to share feelings until you truly trust another person because feelings are fragile concepts, easily destroyed and crushed by inept or uncaring comments. Listen carefully for an expression of feeling from children such as “I hate always being sick.” These admissions are telling you much more than how a child feels today; they represent trust in you and the depth of the relationship the child has established with you.

### **The Fifth Level: Peak Communication**

The fifth level of communication is a sense of oneness, or being able to know what the other person is experiencing without any words being voiced. It sometimes occurs spontaneously in high-intensity situations but generally arises out of long-term relationships.

## **NONVERBAL COMMUNICATION**

Nonverbal communication, such as wrinkling the nose, can be especially important in areas such as intensive care units when a child may be unable to speak because of endotracheal tubes and ventilators. Nonverbal communication can be expressed in a number of ways.

### General Appearance

Children who have high self-esteem tend to maintain good body hygiene and care about their appearance. Those who are depressed may not feel the effort involved in grooming is worthwhile. Personal hygiene varies, however, and it is difficult to assess on your first contact with a child. What you see as ill-kempt may be neat and trim for that particular child; what you think of as well groomed may be comparatively sloppy for the child on that day.

Be aware that your impression of how children look or dress registers very strongly in your subconscious. Do not let an unconscious dislike for something such as body piercings or tattoos cause you to draw back. Preparing to give nursing care is not the same kind of activity as evaluating whether you wish to invite that person to dinner.

### Body Posture and Gait

Children who feel good about themselves usually assume an upright body posture and walk rapidly, and surely, those who are depressed or insecure tend to slouch and move more timidly, and those who are threatened tend to either draw back or act aggressively. Children who are in agreement with you usually maintain eye contact with you as you speak to them. Very depressed or insecure children do not do that (they feel too inferior), nor do children who are very angry. Remember that children from some cultures may not meet your gaze because it is not culturally appropriate ([Box 35.3](#)).

#### BOX 35.3

#### Nursing Care Planning to Respect Cultural Diversity

Cultural differences between a teacher and a learner can complicate techniques of health teaching and the evaluation of its effectiveness. Even when language is not a barrier, the way children show they are listening or comprehending may vary from culture to culture. Looking directly at a speaker, for example, is considered disrespectful in some Asian countries. The “Ok” sign traditional in the United States can be interpreted as vulgar, not positive, in Spain. In South Africa and some Middle Eastern countries, a “thumbs up” sign is insulting. In India, the way people move their head to express yes and no can be opposite to those used in the United States. A hand raised in a “stop” position may not be interpreted as halt by a child from a Middle Eastern culture but as a “go ahead” direction.

Being aware of these cultural differences is important when planning health teaching for diverse cultural groups so neither teaching nor reactions to teaching are

misinterpreted.

## Humor

Some people have a natural knack for finding humor in any situation; others do not instinctively have this quality and so must cultivate it. Those who can laugh at their own mistakes are usually enjoyable people to have around because their laughter at themselves suggests, when you make a mistake, they will be able to accept it the same way (or at least not be angry about it).

Be careful of the use of humor with children, however, because they are usually school age before they appreciate most adult jokes. If they are fatigued or ill, they may be looking for a support person to be with them more than one who is amusing. You can often measure the fall in a child's anxiety after a procedure by noting the first time the child responds to you with a humorous statement. Remember, though, laughter and joking can also be signs of increasing anxiety. Ascertain whether a child really finds a situation amusing or would rather have a serious caregiver.

## Drawings

A useful nonverbal technique to learn how children feel about a frightening experience is to ask them to draw a picture of what happened or a picture of themselves. A child hospitalized for heart surgery, for example, might draw her heart prominently. She's revealing that she realizes she cannot survive if something happens to such an important body part.

A child's use of color may be a clue as to mood (happy children tend to use bright colors; depressed children use black or dark colors). A child with high self-esteem usually fills the full page with a drawing; one with less self-esteem crowds a drawing into a corner. These observations are quite variable, however, as a child may have had only a black crayon with which to color or may be saving the rest of the paper for a second drawing.

## Music

The type of music to which children listen often also conveys their mood. The better they feel about themselves, the more likely they are to choose lively music; if they are sad, they often choose a quieter, more comforting type. Children enjoy repetition, however, and so may play the same music over and over, independent of their mood.

## TECHNIQUES TO ENCOURAGE THERAPEUTIC COMMUNICATION

Several techniques are effective at deepening communication patterns and relationships. These techniques can be learned if they are not a spontaneous part of your present communication pattern (Avegno & DeBlieux, 2013).

## Distance

Although it is affected by cultural and personal variables, the distance at which you position yourself from the person you are talking to can indicate your feelings or the type of conversation you want to initiate. People generally consider the space directly surrounding them (up to 18 in.) as *intimate* space to be crossed only by people who know them well or with whom they are comfortable having close body contact. Those from Middle Eastern cultures may define a wider space as intimate space than those from Western cultures. Sometimes, you will notice, in a heated discussion, one person moves aggressively into this space; the other will automatically step back to protect it. People in elevators usually separate themselves from others by this much space if the car is not full.

Whenever you touch a child, you violate intimate space, so always tell them when you are about to touch them (“I’m going change your bandage now”). If a child agrees to let you enter this space, it means they see you as safe, protective, and helpful.

The space between 18 in. to 4 ft is sensed by most people as *personal* space. This is the distance people usually stand apart from each other for casual conversation or hand shaking. When you stand by the side of a crib or bed or sit next to a person at home, you are within this space. It is a concerned, I-care-about-you distance but does not invade intimate space.

The distance between 4 ft and 12 ft is *social* space, the usual distance used to conduct business or to teach a class. Conversation spoken at this distance is readily heard by others. Do not use social space to ask a personal question. If you ask a child, “How are you feeling?” as you pass by in a hallway, for example, the child will probably answer, “Fine, thank you,” a programmed reply almost everyone is taught in early childhood. In contrast, if you ask that same question from a personal or intimate distance, in a more private setting, the answer might be, “I’m scared I’m never going home again.”

Although it is carried out miles apart, most people perceive texting, speaking on the telephone, or using mail or e-mail as either social or personal space. The tone of voice or the words used help to differentiate which area it appears to be. A message such as “Have I got news for you!” suggests social space. “Can you keep a secret?” brings it into personal space.

The distance beyond 12 ft is *public* space. To communicate from this distance, you need to shout and privacy is not respected. Waving to a friend in a hallway or across a parking lot is an example of public space communication.

### QSEN Checkpoint Question 35.1

#### PATIENT-CENTERED CARE

The nurse wants to review some health educational materials with Barry, age 16 years. To maximize his learning and his comfort level, this activity should take place in which type of physical space?

- a. Intimate space
- b. Social space
- c. Public space
- d. Personal space

*Look in Appendix A for the best answer and rationale.*

## **Genuineness and Truthfulness**

Genuineness is a quality of projecting sincerity or being yourself. Children can have difficulty trusting you and therefore may be unable to move to a deep relationship with you if you change your behavior from one day to the next, such as from maximum patience one day to short-tempered the next, because this causes them to have to spend energy testing to see who you are on that particular day. The way to achieve a feeling of genuineness is being true to yourself, not trying to be what you are not, as the insecurity that comes from pretending can manifest itself as negative feelings such as aggressiveness or a bored attitude.

## **Warmth**

Warmth is an innate quality some people manifest more spontaneously than others. Basic ways in which warmth is demonstrated are direct eye contact, use of a gentle tone of voice, listening attentively, approaching a child within a comfortable space of 1 to 4 ft, and using touch appropriately. Warmth is a quality you display best when you know another person well. Therefore, any action that helps you to know a person better (e.g., taking a health history, talking about school or family or how a child feels about the present situation) not only lets you plan care but also allows you to become increasingly comfortable with the child and creates opportunities to deepen the warmth of your relationship.

## **Empathy**

**Empathy** is the ability to put yourself in another person's place and understand and be sensitive to the feelings of another (DalSanto, Pohl, Saiani, et al., 2014). People who are capable of empathy are the best support people because they can anticipate a child's reactions or fears. Feeling empathy is emotionally draining because when you assume another person's emotions, you experience them at the same depth as that person. Nurses who are capable of empathy need to surround themselves with good support people so they have refueling resources when they need them.

## **Gestures**

Children vary a great deal in the gestures they use to accompany their spoken words. Although gestures are culturally influenced, it is also an individual trait. Be careful not to assess emotion only by a child's gestures. Some children wave their arms wildly

describing an everyday occurrence; others would use that degree of expression only when in extreme distress. Be aware also that your own gestures are not always read well by children. A verbal statement that you approve of something is contradicted by placing your arms across your chest in a disapproving, stern manner.

## Facial Expressions

Facial expressions are an important accompanying gesture to words. Clenched teeth, frowns, and smiles are easily interpreted by most people. The degree of pain a child is experiencing may be more evident by distressed facial expressions than words. Your approval or disapproval of an action may be more evident in your face than in your words.

## Touch

Touch is the most intimate and meaningful of nonverbal techniques. When words are inadequate, touch rarely is. Learn to use touch such as clapping a child's shoulder or squeezing a hand to accompany reassuring words or in place of words as a strong support signal (e.g., I'm here; I understand; it's all right to be afraid). Be aware, however, some children enjoy being touched more than others. Due to individual preferences or cultural variations, some children are not used to being touched or hugged. Assess individually for the appropriateness of using touch.

## Attentive Listening

No one likes to talk to someone who does not appear to be listening or responding. Good listening, therefore, like speaking, is not passive but active. Be aware your posture reveals to a great extent whether you are listening (e.g., sitting, not standing, to convey you are not on the run; leaning forward, not backward; stooping to meet a child's level). Nodding, maintaining eye contact, and stopping all other activities are strong indicators you are attuned to what is being said. Making it clear you are attentively listening indicates you value what the other person is saying. Children who feel valued are much more likely to confide feelings and concerns than those who sense you do not consider them important.

In some instances, it is necessary to repeat a part of what a child said, interject an appropriate "uh-huh" or "m-m-m," or make a direct statement ("I'm listening. Go on") to indicate you are listening. Be certain, when you are listening to the 20th child on any given day, you do not exhibit "end-of-the-day" behavior. To be therapeutic, you have to give everyone's concerns the same alert attention ([Box 35.4](#)).

### BOX 35.4

#### Nursing Care Planning Based on Family Teaching

#### LISTENING TO CHILDREN

**Q.** Barry's mother says to you, "My son always tells me I don't listen to him. How can I be a better listener?"

**A.** Try the following tips:

1. Stop talking. You cannot listen if you are talking.
2. Look and act interested. Don't read or write while he talks. Listen to understand rather than to reply.
3. Remove distractions. Do not doodle, tap, or shuffle papers. Turn off the television or put down your cell phone.
4. Empathize. Try to put yourself in your child's place so you can appreciate his point of view.
5. Be patient. Allow plenty of time. Do not interrupt. Do not edge toward the door as if you're about to walk away.
6. Hold your temper, argument, or criticism. An angry person can easily misinterpret the meaning of words.
7. Ask questions. This is proof that you have been listening.
8. Stop talking. This is the first and last suggestion, because all others depend on it.

## Reflecting

**Reflecting** is a technique, like attentive listening, that is so simple that its importance is easy to discount. Reflecting is restating the last word or phrase a child has said when there is a pause in the communication. A child says, "I'm worried," and then stops. You repeat the last word. "Worried?" The child, assured you are listening and interested, will generally enlarge on the first statement: "I'm worried I'll be too short of breath to make the football team this year." In contrast, adolescents may not respond well to reflection; they may interpret it as imitating them, not seeking information.

## Clarifying

**Clarifying** consists of repeating statements others have made so you can be certain you understood them. This is particularly helpful if a child has been describing a set of symptoms or series of actions. A statement such as "Let me see if I understand this. You said you always get the pain first in your stomach. Then, it spreads to your chest" clarifies or makes clear what you have heard. If you are not quoting correctly, the child will interrupt and restate the problem: "No, the chest pain comes first."

## Paraphrasing

**Paraphrasing** is restating what the child has said not only to assure the child you have heard correctly (as in clarifying) but also to help the child explain a thought. In clarifying, you repeat a child's exact words; in paraphrasing, you retain the meaning of the words but repeat them in a clearer or more condensed form. The child says, for example, "I don't talk about my problems with my parents." A paraphrasing statement

might be, “You’re telling me you and your parents haven’t discussed home care. Is that right?” When paraphrasing, ask for confirmation your interpretation is correct; otherwise, you may find yourself putting words in children’s mouths.

When the topic is embarrassing or emotionally charged (e.g., an adolescent discussing sexual orientation), the child might use such vague terms that the explanation becomes difficult to follow. Paraphrasing using basic terms would let him or her know not only that you understand him but also that if he or she can describe the problem better with such words than with medical terminology, it is all right to do that.

## Perception Checking

**Perception checking** documents a feeling or emotion reported to you. This makes it a step deeper than paraphrasing. In paraphrasing, you document a statement or fact; in perception checking, you document a feeling or emotion. The child says for the second time, “I’m not at all worried about surgery. I mean, what could happen?” You say, “You’re telling me you’re not worried, but the number of times you’ve said it makes me wonder if you really are worried. Are you?”

Always ask for validation that your perception is correct so you do not make false assumptions. Perception checking is helpful because, as a rule, children are not ready to deal with emotions until they can admit they are experiencing them. When you bring an emotion out in this way, it allows them to confront it and deal with it for the first time. They may also lose their reluctance to admit other worries because you have implied worrying is acceptable.

### *What If . . . 35.1*

**Because Barry Sandoz’s family has hypercholesterolemia, Barry, 16 years old, needs to begin a low-cholesterol diet. He needs to learn more about foods so he can eat safely in the school cafeteria. The nurse determines it is most important to provide patient education about Barry’s diet to which person? Barry? His mother who prepares his food? Or his father who does the grocery shopping?**

## Focusing

**Focusing** helps children to center on a subject you suspect is causing them anxiety because they comment about it indirectly or else completely avoid it. It is done by repeating something they said (“You mentioned you feel tired all the time”) or by mentioning the avoided topic (“You haven’t said a word about how you feel about this surgery”). Once a subject is brought up for discussion, most children respond to it. As long as it can be avoided, however, they do not have to face the problem and won’t begin to solve it.

## Supportive Statements

Supportive statements let children know you accept their behavior or at least appreciate they have dealt well with unfortunate circumstances. For example, an adolescent says, “My girlfriend dumped me while I’ve been here in the hospital.” Such a statement deserves a supportive reply such as “That must not feel good.” The adolescent will take this response to mean you want to discuss the topic and, encouraged by your support, may elaborate on it because it still affects him.

## Silence

If you ask a question and a child does not respond immediately, it is natural to ask another question or perhaps change the subject, assuming the child is not interested in the topic. This is a social custom that prevents you from putting someone into the awkward position of having to discuss a sensitive topic. Silence, however, can be an effective therapeutic technique. If you ask an emotion-laden question (e.g., “Are you worried?”) and the child does not answer immediately, allow a period of silence to pass. Because you do not hurry to fill in the silence, the child is likely to respond (by hurrying an answer). When this happens, the answer is usually spontaneous and often open and uninhibited. In other instances, a child may answer the question deliberately and cautiously and, because you have provided a period of time to answer, may offer additional information.

Do not overdo silence, however, either by the number of times you use it or the length of time you allow it to extend. In this era of constant noise, many individuals are extremely uncomfortable with silence. Too much silence can also indicate to a child that you are not interested enough to maintain the conversation.

## Process Recording

Process recording is a method to examine how effective you are at therapeutic communication. After your next interaction with a child, draw three columns on a sheet of paper. Take a few minutes to write down in the left column a statement the child made to you. In the middle column, write what you thought on hearing the statement. In a third column, write your response. Try to record both statements and responses verbatim or as close to the actual words used as possible. The average person can accurately recall about 3 minutes of communication this way.

Next, examine your responses to each statement by asking: Did I encourage the child to tell me more by my response, or did I block communication? Were my responses supportive, critical, or trite? Did I check perceptions, or did I just assume I understood correctly what was told to me? See [Box 35.5](#) for an example of a process recording with an adolescent.

### BOX 35.5

#### A Process Recording

The following is a record of an interaction between a nursing student and Barry Sandoz, a 16-year-old who is hospitalized. Barry has been diagnosed as having a recurrent peptic ulcer.

What Patient Said and Did	What I Thought and Felt	What I Said and Did
	I felt anxious meeting a new patient, although I thought he'd be friendly because he was so close to my own age.	I walked into his room and said, "Good morning."
He was sitting up in bed holding his hands on his abdomen. He asked, "When are you going to get me my purple pill?"	I felt attacked. As if he thought I should have done something sooner, but I had just arrived.	I asked, "What kind of pain are you having?"
He said, "Hydrochloric acid is carving a hole in my stomach lining. Is that enough explanation?"	I felt angry he insisted on putting me down so.	I said, "It certainly is," and left to find my instructor. I returned in 15 minutes with omeprazole (Prilosec) (his "purple pill").
He asked, "Did you have to take so long to do that?"	I was getting really angry at his threatening tone.	I checked his ID band and handed him the pill. I asked him, "Are you always so demanding?"
He turned on his side so his back was to me, clenched his teeth, and pushed his hands into his abdomen again.	I realized my criticism was unfair because he was in pain. But it was too late to take it back.	I said, "I'm sorry. I know you're uncomfortable."
He said, "Hand me that book on the chair over there before you leave, will you? If I don't get to it today, I might as well cash it in."	Getting angry again but also "hearing" what he had said for the first time.	I said, "Cash it in?"
He said, "I can't go back to school with pain like this. If I don't get better soon, I'll fail out."	I was surprised how one quick response on my part had brought out so much emotion. I also knew I was in over my head again (but in a	

good way).

### EVALUATION

My overall interaction with Barry would have been better if I hadn't been caught so off guard in the beginning by assuming he was going to be someone who had a lot in common with me (student–student, close age group). His initial response to me seemed so much more intense because I had stereotyped him that way.

In the final interaction, I was so concerned with my own needs (to get my work done); I completely missed why a book would be important to him. Fortunately, at the last minute, I got my mind off my problem and onto his and was able to produce a therapeutic response for him. He shouldn't have had to describe something with the impact of driving a truck over me before he caught my attention, though. Better listening (and thinking while I'm listening) would make me hear better and be more helpful sooner in this type of interaction.

### *QSEN Checkpoint Question 35.2*

### INFORMATICS

The nurse has heard from a colleague that Barry, 16 years old, hates school. When considering the use of informatics to respond to this statement, which principle should guide the nurse's actions?

- a. Communication is most effective when it is enhanced by cutting-edge technology.
- b. Referral to an appropriate, evidence-based website can likely resolve this issue.
- c. Technology cannot usually substitute for skilled interpersonal communication.
- d. Communication skills are being replaced by technologic innovation in nursing.

*Look in Appendix A for the best answer and rationale.*

## FACTORS THAT CAN INTERFERE WITH EFFECTIVE COMMUNICATION

Because so much of nursing care is influenced by verbal communication, it is important to avoid miscalculations in communication and to recognize common situations in which meanings can easily be distorted.

### Age and Developmental Level

Age and developmental levels are important to communication abilities because they influence vocabulary and reading ability so greatly. Newborns and infants are amazingly perceptive regarding nonverbal communication. They quiet readily at a gentle tone of voice, and they show discomfort if an adult shouts or handles them

roughly. Toddlers and preschoolers remain just as adept at reading nonverbal communication signals. They much prefer a happy approach (e.g., “Isn’t this fun?”) rather than a stern one. Because of their short attention span, their concentration wanders after about 5 minutes of time spent on an explanation. Older children are ready to listen to spoken words, although they are still attentive to nonverbal actions. They like role models and so are very opposed to “Do as I say, not as I do” advice. They are ready to ask questions and use techniques, such as reflection, to be certain they understand what you have just said.

### **Intellectual or Behavioral Level**

Intellectual level, like age, affects vocabulary and ability both to encode and decode messages. It influences the number of languages a child speaks, reading ability, and the depth of explanation a child is capable of understanding. Children with cognitive challenges or autism spectrum disorder can have difficulty both receiving and transmitting messages (Bal, Katz, Bishop, et al., 2016)

### **Physical Factors**

Physical factors, such as speech impairments and hearing or vision challenges, interfere with the transmission and reception of messages (Harris & Lord, 2016). When children are distracted by such sensations as fatigue or pain, they also may have a reduced ability to transmit or receive messages correctly.

### **Technical Terminology**

Adults have heard common medical words and so usually have little difficulty understanding an explanation of one. Children, in contrast, have not heard many medical words. Listen to the explanations you give them to be certain they understand the concepts. You may want to ask yourself if you would have understood terms such as “lung rales” or “colostomy” at their age.

### **Showing Disapproval**

Parents and children do not come for health care to be criticized; they come to learn more about how to stay well or how to recover from an illness. If you criticize them, they may not reveal any further information to you because they do not want you to react in the same way you did to their preliminary statements.

Be aware that nonverbal disapproval signs (e.g., frowning, sighing) can be just as disapproving as spoken words. On the other hand, this does not mean you should show approval of wrong actions. Merely listen to them with no action or comment and make a mental note. At the end of your interaction, introduce the change in behavior you’d like to see (e.g., “Let’s plan some ways you can include more calcium in your meals every day”).

## **Not Showing Approval When Warranted**

Every student has had the experience of completing a difficult assignment and receiving only criticism from a teacher (i.e., no other comments that, aside from the part that was not satisfactory, the rest of the assignment was well done). This happens because the instructor assumed the student would do a good job; no reward was given for meeting minimum criteria. From the other side of the desk, however, it would have been satisfying—and would have offered motivation to continue to do well—to have heard the words “good job.”

When discussing healthcare problems with children, it is easy to forget what you accept as standard behavior may take a great deal of effort for an ill child to accomplish, such as coughing and deep breathing after surgery. Giving children praise for what they do well encourages them to continue what they’re doing and to try more advanced things. If a topic is difficult for them to talk about, saying you realize it is a sensitive topic may help them continue to discuss it.

## **Growing Defensive**

In the same way children who request health care do not enjoy being criticized, neither does the average healthcare provider. If a child makes a critical remark, therefore, it is easy to respond with a defensive or protective comment rather than a therapeutic one. An adolescent might say, for example, “We have to wait so long here; this is a really dumb clinic.” It is easy to reply, “Don’t say that. This is a good clinic.” This type of response implies any complaint is out of line. Try to respond instead with a supportive comment such as “I know it makes a long day for you.” No healthcare agency is so good that there is nothing to criticize.

## **Cliché Advice**

Cliché advice (i.e., advice given from a formula, not individualized to the situation) is meaningless because it is too general to be helpful. Statements such as “Rome wasn’t built in a day” and “You have to walk before you can run” are examples of this kind of advice. Use it guardedly because children consider their problem unique and resent being given advice that could apply to anyone.

## **Topping Up**

“Topping up” is minimizing a child’s views by telling a better story. A child tells you, for example, she has a problem. You say, “You want to know what problems really are? Come and work here.” This implies that their problems are inconsequential, at least in respect to yours. They will not be likely to tell you any more about themselves after such a response.

## **COMMUNICATION SITUATIONS THAT REQUIRE UNIQUE**

## SKILLS

Some communication situations require special skills in addition to the usual therapeutic communication techniques to promote understanding.

### The Shy Child

Shy children, as a rule, have much more difficulty talking to people they meet for the first time and establishing peer relationships than others (Coplan, Rose-Krasnor, Weeks, et al., 2013). A reluctance to express their needs to others can leave their needs unrecognized and unmet. If they do not give you much verbal feedback, it's easy to believe they do not have a concern. That leaves them without support people when they most need them.

Fortunately, in most instances, once children know you and realize they can trust you, shyness fades. A therapeutic response, therefore, would be to not leave them alone but to maintain an active relationship despite the lack of feedback. This does not necessarily involve talking to the child but may involve checking on them frequently, remaining in the room while their primary healthcare provider completes an examination, helping secure the adhesive strip after a technician obtains a blood sample, or sitting with them for a few minutes while a medication takes effect.

### The Angry Child

All children grow angry at some time, although boys may express anger more openly than girls (Olino, Durbin, Klein, et al., 2013). They also express it differently, using more controlled than uncontrolled responses (Sears, Repetti, Reynolds, et al., 2014). It is difficult to work with angry children because you may feel yourself being pulled into their anger. The typical response at hearing an angry outburst is to imitate it (e.g., a child is radiating anger as tight-lipped silence, so you say nothing as well; a child shouts at you, and you shout back). This is not therapeutic, however, so make a point of not allowing yourself to be drawn into children's anger. At the same time, acknowledge that it is all right to be angry (e.g., "I understand that you're angry but please don't shout"). Help them to focus their anger if at all possible, so they can better identify why they are angry and can begin to deal with it.

To encourage focusing, ask children to detail why they are angry. An adolescent who says he is angry at the entire healthcare delivery system, for example, may be feeling highly frustrated because he cannot begin to fight a huge bureaucracy. Establishing what he is really angry about is one nursing action that can build a base for resolving the problem. If a child uses silence as a method of maintaining anger, suggesting possible reasons for the anger can be helpful (e.g., "I know your mother was just talking to you. Are you angry about something she said?" or "I know you were asking about crutch walking before. Does it have something to do with that?"). Once the subject is out in the open, few children can resist describing the extent of or the reason for their anger. Be aware, too, that when you ask someone to explain why he or she is

angry, you ask for all the emotion and all the distress that goes with it to be expressed as well. Even if you are the object of the anger, at that point, you are committed to listening to the child's views. Keep anger from affecting you by reacting to the explanation, not the tone or force of it. Keep any response on your part a tone gentler and quieter than that used toward you.

### **The Demanding Child**

Nursing has few equals in job satisfaction (provided salary and other working conditions are adequate) because the majority of people you care for are grateful for what you do for them. It can be upsetting, therefore, to discover a particular child who is not grateful for or even satisfied with anything you do. This type of child is easy to back away from or avoid.

Demanding behavior generally stems from insecurity or fear (e.g., they're so afraid something will happen to them while you are out of the room they constantly find reasons to keep you in the room; they're so afraid of unplanned events they structure things so nothing unexpected can happen). Give more of yourself, not less, to counteract this response. When you have proven you are dependably there for them, children do not feel so insecure, and the need to be demanding usually fades. Withdrawing from them has the opposite effect if it increases the child's insecurity and the demanding behavior. Ask, "Is there anything else I can do for you?" instead of "Haven't I already done enough?"

### **The Bullying or Sexually Aggressive Adolescent**

Both bullying and sexually aggressive behavior can cause friction in a nurse/child relationship (Espelage, Basile, De La Rue, et al., 2015). As these are similar behaviors, they both probably stem from the same cause as demanding behavior: insecurity. Aggression can be manifested as telling unwelcome, off-color jokes or participating in inappropriate physical touching. This may be most pronounced in adolescents who worry that their illness or surgery will interfere with sexual function. Adolescents with this degree of insecurity may benefit from counseling to help them channel coping responses into more socially acceptable behaviors. Be certain they have factual information as to the extent or effect of their illness. Set limits, as necessary, to make giving care acceptable to you. Always censor the action, not the adolescent. Be aware sexually aggressive behavior can occur with both males and females.

### **The Child Who Is Not Proficient in English**

It is not unusual in any nursing care setting to encounter children who have a different primary language from yours; in other instances, a child's speech may be limited or difficult to understand because of an accent, dialect, or speech impairment. Still, other children may speak your language but their use of words is so different from yours the words appear to have different meanings (Kirk, Prusick, French, et al., 2012). Most

children who speak another language have a support person who can serve as an interpreter. Anticipate the instructions you will need to give the child (e.g., cough, breathe deeply, save urine) and ask the interpreter to write them out in the child's language for when the interpreter may not be present. Post them conspicuously in the room or in the child's care plan so everyone giving care can be familiar with them.

Most healthcare facilities have a list of people who serve as translators as needed. Generally, you can contact such a person by telephone to ask for a specific word you want to know. If you have to give instructions and no translator is present, do not be self-conscious about using hand gestures or drawing a picture to express the action you want the child to perform (e.g., a child lying in bed, an arrow pointing to a chair, and a child sitting in a chair for, "I'm going to help you get out of bed."). Allow children ample paper to draw pictures to show you what they want you to know. Supply pictures for preschool children so they can select the one that applies.

Everyone has a tendency to shout at children who speak a different language as if loudness will increase understanding; try to avoid this. When using an interpreter, be certain to speak slowly and use common words that can be translated literally (e.g., "I need to stick Mary's arm for blood" could be interpreted literally to mean putting a stick in the child's arm).

### **The Unconscious Child**

Be aware that because a child is unconscious, it does not mean he or she cannot hear (Tapson, Sierotowicz, Marks-Maran, et al., 2015). This means you always need to be aware that children who do not respond to you may still be able to hear and interpret anything you say. Never say anything to unconscious children or within their hearing you would not say if they were fully alert. Continue to use nonverbal communication such as touch to help convey a message.

### **The Child With Hearing Impairment**

It's difficult for children with hearing impairment to enunciate words clearly because they're not aware the sounds they are forming are not clear (Lund & Douglas, 2016). When communicating with children with hearing impairment, check whether they use a hearing aid; if so, be certain it is turned on. Face them when you speak so they can follow your lip movements. Use hand gestures as necessary to convey your message, or write out instructions. If you have difficulty understanding what they are trying to say, ask them to write it down if they're old enough. Use common sense about how loud to raise your voice to facilitate communication. As a rule, at the point privacy is lost, it is time to resort to written words or sign language. Children who use sign language to communicate have a right to have an interpreter present to facilitate communication, the same as children who do not use English as their primary language.

### **The Child With Vision Impairment**

Children with vision impairment are capable of understanding spoken instructions well if the instruction does not require an accompanying visual image such as “Take a piece of gauze about this long” (you then indicate the length with your hand) (McLinden & McCall, 2016). Never touch children who cannot see you without asking their permission or warning them first so you do not startle them.

## Health Teaching in a Changing Healthcare Environment

In the past, when children were admitted to hospitals well in advance of surgery and then remained in the hospital after surgery or therapy until they were almost totally well, there was a wide window of time for health teaching. Today, when surgery is often a 1-day experience, the window for teaching is narrowed to hours (Farber, Curie, Brown, et al., 2015). This means that nurses must use more creative approaches to achieve the same health education results. Discharge instructions must also be quickly explained, requiring both verbal and written approaches (Wu, Tyler, Logsdon, et al., 2016).

Children’s sophistication about learning techniques has also changed. Because children today are exposed to such a rich diet of clever animation on TV or in movies, a simple lecture on good nutrition can seem dull and uninteresting. Children who are adept at arcade or electronic games, where dexterity is a requirement, may no longer find handling a syringe or a feeding tube a challenging feat. Before beginning health teaching, assess each child to find out what he or she expects to learn, to identify individual learning styles, and to determine what teaching techniques would best suit the individual child.

### THE ART OF TEACHING

Teaching is more than presenting information; it is presenting information to increase someone’s knowledge or insight. Before teaching can be considered effective, learning has to have occurred. Conversely, before learning occurs, teaching must have been present in some form. Common principles of teaching are summarized in Table 35.1.

**TABLE 35.1 PRINCIPLES OF TEACHING**

Principle	Rationale
Know the subject.	To effectively teach children, you must be able to not only present material but also answer questions about it. Children’s questions can be as probing as an adult’s, and they can often be more frequent because children are used to asking questions of a teacher or a parent.
Know the audience.	Children vary a great deal in cognitive development depending on their age group. To teach preschoolers about oral health, you might choose to teach how to brush teeth using puppets as a teaching aid.

	The same clever puppet and tooth brushing presentation likely would not be well received by adolescents.
Know yourself.	Analyze which teaching techniques (e.g., lecture, role-playing, small group discussion, audiovisual aids) fit your teaching style. Using techniques that are comfortable allows teaching to be most effective.
Assess individual learning styles.	Most children respond well to visual images (e.g., a demonstration, a drawing) to complement learning. Assessing individual learning styles helps to meet each child's best way of learning.
Define expected outcomes.	Expected outcomes serve as guidelines to help you select from all you know about a subject that part which is most pertinent to an individual child. Outcomes should be realistic, measurable, and mutually established. Instructions on how to walk using crutches for an early school-age child might include how to carry school books while using crutches; for an adolescent, instruction might include how to board a city bus so he or she can get to and from a part-time job.
Provide an environment conducive for learning.	Children are easily distracted from learning. Divide material into segments to keep teaching sessions short; avoid competing factors such as television or mealtime.
Be consistent.	Nothing is more confusing to a person learning a new skill than to be told two different ways to do it. Choose one method you anticipate will work best for a child and then consistently stress that method. After a child has learned one method, you then could suggest alternative methods if the child is interested.
Recognize that actions teach as much as or sometimes more so than verbal statements.	Children watch facial expressions and nonverbal gestures as much as they listen. Be certain that a nonverbal statement is not contradicting a verbal one.
Teach from the simple to the complex.	Fundamentals must be grasped before advanced learning can proceed. Because many children have little idea of body anatomy, you often need to begin with the basics. When these are mastered, you can proceed to teach about more complicated aspects.
Teach principles.	Teaching children the principle behind a procedure makes the reason for the procedure make sense. This also allows children to modify

and change to an alternative method as long as the principle is fulfilled.

Emphasize what the child should do; mention, but do not emphasize, what the child should not do.	Teaching from a positive standpoint makes learning more enjoyable. Because healthcare information should last a lifetime, thinking of it in a positive way makes it more applicable to lifetime use.
Include evaluation as a final step.	The only way to determine the effectiveness of teaching is to test or evaluate if learning has occurred. Structure the time and method of evaluation when first establishing a teaching plan.

### The Teacher–Learner Relationship

Effective teaching and learning depend a great deal on the teacher–learner relationship because if such a relationship is based on mutual sharing, it empowers and motivates an individual to learn more readily than a relationship in which a teacher maintains ultimate control and authority. Finally, the teacher–learner relationship is best if it is interactive or the teacher and learner both actively participate in the process and modify the teaching plan as they learn from one another.

### THE ART OF LEARNING

Learning is a two-step process involving both the acquisition of knowledge and a change in behavior based on the new knowledge. Learning has not really occurred unless the change in behavior is measurable. For example, a parent teaching a child about the need to brush teeth daily must not only elicit the child’s statement that daily brushing is important but also see that the child is, in fact, brushing her teeth every day. Principles of effective learning are summarized in [Table 35.2](#).

**TABLE 35.2 PRINCIPLES OF LEARNING**

Principle	Rationale
Learning occurs best when children are ready to learn.	Interferences with learning may be physical (e.g., pain, hunger) or psychological (e.g., fear, anxiety). The first time children are told that they must inject insulin daily, for example, they may be too anxious to learn about it.

Learning occurs most quickly if children can see how the new information will benefit them directly.	Sixteen-year-old children learn how to drive a car quickly because they readily grasp that being able to drive will immediately enlarge their world. Children are only ready to learn how to perform an insulin injection when they can see how it will benefit them.
Learning occurs best if rewards, not penalties, are offered.	Notice the amount of shoulder patting and back slapping high school coaches engage in (i.e., rewarding by praise). Giving positive reinforcement immediately like this makes it more effective than if such reinforcement is delayed. If you must criticize the way a task was done, first compliment children on some aspect they did well and then explain the part that needs improvement. This increases self-esteem and allows children to feel good enough about themselves that they can accept the criticism. Never be reluctant to praise in public; always criticize in private.
Children learn best by actively participating in learning.	Active participation requires involvement in learning. Ask questions to involve participation; allow children to touch and handle equipment to increase participation.
Learning occurs best in a nonstressful and accepting environment.	No one wants to take a chance redemonstrating a procedure or asking a question if they believe that actions or opinions will not be respected. People do learn from “top sergeants,” but the learning experience has so many unpleasant memories attached to it that they may not retain the learning. Health teaching is too important to be presented in a way that will lead to it being quickly discarded.
Children learn best those things that hold a particular interest for them.	Most people have specific interests. A child with diabetes mellitus who enjoys dancing might be most interested in learning regulation of insulin for exercise. A child anxious to leave for college might be most interested in learning how to select a diabetic diet from a cafeteria.
Learning occurs best when ability	Children learn to the point of saturation; learning and interest in learning halt at that point and do not continue until the material learned is thoroughly digested and understood. Wait until

plateaus are recognized. information is processed, and at that point, the child will be interested once more.

## TYPES OF LEARNING

There are a number of different types of learning. For example, learning the mathematical formula necessary to change pounds to kilograms (i.e., a cognitive task) is different from learning how to fill a syringe (i.e., a psychomotor task). Learning to be kind to a brother with a chronic illness is yet another type (i.e., an affective task). For best results, before you begin teaching, analyze the type of learning you want to see take place because this helps in setting goals and designing teaching strategies.

### Cognitive Learning

**Cognitive learning** involves a change in the individual's level of understanding or knowledge (Barrouillet, 2015). Learning the principle behind why a particular medicine must be injected into a muscle, as opposed to subcutaneous tissue, is an example. Cognitive learning requires adequate development, intelligence, and attention span. It can be gained through exposure to any teaching technique but is usually learned through lecture, reading, and audiovisual aids. It's important for techniques for teaching when cognitive learning is the goal to be consistent with the learner's cognitive ability (Singer, 2012).

During the school-age years, learning capability is concrete (e.g., children have difficulty picturing body parts functioning unless they can actually see them doing this); during the adolescent years, it becomes possible to learn abstract concepts, so adolescents can accept that liver enzymes are released with liver damage even though they never see that occur (Piaget, 1952).

### Psychomotor Learning

**Psychomotor learning** requires a change in a person's ability to perform a skill. Learning to hold a syringe, fill the syringe with medicine, and inject it into a muscle is an example of psychomotor learning. Acquiring psychomotor skills depends on muscle and neurologic coordination. It is best mastered through demonstration and redemonstration.

### Affective Learning

**Affective learning** involves a change in a person's attitude and is the most difficult area in which to bring about change. For example, to teach a child the reason for and the skill of giving a self-injection may be easy; teaching the child to *like* giving a self-injection may never be possible. The best goal accomplished could be that the child will *value* the procedure because it will prevent him from developing hyperglycemia. Affective learning is gained best through role modeling, role-playing, or shared-experience discussion.

## INFLUENCE OF AGE AND STAGE ON ABILITY TO LEARN

Learning ability varies a great deal depending on a child's stage of development and the past experiences the child has had in the specific area of learning.

### The Infant

Infants learn by exploring the environment with their senses (i.e., psychomotor learning). They learn best from a primary caregiver because that is whom infants most want to please. Any healthcare points taught must be presented not as a structured activity but as a game or an amusing or attractive activity. For example, you could teach an infant to exercise a leg by hanging a ball next to his foot and encouraging the infant to kick it.

### The Toddler

Toddlers are developing a sense of autonomy or learning to be independent (Erikson, 1993). That means, trying to teach toddlers a new activity such as eating a new food or brushing their teeth may be met with a sharp "No!" This retort does not mean the activity is unappealing to a child; however, only that the child is aware he does not have to do everything he is told to do. Toddlers also sometimes resist a change in routine because they need rituals to feel secure. If an activity will allow children to increase a level of independent functioning, they will usually learn it rapidly. Teaching activities such as exercise or deep breathing by having children imitate the action is an effective teaching method because it presents the activity as a game (i.e., there is nothing to be resisted). Parents can be instrumental in maintaining a new skill their child has learned by incorporating it into a daily routine or a ritual.

### The Preschooler

Preschool children are interested in learning because developing a sense of initiative is the main developmental task of the period. Provided that instructions are geared to their small vocabularies, they "soak up" new methods of doing things. Because they are so imaginative and uninhibited, they have few reservations about the "right" way to do things. They watch a demonstration eagerly and freely redemonstrate a skill; they ask many questions about equipment and procedures. Keep explanations short and words simple; a preschooler's attention span rarely exceeds 5 minutes.

In terms of cognitive development, preschool children "center" or notice only one characteristic of an object. This can limit their ability to learn all aspects of care or more than one method of doing something on any one day (Piaget, 1952).

Preschoolers tend to be frightened of intrusive procedures such as rectal temperature taking, bladder catheterization, or nasopharyngeal suction. They typically remove adhesive bandages minutes after application to check on the condition of their skin underneath (that it has not disappeared); they worry any blood removed may be the last they have. Teaching this type of procedure or explaining to children why it is necessary

calls for clear explanations and praise for learning. Use dolls or puppets to help children visualize details whenever possible because pointing to a place on a puppet's body is not as intrusive as pointing to the child's own body (Fig. 35.2 and Box 35.6).

**Figure 35.2** Teaching with dolls or toys can help to make an intrusive procedure seem less frightening for a preschooler.

#### BOX 35.6

#### Nursing Care Planning Tips for Effective Communication

Wolf Whitefeather is a 3-year-old boy scheduled for a syndactyly (webbed fingers) repair next week. You speak with him through a puppet at a clinic visit to assess his understanding of the surgery.

*Tip:* It is important to ask children about what they expect to have happen during surgery.

**Nurse:** Hello. I'm Nancy Nurse. Could you tell me what the little boy named Wolf is going to have done in surgery?

**Wolf:** His fingers got sick when he was born.

**Nurse:** When is he going to have them fixed?

**Wolf:** The day after we go to church.

**Nurse:** Is his surgery going to hurt?

**Wolf:** No. His fingers are going to be asleep.

**Nurse:** Will he have a big bandage afterward?

**Wolf:** So big he can't see how his fingers got cut off.

**Nurse:** Cut off?

**Wolf:** That's what happens to bad kids.

## The School-Age Child

School-age children enjoy short projects that offer an immediate reward. Therefore, they learn best if a procedure is broken down into different stages and presented as separate short steps. Because they enjoy games, playing “Simon Says” may be an effective way to have school-age children learn deep breathing.

School-age children are used to learning things and accept learning a new procedure or new information as just another experience in a busy day. The “staying power” of school-age children is notoriously short; however, the ability to continue to perform at the level taught tends to decrease sharply if learning is not reinforced. Be certain, therefore, that a support person in the home knows the healthcare information as well as the child so that person can reinforce it or carry out the procedure if necessary.

Toward the end of the school-age period, children become interested in doing only those things their friends are doing. Children may interpret as unreasonable, therefore, a request to do something after school (e.g., taking medication), whereas their friends are stopping at the playground or mall. Modify a teaching plan as necessary to help children fit what they must learn into their school and social schedule. Otherwise, the teaching may be very short lived.

As part of moral development, school-age children thrive on rules, or the “right way” to do things (Kohlberg, 1984). This means that if two or more people are going to be involved in teaching, they must be consistent in their approach because it is frustrating for school-age children to not have a “right way” to do something. Parents who have been supervising their child’s school learning through checking homework easily assume a role in supervising health learning also. Parents who haven’t been previously monitoring learning may need support to fulfill this role.

## The Adolescent

Adolescents, struggling for identity, like to learn things separately from their parents. As a rule, they can be responsible for their own self-care if they understand how the new action they have been taught will directly benefit them and, unlike school-age children, they will continue to carry out those actions conscientiously. Adolescents have a strong need to be exactly like their friends, however. This means they rarely continue any action that makes them different or conspicuous in front of their peers.

Remember, adolescents are also very present-oriented; they learn procedures and new information best if they can see how it will immediately benefit them. They learn poorly if the only benefit of new information presented to them is something that will affect them at some future date. Not rotating insulin injection sites, for example, will cause “pockmark” formations (*lipoatrophy*) in the skin by the time the child reaches adulthood. Given this information, adolescents tend not to rotate injection sites because the benefit is not relevant to them at that moment. An explanation such as “Rotating

injection sites will ensure insulin absorption and allow you to play basketball this semester,” which is an equally true statement, is a better adolescent motivator.

For the first time, adolescents are able to think abstractly or use scientific reasoning. This means they can create hypotheses (“what if” questions) and think through what will be the consequences of an action (Piaget, 1952). This allows them to understand the principle of what they are being taught and enforces the reason for the learning. Parents may find they are not as effective with teaching their child as they were when the child was younger. They may need to “step aside” and let you introduce a subject until a phase of adolescent rebellion passes.

### ***QSEN Checkpoint Question 35.3***

#### **QUALITY IMPROVEMENT**

The nurse wants Barry, age 16 years, to increase his cognitive understanding of his condition. After teaching sessions, which statement from him would best show that his cognitive knowledge has increased?

- a. “I feel so much better now about the care I need.”
- b. “I understand I have to take two types of medicine.”
- c. “I’ve finally learned how to swallow big capsules.”
- d. “I hate having to take medicine but will take it.”

*Look in Appendix A for the best answer and rationale.*

## **Developing and Implementing a Teaching Plan**

A teaching plan is a design of the content to be taught, the teaching/learning techniques to be used, and the evaluation method and tools to be used.

### **ASSESSING TEACHING/LEARNING NEEDS**

Designing a plan begins with assessment of the individual child’s needs and how the new knowledge will meld with the child’s and family’s lifestyle, the child’s intellectual and language level, current knowledge level, physical/cognitive capabilities, sociocultural values, and attention span.

### **FORMULATING THE PLAN**

Formulating a teaching plan begins with establishing expected outcomes and techniques of teaching. It may need to include communication strategies for parents as well as children.

### **Identifying Personal Strengths and Limitations**

When formulating a teaching plan, be honest about your capabilities. If you feel uncomfortable teaching a child about surgery with clever puppets dressed in scrub suits,

it might be better to avoid that approach because, in the wrong hands, such a method can sound so flat or complicated a child is left feeling more confused than comforted by the presentation.

Some health teaching involves giving instructions in areas of care that may be personally embarrassing, such as instructing a member of the opposite sex how to obtain a clean-catch urine specimen. Proceeding blindly may not result in effective teaching because the child may be so embarrassed by your discomfort that concentrating on instructions becomes difficult. In doing this type of teaching (as in any contact with a child), nothing serves you as well as honesty. Admit to children you are not used to giving this type of instruction. This approach will probably evoke a response from children that they are not used to having anyone talk about it either. Once you have found common ground, you have formed a basis for effective health teaching. Honesty also allows a child to recognize your discomfort is not from lack of knowledge on the subject (i.e., the child can trust what is being said) and is also not the child's fault (the subject, not the child, is the disturbing factor).

### **Preparing Expected Outcomes**

Planning outcomes is most effective when they are planned collaboratively with a child and family. They should reflect the type of learning desired: cognitive, psychomotor, or affective. They should help to establish both content and time guidelines based on both the child's cognitive ability to learn and the time frame available for teaching. It is unnecessary (and often overwhelming) for a child to learn everything about an illness in the first day or week after a diagnosis. Likewise, information on how to stay well does not need to be presented in one setting. In many instances, it is effective to teach only part of the information needed; another nurse in another setting, such as in an ambulatory clinic or in the child's home, can teach the remainder. For best results, state outcomes as behavioral objectives or as the activity the child is expected to demonstrate when the child has learned the new knowledge (i.e., not "Tim understands the importance of deep-breathing exercises daily" but "Tim does deep-breathing exercises daily").

### **Identifying Teaching Formats**

Teaching techniques vary with the content to be covered, teacher/learner characteristics, and the environment for teaching.

#### **Formal Versus Informal Teaching**

Because both formal and informal teaching formats can be effective in health education, careful consideration is necessary to determine which format would be the best technique to use for a given situation. An example of formal teaching would be conducting a class on healthy eating as part of a health education course. An example of informal teaching would be explaining to a child who refuses to eat that he needs to at

least drink something because, to get better, his body needs more fluids. Sometimes, informal teaching occurs so spontaneously, it is easy to be unaware it is happening. In response to a question such as “How long will I have to take this medicine?” If you answer “For 2 weeks,” you are just answering a question. If you answer, “For 2 weeks because . . . ,” you are health teaching.

Informal teaching, although communicated in a less structured way, requires the same teaching/learning principles as formal teaching—that is, knowing the subject, recognizing individual learning styles, providing an effective environment, and limiting time span. [Table 35.3](#) lists suggestions for incorporating informal teaching into care.

**TABLE 35.3 WAYS TO INCORPORATE INFORMAL TEACHING INTO NURSING CARE**

Activity	Type of Teaching
Medication administration	Children as young as early school age should know the type, action, and any expected side effects of all medication they are taking. Present medicine not by saying “Here is your pill” but rather “Here is your [name of medication]. It should help your temperature come back to normal. After you take this, you might feel yourself start to sweat. That means it’s working.”
Vital sign measurement	When taking vital signs such as blood pressure, temperature, and pulse, tell children what normal levels are, such as “Your blood pressure is 100/70 mmHg. That’s normal.” If the child is in a high-risk category for hypertension, add some prevention measures to teaching.
Any procedure	Always tell children the purpose and principle of procedures. For instance, do not say “You need to drink a lot of fluid” but rather “You need to drink a lot of fluid because . . . ”
Dressing changes	Dressing changes provide an opportunity to teach the danger of introducing infection into an open wound. The parents or child may not change this dressing, but they will apply bandages to small cuts in the future and so will benefit from teaching.
Mealtime	Provide information about nutrition, such as “I know you’re not hungry enough to eat the entire sandwich, but could you try the meat? Meat is high in protein and that’s important for healing.”
Hygiene	Emphasize the necessity for covering the mouth with a shirt sleeve to prevent the spread of upper respiratory infections or good perineal hygiene (i.e., wiping front to back in girls) to decrease the possibility of urinary tract infections.
Physical assessment	Assure children that their body parts are healthy as you examine them (e.g., “Your hair feels squeaky clean and strong”) as both

	education and reassurance. Explain the importance and technique of self-testicular examination.
Positioning	Don't just reposition children in bed. Teach the hazards of immobility and how a change of position and ambulation increases circulation and respiratory function.
Sleep	Teach that sleep is a healing therapy and so should not be considered a waste of time.
Bowel elimination	Teach children elimination patterns vary and that occasional variations in their elimination patterns are normal but stools should not be loose or black or painful.

### Group Versus Individual Teaching

Although most health teaching with children is done on an individual basis, teaching groups of children can be effective in some situations. Individual instruction more directly addresses a child's unique needs; group teaching can add depth to learning as children share information within the group. For many children, learning they are not the only person with their particular problem is very important to hear. Listening to a peer discuss how to solve a problem may be more meaningful than hearing the same information explained by an adult. Peer learning, therefore, not only improves knowledge but may also improve the child's attitude and motivation to learn (Deibel & Wagner, 2013).

Important guidelines for group teaching include:

1. Assess for common interests and goals so the information presented will appeal to as many in the group as possible.
2. Be certain all members of the group can see and hear all others and you.
3. Encourage all members of the group to participate by calling on individual members if necessary; use a question such as "Juan, you've been quiet. What do you think about that?"
4. Limit any one person from dominating the group by a statement such as "That's a good point, Reneé. Has anyone else had a similar experience?"
5. Avoid competition in the group. No one is always right; no one is always wrong.
6. Ask group members to evaluate the experience afterward to be certain it met the group's needs.

### Alternative Settings Versus Institutional Teaching

Health teaching in a healthcare agency usually focuses on immediate, acute care concerns. Teaching in a school may focus on topics such as basic health promotion and hygiene, reproductive and sex education, and drug abuse prevention. Teaching in the home may focus on medication regimens, dressing changes, or measures to prevent

complications of a particular illness. It may also involve helping a child and parents adapt a procedure to the home setting, such as accommodating a wheelchair or oxygen therapy. Be certain parents know how to obtain the supplies they will need to learn and perform the procedure in the home.

Teaching in the home offers the advantage of being able to assess a child's environment, interactions with other family members, and overall family functioning. This may yield data that prove useful to further planning and implementation of care. It may also provide an opportunity to include other family members—siblings, grandparents, and so forth—in the teaching plan; this can strengthen the impact of teaching and ensure all family members understand the procedures in the same way. Always include evaluation as a step of teaching in all settings so you can feel confident that learning has occurred.

### *What If . . . 35.2*

**The nurse organizes a discussion group of adolescents on special diets so they can learn more about healthy nutrition in general. Barry, who needs to follow a low-cholesterol diet, says he won't participate in the group because nutrition is a "childish" subject. Would the nurse insist he come to the meetings, or take the extra time to teach good nutrition to Barry at his bedside?**

## **Determining Teaching Strategies**

Because children's knowledge base, capabilities, learning styles, and attention spans vary so much, teaching strategies are most effective when they are both intermixed and selected in response to the individual child to be taught. The more interactive the method, the more appealing it is apt to be.

### **Lecture**

Lecture (or directly explaining information) is the most efficient and time-saving method of offering information to both individual children and to groups. A lecture, however, does not allow for much participation, and it is effective only in short, well-structured periods. It is rarely effective for children who are not yet school age.

### **Demonstration**

**Demonstration** is actually performing a procedure, such as a dressing change or instillation of eye drops, so the child can clearly see how the procedure should be done. Do not demonstrate a procedure unless you have all the necessary equipment to do it. If you have to stop in the middle of a demonstration to say, "Be sure to use a sterile syringe, not what I'm using," the poor technique demonstrated may be the lesson learned, not the good technique. The purpose of demonstration is to show how the

procedure is actually done; having to imagine steps is little different than reading about it. School-age children, because of their stage of cognitive development (i.e., concrete operations), learn best by demonstration.

### Redemonstration

To determine whether a child has truly grasped a demonstration, ask the child to perform a **redemonstration**, or an exact imitation of the procedure (Fig. 35.3). This is best if it immediately follows demonstration. Praise the effort to redemonstrate even if the redemonstration was not of the quality desired. No one likes to be put on the spot, and children may be unwilling to expose themselves again by a second redemonstration if criticized. Children do not have to follow your motions exactly because there are many different ways to do almost everything as long as their technique accomplishes the same goal. An effective way to correct a wrong action is to say, “That’s one way of doing that; you might find it easier, though, to . . . .” This type of criticism is nonthreatening because it acknowledges the child’s effort in a positive way before offering a correction.

**Figure 35.3** A school-age child redemonstrates blood glucose monitoring.

### Discussion

Discussion is a shared learning experience in which children ask questions about particular concerns and you answer based on the child’s individual circumstances. At the end of the discussion, hopefully all questions are answered and the problems are solved. The first time children are introduced to a subject, they tend to ask few questions because they do not know enough about the illness or health issue as yet to

anticipate concerns. As their knowledge increases, so does their ability to project and modify information to fit their own lifestyle. Remember, children tend to think in the present: A problem that will arise once tomorrow is usually viewed as more important than one that can be predicted will arise repeatedly in years to come. Because this technique recognizes and respects their opinions, school-age children and adolescents enjoy discussion.

## Role Modeling

Role modeling is demonstrating a certain attitude or behavior that you want a child to learn. Be certain when health teaching not only to present facts but also to radiate a positive role-modeling attitude because children pick up on role modeling cues as readily as a spoken message. Showing annoyance at getting a bubble out of a syringe demonstrates, for example, that giving injections is frustrating; showing a bored attitude toward nutrition implies eating well is boring.

Role modeling is an important technique used to teach new parents newborn care; as they watch a nurse hold, comfort, and talk to their newborn, they quickly learn to model these behaviors.

## Behavioral Therapy

Typically, learning occurs best with **positive reinforcement** (e.g., a child tries to understand a new procedure, is praised for the effort, and tries even harder). **Behavioral therapy**, also called *behavior modification*, is a term used for a system aimed at *erasing* some form of behavior that interferes with healthy functioning. It was originally designed to help people who are cognitively challenged erase socially unacceptable behavior. Currently, it has many uses, including as a way to control disruptive classroom behavior. The basic premise of behavior modification is that a child is rewarded for healthful behavior, whereas unhealthful behavior is ignored or unrewarded. For example, a child who are cognitively challenged may have a socially unacceptable habit of constantly rocking back and forth. The child is not scolded or criticized for rocking, but the action is ignored. The preferred behavior (e.g., sitting for 5 minutes without rocking), however, is praised. Children respond best to behavior modification if, in addition to praise, they receive a tangible reward such as a star on a chart or an extra privilege for good behavior.

A behavior modification program must be discussed with the child before it is begun because no behavior can be modified—just as no new behavior can be learned—until a child truly wants a change to occur. It might be necessary to ask older children to sign a learning contract to be certain both teacher and learner agree on the method to be used. Many older children are able to use self-rewards to reinforce a behavior modification program such as rewarding themselves by playing a video game or going to a movie after an afternoon of efficient studying or an hour of doing breathing exercises.

Behavior modification must be used with common sense and concern so children

are not being manipulated more than they are being helped to achieve a more healthful lifestyle. It is a legitimate device to use to encourage children to do as much self-care as possible or to reduce anxiety disorders (Wergeland, Fjermestad, Marin, et al., 2016).

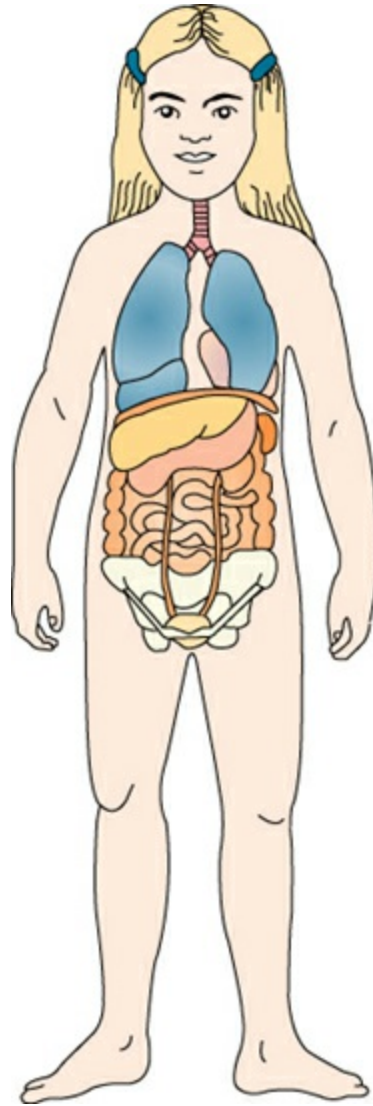

Trying to modify beliefs or values, not actions, by behavior modification is considered unethical and is one reason why behavior modification is often criticized as a learning technique for children. However, some behavior changes also require a change in values to be effective and long term. For example, a child's behavior of talking back to parents can be extinguished by ignoring or not responding to the behavior and by praising polite communication. This method teaches the child to value improved communication and parental approval in order to meet his or her needs.

### Selecting Teaching Tools

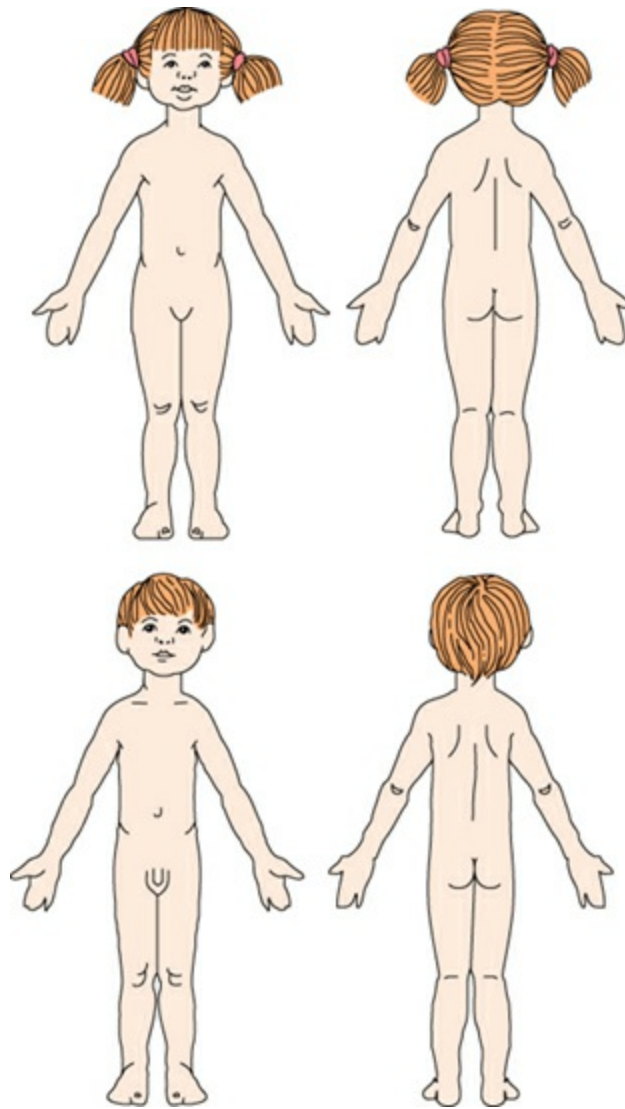

Teaching tools are the mechanical devices used to present content. They vary based on content, teacher/learner characteristics, and environment.

#### Visual Aids

“A picture is worth a thousand words” is not an idle quotation but a realistic one. Because small children know little about their bodies or where body organs are located, using visual aids such as drawings or photographs of anatomy can be very helpful to explain disease. [Figure 35.4](#) shows abdominal contents as an example of such a drawing. You could use such an illustration to show a preschooler how food moves through the body. [Figure 35.5](#) is an example of a good tool to use while naming body parts. Pointing to a figure drawing and saying, “This is the part of your tummy you’re going to have fixed,” is less threatening than actually pointing to the child’s abdomen. Clarifying body parts this way is important because young children may have no clear understanding of where a body part such as a hand ends and an arm begins.

**Figure 35.4** Anatomic drawings are helpful to illustrate basic health education topics and healthcare procedures.

**Figure 35.5** Simple line drawings such as these can be used to explain to a child exactly what part of his or her body will be “fixed” in surgery. For many children, having this pointed out on a drawing seems much less intrusive than having it pointed to on their own bodies.

Do not be afraid to draw a picture of a heart, a kidney, a bladder, or any other organ to make a point about anatomic structure. Children are more interested in understanding procedures or the reason for a health maintenance measure than criticizing your artwork because they likely do not know anatomy well enough to be able to tell if a drawing is distorted.

### Pamphlets

Pamphlets or information sheets are helpful teaching aids with school-age children, adolescents, and parents (Pile, 2013). These usually contain brief, easy to read, and easily understood information and are often cleverly illustrated with cartoon characters

to make them enjoyable for a wide age range. Be certain to read any pamphlet before you offer it to a child to be certain the information included in it is accurate. Medical advances occur so quickly that a 1-year-old pamphlet may contain a gross inaccuracy in the light of subsequent knowledge.

If a pamphlet contains some statements that are inaccurate or do not apply to a child, do not simply cross out the information that would be contradictory before offering it (most children deliberately read what they have been told not to read). Instead, take the time to explain why it doesn't apply. Also, do not be misled into believing that because children are given clever pamphlets, they will necessarily read them and learn from them. Sit with a school-age child and read the pamphlet together. Talk with an adolescent about the pamphlet's contents later to ensure it was not just tossed aside.

## Learning Games

For memorizing certain kinds of information, such as what foods are high or low in potassium or sodium, flash cards can be a helpful learning tool. Many children older than 10 years of age (the age the average child is ready for competition) enjoy playing trivia-type board games. For health teaching, instead of using the game's categories of information, make up new cards with questions such as "Where is insulin produced in your body?" Children learn information quickly this way because the reward for learning is immediate (e.g., they get to move their token on the board). Having parents play the game with their child can effectively educate parents at the same time.

Word scrambles are easy games to develop. Crossword puzzles are fairly easy to design; one might be developed to address the important activities for a child to do after surgery such as deep breathing, exercising legs, and not eating immediately.

## Videos

Many healthcare agencies, homes, schools, and community centers have video playback equipment, such as a DVD player, that can be used to show a short video or PowerPoint presentation as part of a health education program. Most households have CD or DVD players, so discs can be sent home for families to view. Viewing such programs can offer children a sense of power in that the program seems to be talking directly to them. Such a program can also be used over and over to refresh children's knowledge of the steps they need to take to remain well (Aljafari, Rice, Gallagher, et al., 2015). As with pamphlets, view the material first before showing it to a child and be certain the vocabulary used will be appropriate for an individual child or family.

Playing video or electronic games can be used to urge children to exercise, although the worth of these must be carefully compared to more traditional forms of exercise such as walking or joining a sports team (Gao, Chen, Pasco, et al., 2015).

### *QSEN Checkpoint Question 35.4*

#### **SAFETY**

The nurse wants to teach Barry more about his hypercholesterolemia, and he has expressed a preference for video resources. To ensure that such videos are safe, age-appropriate, and accurate, the nurse should do which action?

- a. Preview any potential video resources before referring them to Barry.
- b. Encourage Barry to search YouTube and then report back to you.
- c. Emphasize the fact that written materials are usually preferable to video materials.
- d. Refer Barry to his local public library and have him liaise with a librarian.

---

*Look in [Appendix A](#) for the best answer and rationale.*

---

## Puppets and Dolls

Many children are shy about talking to strangers. This shyness, in addition to their concern about what will happen to them, may make it difficult for them to discuss or explain what they know about their health, illness, or intended surgery. However, they may be able to open up to an uncritical puppet or doll because they see this as a usual part of play (Sposito, Silva-Rodrigues, de Cássia Sparapani, et al., 2015). [Box 35.7](#) shows an interprofessional care map illustrating both nursing and team planning for a preschooler having surgery. Preschool children are particularly receptive to puppets and dolls because, with their imagination at its peak, they believe the puppet or doll is actually talking to them.

### BOX 35.7

#### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR A PRESCHOOLER HAVING SURGERY

Wolf Whitefeather is a 3-year-old boy who is scheduled for repair of syndactyly (webbed fingers) next week.

**Family Assessment:** Patient lives with mother in two-bedroom mobile home. Parents separated. Mother works at local hospital in medical billing. Grandmother does child care 4 hours a day; child attends Head Start program in afternoon. Mother describes finances as “I’m making it.” Father will visit after surgery; mother has custodial authority.

**Patient Assessment:** Favorite activity: coloring. His mother is concerned Wolf will be hard to entertain after surgery because the large pressure bandage he will have in place will prevent him from using that hand. “I don’t even want to begin to talk to him about surgery,” she added. When nervous or frightened, child has a habit of biting his hand; he has done this constantly since admission.

**Nursing Diagnosis:** Deficient knowledge related to what to expect in surgery

**Outcome Criteria:** Child describes expected outcomes of surgery. Demonstrates a

minimum of nervous behaviors such as biting hand, can play “Simon Says” for hand exercises postsurgery, and describes how pain will be relieved by a “special button” (patient-controlled analgesia).

**Teaching Points:** Child is shy with strangers; mother states he learns best by “hands-on” experiences; “cocks head” when puzzled. Also learns better from his mother than from his father (father tends to be authoritarian).

**Cognitive Learning to Be Taught:** Why surgery is necessary

**Psychomotor Skills to Be Taught:** To keep hand in elevated position after surgery

**Affective Aspects to Be Taught:** Accepts surgery as a growth experience

<b>Team Member Responsible</b>				
<b>Responsible</b>	<b>Assessment</b>	<b>Intervention</b>	<b>Rationale</b>	<b>Expected Outcome</b>
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess what child and parent understand about care necessary postoperatively.	Introduce postoperative hand exercises child will need to do by playing “Simon Says.”	Games are an appealing way to keep the preschooler interested and motivated in doing exercises.	Child demonstrates opening and closing hand to help prevent contractions postprocedure.
<i>Teamwork and Collaboration</i>				
Nurse/surgical healthcare provider	Assess which anesthesia team member will be available for operating room and postoperative pain management.	Request anesthesia/analgesia consult.	Child is too young to be cooperative during surgery; needs pain relief afterward.	Anesthesia service meets with child and parent; determines best form of pain management and anesthesia.
<i>Procedures/Medications for Quality Improvement</i>				
Nurse/surgical healthcare provider	Assess health history.	Complete the physical exam.	Health assessment helps ensure readiness for surgery.	Child cooperates with the history and exam.
Nurse	Assess Wolf’s	Introduce dressing	Therapeutic	Child

	and parent's knowledge of surgery and postoperative procedures.	and show how child's hand will be suspended postoperatively by letting Wolf dress and suspend puppet's hand.	play provides an excellent medium for teaching and learning with toddlers and preschoolers.	demonstrates he understands how hand will be positioned by showing position with puppet.
--	---	--	---	--

*Nutrition*

Nurse	Assess if child and parent know child will be nothing by mouth (NPO) for general anesthesia for surgery.	Teach parent importance of NPO preoperatively and immediately postoperatively.	Maintaining NPO status helps prevent aspiration with anesthesia.	Child and parent state they understand need for NPO status and will adhere to requirement.
-------	--	--	--	--

*Patient-Centered Care*

Nurse	Assess child's cognitive level and ability to learn and who is child's main support person.	Using puppets, teach that the child's hand will be washed with antiseptic solution before surgery.	Reducing skin bacteria prior to surgery can help prevent osteomyelitis.	Child cooperates with preprocedure washes. Names mother as person he wants with him.
-------	---	--	---	--

*Psychosocial/Spiritual/Emotional Needs*

Nurse/pain management team member	Assess what past experiences, if any, the child has had with pain.	Teach child he will have pain after surgery, but it can be relieved by a "special button" on his intravenous pump.	Explaining how pain will be relieved before surgery can help reduce amount of stress after surgery.	Child and parent state they know there will be pain and understand method to be used for control.
-----------------------------------	--	--	---	---

*Informatics for Seamless Healthcare Planning*

Nurse	Assess if child and parent feel equipped to	Review with parent a schedule of care based on Head Start	Helping a parent walk through how	Mother states she has a plan for how to
-------	---	---	-----------------------------------	---

change bandages, carry out hand exercises at home, and have return appointment.	and grandmother involvement.	postprocedure activities can be managed helps ensure adherence.	consistently arrange care given by three caregivers and will keep return appointment.
---	---------------------------------	---	--

Teaching preschool children about what to expect from a hospital experience is often taught by using a series of puppets or dolls to represent different hospital personnel such as a surgeon, a nurse, and a nurse’s assistant. Children can practice giving the doll “shots” or submitting it to the procedures they will experience (see [Chapter 36](#) for a discussion of therapeutic play).

### Mass Media

Television and radio are examples of effective mass media that are used to teach many children about self-help or self-care. Consulting on the topics to present or helping develop the material used in these types of health messages can be an important role for nurses. Messages originated for these media must be attention getting and brief to compete with the programs and commercial messages that precede or follow them.

### Computers and Internet

Many children learn to solve problems using computers as early as preschool age. Using an Internet application to answer questions about an illness or prepare children for surgery is effective because this type of activity can be both entertaining and informative ([Kain, Fortier, Chorney, et al., 2015](#)). Caution children not all information posted on the Web is reliable, and participating in chat rooms can lead not only to the information they were seeking but also to exposure to Internet predators ([Briggs, Simon, & Simonsen, 2011](#)). Giving the family a list of appropriate YouTube videos or website addresses can also support learning at home.

### Preparing Teaching Supplies

To avoid having to reorganize equipment or instructions each time a procedure is taught, put together a basket or box containing all the information and equipment needed to teach a particular task. This helps ensure that teaching will not only be organized but also economical in that everyone on a hospital unit is not opening new equipment for demonstrations. It also helps to ensure everyone is teaching the same information. Nothing is more confusing to someone learning a new skill than to be taught two different principles or techniques for doing something.

## IMPLEMENTING THE PLAN

Health teaching can begin immediately after contact with a child and should flow easily if goals have been well developed and strategies for teaching have been carefully designed.

### Using Designated Teachers

Many healthcare agencies, including home care agencies, have specific people who are available for health teaching about specific subjects such as diabetes, stomal care, respiratory exercises, or drug abuse prevention. Using such people is helpful because they know all the “tricks of the trade” for teaching that particular subject.

Some children do not learn as well from such designated teachers, however, because they see them only infrequently, unlike a primary nurse, whom they may see daily. Some parents react badly to the thought that if it takes an expert to tell them about the care needed, how can they possibly learn it? They may also find it inconvenient to be told their questions cannot be answered until the following day when the designated teacher is available to answer them. Be certain if a designated teacher does teach a subject, you coordinate your teaching with that person. Make a point of introducing the person to the child so the child does not view the person as a suspicious stranger.

### *QSEN Checkpoint Question 35.5*

#### **EVIDENCE-BASED PRACTICE**

Preparing children, through the use of parental preparation, for surgery can vary in effectiveness depending on the method of education. A study was conducted to determine if a preoperative DVD instructional program could have an effect on parental knowledge, participation, and anxiety and thereby reduce the distress, pain, analgesic requirements, and length of recovery in a child undergoing same day surgery. The DVD intervention was provided to 123 parent–children (ages 3 to 10 years) dyads undergoing same-day surgery, whereas the control group received standard care. Parents in the intervention group demonstrated an increase in knowledge, provided more positive reinforcement, and increased their use of distraction and relaxation methods toward their child as compared with the control group. The children’s postoperative pain was significantly lower in the intervention group as compared with the intervention group ([Chartrand, Tourigny, & MacCormick, 2017](#)).

Based on the previous study, what does the nurse determine for Wolf, 3 years old, if he seemed exceptionally anxious before surgery?

- a. Face-to-face instruction is preferable because it is most effective.
- b. He has no reason to feel anxious because 1-day surgery is finished so quickly.
- c. He should be given the choice between a Web-based/DVD program or face-to-face instruction.
- d. He, like most preschoolers, is too young to understand an explanation of his surgery.

---

Look in *Appendix A* for the best answer and rationale.

---

## Parent Education

With very young children, parents as well as children need teaching. It's good practice with all children to be certain at least one adult in the household has the necessary information or can perform the required skill as well as the child. If at all possible, allowing for cultural beliefs that may dictate child care responsibilities in the family, let the child choose this person because the individual who everyone assumes is a child's chief support person may not be the person the child perceives as the most reliable choice for a healthcare backup. This person, when identified, needs as much information as the child about why the health measure is important.

### *What If . . . 35.3*

**Wolf, 3 years old, refuses to tell the nurse whether he has pain because the nurse is a “stranger” and he doesn't talk to strangers. How would the nurse best respond?**

## EVALUATING THE EFFECTIVENESS OF TEACHING

*Evaluation*, or assessing whether teaching has been effective, is the final step in teaching. It is optimum if evaluation occurs not only after the teaching plan has been implemented but also throughout the entire learning process. This ongoing evaluation helps both teacher and learner modify the teaching plan to better meet changing needs.

There is some advantage in asking children questions before and after teaching to prove teaching was effective and the child has safely learned a new healthcare measure. Demonstration of a change of behavior or attitude, however, is the real proof learning has occurred.

### *QSEN Checkpoint Question 35.6*

#### **TEAMWORK & COLLABORATION**

The nurse wants Wolf, 3 years of age, to know how to do the hand exercises he will need to do after surgery. When collaborating with the physiotherapist, which technique below would probably be most effective with Wolf?

- A pamphlet you read together
- A lecture from a sports hero
- Playing a game of Simon Says
- A group discussion on hand pain

---

Look in *Appendix A* for the best answer and rationale.

## Health Teaching for a Surgical Experience

Teaching to prepare a child for surgery is an example of teaching that requires planning for several stages of learning. The child and the child's parents often feel anxious about surgery because this is always a potentially frightening experience. Therefore, teaching must first address this anxiety. Such preparation differs according to the type of surgery being performed, but certain activities apply to all surgery and all children.

A psychological preparation of both the child and the parents is aimed at reducing a child's fears about the procedure and consists primarily of providing health teaching and opportunities for therapeutic play. A physical preparation includes providing for restrictions on food and fluid intake before surgery, preparing the incision site on the child's skin, and arranging for transportation of the child to surgery. Because many children's surgical procedures are done on an ambulatory basis, parents often perform a part of physical preparation in preparation for the surgery as well as postoperative care and so must have clear instructions as to their responsibility. Do not downplay a family's fears but allow the child and family opportunities to express their concerns as part of the teaching/learning process.

### ASSESSING CURRENT LEVEL OF KNOWLEDGE

On admission to the healthcare setting, whether the surgery will include a 1-day or longer hospitalization experience, elicit from parents what preparation they have made for this experience and what specifically they have told their child about what will happen. It's good to also ask whether a child's concerns about the experience seem more or less than the parents had anticipated. To see if the child is emotionally prepared, ask if there has been an unpleasant surgery or hospitalization in the family recently the child might have heard discussed or if the child has seen anything recently on a medical show on TV that might have been upsetting?

### Emotional Preparation

Preparing a child emotionally for surgery requires minimizing fears common to all children such as fear of separation, fear of mutilation, or fear of death. Give careful explanations of what the procedure will entail and describe any specific equipment or techniques that will be used, such as anesthesia, eye bandages, nasogastric tubes, sutures, or special aftercare. Be certain all preparation is appropriate to the child's age. Most children who need surgery receive a general anesthetic rather than a local or regional anesthetic, as might be used with adults, because this minimizes their fears of intrusive or mutilating procedures, and because children who are not yet adolescent are not mature enough to cooperate adequately during surgery if they are not fully anesthetized.

It is best to prepare a child for a major experience like this in stages rather than all at once because it is difficult to absorb so much information in a short time span. However, contact before surgery may be limited to only one office or clinic visit, or the

morning of surgery, so time constraints can force information to be more compacted.

Be certain to discuss presurgery preparations such as necessary blood work and not eating in the morning of surgery. If the child will have general anesthesia, it is important to emphasize that anesthetized sleep is “special” sleep. Otherwise, toddlers or preschoolers may be reluctant to fall asleep after surgery for fear people will come and do strange things to them. Do not say a child will be “put to sleep” (dogs and cats that are “put to sleep” are never seen again). To help prepare a young child for surgery, a doll’s abdomen could be washed, a hospital gown put on, and an injection given to make the doll sleepy. It could be carried to a cart made from a cardboard box. After saying goodbye to its parents, the doll could be wheeled to surgery by a puppet nurse.

The surgery procedure should be discussed but minimized. “After you’re asleep, the doctor will fix your tummy. You won’t feel anything because of the special sleep. When you wake up, you’ll be in a room called a recovery room where you’ll stay until you’re wide awake.” Be honest concerning pain: “Your tummy will feel sore afterward, but I’ll give you something to make it feel better” is a fair statement.

It is important to alert children that personnel in surgery wear surgical masks. Assure toddlers and preschoolers the persons behind the masks are doctors and nurses, some of whom the child has probably already met, not superheroes or bandits.

It is also good to mention recovery rooms in preparation because this is often an area parents neglect to mention. In fact, parents may not be aware that in some institutions, they will not be allowed in the recovery room and may have promised the child, “As soon as you wake up, I’ll be there.” Clarify the parents’ misconceptions about recovery rooms and reiterate the child will get to see his parents back in his own room once he is fully awake. This both makes the parents’ preparation correct and saves the child from feeling deceived.

Explain postsurgery items, such as the use of oxygen, monitors, bedpans, bandages, or intravenous equipment. Furnishing a doll with such equipment is especially helpful in preparing younger children (Fig. 35.6). This play level is less stressful for preschoolers rather than being taken to an intensive care unit where they can feel overwhelmed by the sight of actual monitors and ventilators. After surgery, be certain to evaluate whether a child’s preparation was adequate, both to document the experience was as trauma free as it could have been and to evaluate your expertise in teaching children.

**Figure 35.6** Pretending to be a pirate helps this young child prepare for having to wear an eye patch after surgery.

#### *What If... 35.4*

The nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to communication and teaching with children (see [Box 35.1](#)). What would be a possible research topic to explore pertinent to this goal that would be applicable to Barry's or Wolf's family and that would also advance evidence-based practice?

### Unfolding Patient Stories: Sabina Vasquez • Part 1

**Sabina Vasquez** is 5 years old and was diagnosed with asthma at age 3 while living in Mexico. Now living in the United States, she is at her first visit to the primary care provider's office with asthma symptoms, and the mother shows the nurse Sabina's albuterol inhaler. The family is learning English, but Spanish is the primary language spoken at home. What decision making by the nurse determines if an interpreter is needed to assess the family's knowledge of asthma and to provide asthma-related patient education? What appropriate age-related strategies should be used in planning asthma education for this patient and her family? (Sabina Vasquez's story continues in [Chapter 40](#).)

Care for Sabina and other patients in a realistic virtual environment: *vSim for Nursing* ([thepoint.lww.com/vSimMaternityPed](http://thepoint.lww.com/vSimMaternityPed)). Practice documenting these patients' care in DocuCare ([thepoint.lww.com/DocuCareEHR](http://thepoint.lww.com/DocuCareEHR)).

## KEY POINTS FOR REVIEW

- Communication is the exchange of ideas between two or more persons. It can be verbal or nonverbal.
- Therapeutic communication is a planned interaction, has structure, and is constructive. Nontherapeutic communication lacks deliberate purpose other than socializing.
- Successful communication requires an encoder, a code, a decoder, and feedback or a response.
- Levels of communication include: (1) cliché, (2) fact reporting, (3) shared ideas, (4) shared feelings, and (5) peak communication.
- Typical methods of nonverbal communication are using distance, gestures, body posture, touch, use of drawings, and empathy.
- Techniques that encourage therapeutic communication are attentive listening, open-ended questions, reflecting, clarifying, paraphrasing, perception checking, focusing, supportive statements, and silence.
- Some situations require special communication techniques such as interacting with demanding or shy children, children who are visually or hearing challenged, or children who are not proficient in English.
- Establishing a teacher–learner relationship based on mutual input and setting expected outcomes are effective ways to meet the unique needs and goals of a child and family as well as to help in planning nursing care that meets QSEN competencies.
- There are three types of learning: cognitive, psychomotor, and affective. For something to be learned well, all of these areas may need to be involved.
- To individualize a teaching program for a child, assess the child’s attention span, cognitive or intellectual capability, lifestyle, and learning style and your own teaching strengths and limitations.
- In many instances, there is a great deal of material a child must learn about an illness. If possible, divide material into lessons that can be taught immediately and lessons that can be taught at return health visits.
- The format and strategies of teaching used with children vary depending on a child’s age and developmental level. Various types to consider are formal versus informal, single or group teaching, lecture, discussion, and role-playing.
- Behavior modification is a special technique aimed at erasing some form of behavior that interferes with good health.
- Children learn many other things besides health information every day. This may make the retention of information not as great as you would like. You may need to schedule frequent reviews and updates to keep information current.

## CRITICAL THINKING CARE STUDY

Lucy is a 7-year-old who is scheduled to have her tonsils removed. She lives with her

mother and father in a central city apartment. Her father works as a taxi driver. Her mother is a stay-at-home mom. Lucy is home schooled because she is cognitively challenged due to a birth injury and because she doesn't want other children to "laugh at her because she's in a special class." Her mother does not know her exact developmental age but says, "She can't begin to comprehend" second-grade work. Because Lucy is becoming overweight, you'd like to teach her more about the importance of exercise, so hopefully she can include some every day into her home schooling schedule.

1. You schedule a hospital tour every week for children who will have a tonsillectomy the following week. Lucy's mother replies she doesn't want to take advantage of this learning opportunity. Are you surprised by this? Is declining the tour in Lucy's best interest?
2. Following Lucy's tonsillectomy, you bring your teaching basket about exercise to her bedside. Lucy refuses to look at anything you show her; instead, she just concentrates on putting shoes on her doll. Would you continue teaching?
3. Lucy's mother has told you she doesn't know Lucy's developmental age. Would it be important for her to have a psychology consult prior to surgery so you could be certain your preparation for surgery will be effective?

UNIT 6

The Nursing Role in Supporting the  
Health of Ill Children and Their  
Families

## Nursing Care of a Family With an Ill Child

*Becky is a 7-year-old whose foot was unintentionally burned by a campfire. She is going to be admitted to the hospital for a 1-day surgery to have the wound debrided. Becky's parents tell you that Becky "hasn't been herself" since the injury. She has reverted to temper tantrums and sulking, more like a 3-year-old than one of school age. Even though she has been told eating meat is important because it provides protein for healing, she refuses to eat anything but Jell-O or soup. In the admission suite of the hospital, she picked up a doll and twisted its leg off. "How can we get our old daughter back again?" her mother asks you.*

*Previous chapters described the normal growth and development of children and their special needs at each stage of development. This chapter adds information about the additional needs of children when they become ill. Such information builds a basis for nursing care and health teaching.*

**Becky is obviously showing some effects of her unintentional injury. What type of additional explanation might be helpful to her? What advice would you give her mother to help her better prepare Becky for the upcoming debridement procedure?**

### KEY TERMS

calorie counting  
 case management nursing  
 non-rapid eye movement (NREM) sleep  
 play therapy  
 primary nursing  
 rapid eye movement (REM) sleep  
 sensory deprivation  
 sensory overload  
 sleep deprivation  
 therapeutic play

### OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe illness and illness experiences as they must appear to children.
2. Identify 2020 National Health Goals related to the care of ill children that nurses can help the nation achieve.
3. Assess the impact of an illness, especially one requiring a hospital stay, on a child.
4. Formulate nursing diagnoses related to the stress of illness in children.
5. Establish expected outcomes for an ill child to help manage a childhood illness as well as manage seamless transitions across differing healthcare settings.
6. Plan nursing care to reduce the stress of illness, such as helping parents plan for ambulatory care or therapeutic play.
7. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of a child's response to illness with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

Illnesses that require the attention of healthcare professionals are outside the usual occurrences of childhood, so most children typically have little knowledge about them. Helping a child and family prepare for or adjust to such an experience is a fundamental nursing role. This role goes well beyond just providing information on what to expect throughout an illness. It involves providing emotional support as well.

Studies from the 1980s and 1990s found that family visitation was associated with lower anxiety levels among adult postanesthesia care unit (PACU) patients, and similar results have been found among pediatric patients. The literature has repeatedly shown that unrestricted visitation in healthcare settings increases family satisfaction, improves children's morale, and can improve communication among the staff, the patient, and the family (Houle, Belew, & Miller, 2015). In response to this, children and families should be enrolled in orientation programs before hospital admission, and nurses should advocate for the use of therapeutic play and be more open to parental visiting and overnight stay policies, even in intensive care areas, if these are not already in effect (Zempsky, Palermo, Corsi, et al., 2013). In addition, nurses can help families establish a therapeutic environment for the care of an ill child in the home after a hospitalization. **Box 36.1** shows 2020 National Health Goals concerned with children and illness.

**BOX 36.1**

**Nursing Care Planning Based on 2020 National Health Goals**

Illness and hospitalization can be major stressors for children; therefore, three 2020 National Health Goals address this:

- Increase the proportion of children with special healthcare needs who have access to a medical home from 47.1% to 51.8%.
- Increase the proportion of children aged 0 to 11 years with special healthcare needs who receive their care in family-centered, comprehensive, and coordinated systems from 20.4% to 22.4%.
- Increase the proportion of children aged 0 to 11 years with special healthcare needs who receive their care in family-centered, comprehensive, and coordinated systems from 20.4% to 22.4% (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by helping reduce the stress of hospitalization or health care so families use preventive services to help children stay well rather than totally use emergent or ill child care services.

## *Nursing Process Overview*

### FOR AN ILL CHILD

#### **ASSESSMENT**

An assessment for a child diagnosed with an illness that requires hospitalization begins with an interview of the child and parents to identify ways they think the illness will change their lives. This could include a wide range of situations such as increased expenses, changes in schedules to visit or stay with a hospitalized child, the need for one parent to take a leave from work to care for an ill child at home, the need to schedule frequent ambulatory visits, consultation to handle body image changes, and the need to arrange for child care for other children. Because these needs change as the course of an illness changes, the assessment must be ongoing.

#### **NURSING DIAGNOSIS**

Nursing diagnoses vary greatly depending on the extent of a child's illness, the care needed, and the age of the child. Those often used with families of children seen in ambulatory and in-hospital settings include:

- Health-seeking behaviors related to lack of knowledge regarding illness
- Anxiety related to pending hospital admission
- Risk for social isolation related to hospitalization
- Fear related to being away from home for the first time
- Activity intolerance related to fatigue from illness
- Potential for unintentional injury related to high-tech therapy equipment

#### **OUTCOME IDENTIFICATION AND PLANNING**

Planning for the care of an ill child requires consideration of all aspects of the child's and the family's life: financial, social, and personal. When children become ill, many

of their needs, such as those for nutrition, play, and family support, change. If a child will need long-term care or hospitalization, the entire family may find their priorities changing. Identifying additional needs and putting in place necessary services or interventions is an important nursing role.

Helpful resources and support programs that address the needs of the ill child and their families are available. Refer families to online resources for further information when appropriate.

Mayo Clinic: educates and instructs parents on procedure preparation	<a href="http://www.mayoclinic.com">www.mayoclinic.com</a>

## IMPLEMENTATION

Five hazards that may occur with children with all illnesses are (1) experiencing harm or injury, such as physical discomfort, pain, mutilation, and death; (2) being separated from routines, parents, peers, and respected adults; (3) facing the unknown (new and strange sights and sounds and happenings); (4) facing uncertain limits (unclear definition of acceptable and expected behavior); and (5) experiencing a loss of control (loss of competence or loss of the ability to make decisions).

Being aware of these potential concerns is important to guard against those that are preventable and to reduce a child's concern associated with those that cannot be prevented (such as facing new sights and sounds). Discussing these hazards with children based on their developmental age is important so that implementations to reduce their impact can be tailored to each child. Based on the child's developmental age, methods for assessing these potential concerns and introducing effective strategies to help the child cope may include reading to a child, role-playing, and puppetry.

## OUTCOME EVALUATION

An evaluation of expected outcomes for ill children should include specific measures such as whether discomfort was kept to a minimum during the experience. Indicators to evaluate outcomes that are long term should include whether children were able to return to usual behaviors after the experience. The following are examples that suggest achievement of outcomes regarding a hospital experience:

- Parents state their level of anxiety regarding hospitalization of their infant is now at a tolerable level.
- Parents have effectively changed work schedules to be able to stay with their child in the hospital.
- Social isolation of a toddler is minimized through a case manager nursing assignment.

## The Meaning of Illness to Children

The response of children to illness depends on their cognitive ability, past experiences, and level of knowledge. It parallels cognitive development (see [Chapter 28](#)). From early school age, children generally know quite a bit about the workings of their major body parts. As general guidelines, early grade-school children are usually able to name the function of the heart, lungs, and stomach. However, children are not able to see the body as a system until the age of 10 to 11 years ([Bibace & Walsh, 1980](#)).

Younger children may think the cause of illness is magical or that it occurs as a consequence of breaking a rule. With this perspective, they may also think getting well again is possible only if they follow another set of rules, such as staying in bed and taking medicine. By fourth grade, children are generally aware of the role germs play in illness but may be fooled by thinking that all illnesses are caused by germs. Because of this, they may see a passive role for themselves in getting well because illness comes from outside influences. At about eighth grade, children are able to voice an understanding that illnesses can occur from several causes, such as being susceptible to chickenpox because they did not get a vaccine. This understanding is due to the formal logical stage that [Piaget \(1930\)](#) described. Where there is differentiation between self and other.

An illness in a child is a stress, especially if it includes hospitalization ([Foster, Whitehead, & Maybee, 2016](#)). Knowing how children of each age view illnesses affects the planning of nursing care and influences how explanations should be worded. For example, saying you are going to “stick” a child for blood work could be interpreted by young children as meaning you are actually going to put a stick in their arm. Saying a child will receive dye for a test could be interpreted as meaning the child will “die” during the procedure. Explanations of procedures can sound confusing if words sound alike or have double meanings (e.g., “drawing” as in making a picture vs. “drawing” blood). Because of these distorted perceptions, explanations of procedures do not always relieve children’s stress.

## DIFFERENCES IN RESPONSES OF CHILDREN AND ADULTS TO ILLNESS

Keeping in mind that children are not just small adults is important when evaluating how children react to illness, perceive an illness, or react to health care ([Fig. 36.1](#)).

Their body images, for example, as evidenced in their drawings, are different from those of adults. They may have difficulty telling which body parts are indispensable and which are not (this is why it is wise to talk to preschool and early school-age children about “fixing” body parts, such as tonsils, rather than “taking them out”).

**Figure 36.1** Illness is potentially traumatic because of the unknown and because of the pain and discomfort that may be involved. Children need extra attention and reassurance to calm their fears.

### **Inability to Communicate**

Very young children do not have the vocabulary to describe symptoms. Children younger than 5 years of age have a great deal of difficulty describing a headache. Dizziness and nausea can be equally bewildering because young children do not know the words to express these phenomena.

By the time children reach school age, most can describe symptoms with accuracy. They may intensify their concerns if they believe someone expects symptoms to be more serious. They may minimize symptoms if they are afraid that an illness will interfere with an activity they want to do; thus, it is important to evaluate a child’s symptoms as much by observation as by a child’s report. A crying, whining preschooler who is “just not herself” probably has a symptom she cannot describe. A school-age child who guards her abdomen (i.e., keeps abdominal muscles rigid) is in pain just as clearly as a child who verbalizes a source of discomfort.

### **Inability to Monitor Own Care and Manage Fear**

Adults who are ill often ask questions about medications prescribed for them or procedures they are scheduled to undergo. If a hospitalized adult knows he is to receive a diuretic three times a day and by 10 AM has not been offered it as yet, he usually reminds someone of the oversight. School-age and younger children cannot monitor their own care this way because they may not know which medicine or procedures they are scheduled to receive. If they do know, they may be confused about the time. In

addition, children have fears that adults do not experience. For example, by 8 to 9 months, the infant fears separation above all else; the toddler and preschooler enlarge their fears to include separation, the dark, intrusive procedures, and mutilation of body parts. The school-age child and adolescent may be concerned about the loss of body parts, loss of life, and loss of friends. Adults have fears also, but most have prior experiences to draw from, making coping easier. Children in a strange environment, such as a hospital, have not learned coping skills as yet and so require proportionally more support and active intervention to manage their stress and fears. Otherwise, hospitalization, particularly if it follows trauma from unintentional injury, can result in posttraumatic stress disorder (PTSD) or the development of characteristic symptoms, such as difficulty falling asleep, outbursts of anger, difficulty concentrating, difficulty completing tasks, or experiencing symptoms such as stomach aches or headaches (Franck, Wray, Gay, et al., 2015).

### **Nutritional Needs**

Children differ from adults in many ways. In addition to psychological differences, there are major physiologic differences in the way illnesses affect children compared with adults. Children have greater metabolic demand, breathe in more air per pound of body weight than adults do, have a higher surface to body mass ratio (Centers for Disease Control and Prevention [CDC], 2015a), and are at greater risk for insensible fluid loss when they are sick.

For example, children need more nutrients (calories, protein, minerals, and vitamins) per pound of body weight than adults because their basic metabolic rate is faster, and they must take in not only enough to maintain body tissues but also enough to allow for growth. The infant, for example, requires 120 kcal/kg of body weight per day; the adult requires only 30 to 35 kcal/kg of body weight per day. An ill child who must limit food intake because of nausea or vomiting, therefore, may require hospitalization for intravenous therapy, even though this might not be necessary for an adult under the same circumstances.

### **Fluid and Electrolyte Balance**

In the adult, extracellular water (the water held in plasma and outside body cells) represents approximately 23% of total body water; in a newborn, extracellular water is closer to 40%. This means that an infant does not have as much water stored in the cells as an adult and so is more likely to lose a devastating amount of body water with diarrhea or vomiting. The full implications of both vomiting and diarrhea are discussed in Chapter 45.

### **Systemic Response to Illness**

Because a child's body is continually growing, young children tend to respond to disease systemically rather than locally. The child with pneumonia, for example, may be

brought to an emergency department not because of a cough (although the child may have one) but because of accompanying systemic symptoms such as fever, vomiting, and diarrhea. In fact, nausea and vomiting occur so frequently in children with any type of illness that these symptoms do not have the diagnostic value that they may have in adults. Systemic reactions of these kinds can delay diagnosis and therapy and can cause increased fluid and nutrient loss, circumstances that compound the initial illness.

### **Age-Specific Diseases**

Most adults have achieved immunity to common infectious diseases; children, however, are very susceptible to illnesses such as measles, mumps, and chickenpox. Febrile children between the ages 6 and 60 months who do not have an intracranial infection or metabolic disturbance are typically diagnosed with “febrile seizure” ([Steering Committee on Quality Improvement and Management & Subcommittee on Febrile Seizures, American Academy of Pediatrics, 2008](#)).

## **Care of the Ill Child and Family in the Hospital**

Research has raised awareness about the psychological trauma children and their parents face when hospitalized. This trauma can have lasting effects after discharge, undermining the child’s recovery and the overall well-being of the family ([Franck et al., 2015](#)). The caregivers of a child admitted to an intensive care unit (ICU), neonatal intensive care unit (NICU), or general pediatric unit are likely to experience a high degree of stress during their child’s hospitalization both because of the severity of their child’s illness and the high-tech pediatric ICU (PICU) or NICU setting. The child in an acute care setting is much more apt to have invasive procedures compared with children on a general pediatric floor, which can also increase anxiety not only for the child but also the parent. A child’s type of surgery is also related to parental anxiety and should be taken into consideration when speaking with the family ([Woolf, Muscara, Anderson, et al., 2016](#)).

### **THE EFFECT OF HOSPITAL SEPARATION AND CHILDREN: DECREASING SEPARATION ANXIETY**

Social/emotional development begins early in infancy. Babies display sadness, happiness, and anger at a young age, and they begin to change their facial expressions to register changes in their emotions around 5 months. During this period, infants also become attached to parents and caregivers. When in the presence of strangers, infants fix their eyes on them, become restless, perhaps thrash arms or legs, and begin to cry. This activity peaks at approximately 9 months of age. It is a developmental milestone that shows that an infant is able to distinguish a primary caregiver from other persons. The timing of separation anxiety can vary widely from child to child. Within the hospital setting, that anxiety may be relieved by establishing a primary nurse.

In many instances, toddlers and preschoolers can be as affected by separation as infants and even express their feelings better, louder, and longer. Although many toddlers and preschoolers attend day care and have had prior experiences with separation, others may have had only limited experiences being away from their parents. Being hospitalized may be the first time they are away from parents in a strange setting or away from home overnight. The effect of separation can become especially intense in young children before they are able to understand time, because statements such as “Mom will visit again tomorrow” or “Dad will be here by 6 o’clock” are meaningless unless they know what “tomorrow” or “6 o’clock” means.

School-age children and adolescents react better than younger children to the separation imposed by hospitalization because they have experiences they can use for comparison. They have been to school for whole days, perhaps they have stayed with a grandparent or a friend overnight, and they may have been to a summer camp. This can make hospitalization a time for developing self-esteem and confidence in their ability to be independent. Even in light of this, ill school-age children and adolescents appreciate their parents being near them and reassurance that their parents will be there to support them through this crisis.

Remember that being separated may create an equally difficult time for parents. You may need to spend time with them, assuring them that their child will receive comprehensive, evidence-based care at all times, even if they have to leave for a commitment or to care for other children at home.

To appreciate why preventing separation is so important, it is helpful to review the research that provided the foundation for this method of care. [Spitz \(1945\)](#) was one of the first researchers who documented the effects of separation on children. He observed children in a penal nursery and in a foundling home who had been separated from their mothers for both short and long periods of time. From this observation, he was able to document that infant’s growth and development slowed the longer they were away from their parent. [Bowlby \(1951\)](#) conducted additional studies with children separated from their parents during World War II. Building on Spitz’s and Bowlby’s work, [Robertson \(1958\)](#) applied these effects to the hospitalization of children and supplied labels for separation effects. Although defined over 50 years ago, these findings are still applicable to children today.

Reducing the ill effects of separation and hospitalization to the extent possible should be a high priority for all healthcare providers ([Hilton, 2014](#)). Nurses play a major role in this on both direct care and management levels. Unfortunately, even despite the best preparation by parents or nurses, not all of these effects of hospitalization can be prevented.

### *QSEN Checkpoint Question 36.1*

#### **TEAMWORK & COLLABORATION**

The nurse collaborates with an interprofessional team to care for Becky, age 7 years.

The social worker believes that Becky is showing the first signs of separation anxiety. The nurse determines which symptoms of anxiety corroborate the social worker's assessment?

- a. Loud, demanding crying
- b. Silent, sullen protesting
- c. Quiet, introspective thought
- d. Inability to respond verbally

*Look in Appendix A for the best answer and rationale.*

## PREPARING THE ILL CHILD AND FAMILY FOR HOSPITALIZATION

Preparing for hospitalization involves disseminating developmentally appropriate information, facilitating communication and developing trusting relationships with healthcare professionals (Koller, 2008). Many childhood illnesses such as febrile seizures, appendicitis, poisonings, and asthma exacerbations are acute, making advance preparation for hospital admission impossible. However, when hospitalizations such as elective surgeries are scheduled, advance preparation is possible with programs such as preoperative orientation. The preparations parents make for a child obviously vary depending on the child's developmental age and experiences.

Depending on the age of the child, there may be anxiety if the child is told about an approaching hospitalization too far in advance. Conversely, few things are more frightening for children than to hear a conversation halt as they enter a room or to hear adults spelling out unknown words. As a rule, therefore, children between 2 and 7 years of age should be told about a scheduled ambulatory or inpatient hospitalization as many days before the procedure as the child's age in years. For example, a 2-year-old should be informed 2 days before hospitalization; a 4-year-old, 4 days before; and so forth. Children older than 7 years of age can be told as soon as the parents are aware of it.

On the day of hospital admission, it is important for you to ask the parents what preparation they have done to ensure the child and family accurately understand the child's condition and upcoming procedures. Based on that, you can provide further health teaching and clear up any misunderstandings as necessary (Box 36.2).

### BOX 36.2

#### Nursing Care Planning Tips for Effective Communication

Becky, 7 years old, is admitted to your ambulatory surgery unit for burn debridement.

Becky and her mother arrive together on the unit.

*Tip:* Ask direct questions and be careful not to assume anything regarding the level of patient knowledge or preparation.

**Nurse:** Hello, Becky. How are you?

**Becky:** Good.

**Nurse:** Do you know why you're coming into the hospital?

**Mrs. Miller:** We've talked about surgery. She knows that's why she's here.

**Nurse:** Tell me why you're here yourself, Becky.

**Becky:** To read a book. I brought a book.

**Nurse:** Let's talk about everything you told her, Mrs. Miller.

**Mrs. Miller:** Well, I didn't want to introduce anything scary.

**Nurse:** Let's take some time and talk about the whole procedure.

Many hospitals sponsor hospital orientation programs for children's groups or school groups during which hospitalization is discussed. These programs are beneficial because they lay a foundation for all children about what to expect during a hospitalization; then, if they must be admitted on an emergency basis, they may not be so frightened. Programs are offered by nurses at the hospital or on visits to children's groups or schools (Fig. 36.2). Box 36.3 provides guidelines for setting up hospital tours or discussions for early school-age children.

**Figure 36.2** Children learn what to expect from hospitalization by becoming familiar with some of the equipment that might be used.

### BOX 36.3

#### Guidelines for Conducting Hospital Tours With Early School-Age Children

1. Keep groups small (about 10 children per group) so individual reactions to the presentation can be assessed.
2. Allow or encourage parents to join the tour so their concerns about the hospital can also be relieved.
3. Conduct the tour for only 20 to 30 minutes to meet the short attention span of children.
4. Use an indirect method to present various aspects of a hospital that would be exceptionally anxiety producing such as the intensive care unit (ICU) or an

operating room by using puppets, films, or a PowerPoint slide show. Include nonthreatening features such as a hospital playroom.

5. Present explanations about hospitalization in concrete terms and at the child's level of understanding. Include only what the child will see, hear, and feel.
6. Avoid dwelling on unpleasant and threatening events or intrusive procedures, such as blood drawing or anesthesia, that may create apprehension.
7. Allow children opportunities to ask questions.
8. Allow children opportunities to play with dolls and hospital equipment to decrease anxiety and satisfy curiosity.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Deficient knowledge related to preparation for hospitalization

**Outcome Evaluation:** Parents and child both state they feel prepared for hospitalization; child has brought some personal item important to self. Child describes with accuracy and detail appropriate to age the reason for hospital stay; asks questions and expresses feelings appropriate to age about hospitalization.

**Preparing Family Caregivers.** Planning for hospitalization should begin as soon as parents know hospitalization will be necessary. Some parents, however, may be so concerned about the reason for hospitalization that they cannot begin to prepare their child until they are better prepared themselves. Easing parental concerns regarding illness and hospitalization is particularly important because children may be able to sense a parent's stress. Even though a parent says, "Don't worry, everything will be all right," a child can sense if parents really do not believe everything will be all right.

As part of preparation, urge parents to ask questions about things such as what diagnostic procedures will be necessary, how long the hospital stay will be, and what kind of dressings or other equipment will be used, so they can be as familiar as possible with what will happen. Informing parents can help allay anxiety and will also keep them abreast of what the plan is so that they can be active in shared decision making. This is important as they are an integral part of their child's care.

Depending on your practice setting, familiarize yourself with available resources to help caregivers navigate what is available to them before, during, and after a hospital stay. Many parents ask a nurse to repeat their primary care provider's explanation for a procedure or to have instructions clarified to be certain they have understood everything correctly. If parents arrive at a hospital unit with questions still unanswered, continue to keep them informed and educate as new questions or concerns arise.

**Preparing an Infant.** Because an infant cannot understand explanations of surgery or

treatments, verbal preparation is minimal. Remind parents to pack special items such as a favorite toy, blanket, or pacifier because these objects provide a special kind of security for which there is no substitute.

The infant's primary caregiver should plan to spend a great deal of time in the hospital with the infant. Ask whether the parent who will be staying with the infant has made plans for other children, a spouse, work, or other obligations ahead of time. If a parent cannot arrange to stay with the child during the hospital stay, attempt to have a consistent nurse assigned to the infant, which may help to lessen caregiver anxiety and minimize separation anxiety in the infant.

***Preparing a Toddler or Preschooler.*** Three chief fears of toddlers or preschoolers are fear of the unknown, fear of abandonment or separation, and fear of mutilation. Preparation for children of this age, therefore, should clearly aim at alleviating these three fears. Bringing a favorite toy or personal item such as a blanket can help. Referred to as "transitional objects," these items are reminders about something familiar from home.

When making hospital beds or changing paper on examining tables, be alert for ragged blankets and threadbare stuffed animals because it is easy for these to cling to sheets and be easily discarded. Throw nothing away in a child's room without first asking a child or parent if it is important. What looks like a useless alphabet block to you may mean security and home to a 2-year-old.

Several helpful books about hospitalization are available for parents to read with children and to also learn more about children's health care (Box 36.4). These can be obtained from local bookstores, libraries, or websites and may also be found in the hospital library. For preschool preparation, parents could read one of these books to a child, adapting the story to include information specific to their child.

#### BOX 36.4

#### Books on Hospitalization for Children and Parents

- Bourgeois, P., & Clark, B. (2000). *Franklin goes to the hospital*. New York, NY: Scholastic Publishers. (Grades pre-K to 3)
- Bridwell, N. (2011). *Clifford visits the hospital*. New York, NY: Scholastic Publishers. (Grades pre-K to 3)
- Civardi, A. (2005). *Going to the hospital*. Tulsa, OK: Usborne Publishers. (Infant to preschool)
- Keen, N. (2015). *Your child in the hospital: A practical guide for parents*. (3rd ed.). Bellingham, WA: Childhood Cancer Guides.
- Mills, J. C., & Sebern, B. (2003). *Little tree: A story for children with serious medical illness*. Washington, DC: Magination Press. (Early school age)
- Rey, H. A. (1999). *Curious George goes to the hospital*. Boston, MA: Houghton Mifflin Co. (Grades 2 to 3)
- Ross, T. (2013). *I don't want to go to the hospital!* London, United Kingdom:

Andersen Press Picture Books. (Early school age)

Slanina, A. M. (2011). *The adventures of Annie Mouse: Baby brother goes to the hospital*. Harrisville, PA: Anna Mouse Books Publishing. (School age)

Because the imagination of preschoolers is at a peak, role-playing can be an effective means of preparing a child of this age for a new experience. To do this, a parent could encourage a child to act out a hospitalization experience with puppets or dolls. Or the child could change into pajamas and get into bed and have a meal in bed. Due to their developmental stage, children often apply literal meaning to spoken words. Be cautious of using common phrases for procedures, such as “put you to sleep” or “taking your blood” as these phrases can be interpreted as literal, leaving the child scared or confused. For example, a child may realize that animals that are put to sleep are not seen again. Talking to another child who has undergone the same experience and come through it intact is yet another helpful way to introduce children and adolescents to hospitalization. Although parents cannot usually supply such a person in advance, upon admission to the hospital, a visit to a recovering patient is often possible and is a constructive way to give reassurance.

If hospitalization is to be more than 1 week long, parents need to think about how their child will continue schooling. Advise them to ask their care provider at what point the child will be able to do homework. Many school systems provide tutors, and children’s hospitals often have their own teachers from the local school system to carry out this service so children do not fall behind due to hospitalization (Steinke, Elam, Irwin, et al., 2016).

***Preparing a School-Age Child or Adolescent.*** School-age children enjoy reading and visual media; thus, books or videos about surgery and hospitalization can be helpful for preparation. Be sure both school-age children and adolescents receive factual explanations of what will happen during surgery.

If parents do not have enough information to be able to answer a school-age child’s questions, remind them that few people know everything and caution them that their best response may be “I don’t know, but I will find out.”

***Preparing a Child With a Different Cultural Background.*** Perhaps the most important aspect to consider when preparing a child from a different culture for hospitalization is to identify if there are traditions or practices that will be in opposition to usual healthcare facility practices. Ask enough questions and practice good listening skills to gain information about the particular needs of a child and his or her family. When cultural differences do exist, be prepared to act as a liaison between the family and the healthcare team. If a different language is interfering with communication, a medical translator may be necessary in this preparation phase. Provide the opportunity for parents to voice their fears and ask questions and allow time and opportunity for discussion and effective communication.

***Preparing a Child With Unique Concerns or Who Is Chronically Ill.*** Children with

unique physical concerns or those who are chronically ill frequently come to ambulatory healthcare settings for care; they also are often admitted to the hospital for care and possibly remain in the hospital for an extended time followed by continuing care at home. Children with chronic illness are likely to have been admitted to the hospital in the past, draw upon past experiences, and may be able to let you know how they like certain things (e.g., taking medications a certain way). A child with a chronic illness is still at risk for the same type of anxiety that a child with an acute illness requiring hospitalization has. To decrease anxiety, help children to maintain contact with their families and school friends during a long hospitalization by encouraging telephone calls, social media use, e-mails, text messaging, letters, and visits.

### *What If . . . 36.1*

**The nurse notices the mother of Becky’s roommate, a 2-year-old, brought pots and pans to the hospital as her child’s favorite play items. Would the nurse suggest that she bring an actual toy?**

### *QSEN Checkpoint Question 36.2*

#### **EVIDENCE-BASED PRACTICE**

Preparing children and their families for surgery is crucial and also challenging. Prior to elective surgery, children and their families are often invited to visit the hospital, whereby the child is allowed to learn about the procedure in age-appropriate terms and express his or her concerns through play. Studies have investigated the use of providing age-appropriate preparatory information about procedures, through board games (Fernandes, Arriaga, & Esteves, 2014), interactive puppet shows (Cuzzocrea, Gugliandolo, Larcan, et al., 2013), or web-based programs. Utilizing different platforms not only informs and prepares the child but also reduces anxiety for the child and their caregiver(s).

Based on the study, what would be the best outcome to establish after teaching Becky and her family about surgical process and her anticipated course of recovery?

- a. Becky and her family will adhere to preoperative and postoperative instructions.
- b. Becky will be able to describe the reasons why a surgical intervention is necessary.
- c. Becky will state that she understands the basic principles of asepsis better than before the teaching.
- d. Becky will state that she feels less anxious about the prospect of having her foot debrided.

*Look in Appendix A for the best answer and rationale.*

## Unfolding Patient Stories: Eva Madison • Part 2

Recall **Eva Madison**, the 5-year-old child you met in **Chapter 34**. She is diagnosed with bacterial gastroenteritis. How would the nurse prepare Eva and her parents for hospitalization? What nursing actions can promote a more favorable hospital experience in this age group?

Care for Eva and other patients in a realistic virtual environment: **vSim for Nursing** ([thepoint.lww.com/vSimMaternityPed](http://thepoint.lww.com/vSimMaternityPed)). Practice documenting these patients' care in DocuCare ([thepoint.lww.com/DocuCareEHR](http://thepoint.lww.com/DocuCareEHR)).

### ADMITTING THE ILL CHILD AND FAMILY

Whether an ambulatory or inpatient hospital unit admission, children and parents need to be admitted as a single entity to encourage parents to feel that they are true partners in care (**Fig. 36.3**). A child coming to a hospital for an elective admission generally arrives at a reception area where demographics are obtained, such as name, age, address, and hospital insurance coverage. The child and parents are then brought to the hospital unit. Remember that first impressions count. If parents are left standing at a counter without being addressed, they can easily feel that no one appreciates their concern and that possibly their child will not receive optimal care. Introduce yourself, explain your role to the parents and child, and find a comfortable place for the family to wait until someone is available to orient them to the unit. When introducing yourself to children, stoop down so that your face is level with the child's face. Call the child by his or her name or ask for a nickname.

**Figure 36.3** A child is admitted to a hospital unit. Notice how the nurse engages all the family's members. (© F1online digitale Bildagentur GmbH/Alamy.)

All children should have an armband attached which lists their name, date of birth,

and hospital medical record number. Because their hands are not much larger than their wrists, and their feet are not much larger than their ankles, small infants often need two bands in place as an extra safeguard. If a band should fall off, verify the patient's identity using at least two patient identifiers (acceptable identifiers may be the individual's name, an assigned identification number, telephone number, or other person-specific identifier) ([Joint Commission on Accreditation of Healthcare Organizations, 2015](#)) and secure it back onto the child; never tape it to the crib or bedside stand because this will not properly identify the patient, and the child could be given a wrong medication or have an unintentional procedure.

### Assessment on Admission

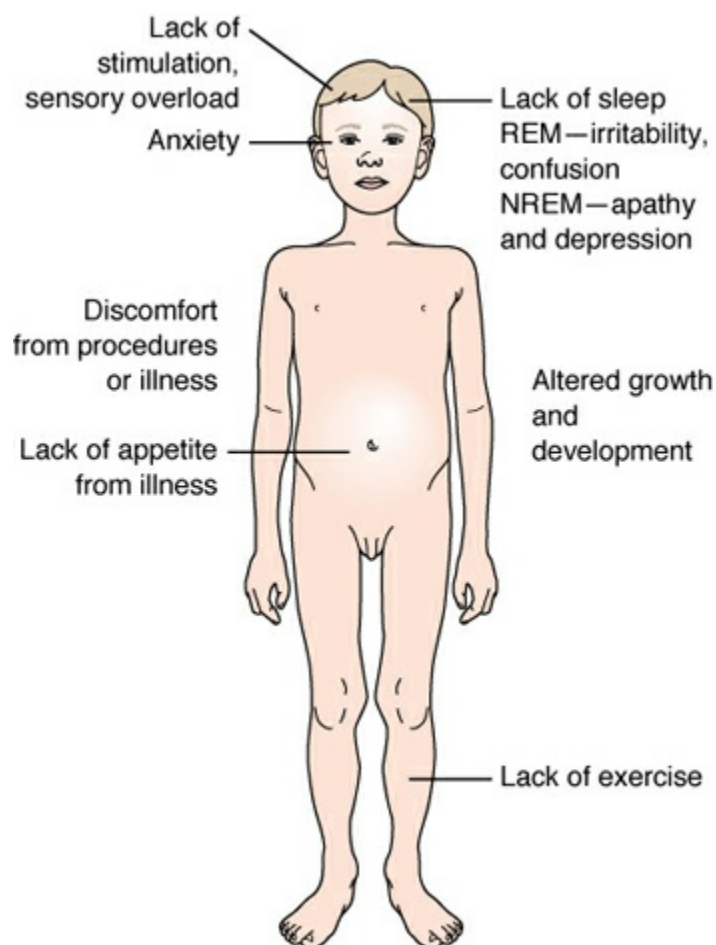

Assess each child's level of preparation for a hospitalization on admission ([Box 36.5](#)). Be aware of not only what the child describes verbally but also note any facial expressions or nervous manifestations.

#### BOX 36.5

#### Nursing Care Planning Using Assessment

#### ASSESSING A CHILD FOR THE EFFECTS OF AN ILLNESS

Interview parents upon hospital admission for a nursing history to obtain the information needed to plan nursing care (see [Chapter 34](#) for a description of a full child database interview history). Many hospitals have information checklists for parents to bring with them. Obtaining information in this way is highly efficient; however, the nurse should review the checklist and ask caregivers if they have any questions and/or concerns. Typical information that is necessary to obtain about a child and that should be included in a plan of care is shown in [Table 36.1](#). [Box 36.6](#) shows an interprofessional care map illustrating both nursing and team planning for a child admitted for 1-day surgery.

**TABLE 36.1 INFORMATION NECESSARY FOR THE CHILD’S PLAN OF CARE ON ADMISSION**

Area of Information	Specific Knowledge
Chief concern	Determine what the parents’ understanding is of why the child is being admitted. (This view may differ widely from the family care provider’s view regarding the reason the child is being admitted.) What has the child been told about the reason for hospitalization?
Family profile	Obtain child’s name and birthday. Who lives at home (including pets)? Ask about the parents’ occupation and education levels. Who is the child’s primary caregiver? Have there been any disruptive happenings lately in the child’s life, such as a move or a divorce, that would make the child particularly insecure at this time? Will a parent be staying with the child? If parents are separated or divorced, what will the visiting arrangements be? Who has legal authority to sign medical permission?
Past experience with illness or separation	Ask about previous hospital experiences and how the child feels about them. Has there been a recent hospitalization for anyone in the family that resulted in a bad outcome? Has the child been away from the parents before? Overnight at a grandparent’s? Summer camp? What is the child’s past experience with taking medicine? Has the child swallowed pills before? Does the child have any known allergies to food or medications? (Document these by asking for exact symptoms and happenings.)
Daily routines	Ask about the child’s regular bedtime and sleep times. Does the child nap? Is there an important bedtime ritual? What type of bed does the child sleep in at home? Does the child sleep with a favorite toy or blanket? What is the bath time routine? Does the child need help brushing teeth or combing hair or is this done

independently? What words does the child use for voiding and defecating? Is the child completely toilet trained? If a preschooler, is the child accustomed to using a potty chair or toilet? Does the child have enuresis (bed-wetting)? What is the child's usual meal plan? Are there foods the child does not eat? Did the child pack a favorite toy for the hospital? What are the child's favorite games and hobbies or interests? Are there television programs the parents especially like the child to see or not see?

Developmental survey	Ascertain the child's developmental level. Does child feed self? Use a spoon, cup, bottle? Dress self? If school age, what grade in school?
Special information	Obtain any special information about the child the parents think would make him or her more comfortable in the hospital.

## BOX 36.6

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR A CHILD HAVING 1-DAY SURGERY

Becky is a 7-year-old who burned her foot in a campfire accident. She is going to be admitted to the hospital for 1-day surgery to have the wound debrided.

**Family Assessment:** Child lives with parents and two older brothers (10 and 14 years of age) in a three-bedroom suburban home. Father works as sound technician at a recording studio; mother was a grade-school teacher, now is stay-at-home mom; home schools all three children. Father rates finances as, "All right. We have everything we need."

**Patient Assessment:** Patient burned left foot on a campfire while on a family weekend camping trip. Was playing hide and seek with brothers and ran into the fire. Treated at local hospital for third-degree burn; transferred to burn center for follow-up care. Becky's parents tell you that Becky "hasn't been herself" since the injury. She has reverted to temper tantrums and sulking, more like a 3-year-old than one of early school age. Even though she has been told eating meat is important because it provides protein for healing, she refuses to eat anything but Jell-O or soup. In the admission suite of the hospital, she picked up a doll and twisted its leg off. "What can I do with her?" her mother asks you. "How can we get our old daughter back again?"

**Nursing Diagnosis:** Anxiety related to hospital admission and burn debridement

**Outcome Criteria:** Child accurately describes what debridement will entail; cooperates with procedures with age-appropriate responses. Describes measures she will need to take after returning home to aid burn healing.

<b>Team Member Responsible</b>	<b>Assessment</b>	<b>Intervention</b>	<b>Rationale</b>	<b>Expected Outcome</b>
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess the degree of self-care child usually carries out.	Allow child maximum inclusion in procedures.	Ability to carry out self-care helps “normalize” hospital procedures.	Child participates in self-care to extent possible with postprocedure bandage.
<i>Teamwork and Consultation</i>				
Nurse/child life specialist	Consult with child life service on what type of therapeutic play would be most beneficial.	Conduct therapeutic play with child before and after debridement procedure.	Therapeutic play can be helpful to children to relieve their anxiety about a painful procedure.	Child participates in therapeutic play and demonstrates less anxious behaviors following debridement.
<i>Procedures/Medications for Quality Improvement</i>				
Nurse	Assess what is the child’s greatest concern about the debridement procedure.	Prepare child for surgery, stressing anesthesia will be used to relieve pain during procedure and analgesia will be available after procedure.	A clear understanding of what is to happen helps relieve concern, and knowing pain relief is available is invaluable to well-being.	Child and parent state they understand what procedure will entail, and child cooperates in age-appropriate ways.
<i>Nutrition</i>				
Nurse/nutritionist	Assess what are child’s favorite foods.	Suggest ways mother could incorporate protein into soup (meat or	Jell-O is a protein source, and adding meat to what child eats will provide	Mother details ways she can increase child’s protein intake without

		beans) to increase protein in child's diet.	protein yet respect the child's choice of food.	opposing child's food preferences.
--	--	---	---	------------------------------------

*Patient-Centered Care*

Nurse/nurse practitioner	Assess what child and parent understand about debridement procedure.	Educate family about procedure and pre- and postoperative care.	Well-prepared child and the family can better cooperate with care to make the experience a positive one for child.	Child and parents ask questions about the procedure; state they understand what it will entail.
--------------------------	--	---	--	---

*Psychosocial/Spiritual/Emotional Needs*

Nurse/nurse practitioner	Take history about unintentional injury resulting in severe burn.	Review with mother what she believes has caused the change in child's attitude. Does she think the child or parents feel guilty about the child's injury?	Children can believe they are being punished by procedures if they believe an injury was their fault; guilt can also influence parent's relationship with child.	Child and parent state they both should have been more diligent to avoid the unintentional injury, but these do happen even in the best circumstances.
--------------------------	---	---	--	--

*Informatics for Seamless Healthcare Planning*

Nurse	Assess what will be a typical day for the child after returning home.	Plan with parent what measures child will need to carry out to keep the bandage clean, to exercise the foot, and to return to home schooling.	Prospective planning can help avoid problems in home care.	Child and parent review a typical day and decide on actions that will promote healing.
-------	---	---	--	--

Nurse/primary healthcare provider	Assess when follow-up visit will be necessary.	Schedule follow-up visit as determined by primary healthcare provider.	A follow-up visit will help ensure the burn is healing without further complications.	Child and parent state they understand importance of follow-up visit and will keep appointment.
-----------------------------------	--	--	---	---

Make a note of any medication or food allergy on the child’s plan of care and, if pertinent, post this information in the child’s chart and per hospital protocol such as with a specific identification bracelet/band. Unlike an adult, a child cannot call these things to the attention of healthcare personnel when food or medication is offered.

Based on hospital’s protocol, the timing of a child’s vital signs varies. Initial vital signs include temperature, pulse, and respirations. Measurement of height and weight to determine overall growth and to allow for the determination of safe medication dosages is also warranted. Dependent on the age of the child and diagnosis, blood pressure should be taken using the appropriate size cuff (usually obtained in children over 3 years of age). Review any orders for routine labs and obtain a specimen. Be sure to explain all equipment used and allow the child to touch and handle the equipment as much as possible to help reduce fear.

Inspect for gross motor ability when weighing a child and measuring height. Listen for language ability. Perform a physical examination (see [Chapter 34](#)) to gain the information necessary for nursing diagnosis and planning.

The way children deal with hospitalization is based on the same factors that determine how they deal with any crisis: perception of the event, whether support people are available, and effectiveness of past coping experiences or skills. After an assessment, analyze whether a child’s coping ability seems to be enough to balance the hazards of inpatient or ambulatory care hospitalization.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Parental and child anxiety related to the need for the child’s hospitalization

**Outcome Evaluation:** Parents and child accurately state the reason for the child’s hospital admission and therapy the child will receive; state that although worried, they feel confident they can manage their apprehension.

To help reduce family anxiety regarding hospitalization, assess whether a family is oriented to a hospital stay by discussing the need for hospitalization and what they can expect when the hospitalization is first suggested to them in an ambulatory care

setting. When children are admitted for emergency care, this type of orientation must be completed immediately, as soon as their physical needs are met.

On admission, both parents and the child need at least basic information. If the child's diagnosis is uncertain, tell them what steps are being taken to confirm it. It helps if these steps are named specifically (e.g., blood work, X-ray studies, observation, recording of vital signs, calling in a consultant). Ascertain whether they know the tentative plan for the child (e.g., complete bed rest, infection control procedures until the results of blood work or cultures are back, special diet, special procedures). If the plan of care changes, inform the parents and/or child as soon as possible. If the plan of care is uncertain, explain to the family that you are in communication with the healthcare team to obtain it.

If a child is admitted from the emergency room, parents may have little understanding of their child's condition or the treatment plan. Conversely, someone might have taken a great deal of time to explain what was happening while the child was being cared for in the emergency department. Ask them what they have been told and if they have any further questions about their child's condition or the course of treatment they want to discuss with the inpatient facility's healthcare team.

Ideally, a parent or caregiver should be prepared to stay with the child, but if the admission was an emergency, a parent may have to leave rather than remain because of other obligations. If this happens, be certain the parent sees the child's room before leaving because it is important for children to feel confident that their parents know where they can be found when the parents return. If there are other children in the room, introduce the new child to them. Let children wear their own clothes if possible rather than change into hospital gowns for a greater sense of control.

## PROMOTING A POSITIVE HOSPITAL STAY

Several nursing actions lay an important foundation for creating a successful, rather than an unsuccessful, hospital experience.

### Providing Continuity of Care

To ensure that children are exposed to as few caregivers as possible and to maintain the consistency and quality of care, nursing assignments are best if one nurse gives as much care to the same child as possible (**primary nursing**) (Fig. 36.4). "Primary nursing promotes ongoing communication between the patient, family, nurses, and physicians by building rapport and facilitating discharge planning beginning on admission" (Baynton, 2015). These staffing patterns allow the same nurse to admit the child, take the nursing history, establish nursing diagnoses, set goals for care in cooperation with the parents and the child, and evaluate progress toward achieving goals. It allows children to have one main nurse to call their own. It is also helpful to parents because it allows them to establish a meaningful contact with the hospital staff and maintains continuity of care, planning, and implementation.

**Figure 36.4** Hospitalized children should have one nurse who is “theirs” to minimize the effect of separation from parents (primary care nursing).

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Anxiety of child related to separation during hospitalization

**Outcome Evaluation:** The child will have the ability to eliminate or reduce feelings of apprehension and tension from an identified source. The child will express their feelings and remain calm.

**Promoting Open Parent Visiting.** When possible, young children should have a parent room-in with them when they are in the hospital (Fig. 36.5). Even children 10 to 12 years of age enjoy short time spans alone but also continue to enjoy the feeling of security rooming-in provides. Because a parent will be sleeping alongside the child, check the room has a parent as well as a child bed. When parents were first

allowed to sleep over in children's units, it was thought their presence would reduce the need for nursing care. In many instances, because so much parental education is needed, requirements for healthcare personnel actually increase.

**Figure 36.5** Rooming-in helps alleviate separation anxiety for both the child and the parent.

If parents cannot stay continuously, they may ask for help in smoothing the transition of coming or going. You may need to remind them that it is not uncommon for this age group to go through three different phases: protest, despair, and detachment. Initially, if a child is left alone by his or her parent, they may scream and cry in protest. Explain to the parents that this is normal and to not feel guilty leaving their child if they need to attend to other commitments. Once the crying stops, children will act depressed and withdraw themselves from the parent and healthcare providers. During the detachment phase, children often become more interested in their surroundings than in visitors. This is a coping mechanism only and is not a sign that they have accepted separation from their parent. It is not unusual that when a toddler first sees parents after being separated, a common reaction might be to ignore them (a sign of despair). This is a defense mechanism: “I won’t show you I love you until you show me you love me; that way I won’t be hurt again.” If a parent’s reaction to being treated this way causes the parent to play with a child in the next bed—a “well, be that way then” reaction—the toddler’s worst fears are fulfilled: a parent has forgotten about him. To avoid this type of interaction, urge parents to speak to the child for a few minutes or try to interest the child in a toy despite the child’s “cold shoulder”; after a short time, a child will generally reach out to be comforted and will act relieved the parents are there.

Parents often need help in saying goodbye when it is time to leave a child so they can eat a meal or go home for the night (if the parent is not sleeping in). Assure parents that although someone will not be in their child’s room every minute while they are gone, the child will be well cared for. When the parents of an infant are leaving, go into the room a few minutes before they leave and hold or play with the

infant. Help a parent to say once, “I have to go now,” and then leave. Prolonged departures only delay the process and do not reduce the amount of crying that may occur. After parents leave, hold and rock infants to let them know that they are safe even though their preferred caregiver is no longer present.

If the parents of a toddler or preschooler have to leave, urge them first to give a warning they will soon have to go: “I have to leave in a minute to fix dinner for Daddy.” When the time to go has come, the parent should say firmly that it is time to go and then explain the time he or she will return. Time for a preschooler is best measured in terms of events rather than clock hours. “I’ll be back after you’ve eaten supper,” is better than “I’ll be back at seven”; and “after you wake up tomorrow,” is better than 8 AM as these times give the child a concrete event by which to measure time. Like infants, toddlers need someone with them when their parents leave; they like to be held or played with so they know they are not alone.

When parents leave a school-age child or adolescent, urge them to provide definite times when they will return and to leave suggestions for activities a child could do to occupy the time (e.g., “Why don’t you finish your book? Get a start on your homework and I’ll check it when I come back”). Remind them it is more comforting to name a specific time, “I’ll be back around 9 tomorrow morning” rather than a vague time period such as “I’ll be back sometime tomorrow.”

When a child has to leave the patient unit for surgery, it may be especially difficult for parents to separate. Reminding them that the surgery is important and helping them manage this is an important part of preoperative nursing care.

***Providing Opportunities for Parents to Participate in Child’s Care.*** One of the most stressful parts of a child’s hospitalization is the parents feeling that their parental role is diminished (Foster et al., 2016). Participating in their child’s care can make parents feel more in control, thereby reducing their unease, which then hopefully transmits to reducing anxiety in their child. Encourage parents, therefore, to give as much care as possible during a hospital stay, such as bathing or feeding their child, giving oral medicine, helping with procedures such as warm soaks, or assessing that their child is awake from anesthesia. Most parents are eager to help and do these things spontaneously. Be certain they have proper instruction on the tasks they will be able to do. Be sure parents who change diapers or feed children know whether the number of diaper changes or the amount of food intake needs to be recorded; ask them to report when they do these things or write them down on a flow sheet attached to the child’s door or crib. Do not ask them to restrain children for a procedure that will be painful because their main job should be to comfort. Occasionally, parents may be reluctant to give care for fear of being judged inadequate. You can assure them they are the persons from whom their child would most like to receive care.

Because children may be especially apprehensive about undergoing a procedure without a parent present, there is rarely any reason a parent cannot accompany a child into a treatment room to help with undressing, measuring weight and height, and

taking a temperature or accompanying a child to another department for a procedure such as an ultrasound or blood work. Most importantly, the mother or father can continue to comfort the child in these strange surroundings.

Patient- and family-centered care includes the whole family, whereby the family has an integral part in shared decision making. Patient- and family-centered care is an approach to the planning, delivery, and evaluation of healthcare that is grounded in mutually beneficial partnerships among healthcare providers, patients, and families. It redefines the relationships in health care ([Institute for Patient- and Family-Centered Care, 2016](#)).

Promoting patient- and family-centered care is essential and allows parents and caregivers to participate in their child's care. Family-centered care opportunities include allowing caregivers to be active in patient rounds, which include decision making regarding clinical management and communication among the team members and serve as a venue for teaching and discussion ([Blankenship, Harrison, Brandt, et al., 2015](#)).

### *What If . . . 36.2*

**Becky's father does not call the nurse when her intravenous pump alarms that it is finished. Instead, he resets the pump himself. How would the nurse best respond?**

***Supporting Sibling Visitations.*** Children in a family are under considerable stress while a sibling is hospitalized because their world changes as much as the parents' world does ([Ivany, LeBlanc, Grisdale, et al., 2016](#)). Incorporating family-centered care supports the need for sibling visitation. Sibling visitation refers to allowing the brothers and sisters of a hospitalized child to visit the ill child along with parents. Allowing this alleviates loneliness on both sides, helps prevent other children at home from imagining the ill child is sicker than is true, and helps the ill child continue to feel a part of the family. Check with parents that siblings who visit are free of communicable disease. During a visit, you may need to help parents divide their time between the ill child and siblings (short, frequent visits may be better for young children than long ones).

***Minimizing Negative Effects of Procedures.*** Children often undergo numerous diagnostic and therapeutic procedures that have the potential to cause pain, fear, and anxiety. Details related to specific procedures are discussed in [Chapter 37](#). General guidelines designed to make any procedure less painful or frightening are discussed in the following sections.

**Nursing Diagnosis:** Fear related to diagnostic or therapeutic procedures

**Outcome Evaluation:** Child voices satisfaction with comfort measures; describes

self-participation in a procedure; rates experience as no less than “tolerable” after the procedure.

***Reducing or Eliminating Pain.*** Some pain and discomfort are unavoidable in association with health care. Limit this whenever possible, however, by such measures as advocating for the use of intermittent infusion devices such as heparin locks (see [Chapter 38](#)) to eliminate multiple punctures for intravenous medication or blood sampling, providing traditional comforts such as a change of clothing or position, or talking about a favorite subject. Children respond well to alternative therapy techniques, such as distraction or imagery, to divert attention from painful stimuli, lessening pain and distress. Music, video, breathing exercises and storytelling are examples of distraction techniques that have been effective ([Al-Yateem, Brenner, Shorrab, et al., 2016](#)). Children may not always express discomfort as freely as adults; thus, age-appropriate assessments before and after a procedure are necessary to assess their pain.

***Maintaining the Child’s Bed as a Safe Area.*** To assure children that their bed is an area that is safe, all painful procedures should be done in a treatment room or another department, away from the child’s bed. Decreasing painful procedures at the bedside promotes a child’s feeling of safety. Remember that finger punctures for blood work, although done quickly, can cause as much pain and stress as a venipuncture. In addition, dressing changes, although not necessarily painful, can cause worry and also should be done in a treatment or procedure room, when applicable.

***Helping Children Maintain Control.*** Events are always more frightening if they seem to be beyond our control. Based on the child’s *developmental age*, explaining to children what will happen, including what they will feel or what they will see, and helping them to make choices whenever possible limits this type of fear because these actions offer a sense of control ([Fig. 36.6](#)). In almost any procedure, there is some choice a child can make (e.g., whether or not to use a straw to drink, deciding what size of tape to use on a bandage, or deciding which direction to walk down the hallway).

**Figure 36.6** Include children in procedures whenever possible to offer them a feeling of control. (gpointstudio/Shutterstock.com)

### Providing Adequate Play Facilities

Play is often described as the work of children because it is the medium through which they learn. Play is often an indicator of how the child is coping with the stressors of hospitalization and may act as way to control their environment (Potasz, Varela, Carvalho, et al., 2013). Children need to be able to play as much as possible not only to aid in distraction but also to encourage emotional well-being. Most children's hospital units are equipped with a playroom or play space that is maintained as a "pain-free" zone. No medical procedures, not even painless ones, should be performed in this area because the child may then perceive the space as frightening. Children who are on bed rest need age-appropriate activities supplied for them to prevent boredom and a loss of control, which can lead to depression or behavioral regression.

**Therapeutic play** is play designed to help children express their feelings about painful or frightening procedures (He, Zhu, Chan, et al., 2015); however, play needs are different for each child. A child's characteristics, such as temperament, coping style, and cognitive abilities; family variables such as parental anxiety, presence, and involvement; and diagnosis/treatment variables are known to affect psychosocial vulnerability and thus influence the child's particular needs in terms of play (Brown, Chitkara, Percelay, et al., 2014; Koller, 2008). The uses of therapeutic play and guidelines for providing this are discussed later in this chapter.

### Setting Limits on Behavior

Setting limits on behavior can help promote a positive hospital stay because it can help to provide a sense of security and safety. Children who refuse to cooperate for procedures generally do so out of fear of the unknown rather than deliberate misbehavior. The better prepared a child is for a procedure, the more apt the child is to accept it (Raleting, 2015). If limit setting is necessary, such as with a child who hits or bites other children, confer with the child's parents about the need for limit setting and what measures they would suggest. Gain their cooperation and approval so that what you do is consistent with their usual care. Using "time-out" periods or removing the child to a nonstimulating area for a short time could be an effective measure. Be certain a child understands time-out rules (e.g., if the child bites or hits again, sitting alone for a designated period will be necessary). The next time the child does misbehave, give one warning that the behavior is against the rules; if the behavior continues, take the child to the time-out spot. If the child is disruptive, begin timing the period from when the child quiets down. When the child has been quiet for the specified duration (usually 1 minute per year of age), the child can leave the time-out place and rejoin activities.

## DISCHARGE PLANNING

Discharge planning is not only an important link between the hospital and the home, but it is also a final way to create a satisfying hospital experience.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Parental health-seeking behaviors related to care for child at home after hospital discharge

**Outcome Evaluation:** Parents state accurately the care their child will need at home; describe and demonstrate any procedures they will need to perform with child.

Discharge from the hospital involves education, even if the hospitalization lasted a few hours (e.g., same-day surgery). It is vitally important that nurses anticipate the family's and child's discharge needs so the discharge process is one of continuity with hospital care. It is important to collaborate with the interdisciplinary team and assess the family's resources (physical and emotional) for the ability to provide continued care before the child is discharged home. Discharge planners can be indispensable in helping to ready parents for home care. Often, discharge follow-up instructions include referrals to services such as physical therapy, mental health, and visiting nurses. Communicating with the family through verbal and written instructions is essential for maintaining comprehensive care. Electronic communication, in the form of e-mail, text messaging, and mobile apps, are being utilized for follow-up care (Holland, Conlon, Rohlik, et al., 2015).

If a child has been admitted to an ambulatory care unit, preparation for discharge should begin at almost the same time as admission. If caregivers are instructed to continue a procedure at home, allow them to demonstrate that skill in the hospital; this allows for education and guidance before a parent is to perform independently at home. For example, if a parent is to continue changing sterile dressings, where can they buy dressings? Will they be able to afford them? Allowing communication between the nurse and parent is essential for transition of care to the home.

It is not uncommon for preschool children to manifest regression in behavior, such as thumb-sucking, bed-wetting, temper tantrums, and nightmares, after returning home from a hospital stay; school-age children may manifest these behaviors to a lesser extent. Reassure parents that this regression in behavior is often temporary. More serious manifestations after hospital discharge include posttraumatic stress and are often seen after a stay in a PICU. "Parents describe decreases in children's self-esteem and emotional well-being, increased anxiety, and negative behavioral changes, e.g., sleep disturbances, social isolation" (Rennick, Dougherty, Chambers, et al., 2014).

## Nursing Responsibilities for Care of the Ill Child and Family

Nursing responsibilities will vary, naturally, with the type, extent, and seriousness of a child's illness, age, care setting, and individual circumstances. [Chapter 37](#) discusses specific responsibilities related to diagnostic tests or interventions. [Chapter 39](#) discusses the important role of promoting comfort in an ill child. A number of responsibilities such as promotion of normal growth and development, sleep, stimulation, and play are more global, cross all ages and phases of care, and are discussed here.

### PROMOTING GROWTH AND DEVELOPMENT OF THE ILL CHILD

It is easy for children to fall behind in growth and development because of an illness unless healthcare providers monitor for and strengthen this.

#### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for delayed growth and development related to the effects of illness

**Outcome Evaluation:** Child demonstrates only limited signs of regression to previous stage; is able to continue doing the activities most recently accomplished.

Illness represents a crisis event, and, in a crisis state, children, like adults, can grow from the experience or, in contrast, can be overwhelmed and regress.

**The Ill Infant.** To promote optimal growth and development in infants, maintain their at-home schedule when possible. Sameness provides security to an infant and encourages the development of trust. An infant who is used to sleeping in a bassinet, for example, may feel loose and insecure in a large crib. Swaddling such a child in a receiving blanket in a large crib would help to offer the same close, bound feeling of a smaller sleeping area. Providing a singular room in a NICU has been shown to improve parent satisfaction with care because it removes the parents from the noise and tension of the larger, unstructured room ([Caldwell, 2015](#)).

Unless a child is diagnosed with failure to thrive or is obviously underweight, illness is not an ideal period in which to introduce new foods or formula. Breastfeeding should be continued if at all possible. If a mother cannot be at the hospital constantly, urge her to pump milk, freeze it, and bring it in so her child can continue to receive the immunologic protection of breast milk. Overall, because infants cannot begin to understand the strange feelings accompanying illness, they need increased swaddling and comforting. As their condition improves, provide stimulation and play opportunities suitable for their developmental age.

***The Ill Toddler and Preschooler.*** Because illness can limit autonomy and prevent children from learning how to do new things, try to find opportunities to promote both autonomy in toddlers and initiative in preschoolers. One way to accomplish this is to encourage children to make choices about their care whenever possible. For instance, taking medications is not a choice, so never ask “Do you want to take your medicine now?” unless there’s really a choice—almost all children will say “NO!” Instead ask, “Which do you want to take first, the white medicine or the pink?” Toddlers and preschoolers who are not used to sleeping in cribs at home may resent being placed in a crib in a hospital unless you explain to them, “All our beds here have side rails.” Watch energetic toddlers closely to be certain they do not attempt to climb over crib rails to get out of bed. A child who does try to climb out of a crib might be safer sleeping in a bed or may need a safety crib cover when a parent is not in the room.

As with infants, illness is a poor time to change the eating habits of toddlers and preschoolers. Because children of this age insist on self-feeding, they often eat better at a small table than using a tray in bed. Many child care units organize “toddler tables” so children this age can eat together. Supervise children carefully if they are eating with others to be certain they eat only their own food, not food belonging to someone else. Also be certain they are not so distracted by other children that they do not eat. All children may eat better when a parent joins them for a meal.

Illness is also a poor time to introduce toilet training, even if this is an appropriate activity for the child’s age. However, if parents have already begun toilet training, continue this if possible, so you maintain a usual routine.

***The Ill School-Age Child.*** Ill school-age children need to continue to work on a sense of industry or learning more about how and why things are done. Explaining specific procedures and involving them as much as possible in planning their care allows school-age children to have some semblance of independence and control, which in turn promotes self-care. Self-care attributes the practice of activities that an individual initiates and performs on his or her own behalf to maintain life, health, and well-being (Orem, 2001).

School-age children (and adolescents) who are hospitalized for the short or long term become socially isolated from their families, classmates, and friends and from the normalcy of everyday life (Hopkins, Green, Henry, et al., 2014). They need to continue schooling, provided their condition allows it. Maintaining that routine, everyday activity provides security to an otherwise insecure day. With increased, readily available technologies providing access, communication and interaction, and with a variety of tools and software applications, the use of technology may offer opportunities for learning for children in hospitals who otherwise will not be able to connect to their original schools (Maor & Mitchem, 2015).

Remember, school-age children also are developing moral responsibility and so may find comfort in spiritual practices. Ways to assist with spiritual needs during a

hospitalization are shown in [Table 36.2](#).

**TABLE 36.2 NURSING INTERVENTIONS TO MEET CHILDREN'S SPIRITUAL NEEDS**

Action	Implementation
Rituals/religious/spiritual practice	Ask on hospital admission whether a child follows rituals or a religious/spiritual practice. Write it on the plan of care so all health care providers know to provide time for this.
Services	Include time for children and their families to attend religious and/or spiritual services. When warranted, ensure transportation by wheelchair or other means available.
Spiritual support	Allow volunteers representing different faith communities or congregations to be providers of spiritual care.
Religious articles	A child's parent may wish to attach a religious article to the child's clothing or pillow or to post it over the bed. Be careful when changing linen or gowns so that you do not throw away such articles. Mark their presence and importance on the child's plan of care.

Encourage school-age children to carry out as much self-care as usual, and, if being cared for at home, to continue to contribute to household routines, such as helping with dishes or picking up after themselves as much as they are able. This not only takes some burden off caregivers but also sends a signal that people expect this illness to pass and the child to become a full family member again.

**The Ill Adolescent.** An adolescent who is struggling to develop a sense of identity may find it difficult to be ill because the limitations imposed by an illness make the development of a sense of identity so difficult. If possible, help adolescents to continue to participate in activities they did before becoming hospitalized to help them feel that their world is not totally changing. Encourage them to maintain self-care activities and good hygiene practices to help preserve self-esteem.

Illness can be especially difficult for adolescents also because peer relationships are so important to them and a hospitalization automatically interferes with those. They may miss acting in a school play, being chosen for a sports team, or competing for a scholarship. A girlfriend or boyfriend may break off a relationship. To help avoid feelings of exclusion and hurt, urge them to welcome visitors from their peer group. Suggest electronic communication formats such as texting or e-mailing as easy ways to keep in contact with friends and maintain relationships with individuals who are important to them while separated from them.

Adolescents usually appreciate being hospitalized in a special adolescent unit or at

least in a room free of childish decor. Consider that parents of an adolescent have the same anxiety and concerns as parents with younger children. Fear of procedures and pain of separation are not limited to the younger than 13 years of age set. Although many adolescents enjoy having parents stay overnight because it is reassuring to know that they are concerned, they may also enjoy being separated (assuming everything is going well) and may not want their parents present all day and night.

Often, adolescents convey a blasé attitude toward procedures (e.g., having an X-ray taken is nothing, surgery is a cinch, a cast change is a snap). Listen carefully to make certain adolescents really feel this way and are not trying to convince themselves that a procedure is harmless. Remember that adolescents are extremely worried about their body image. Explain to them what is going to happen in surgery or in other departments because it is easy to assume from their attitude they know more than they do.

## PROMOTING NUTRITIONAL HEALTH OF THE ILL CHILD

Nursing responsibilities related to nutrition for ill children include maintaining optimal nutritional status in the face of an illness or therapy that interferes with adequate intake, correcting nutritional deficiencies or otherwise aiding children and families to follow the nutritional care plan devised by the healthcare team, and educating a child and family regarding specific nutritional needs as well as overall sound nutritional health. Specific procedures for promoting nutrition such as measuring fluid intake and output and providing enteral feedings, gastrostomy tube feedings, and total parenteral nutrition are described in [Chapter 37](#).

### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for imbalanced nutrition, less than body requirements, related to lack of appetite

**Outcome Evaluation:** Child will exhibit no further weight loss and, if malnourished, will gain 2.2 lb (1 kg) per week. The child will maintain adequate nutritional status as evidenced by weight within the normal range for age.

An acute illness in a child, such as pneumonia, is often accompanied by a loss of appetite; gastrointestinal illnesses frequently cause nausea, vomiting, and diarrhea, making hydration difficult to maintain. Because most acute illnesses last only a few days, there is no need for children to eat more than a small amount during this time as long as they can drink fluid. Trying to force them to eat only increases nausea and vomiting, which increases the possibility of creating an electrolyte imbalance. The need for IV hydration is discussed in [Chapters 38](#) and [45](#). When an illness lasts for more than a few days, however, providing adequate nutrition becomes increasingly

important because children need nutrients not only to repair ill or diseased tissue but also to maintain normal childhood growth.

Important points to address when planning nutrition for ill children are summarized in [Table 36.3](#). Children who are hospitalized often tolerate hospital-prepared food, which can be repetitious and bland, better than adults. Provided that it is the kind of food they like, such as chicken fingers or pizza, these may appeal to children more than the elaborate dishes with spices and sauces preferred by adults. Children who are receiving care at home need as much nursing supervision of their nutrition as those in healthcare agencies (possibly more) because they may not have a dietitian planning meals to ensure adequate nutrition. Assess not only the quantity but also the quality of food to ensure that intake is optimal. If prescribed, ask whether nutrition supplements are being offered to increase intake.

***Encouraging Fluid Intake.*** Increasing oral fluid intake when a child is at risk for dehydration is important. A primary care provider's instruction should state in detail the amount of fluid a child is to receive during 24 hours because the amount differs from age to age.

- Offer small, full glasses frequently rather than larger, half-full glasses; children are mid-school age before they evaluate the amount of fluid in a container rather than the size of the container.
- Determine the child's favorite fluid and then offer it, if appropriate.
- Popsicles and Jell-O count as fluids.
- Children can drink more of a clear fluid (e.g., ginger ale, water) than a thicker fluid (e.g., milk shakes, cream soups) because thicker fluids are absorbed from the stomach much more slowly.
- Suggest soothing beverages such as milk or Pedialyte popsicles for children with mouth lesions. Avoid carbonated beverages and citrus or acidic fruit juices because the acid content and/or carbonation sting their mouths.
- Ice melts to one half its volume. Count a glass of ice chips as only a half-full glass of fluid.
- Encourage breast feeding whenever possible.
- Unless contraindicated, let children drink fluids with a straw; this is a novelty to many who do not normally use these and so encourages intake.
- Introduce a game, such as Simon Says (Simon says, "Drink") or a board game in which a child takes turns and with each turn has to take a drink. Use play as a method of teaching nutrition and sound dietary habits to children ([Hayes, Spano, Donnelly, et al., 2014](#)).

***Encouraging Food Intake.*** **Calorie counting**, as the name implies, involves counting the number of calories that children ingest each day. To do this, record all the foods that a child eats during each 24-hour period, being certain to include snacks, candy, or gum. A dietitian then will analyze the list and determine the caloric intake. Be certain when doing this that you describe the types of food and amounts (i.e., not

“some toast,” but “half a slice of whole wheat toast”). Make sure that everyone caring for the child (including parents) is aware that calories are being counted so that they also record this information accurately.

**TABLE 36.3 AREAS TO CONSIDER WHEN PLANNING NUTRITION FOR ILL CHILDREN**

Area	Importance
Meaning of food	Early in life, infants learn to associate eating with being held and loved; if they cannot eat for some reason, such as while waiting for surgery, they may view the restriction as punishment or a restriction of love. Encourage a parent to sit and rock them or read to them to lessen this uncomfortable time.
Opportunity for socialization	Mealtime is an ideal time for family members to socialize and share their day; being separated from family for meals can create loneliness and, consequently, a poor appetite. Urge parents to visit at mealtime if possible, so “sharing a day” can continue.
Level of stress	Children under stress may either feel a loss of appetite or experience a need to snack frequently; this can make it necessary to be certain children maintain adequate intake if not hungry and that, when hungry, their snacks are nutritious.
Custom and culture	Food customs are important; for example, many children like foods served separately and resist eating them if they are mixed into a casserole. They like best the foods they typically eat at home. If possible, ask if a parent could bring in a favorite food treat to stimulate appetite.
Environment	Hunger is associated with the sight and smell of food; many children are normally in the kitchen and help prepare meals; they may not feel as hungry, therefore, when food is served to them without their having seen and smelled it being prepared. Allowing them to pick what foods they want for meals, if possible, gives them at least some sense of food preparation and selection.

**QSEN Checkpoint Question 36.3**

**QUALITY IMPROVEMENT**

The nurse wants to encourage Becky to drink a lot of water to promote hydration. During the most recent rounds, Becky drank an entire 10-oz glass at once and vomited several minutes later. Considering the failed attempt to encourage oral hydration, what would be the nurse’s best next course of action?

- a. Teach Becky about the consequences of failing to drink sufficient water.

- b. Set up a plan with Becky and her parents to provide small glasses of water frequently.
- c. Continue to offer her large glasses of water so she does not have to drink so often.
- d. Alert her that if she does not increase her fluid intake she will likely have to receive IV fluids.

Look in *Appendix A* for the best answer and rationale.

## Promoting Safety for the Ill Child

A prime consideration of nursing interventions is to keep children safe during illness care.

### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for injury related to procedures or therapy necessary for care

**Outcome Evaluation:** Child remains free of injury, such as a fall from bed or injury from medical equipment.

Promoting safety for children is a responsibility for all healthcare providers. Care of a child who is ill and being cared for at home includes assessing the safety of the house and providing family teaching. It also includes making provisions for emergencies. For example, a family may need to install a counter-level telephone or purchase a cell phone so a child in a wheelchair can call for emergency help. Parents might also need to make a plan for how to evacuate an ill child from the home in an emergency such as a fire.

Safety on a children's unit or clinic is the responsibility of all healthcare providers, from the administrator of the institution to part-time healthcare personnel. Important steps to follow to make a child healthcare environment a safer place include:

- Always be sure of the location of all children in your care.
- Ensure that doors or gates are provided near stairways or elevators.
- Ensure that doors of healthcare facilities have working alarms to prevent children from going out and to prevent strangers from coming in.
- Be sure windows are covered by screens or guards so children cannot climb up on sills and fall out.
- Check that the side rails of beds and cribs are in good repair, raised appropriately, and locked.
- Always raise bedside rails after a child has received preoperative or sedative medication.

- Test a crib rail after it is raised to ensure the lock has caught so the rail will remain raised.
- Push bedside tables or stands away from cribs so a child cannot climb over the railing and use the stand as a step down.
- Be certain crib caps are available for small children to prevent them from climbing out of bed.
- Fasten the seat belt restraint for infants in high chairs. Never leave an infant in a high chair (at home or in a hospital) without someone close enough to reach the child because infants can easily squirm out of a high chair restraint.
- Ensure that electrical cords or appliances such as hair dryers are not used in bathrooms, where they could come in contact with water.
- Be careful of the placement of television/call cords or window blind cords so they cannot lead to strangulation.
- Never leave children alone in a bathtub; they could turn on the hot water and scald themselves or slip under the water and drown.
- Never leave equipment or items that would be harmful to eat within the reach of children.
- Adhere to all fire precaution measures.
- Closely follow standard infection precautions to prevent the spread of infections.

**Promoting Fire Safety.** Fire precautions both in the home and in the hospital are essential in preserving the safety of children. Adults can usually take responsibility for removing themselves from a burning structure, but children depend on care providers. Ensure that there is a plan of action in case of a fire and that everyone in the home, in the clinic, or on a hospital unit knows it. To be certain a home is safe, having a smoke detector on each floor is a wise precaution. A downstairs bedroom is not only safest in case of a fire but also allows a child more self-care ability. Fire departments supply free decals for the bedroom windows of children or those with a unique concern so they can be easily located in a fire. Parents can contact their local fire department for this safety measure.

Electrical equipment such as respiratory and cardiac monitors, radiant heat warmers, special-care equipment, and electrical heating pads are often used in the care of children. Do not use equipment with frayed cords or equipment that is not properly grounded. Plugs should be three pronged for extra safety; do not overload circuits with additional plugs. Electrical outlets should have safety caps to cover them when they are not in use so toddlers cannot poke objects into them and electrocute themselves.

**Adhering to Standard Infection Precautions.** In every healthcare setting, closely follow standard infection precautions to protect ill children, the family, and staff from infections (CDC, 2015b). With a compromised immune system, ill children may be more susceptible to repeat or secondary infections than usual, especially drug-resistant strains of bacteria such as methicillin-resistant *Staphylococcus aureus*

(MRSA), which can spread easily if not everyone is conscientious about precautions. A proper hand washing technique, disposal of tissues and waste materials, and efforts to minimize exposure of other ill children or adults are all effective methods to decrease the risk of infection. For more details on infection control, see [Chapter 43](#).

## Promoting Adequate Sleep for the Ill Child

Ill children need adequate rest and sleep so their body tissues can effectively use nutrients for repair and normal growth can continue ([Stremler, Adams, & Dryden-Palmer, 2015](#)). Children may not sleep well when they are ill because of discomfort, pain, the administration of medications, or intensified symptoms of chronic sleep problems. They may not sleep well in a hospital because it is a strange setting; they may have to undergo so many procedures that they also do not nap or rest as much during the day as usual. Children who are recovering from trauma such as injuries from a car accident or burns may be unable to sleep because of nightmares about the accident. These nightmares can cause them to suffer sleep deprivation in the same way as a child who is frequently awakened for procedures during the night. Encourage parents to stay with these children for support and comfort. Remember, though, that parents who sleep in hospital rooms do not obtain adequate sleep either. Although their presence is healthy for children, it can limit the parents' capacity to meet the child's needs ([Angelhoff, Edéll-Gustafsson, & Mörelius, 2015](#)).

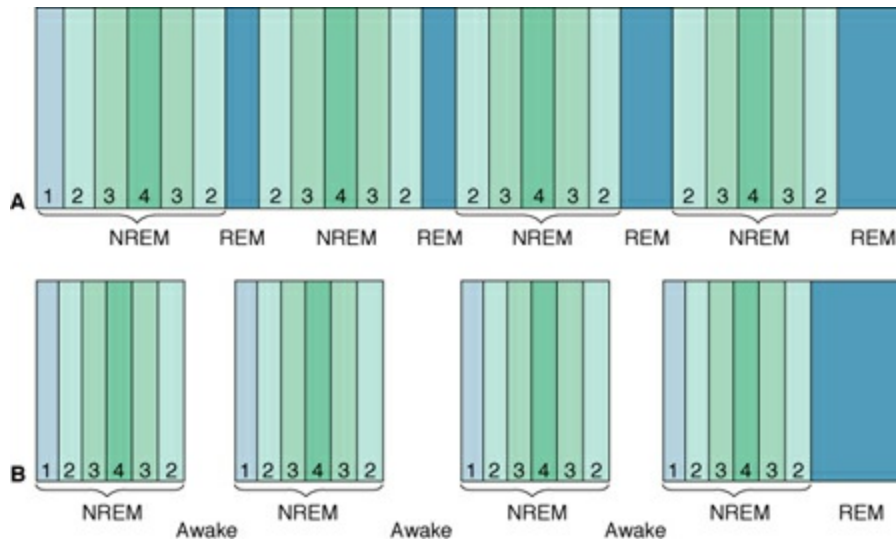

### SLEEP PATTERNS

Sleep is influenced by apprehension level, state of health, habit, medication, and environment at the time of sleep. Stages of sleep are summarized in [Table 36.4](#). [Figure 36.7A](#) shows a pattern of normal sleep. According to the [National Sleep Foundation \(2017\)](#), as a sleep cycle begins, children first enter **non-rapid eye movement (NREM) sleep**. This type of sleep occurs in up to 80% of total sleep time. As children fall deeper and deeper asleep, they pass from stage I to stages II, III, and IV of NREM sleep over a period of 20 to 30 minutes. **Rapid eye movement (REM) sleep** follows. In infants, most of sleep time is REM sleep, whereas late adolescents have the least amount of this type of sleep. The sleep pattern of a child who is awakened frequently during the night for procedures would resemble that shown in [Figure 36.7B](#).

**TABLE 36.4 STAGES OF SLEEP IN CHILDREN**

Stage	Description	Nursing Implications
Non-rapid eye movement (NREM)	A feeling of drifting or falling. Often described as twilight sleep. Temperature and heart rate decrease slightly; electroencephalogram (EEG) waves show	A child can be roused easily from this early sleep by the slightest noise or silent presence

stage I	peaked, frequent (alpha) waves.	of another person in the room. Reduce noise level in room to promote sleep.
NREM stage II	Sleep deepens. Temperature and heart rate decrease slightly more.	It is more difficult to wake a child from sleep when this point is reached.
NREM stage III	Sleep deepens still further. An EEG tracing reveals mixed spindle and slow (delta) waves. Temperature and heart rate decrease further. This period lasts about 10 min.	It is very difficult to wake a child from stage III sleep. Use patience to wake a child fully to offer medicine.
NREM stage IV	Approximately 20–30 min after beginning to fall asleep, a child enters stage IV sleep. Respirations and heart rate slow even more, and blood pressure and temperature decrease; EEG shows slow, steady (delta) waves. Children remain at a stage IV sleep level for approximately 30 min and then progress back through stages III and II until they then pass into a phase of REM sleep.	Children may be confused and unable to orient themselves readily if awakened from stage IV sleep. Use patience until a child is fully awake, particularly if asking a question.
Rapid eye movement (REM)	Eyes move in rapid, involuntary motions. Respirations are irregular; body turnings, movements, and penile erections may occur. Lasts 10 to 30 min and then a new sleep cycle with NREM sleep begins.	Dreaming occurs during REM sleep. Although children appear to be close to waking because of the active eye movements, they are really very soundly asleep. Children may wake afraid and crying, disturbed by a frightening dream.

**Figure 36.7** Sleep patterns. **(A)** A normal sleep pattern. Notice how the periods of rapid eye movement (REM) sleep increase in length during the last half of the night. **(B)** The sleep pattern of a child who has been awakened frequently during the night. Notice how little REM sleep is present.

The purpose of NREM sleep, the first phase of sleep, is rest and restoration of the body; this stage keeps body cells functioning and healthy. During the periods of stages III and IV NREM sleep, the secretion of growth hormone (somatotrophic hormone) from the pituitary is at its highest level. Growth hormone is necessary for protein synthesis, for the growth of new cells, and for the repair and maintenance of all cells. Corticosteroids and adrenaline from the adrenal gland, which are instrumental in the catabolism or breakdown of cells, are at their lowest levels. This balance of hormones produces the ideal combination for protein synthesis and cell growth and repair.

The purpose of REM sleep is less clear. The REMs may serve to coordinate binocular vision. Dreams that occur during this time apparently serve as a release of tension or help to integrate new knowledge and experiences with the old in the brain's memory system. Vital signs may fall during NREM sleep. During REM sleep, vital signs rise to near normal levels. These periods of REM sleep interspersed with NREM sleep, therefore, may be a fail-safe measure to prevent vital signs from falling too low during sleep.

## SLEEP DEPRIVATION

Infants are dependent on sleep to promote brain development. Deprivation of sleep from 2 to 4 hours in healthy infants has been studied and thought to lead to short-term variations in cardiac function as well as an increase in apneic events (Allen, 2012). Children who do not receive enough sleep can suffer **sleep deprivation**, just as adults do. After approximately 4 days of poor sleep, this can cause them to experience difficulty in concentrating and episodes of disorientation and misperception.

If the sleep loss is mainly REM deprivation, children show symptoms of irritability and difficulty concentrating. Lack of stage IV NREM sleep, in contrast, tends to cause apathy, physical fatigue, and depression and can slow recovery. This is the same phenomenon that can happen in adolescents if they are studying for exams. It easily occurs in younger children during illness if they are awakened frequently for treatments.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Disturbed sleep pattern related to timing of medication, discomfort, or sleep disorder

**Outcome Evaluation:** Child sleeps through the night without interruption (when therapeutic regimen allows); is alert and active during the day; is able to take nap during the day if that is part of his or her usual sleep schedule.

Because sleep is so important for ill children, you need to take special steps to ensure that children are able to sleep during an illness. Be certain children are as free of pain and worry as possible. Try to let them maintain as normal a bedtime routine as possible (e.g., bath, change to nightclothes, nighttime story, prayers). Provide an atmosphere conducive to sleep (e.g., lights out, quiet surroundings, reassuring support people). Children who are bored with bed rest may catnap constantly during the day and then be wide awake at night. Providing more interesting activities for them during the day can help reduce their naps and increase nighttime sleep.

**Managing Chronic Sleep Problems.** Some children may have chronic sleep problems such as night terrors, nocturnal enuresis, somnambulism (sleepwalking), sleep talking, and sleep apnea. These sleep problems can intensify with illness and can increase sleep deprivation in ill children.

Somnambulism is a common sleep problem in children. It apparently occurs during NREM sleep, probably during the deepest part of stage IV. It is frightening for children to wake and realize they have been sleepwalking. Sleepwalking can be potentially dangerous when children are ill because, while getting out of bed, they could dislodge intravenous tubing or oxygen equipment. It is untrue that sleepwalkers should not be awakened; instead, wake them gently, help them get reoriented, and then return them to bed after reassuring them they are safe. Be certain that the side rails are raised on the bed of a child who tends to sleepwalk. In a hospital, it may be necessary to move a child's bed out into the hallway at night near the nurses' desk if a parent will not be sleeping over so the child can be observed for sleepwalking.

Sleeptalking seems to occur during REM sleep. Dreaming of some frightening or puzzling situation, a child calls out a name or instruction such as "Stop!" Because illness is a stressful situation that increases anxiety, sleeptalking may also occur at an increased rate during this time. It is unnecessary to wake a child who is sleeptalking

unless the child is thrashing about and would dislodge equipment such as intravenous tubing. However, because sleeptalking usually results from a frightening dream, waking the child gently can be comforting. Parents may need to be assured that sleeptalking is harmless and will probably subside when their child is well again.

Some children are prone to night terrors, or wake up screaming approximately 20 minutes after they fall asleep. The condition tends to be familial. Waking children and comforting them helps everyone in the house or hospital unit return to sleep. In the morning, children rarely remember the incident.

Sleep apnea is the cessation of respirations during sleep for 20 seconds or more. It tends to occur more frequently in obese children, possibly because of the increased weight of their chest. It may contribute to sudden infant death syndrome or failure to thrive (Qubty, Mrelashvili, Kotagal, et al., 2014) (see Chapters 26 and 55). Infants who are diagnosed with sleep apnea may be prescribed respiratory monitors to evaluate their breathing pattern and warn against any cessation of respirations.

## Promoting Adequate Stimulation for the Ill Child

Children are in constant interaction with both their internal environment (body) and their external environment (surroundings) by means of their five senses and the central nervous system. This makes them capable of responding to changes in the environment and, by so doing, meets basic needs. Any illness that changes their ability to respond to their environment can cause either sensory deprivation or sensory overstimulation.

### SENSORY DEPRIVATION

**Sensory deprivation** is the condition of being deprived of, or lacking, adequate sensory, social, physical, or cognitive stimulation. When this happens, children tend to lose the ability to make decisions and become easily confused and depressed. Some children are more prone to sensory deprivation than others.

Ill children may have sensory deprivation because they are confined to their homes or hospital rooms and their varied activities such as school, sports, and clubs are replaced with hours of watching television or playing video games. Hospitalized children respond best to a diversity of readily available, independently accessible, age-appropriate, gender-appropriate, and developmentally appropriate leisure and entertainment facilities seamlessly integrated throughout the hospital environment (Lambert, Coad, Hicks, et al., 2014).

Children with hearing or visual deficits are more prone than others to sensory deprivation. Children with forms of sensory nerve loss or those receiving chemotherapy may lose their sense of touch, taste, or proprioception (the sense of where they are in space). After losing these forms of perception, children may draw back from interacting with other people because they are self-conscious about the loss, so they may be further deprived of social and cognitive stimulation. Techniques for interacting with sensory-

deprived children are discussed in [Chapter 50](#).

Some children receive medication to lessen awareness of the stimulating factors in their environment. To ensure they do not suffer sensory deprivation, give them definite orientation measures, such as always mentioning the time of day and the day of the week in conversations with them.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Deficient stimulation from (or interest or engagement in) recreational or leisure activities

**Outcome Evaluation:** Child demonstrates alert and interested attitude toward self-care and play activities.

**Providing Stimulation for the Child on Bed Rest.** Children on bed rest cannot secure materials for cognitive stimulation by themselves or participate in physical activities, except to a limited degree. A room where walls and windows offer no visual appeal and therapeutic equipment provides the only sound offers them little sensory stimulation. If no one comes into the room, they may suffer from social deprivation. When possible, encourage a child with restricted mobility to move out of bed into a wheelchair; this can provide some mobility and transportation to a place of interest, such as near a window or, in a hospital, near the nurses' desk. Watching television, playing with tablets/phones, and engaging in social media are all common activities for children on and off bed rest; however, these activities can actually overstimulate the infant or child's brain and can decrease executive function. Executive function comprises the cognitive skills that undergird self-regulation. In other words, it helps us plan, focus attention, remember instructions, and perform multiple tasks at the same time ([Lillard, Drell, Richey, et al., 2015](#)).

Occasionally, a child must remain in bed, depending on the diagnosis (e.g., a liver or spleen injury). When possible, other stimulation, such as a favorite toy, games, books, or simply talking with someone, must be provided for these children to help them maintain physical bed rest; otherwise, they become bored and irritable and thrash and turn instead of lying still ([Fig. 36.8](#)).

If a child is home on bed rest and the bedroom is away from the main activities of the home, encourage family members to include the ill child in as many family activities as possible (e.g., bring the television set into the child's bedroom so the entire family gathers there, set up a card table in the room so everyone can eat there) or encourage the child to join the rest of the family for activities by resting on the couch in the living room, a lounge chair in the backyard, or a chair in the kitchen. This principle applies to hospitalized children as well. A toddler, for example, may rest in a parent's lap rather than in a bed.

***Providing Stimulation for Children on Transmission-Based Precautions.*** Children who are placed on transmission-based precautions because of the possibility of contagious illness may experience severe sensory deprivation if everyone who enters the room must wear a gown and mask or if the number of visitors must be kept to a minimum. If gloves are part of precautions, a child can experience a significant loss of skin-to-skin contact as well. Transmission-based precautions are discussed in [Chapter 43](#). Careful planning must be done to ensure that a child who is isolated this way is not psychologically isolated and that every possible measure is carried out to maintain sensory, social, physical, and cognitive stimulation. For example, try to visit with a child at a time other than those times in which you must perform procedures so you can simply talk, place the bed so the child can see out of the room, encourage the child to text message or video chat friends, make posters to decorate their room, or encourage interactive play with electronic games. For ideas on providing stimulation to children in specific age groups, refer to [Chapters 29 to 33](#).

Providing safe, reliable Internet resources for immunosuppressed adolescents with chronic conditions wanting to socialize with peers can be an alternative to direct socialization and also decreases the risk of contracting a communicable illness ([Maor & Mitchem, 2015](#)).

**Figure 36.8** Children on bed rest need stimulation. Here, a young child enjoys coloring. (sonya etchison/[Shutterstock.com](#))

## **SENSORY OVERLOAD**

**Sensory overload**, in contrast to deprivation, occurs when children receive more stimulation than they can tolerate or process. Children with sensory overload react similarly to those with sensory deprivation or feel confused, unable to make decisions, and feel severely fatigued. Sometimes, it is difficult to determine the cause of these

symptoms (whether they are caused by sensory deprivation or overload) unless assessed carefully.

The lights in ICUs, for example, are never turned out. Although children may find this comforting, it can also result in excessive stimulation. In addition to constant light, there is excessive sound such as the whir of machines, the buzzing of ventilators, the ringing of alarms, or the mix of voices in consultation. Excessive noise levels in the NICU have been studied as a factor influencing the function of a premature infant's brain through alterations of cortisol levels, apnea, decreased oxygen saturation and perfusion from exaggerated startle response, and abrupt fluctuations in heart rate (Campbell, 2016). The U.S. Environmental Protection Agency (EPA), Office of Noise Abatement and Control (1974) and American Academy of Pediatrics (1997) recommend that hospital noise not exceed 45 dB during daytime hours and 35 dB at night. Using indirect lighting whenever possible, implementing the national recommended safe sound level (NRL) of 45 dB in infants' rooms, reducing unnecessary conversations, and covering incubators for "quiet times" are all measures used to reduce these types of stimulation (Laubach, Wilhelm, & Carter, 2014).

### *QSEN Checkpoint Question 36.4*

#### **PATIENT-CENTERED CARE**

Becky's mother is worried Becky will have a traumatic hospital experience. Which of the following would the nurse advise her to do to help make Becky's hospitalization less traumatic?

- a. Suggest she keep her visits short so Becky can spend time with her nurse.
- b. After visiting, don't tell Becky she is leaving. Just try to slip quietly away.
- c. Insist Becky have blood drawn by her bed because she fears the treatment room.
- d. Take Becky to the playroom, a place where she can feel free from being hurt.

*Look in Appendix A for the best answer and rationale.*

## **Promoting Play for the Ill Child**

Play, often described as "the work of children," is an invaluable component of child health care. Providing a space and opportunity for play can help children feel more comfortable and allow for an important release of energy for children who are confined to a room or bed. Play also may be used to help assess children's level of knowledge and feelings about their condition so that more individualized nursing care can be planned. Depending on a child's age, play can also be a useful tool in health teaching (see Chapter 35). Children enjoy making friends with other children, talking to other children in nearby beds, and being in the playroom where they can talk to and get to know other children (Lambert et al., 2014).

Defining play is not a simple task because play activities vary greatly from child to

child and among different developmental age, cultural, and socioeconomic groups. A common definition is that play is any voluntary activity engaged in for the purpose of enjoyment. If a child views an activity as enjoyment, therefore, no matter what it is and whether it would be fun or not for an adult, it is play.

Play is clearly the means by which children develop increasing cognitive, psychomotor, and social capabilities. Touching a soft toy, passing colored blocks from one hand to the other, pounding with a plastic hammer, feeding a doll, and playing board games are all ways in which children are exposed to and learn about different textures and colors, experience the feeling of possessing and owning, and learn about competition, winning, and losing as well as develop fine motor skills. Colored blocks reveal how parts can join to make a whole, how things stacked too high will fall (there are limits one cannot go beyond), and practice makes perfect. As children talk with playmates during play, they develop both language and social skills. The repetitive acts involved in most games encourage the development of musculoskeletal skills. Therefore, play is not something children do when they have nothing else to do, but rather, it is something children *have* to do. During illness, it provides a feeling of security because it is an activity that has continuity with everyday life.

The manner in which children play differs as they mature. Types of play and the developmental age groups in which these types are seen most frequently are shown in [Box 36.7](#).

### BOX 36.7

#### Nursing Care Planning Based on Family Teaching

##### UNDERSTANDING DIFFERENT PLAY TYPES

**Q.** Becky’s mother tells you, “When Becky was younger, she didn’t like toys as much as the boxes they came in. What’s normal for children and play?”

**A.** Children play differently at different ages. Examples of typical play patterns include:

Type of Play/Age	Description	Example
Observation/infant	Child watches particular play intently, although not actively engaged in it.	Watching a mobile
Parallel/toddler	Two children play side by side but seldom attempt to interact with each other.	Playing separately with a similar push toy
Associative/preschooler	Children play together in a similar activity; there is little organization of responsibilities.	Engaging in typical backyard play Playing

Cooperative/school age	structure or compete for desired goal or outcome.	organized games with rules
------------------------	---	----------------------------

## ASSESSING CHILD HEALTH THROUGH PLAY

Children who are acutely ill do not play or play very little because they do not have the strength, the attention span, or the interest in activities required for play. They continue to enjoy being read to, and they find comfort in holding a favorite toy even if they do not actively manipulate it. Once children are over the acute phase of an illness, interest in play returns. Therefore, whether a child is spontaneously playing is a good index of health. The toys children use at play are a good indication of their growth and development level and emotional state.

Parents typically know a child’s play preferences and current favorite game or toy. Asking for this information during a health interview helps to assess a child’s developmental level and helps to assess the quality of parenting (if parents view play as important or are familiar with the child’s activities).

## PROVIDING PLAY IN AMBULATORY SETTINGS

Children and families in ambulatory department may be under a great deal of stress as they sit in a waiting room, waiting for their name to be called. This anxiety for the family may be diverted with the use of child life services, if available, or toys/books/games that the child may redirect their focus to.

It is best if ambulatory departments are stocked with toys that can be played with quickly and by single children. There should be a low table and chairs so a parent can come to a table and play with a child. Examining rooms should have toys, which may be used to distract a child while a procedure such as an ear examination is performed, and because the wait in an examining room may be as long as the wait in a waiting room. Well siblings who accompany a parent and sick child to the facility can play with toys to distract them as well so that a parent can concentrate on the ailing child. Some hospitals furnish computer games for older children for this reason. Examples of ways that play can be used in an ambulatory care setting are shown in [Table 36.5](#).

**TABLE 36.5 WAYS TO INCORPORATE PLAY INTO NURSING CARE**

Nursing Care	Play Activity
Aid with physical assessment	Distract child’s attention with puppet during respiratory and cardiac assessment. Play Simon Says to encourage child to take deep breaths for respiratory assessment. Allow child to listen to own heart with a stethoscope. Play Follow the Leader to assess gait. Draw a face on the tongue blade used to assess the throat.

	Draw a face on the tongue blade used to assess the throat. Show child how to “blow out” the otoscope light. Draw child’s outline on the table examining paper and give it to the child to take home to color.
Health teaching	Use puppets as a teacher. Create word scrambles or crossword puzzles.

## PROVIDING PLAY IN THE HOSPITAL

Ideally, all hospital units in which children are cared for should have a play space big enough for most of the children on the unit to come to. There should be enough space to accommodate children who are not fully ambulatory, such as those with casts or who are in wheelchairs (Fig. 36.9). Tables for board games and play materials such as crayons and paints should be available. Children can release a great deal of anger or tension by splashing water, squeezing or pouring sand, or smearing finger paint.

**Figure 36.9** Children enjoying themselves in a hospital playroom, which is spacious and well equipped with age-appropriate toys and

School-age children can play games and create objects with arts and crafts. Adolescents enjoy table tennis and pool tables. A great deal of “play” by older school-age children and adolescents centers on conversation with peers they meet in the playroom.

## PROVIDING PLAY FOR CHILDREN ON BED REST

Children who are on bed rest, at home or in a hospital, need to have play periods built into their day. The length of time for play and the toys individual children can play with depend on their developmental age and physical and emotional states. Suggestions for play activities for children on bed rest are shown in [Table 36.6](#).

**TABLE 36.6 PLAY ACTIVITIES FOR CHILDREN ON BED REST**

Care Measure	Play Activities
Bathing	Allow children to play in bath water with water toys.
Encouraging fluid	Hold a pretend “tea party” for a preschooler and drink “tea” with important but imaginary guests. Play a board game with a school-age child in which each turn starts with taking a drink. Draw a circle and let the child color in a section each time a drink is taken. Play Simon Says, in which Simon says, “Drink.”
Deep breathing exercises	Have child blow soap bubbles in a glass of soapy water with a straw. Have child blow a cotton ball across the surface of a bedside table. Play Simon Says, in which Simon says, “Take a deep breath.” Allow the child to score points for reaching a high number on an incentive spirometer.
Muscle-strengthening exercises	Have children throw bean bags or large wads of paper (computer waste) at a wastebasket. Play Simon Says, in which Simon says, “Raise your arms,” and so forth. Have children throw and catch a ball. Have children squeeze and mold modeling clay. Help preschoolers pretend they are butterflies, airplanes, and so forth.
Procedures such as blood transfusion	Save a favorite game or activity only for these times.
Health teaching	Use puppets as teacher. Make up board games, word scrambles, and crossword

Health teaching	Use puppets as teacher. Make up board games, word scrambles, and crossword puzzles.
-----------------	--

Infants need toys in their cribs, such as mobiles, blocks, soft toys, and rattles. They also need to be out of cribs, sitting on a parent's or a healthcare provider's lap, or securely sitting in strollers or swings. As soon as they are able, they need some time on the floor (with a sheet or other covering under them) to practice crawling or walking. At about 3 months, when infants discover their hands, those become that month's "toys." For a child learning to crawl, "cruise," or walk, that activity is the toy or interest for the month.

Toddlers need put-in and take-out types of toys such as blocks that can be repeatedly dropped into a box or that can be stacked to play with in bed. They enjoy listening to songs and nursery rhymes. Toddlers are in constant motion. They need to be out of bed as much as their physical condition allows, playing with take-apart, put-together, or pull-and-push toys. Preschoolers need creative materials such as modeling clay or sand. School-age children need quiet games such as books or crayons or markers by their bedside. They also enjoy electronic devices such as tablets, iPads, or iPods. Most activities for hospitalized children must be short-term projects because children are called away for treatments or procedures, and because, when they are ill, their attention span is shorter than usual. Short-term projects always appeal to the school-age child because they help a child of this age achieve a sense of industry.

Watching television is a nonparticipant activity, so it is not the best activity for children. There is some value, however, in watching nature programs or specials on television that depict school-age children in real-life situations coping with problems common to the child's age group. Encouraging parents or friends to watch a game show with a school-age child and help the child guess the solution to a puzzle or watch "Sesame Street" with a preschooler can make the activity a participatory one. Watching a DVD or video download with an adolescent and then discussing the people and their problems can also turn television watching into active participation.

## SAFETY WITH PLAY

Inspect all toys for safety. They should be washable to prevent spreading disease, without sharp edges and small parts that could be swallowed or aspirated. Toys should be at least 1¼ in. (3 cm) in diameter and 2¼ in. (6 cm) in length to prevent aspiration and choking. A cylinder 1 in. in diameter, such as a rubber hot dog, is the most dangerous size for a toy because it totally occludes the trachea if it is aspirated. A toy smaller than this would cause only partial obstruction; something larger could not be inhaled into the trachea. As a rule, if a toy can fit through the center of a toilet tissue tube, it is too small for safe play.

Consider the type of toy for a specific patient. Tossing a ball to a child on bed rest is generally a safe activity. One who has a large cast in place, however, might lean over to

If children become bored with an activity or toy because it is not stimulating enough or they have had it for too long a time, they may begin to use the toy in an unsafe way. After toddlers grow tired of stacking blocks, for example, they may begin to throw them. Children who normally play safely with modeling clay but who are on a restricted diet may eat it because they are hungry. Knowing where children are and what activity they are engaged in at all times is the best prevention against unsafe play.

For the child cared for at home, parents may need to purchase new toys. This is especially true if the bulk of the toys they furnished previously were for outside play such as balls, in-line skates, or skateboards. Because of an illness, they may now need to provide more “sit-down” toys such as markers, puzzles, or board games.

## CHILD SUPPORT PROGRAMS

Child support programs, such as child life services, are incorporated into major children’s hospitals and are an integral feature of child health care (Brown et al., 2014). As part of a child support program, a specialist offers children the opportunity to reenact and thereby master the unease associated with illness. Through therapeutic play, child specialists provide programs that prepare children for hospitalization and, once hospitalized, prepare children for surgery or for procedures that could be painful. They consult with parents about good toys to choose for home care. These specialists also help children air their frustration about painful or intrusive procedures, prevent social isolation of children by means of an active recreation program, and ensure that the total healthcare environment is conducive to children’s well-being.

Such a program not only aids in promoting children’s mental health but also leads to more cooperative responses of children to treatments or procedures. It is complementary to play programs initiated by nurses.

### *QSEN Checkpoint Question 36.5*

#### **SAFETY**

The nurse is worried Becky’s 2-year-old roommate might aspirate a toy the family friend brought in for her. Which of the following items is most likely to be aspirated and therefore poses the greatest risk to safety?

- a. Puzzle pieces
- b. Clothing for a baby doll
- c. Crayons
- d. Blocks that are 1-in. square

*Look in Appendix A for the best answer and rationale.*

## THERAPEUTIC PLAY

Anything almost automatically becomes less threatening when a person can talk about it. Many children cannot talk about what is happening to them during illness because of

Anything almost automatically becomes less threatening when a person can talk about it. Many children cannot talk about what is happening to them during illness because of fear or because their vocabulary is so limited they cannot describe their feelings.

Because play is the language of children, children who have difficulty voicing their thoughts in words can often speak clearly through play. Play that involves specialized activities that are developmentally supportive and facilitate the emotional well-being of a pediatric patient is considered therapeutic play. It should be noted that therapeutic play and play therapy are different. **Play therapy** addresses basic and persistent psychological issues associated with how a child may interact with his or her world (Koller, 2008).

For therapeutic play, only the child's verbal cues are used as responses. Therapeutic play can be divided into three types:

1. Energy release
2. Dramatic play
3. Creative play

### Energy Release

Children release energy by pounding, hitting, running, punching, or shouting. Furnishing children with materials that allow them to do these things helps them release anxiety as well. Toddlers enjoy pounding pegs with a plastic hammer or pretending to cut wood with a toy saw. Other examples include giving modeling clay to a preschooler (an anxious child often pounds it flat; a relaxed child, however, will build it into shapes). The overall goal is to maintain a sense of empowerment and self-efficacy during hospitalization (Teksoz, Bilgin, Madzwamuse, et al., 2017).

### Dramatic Play

Dramatic play is acting out an anxiety-producing situation. It is most effective with preschool children because they are at the peak of imagination. During illness, the situations about which children need to express feelings are illness related, and therefore, the equipment needed for therapeutic play is common healthcare equipment, such as dolls, doll beds, play stethoscopes, IV equipment, syringes, masks, and gowns. Puppets of doctors, nurses, mothers, fathers, and children help young children express their feelings. Anatomically correct dolls are used to help children describe their feelings about sexual maltreatment.

It is good to have a play session with a child near the beginning of an illness to see whether the child communicates any fears about this experience through play. This initial session also serves as a way of preparing the child for events that will occur during the illness (Fig. 36.10). Repeat a play session after any painful or traumatic procedure such as surgery so that the child can express new feelings. A list of procedures that fall into this category is shown in Table 36.7. If such play sessions reveal fears, a child should be scheduled for other play sessions, perhaps once daily.

**Figure 36.10** Therapeutic play allows children the opportunity to voice their fears of illness and procedures.  
(Ivolodina/Shutterstock.com)

**TABLE 36.7 THERAPEUTIC PLAY TECHNIQUES FOR CHILDREN AFTER PROCEDURES**

Procedure	Play Activity (Provide a doll and . . .)
X-ray	A table and box labeled “X-ray machine”; children sometimes worry X-rays will injure them, just as laser rays in science fiction shows do. Handling a “machine” can reduce anxiety.
Blood drawing	Syringe, alcohol wipes, tourniquet, or finger lancets; remember that finger sticks are as frightening for children as needles.
Clean-catch urine	Alcohol wipes and a collection cup; children are often more embarrassed by urine collection than adults realize.
Intravenous therapy	Intravenous tubing, as well as tape and an armboard; some children are as angry about being restrained as having the needle inserted.
Endoscopy such as bronchoscopy, cystoscopy	Catheters or a penlight to simulate an endoscope.
Scans	Intravenous fluid and tubing because scans usually require the intravenous injection of isotopes
Bone marrow	Alcohol wipes, syringe
Electroencephalogram (EEG), electrocardiogram	Electrode leads that attach to a box; children might be afraid of these procedures because of their fear of electricity.

(ECG)	
Surgery	An anesthesia mask and a blunt kitchen knife; watch and listen for where the child cuts and how the experience is described.
Dental examination	Suction catheter, a penlight to simulate a drill, and a 4 in. × 4 in. piece of plastic to simulate a dental dam; some children are angered by the use of plastic in their mouth.
Dressing changes	Gauze and paper adhesive tape
Cast application or removal	Provide plaster to soak and apply; simulate a cast cutter with an electric razor or hair dryer.
Nasogastric tube insertion, enema, catheterization	Appropriate tubes
Temperature assessment	Thermometer

Furnish children with a wide range of equipment and then let them choose those items with which they wish to play. Children invariably choose a piece of equipment that has been used with them. They poke at a doll with a syringe without a needle or with a small rubber tube attached to simulate a needle or enjoy giving it a “shot.” They wrap the doll in bandages or put tubes into its mouth or stomach, acting out things that were done to them or that they saw done to other children on a nursing unit or at a clinic visit they fear will be done to them. Allow play to be nondirective (let children proceed at their own pace, choosing freely what equipment to play with and what they want to do with equipment). As a child works through an experience this way, the experience becomes less fearful and the child gains increased control over it.

Observe for children who may be using equipment in an unusual way, such as hitting dolls with stethoscopes or poking them in the eye with a thermometer (suggesting they are confused about the purpose of such equipment or are acting out for another reason). Such behavior can alert you to the importance of explaining the purpose of equipment to children. Listen to what children say as they play. A comment such as “I’m giving shots to all the bad dolls” suggests the child thinks injections are punishment. It would be important to stress the next time the child needs an injection that medicine is to make the child feel well again. A comment such as “They are going to put you to sleep” when explaining anesthesia could infer that she will never wake up (she may have had a pet that needed to be put to sleep). Do not be surprised about the force with which children insert nasogastric tubes into dolls. In part, this reflects how they perceive these procedures, but it also represents energy or nervous release, in the way that pounding or hitting releases anger.

To better understand how a child feels, repeat what the child says verbally: “You are giving the bad dolls shots?” or ask the child to tell you more about the activity: “Do you

think that’s the only kind of children who get shots—bad children?” Do not rush to reassure (“Do not worry, that is not going to happen to you”). Quick reassurance tells children they should not ask any more questions or that the topic is not open for discussion.

Sometimes, even children who seem well prepared may be taken by surprise during a procedure. For example, 7-year-old Tanya, seen in an ambulatory setting for a diagnostic workup after a urinary tract infection, showed little interest in dolls and syringes and tubing in the playroom. She had been prepared by her mother for the experience and seemed to understand what would happen during her X-ray procedure. After returning from the X-ray room, where she had a voiding cystourethrogram; however, she was obviously upset. Her nurse brought her a rag doll, a doctor and a nurse figure, a play X-ray machine, and some tubing that could simulate a urinary catheter and encouraged Tanya to play with them. Tanya picked up the girl doll and put her under the X-ray machine. She imitated the doctor doll shouting, “Pee in front of everybody!” Tanya’s mother had not realized that she would have to void during a cystourethrogram and so had not prepared her for that. Tanya felt betrayed by not being really prepared for this embarrassing situation. Her play brought her emotion out in the open, where it could be talked about and handled. When Tanya was scheduled the next day for ureteral reflux surgery, her nurse was alerted to make the preparation absolutely thorough.

Children older than 9 or 10 years of age may find playing with dolls too childish to be of benefit. They would rather handle equipment such as nasogastric tubes in advance of them being inserted. Active handling helps to eliminate fear because it identifies exactly what the child has to face, and it meets their concrete-level learning needs.

## Creative Play

Some children are too angry to be able to act out their feelings through dramatic play. However, they may be able to draw a picture that expresses their emotions or conveys the extent of their knowledge. To encourage this, give a child a blank paper and crayons or markers. If a child seems reluctant to draw something spontaneously, suggest a topic: “Why don’t you draw a picture of yourself?”

Some children are so concerned with particular parts of their bodies that when asked to draw pictures of themselves, they draw only the body part about which they are worried. Such children generally are saying they need to talk about that part of their body to be given reassurance that it is going to be all right. [Figure 36.11A](#) shows a picture drawn by Becky when she was admitted to the hospital for 1-day surgery for debridement of a campfire burn on her left foot. She stated on admission that she was being admitted to have the burn on her foot “cleaned out.” This sounds like a child who understands what debridement involves. Note, however, that the figure she drew has no left leg. One has to wonder whether she was concerned that she was going to surgery to have more than debridement. After the word “debridement” was explained to her, she drew the picture in [Figure 36.11B](#). The child in the drawing now has a left and a right

leg, with the left leg covered by a bandage. Through a drawing, this child was able to say something she could not express without this help.

**Figure 36.11** (A) Children who are concerned about body parts may draw pictures with that part missing or exaggerated. Note the missing left leg here. (B) After reassurance that her leg will be all right, the girl who did the drawing in A now draws a girl with two legs.

Many ill children draw pictures that reflect punitive images: a boy or girl tied to a bed or shut behind bars, or doctors and nurses frowning at them, obviously unhappy with them (Fig. 36.12). Such children may need assurance that they are not being punished but rather that they need to stay in bed or are being cared for by doctors and nurses to be made well. Other children draw pictures that are symbolic of death: airplanes crashing, boats sinking, buildings on fire, or children in graveyards. They need assurance that they will not die.

**Figure 36.12** A picture drawn by a hospitalized child. Note the prison like appearance of the crib. (Courtesy of Rita Crever.)

Other concerns such as fear of abandonment and loss of independence may also be manifested in drawings. For example, preschoolers may draw a child in one corner of a picture and an adult in a far corner. They may comment that the parent cannot find the child because she's gone to the hospital. They need to be reassured that their parents know where they are and, although they're not there constantly, they will visit them each day after work.

Older school-age children and adolescents may not be interested in drawing but can be interested in making a list of procedures or experiences they like and dislike. Examine the dislike list for procedures such as "shots" or "chemo." Mark the nursing care plan for nurses to take special time to explain these procedures and to offer special support when they must be done.

### *What If... 36.3*

**While the nurse is playing with Becky, Becky draws a purple person with only three body parts. Would this worry the nurse? Why or why not?**

## **Guidelines for Conducting Therapeutic Play**

Use common sense when conducting therapeutic play. For example, try not to interpret a child's black and gloomy drawing as meaning the child is depressed when a black marker was the only one available. Many children 4 to 5 years of age draw a person lacking many body parts because, from a developmental standpoint, that is how they start to draw (usually just a head and no body, with lines representing arms and/or legs coming out of the head).

Remember, too, that all children occasionally treat dolls badly. A 2-year-old who pounds and bangs a rag doll may not be expressing anger toward the doll image at all

but may be intent on discovering the feel of a new texture and is unaware for the moment that the object is a doll.

A conference with healthcare team members, including a psychologist or a psychiatric nurse specialist, may be needed if a child continues to express mutilating behavior after normal reassurance. Guidelines for conducting therapeutic play are summarized in [Box 36.8](#).

### BOX 36.8

#### Guidelines for Therapeutic Play

1. Allow children to choose the articles with which they want to play (something may be too frightening for a child to play with immediately, or more time may be needed to work up to the activity).
2. Provide the materials specific to the child's experiences of which you are aware, such as a nasogastric tube, syringe, or bandages but do not supply only those things; a child may have misunderstandings and fears of situations you cannot know about.
3. Allow play to be unstructured; let children use the materials however they wish. If a child seems uninterested in materials, initiate play such as giving a doll an injection to see if this reduces the child's fear enough to be able to handle items.
4. If a child cannot manipulate materials for some reason such as a large cast or traction, ask the child what would be good for you to do with an item.
5. Reflect only what the child expresses (verbal expression).
6. Do not criticize play; this inhibits further expression.
7. Use a therapeutic response; not "Don't worry, that won't happen," but "Are you worried that could happen?"
8. Ask children to describe paintings; not "That's a good picture of yourself," but "Tell me about your picture."
9. Do not be reluctant to use real equipment such as real catheters and blood lancets. Handling real equipment best helps to reduce stress.
10. Supervise therapeutic play because some equipment could cause an injury (and therapeutically responding to the child's comments is necessary).

#### *What If... 36.4*

**The nurse is interested in exploring one of the 2020 National Health Goals related to illness in children (see [Box 36.1](#)). Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Miller family and that would also advance evidence-based practice?**

## INFORMATICS

Becky's mother and father ask the nurse what type of therapeutic play would be best for Becky. Which type of therapeutic play would best meet Becky's needs if she will have a large bandage on her foot after surgery?

- a. Letting her hold and handle a syringe (with no needle attached)
- b. Giving her a doll and a bandage to change
- c. Supplying a video tape of a child having surgery for her to watch
- d. Giving her a book to read about a child's hospitalization experience

*Look in Appendix A for the best answer and rationale.*

## KEY POINTS FOR REVIEW

- Illnesses may be more traumatic for children than for adults because of children's inability to communicate and monitor their own care and because they have different nutrition, fluid, and electrolyte needs. The stress of hospitalization can be so acute that it can result in PTSD.
- Separation from parents because of hospitalization can have permanent psychological effects on children. Methods to reduce this include keeping hospital stays as brief as possible, promoting open parent and sibling visiting, and providing primary or case management nursing. **Case management nursing** is a collaborative approach of applying the nursing process to meet the needs of patient and their family.
- Currently, many medical procedures can be done on an ambulatory basis. Advocating for care to be done in such settings is a nursing responsibility.
- The presence of parents during health care can help reduce trauma to children. Making parents as welcome as possible in healthcare facilities makes it possible for them to room-in. Include parents in both the planning and the implementation of care. Parents reinfect children with fear if their own fear is not reduced.
- Preschoolers may have the most difficult time during hospitalization because they have so many fears. Preparation and promotion of therapeutic play may be essential to reduce trauma to a tolerable level.
- Because hospitalizations currently are so brief, parents need good discharge instructions to continue to care for children safely at home. Providing clear instructions, including suggestions for play or how to avoid sleep deprivation, is important to help plan nursing care that not only meets QSEN competencies but also best meets a family's total needs.

## CRITICAL THINKING CARE STUDY

Timothy, a 10-year-old child, has been in the hospital for 10 days due to a nephrectomy because of a malignant tumor. He has been having significant difficulty

sleeping because of pain. His mother is a single parent who works days. She spent several days with him but then needed to return to work.

When his mother comes to visit in the evenings, you notice he is irritable and acts rude to her. He tells her not to visit and then throws books at the wall when she leaves. His mother is distraught and does not know how she can cope with his subsequent hospitalizations for future chemotherapy.

1. What is a likely cause of Timothy's behavior?
2. What could you do to help Timothy adjust to hospitalization better?
3. What could you do to assist Timothy's mother?

## Nursing Care of a Family When a Child Needs Diagnostic or Therapeutic Modalities

*Felipe Ramos is a preschooler who is about to undergo computed tomography (CT) of his brain because he was pushed off a 6-ft-high slide at a playground and hit his head, causing a brief loss of consciousness. Felipe's mother asks you through an interpreter, "He's upset because of being bullied at school and he's afraid of the dark, how can I allow him to be put inside a long dark machine that way? What will this exam be like and how can we make sure he will be safe?"*

*Previous chapters described the growth and development of well children. This chapter adds information about how to care for children who are having diagnostic or therapeutic procedures. This is important information because it builds a base for both care and health teaching.*

**How would you explain the CT scan to Felipe and his mother?**

### KEY TERMS

aspiration studies

bronchoscopy

clean-catch urine specimen

colonoscopy

computed tomography (CT)

electrical impulse studies

endoscopy

magnetic resonance imaging (MRI)

positron emission tomography (PET)

radiopharmaceuticals

single-photon emission computed tomography (SPECT)

total parenteral nutrition (TPN)

ultrasound

### OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe common nursing interventions used in the health care of children to aid diagnosis and therapy.
2. Identify 2020 National Health Goals related to diagnostic and therapeutic procedures for children that nurses can help the nation achieve.
3. Assess children regarding their developmental stage and knowledge level before beginning diagnostic or therapeutic procedures.
4. Formulate nursing diagnoses related to common diagnostic or therapeutic procedures used with children.
5. Identify expected outcomes for a child who needs a diagnostic or therapeutic procedure as well as help families manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care relevant to diagnostic or therapeutic procedures, such as preparing a child for magnetic resonance imaging.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of common diagnostic and therapeutic procedures with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

Illness can be particularly stressful. When illness requires diagnostic and therapeutic procedures, that stress can worsen. In today's healthcare climate, time is crucial for teaching and preparation, so detailed planning and evaluation of understanding are essential when procedures are scheduled. [Chapter 36](#) described measures to make an illness experience, inpatient and outpatient, more positive. Health teaching, discussed in [Chapter 35](#), is also a cornerstone in this process.

Many nursing actions offer an opportunity to accomplish several goals. Supporting a child and family during a diagnostic procedure, for instance, not only aids in an efficient diagnosis but also may help establish a trusting relationship between the family and healthcare providers that will make all future interactions more successful. This chapter describes the most common diagnostic and therapeutic techniques used in the care of ill children, including modifications needed to make these procedures safe and to reduce associated stress, depending on the child's age and condition. [Box 37.1](#) shows 2020 National Health Goals that address this area of child health practice.

**BOX 37.1**

**Nursing Care Planning Based on 2020 National Health Goals**

2020 National Health Goals speak to efforts to keep children well so they need a minimal number of diagnostic or therapy procedures.

- Reduce hospitalizations for asthma among children under age 5 years from a baseline of 41.4% to a target level of 18.1%.
- Increase age-appropriate vehicle restraint systems in children aged 4 to 7 years from a baseline of 43% to a target level of 47%.
- Increase the number of adolescents who have had a wellness checkup in the past 12 months from 68.7% to 75.6%. (U.S. Department of Health and Human Services, 2014; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by providing health counseling to parents and children to help prevent children from becoming ill and subsequently requiring hospitalization, such as teaching sound nutrition and common practices on avoiding unintentional injury.

### *Nursing Process Overview*

## FOR A CHILD WHO NEEDS DIAGNOSTIC OR THERAPEUTIC PROCEDURES

### **ASSESSMENT**

Before performing procedures such as assisting with a diagnostic test or collecting laboratory specimens, first carefully evaluate a child's age and developmental stage as well as any special needs a child may have. Even the most common and painless procedures create a certain amount of stress for children and parents. During complex diagnostic procedures, this stress level is almost certain to increase even further due to fear of the unknown. Unfamiliar people (e.g., doctors, nurses, other health team members), high-tech supplies and equipment, and strange surroundings all add up to a frightening experience for most adults; imagine how frightening they are to children.

It is important to acknowledge that many procedures that involve highly technologic equipment may be painful or uncomfortable for a child, especially if the child has a chronic disease. Assess a child's level of anxiety associated with a procedure as well as the child's knowledge concerning a technique before initiating the procedure or beginning health teaching. Pointing out a child's past experience with similar procedures can lay a foundation for increased cooperation.

### **NURSING DIAGNOSIS**

Common nursing diagnoses related to diagnostic and therapeutic procedures are as varied as the procedures themselves. Some examples include:

- Fear related to new and strange surroundings of the procedure room
- Pain related to a lumbar puncture procedure
- Deficient knowledge related to the technique for 24-hour urine collection

- Deficient diversionary activity related to hospitalization and lengthy procedures
- Imbalanced nutrition, less than body requirements, related to need for food restriction preprocedure and postprocedure
- Risk of injury related to need for intrusive procedures

### **OUTCOME IDENTIFICATION AND PLANNING**

Procedures can produce stress in addition to the anxiety caused by a primary illness. An important nursing goal, therefore, is to perform procedures and complete interventions with the least amount of anxiety possible. To achieve this goal, plan specific ways to prepare children in advance and apply the best communication techniques possible to explain a procedure at the level of understanding and developmental stage appropriate for each child. Consideration should be given to the number of diagnostic or therapeutic procedures and the time frame in which they are performed. Some children may have less anxiety if diagnostic tests are scheduled over several days to preserve the child's coping ability. Conversely, some older children (and parents) do better if they can complete all necessary tests in 1 day to reduce the anxiety produced by the anticipation of more testing still to come. Refer families to online resources for further information when appropriate (see [Chapter 36](#)).

### **IMPLEMENTATION**

Whether assisting with a procedure or performing a therapeutic intervention, it is necessary to function in several roles simultaneously: organizing supplies, performing (or assisting with) the procedure, providing active support to the child and parents, and observing and then documenting the child's reactions. As a final follow-through step, plan for introducing therapeutic play techniques that would be helpful in relieving stress caused by the procedure.

### **OUTCOME EVALUATION**

Evaluating expected outcomes related to diagnostic and therapeutic procedures is not only helpful in determining the effect of the procedure on a child but also aids in future planning should other procedures be required. Recording that a particular child who did not appear nervous during a procedure later admitted to being "more scared than I've ever been before," for example, can help another nurse provide reassurance to this child, even if the child is successful at masking emotions the next time the procedure is performed. Examples suggesting achievement of expected outcomes include:

- The child reports the ability to cope with a second bone marrow aspiration.
- The child lists steps for successful 24-hour urine collection at home.
- The child participates in 1 hour of active exercise daily.
- The child eats a minimum of 1,000 calories per day.
- The child experiences minimal loss of blood, less than 10 ml, during a diagnostic procedure.
- The parent outlines plan to use alternative therapies to reduce the child's

anxiety.

## Nursing Responsibilities With Diagnostic and Therapeutic Techniques

Stress related to hospitalization occurs across the life span. A greater awareness regarding psychological trauma for children and their parents that can occur with hospitalization and that can undermine the child's recovery is a major focus of research (Franck, Wray, Gay, et al., 2015). Reducing the number of hospitalizations is likely to reduce the overall stress; however, when this cannot be accomplished, the next step is aimed at reducing the number of diagnostic or therapeutic procedures children have to undergo. Despite these attempts, some children, such as those who are chronically ill or are dependent on technology such as a ventilator, require 24-hour care in either a healthcare setting or their home. Children who show initial symptoms of a progressive illness likely require diagnostic procedures in order for their condition to be confirmed and effective therapy initiated.

When hospitalization is indicated, the stress of the experience can be reduced for both the child and parents if procedures are carried out in the least stressful way possible. The use of new information technology devices (NITDs) allows healthcare providers to engage, educate, and communicate with patients and families and reduce anxiety related to hospitalization (Kompany, Luis, Manganaro, et al., 2016). When performing or assisting with procedures on children, remember to maintain safety and legal responsibilities for care such as:

- Verify that an informed consent is obtained, as needed.
- Utilize the electronic health record to verify the prescription for the procedure.
- Explain the procedure to the child and parents to ensure both are well informed.
- Schedule the procedure.
- Prepare the child physically and psychologically.
- Obtain necessary equipment for the procedure.
- Accompany a child to a treatment room or hospital department where the procedure will be performed.
- Coordinate and collaborate with other healthcare providers to ensure the safety and efficacy of all procedures.
- Provide support during the procedure, using the least amount of restraint possible.
- Ensure adherence to standard infection precautions.
- Assess a child's response to the procedure.
- Provide care to a child and specimens obtained once the procedure is completed.
- Document the outcome of the procedure and the child's reaction to the procedure.

## OBTAINING INFORMED CONSENT

Informed consent is a process in which the healthcare provider discloses or explains a proposed medical treatment, along with the risk(s), benefit(s), and alternative(s) for that treatment. Informed consent is legally required and must be obtained before any procedure or treatment that has a risk of causing injury to the child is performed. Each procedure or treatment must have a documented consent. The benefits and risks of the treatment or procedure must be discussed along with the risks if the treatment or procedure was not performed. Although obtaining consent is the provider's responsibility, ensuring that it is obtained is a nursing responsibility. Acting as an advocate for a family if they do not understand the consent form, the procedure, or the risks of the procedure is an important nursing role.

According to [Katz and Webb \(2016\)](#), informed consent is valid when the following criteria are met:

- Disclosure of information to patients or their surrogates
- Assessment of patient and surrogate understanding of the information and their capacity for medical decision making
- Obtaining informed consent before treatments and interventions

A minor who is emancipated by the state is considered to have the same legal rights as an adult and may consent to treatment. Adolescents who are living on their own, are married, and/or serving with the armed forces are generally considered legally emancipated and able to provide informed consent or refusal for their own medical care ([Katz & Webb, 2016](#)). All 50 states recognize an adolescent's right to consent for healthcare needs related to sexual activity, including treatment of sexually transmitted infections, contraceptive services, and prenatal care ([Katz & Webb, 2016](#)); however, consenting to these services does not always guarantee confidentiality.

In emergent or life-threatening situations, when a legal guardian or parent is unavailable to consent, the Emergency Medical Treatment and Active Labor Act mandates that a medical screening examination and delivery of appropriate medical care for the pediatric patient are never withheld or delayed.

When a legal guardian refuses to consent to medical care or transport that is necessary to save the child's life, law enforcement may be needed. When feasible, it is always better to discuss why the legal guardian is refusing treatment so that an amenable plan for the child's health can take place.

The pediatric population is considered vulnerable; thus, parents must consent on the child's behalf prior to a procedure or involvement in research. To maintain the child's autonomy, assent is also often obtained much like consent is. The American Academy of Pediatrics (AAP) Policy Statement ([Katz & Webb, 2016](#)) states that assent must have at least the following four elements: (a) helping the patient achieve a developmentally appropriate awareness of the nature of his or her condition, (b) telling the patient what he or she can expect with tests and treatment(s), (c) making a clinical assessment of the patient's understanding of the situation and the factors influencing how he or she is

responding (including whether there is inappropriate pressure to accept testing or therapy), and (d) soliciting an expression of the patient’s willingness to accept the proposed care.

According to the regulations at 45 CFR 46.408(a), assent may be waived if ([U.S. Department of Health and Human Services, 2010](#)):

1. The capability of some or all of the children is so limited that they cannot reasonably be consulted.
2. The intervention or procedure involved in the research holds out the prospect of direct benefit to the health or well-being of the children and is available only in the context of the research.
3. The research meets the same conditions as those for waiver or alteration of informed consent in research involving adults, as specified in the regulations.

## EXPLAINING PROCEDURES

To be able to explain procedures clearly and answer questions about them appropriately, try to observe as many procedures as you can. After any procedure, asking children to describe what sensations they experienced can help them work through possibly frightening situations (often called “debriefing”) and can also increase your knowledge of common procedures.

As a general guide, before a procedure, a child needs a detailed description of what to expect, such as “I’ll clean your finger. You will feel a small pinprick” as well as an explanation of:

- Why the procedure is being performed (e.g., “Your doctor needs to look at your blood to see why you’re so sick”)
- Where the procedure will be done (e.g., the X-ray department, a treatment room)
- Any unusual sensations to be expected during the procedure (e.g., “The alcohol I use to clean your skin will feel cold”)
- Any pain involved (e.g., “The needle will sting, although I’ll put some cream on first to dull the feeling”)
- Any equipment that will be unfamiliar such as a magnetic resonance imaging machine
- The approximate length of time the procedure will take
- Any special care after the procedure (e.g., “You will need to lie quietly for 15 minutes afterward”)

Use age-appropriate language when explaining procedures and be careful not to use words that might be confusing during an explanation, such as “transducer” or “electrode,” without defining them in age-appropriate terms. Try to associate the procedure with something you know the child is already familiar and comfortable with, such as describing an X-ray machine as “a big camera.” Try not to use the word *test* in explanations because school-age children associate the word *test* with a pass/fail situation. Wondering if they “passed” a procedure can make them unduly worried afterward.

If you are unfamiliar with what a procedure entails, do not guess the answers to a child's questions because nothing is more confusing than being told two different versions of an answer to the same question. Familiarize yourself with the procedure and explain to the child and/or parent in terms that are understandable. When possible, encourage parents to stay with their child during the procedure, if possible, as they can be extremely helpful in reducing the threatening aspects of a procedure.

## SCHEDULING

If a child is having more than one diagnostic procedure in a day, try to arrange for the child to have time for meals and some free play time between the procedures. If food or fluid must be restricted, monitor the child's degree of discomfort and physiologic needs related to the restriction. Advocate as necessary for sufficient periods of time between examinations so a child can eat or for decreased time between procedures so the time spent without food or fluid is limited.

## PREPARING A CHILD AND FAMILY PHYSICALLY AND PSYCHOLOGICALLY

Physical preparation varies with each procedure to be performed. In many instances, preparing a child for an examination, such as a barium enema, involves another procedure such as a saline enema, so that physical preparation also becomes education for the actual examination. In all instances, explain both the preparative and actual procedures and allow the child to ask questions because appropriate explanations aid in reducing anxiety and fear (Box 37.2).

### BOX 37.2

#### Nursing Care Planning to Respect Cultural Diversity

Professional nursing practice must continually adapt to the changing values and beliefs of the population it serves. The diversity of the population is reflected in pediatric patients and their families, many of whom are from various cultural backgrounds, have a language other than English as their primary language, have difficulty reading English so have questionable health or reading literacy, and may be overwhelmed by the information and expectations of adaptation to a new healthcare system. Translators should be available to comply with The Joint Commission (TJC) standards in health care to ensure effective communication. Prior to educating parents and children on certain procedures or handing out written instructions, first assess the child's and parent's ability to understand English.

Before a procedure, children may be given an anxiolytic, such as midazolam (Versed), to both relieve apprehension and allow them to be mildly sedated. For painful procedures or those that demand extreme cooperation, such as a bronchoscopy (see

section on Direct Visualization Procedures) or closed fracture reduction, children may be administered moderate sedation. Used in both ambulatory and inpatient settings, moderate sedation results in a depressed level of consciousness induced by the intravenous administration of a sedative such as midazolam in combination with a dissociative anesthetic, such as ketamine. It is administered by an anesthesiologist, a physician, or a nurse specially prepared in the technique.

While under moderate sedation, children are able to maintain their ability to breathe independently and also respond appropriately to verbal commands such as “Lift your head.” They feel minimal pain, however, because of the analgesic administered. Before the technique is started, emergency equipment, including respiratory and pharmacologic measures for medication reversal, must be on hand. The child’s level of consciousness and ability to respond, heart rate, respiratory rate, blood pressure, oxygen saturation, and end tidal CO<sub>2</sub> must be monitored throughout the procedure. Using moderate sedation is an excellent technique to allow children to accept a potentially painful procedure both emotionally and physically. Preparation is essential for both the child and the family in terms of medication and possible side effects that may occur.

## ACCOMPANYING THE CHILD

Parental presence is essential when a child is undergoing a procedure because it reduces the child’s stress (Matziou, Chrysostomou, Vlahioti, et al., 2013). However, if the parents are unable to be present during a procedure, allow them to remain close by, such as a waiting room, so that they can be called once the procedure is completed. Ideally, a nurse whom the child knows should accompany the child to the procedure and remain with the child throughout the procedure, or at least until the child has met a primary person who will be responsible for the procedure. Check for any medication or specific baseline assessment procedures such as vital signs that should be performed before leaving the unit for another department, in case the child will be away from the primary unit for an extended time. If a child is an inpatient, also check that the identification band is securely in place and readily visible despite any intravenous equipment. In most healthcare settings, variations of the SBAR (Situation, Background, Assessment, Recommendation) or ISBAR (Introduction, Situation, Background, Assessment, Recommendation) format is implemented for interdisciplinary/interdepartmental communication to safeguard preparation procedures follow The Joint Commission standards on communication (The Joint Commission, 2014). If there will be a considerable wait in another department, ask children if they would like to bring along an activity such as a game or book. In addition, hallways can be cool. Provide adequate blankets for comfort, especially for infants; because their temperature-control mechanisms are underdeveloped, their temperature can decrease quickly. Always use cart straps and side rails for safety because safety is a priority during all procedures performed on children (Jain, Petrillo-Albarano, & Parks, et al., 2013).

## PROVIDING SUPPORT

Children do well with diagnostic and evaluative procedures as long as they have adequate support from a familiar provider or parent with them. Try to provide support both verbally (i.e., explain what is going to happen in age-appropriate terms) and nonverbally (e.g., a hand on the arm or a nearby presence).

## **MODIFYING PROCEDURES ACCORDING TO A CHILD'S AGE AND DEVELOPMENTAL STAGE**

It is important to consider a child's age and potential understanding of procedures when planning the number and order of tests and the way they will be performed.

### **The Infant**

The number of painful or uncomfortable procedures done on infants should be kept to an absolute minimum to avoid interfering with an infant's developing sense of trust. Advocate for limitation of unnecessary procedures and always keep parents informed of what type of procedure the infant may need to undergo.

Advocate for parents to remain during procedures to offer support. Some parents may ask to hold their child during a procedure that causes pain, but do not ask parents to restrain the child during such a procedure. Their role should be supportive and comforting, not one that causes pain.

Infants become dehydrated quickly, so the time they can remain nothing by mouth (NPO) for procedures should not exceed 6 hours (4 hours for breast milk and 6 hours for formula; [Academy of Breastfeeding Medicine, 2012](#)). You may need to advocate time for breastfeeding before and after a procedure for the comfort of both the infant and mother. If a procedure continues for longer than 3 to 4 hours, provide the mother a room in which to use a breast pump, if needed. Assess the infant's temperature to guard against extremes. Have a blanket available to prevent chilling.

After procedures, allow parents to pick up infants and actively comfort them.

### **The Toddler and Preschooler**

Toddlers and preschoolers resist any diagnostic testing that involves any degree of discomfort or pain or any procedure that is unfamiliar to them. Give children of this age short explanations of what to expect close to the time of the procedure so that little time can be spent worrying. Try to associate any new equipment with things that they are already familiar, such as comparing a magnetic resonance imaging to a giant cell phone camera. If possible, introduce any equipment that will be used in procedures such as a nasogastric tube in a play session with a doll so the child can handle the new object and see that the doll is not injured or minds having the tube inserted.

### **The School-Age Child and Adolescent**

School-age children are concrete thinkers and so are interested in the theory and reason for procedures. They can often be persuaded to cooperate for a procedure by being

promised a look at their X-ray or a point-of-care meter readout afterward. Be careful, however, to ensure that viewing the results is actually possible before promising this to children; otherwise, it can be difficult to obtain any further cooperation. Adolescents may project an air of maturity or sophistication beyond their years to remain in control of themselves in the face of frightening procedures. Do not be misled into thinking an adolescent would not appreciate an explanation or a comforting hand on a shoulder during a procedure.

### *What If... 37.1*

**Felipe, who is scheduled for a cranial MRI, puts his hands over his ears and refuses to listen to the nurse's explanation of what will happen during the MRI. How could the nurse give an explanation to him? Why do you think he is acting this way?**

## PROMOTING SAFETY DURING PROCEDURES

Whether a procedure will be safe depends a great deal on the nursing planning and support that accompanies the procedure. Children are unable to guard their own safety because they are unable to form mature judgments, a situation that leaves them vulnerable to harm unless their caregivers give special consideration to promoting safety during procedures.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for injury related to diagnostic procedure

**Outcome Evaluation:** Child remains free of injury from diagnostic equipment; voices afterward that procedure was not as frightening as anticipated.

As the first safety measure, before performing any procedure, and even before offering food or a medication, read the name on a child's identification armband. If an armband must be removed because it interferes with an intravenous infusion site, cut it away but immediately anchor it to another extremity with adhesive tape. Ask the registrar to provide a new armband as soon as possible. Do not leave the old one off while waiting for a replacement band because this leaves the child susceptible to the danger of mistaken identity during the waiting period.

Because of their natural curiosity, children tend to fuss with equipment to see what will happen if they turn a knob or spin a dial. This means they need close monitoring while procedures are performed to ensure they do not touch any buttons or in other way unintentionally harm themselves. After a procedure, remove all equipment from a room. Syringes and needles can cause puncture wounds. Infants

and young children can choke on small objects such as needle covers.

## Use of Restraints

The purpose of a restraint (physical or chemical) during a procedure is to keep a child safe from injury. Whenever possible, healthcare providers should use alternative means of keeping a child safe. Alternative methods include “family member presence, the use of sitters, distraction, and placing the patient near the nurses’ station. When alternative methods are deemed ineffective or the actions of the patient indicate immediate need for restraints, the least restrictive type of restraint should be utilized and only as a last resort. Additionally, restraints should be removed at the earliest opportunity” (Longo & Miller-Hoover, 2016).

Patients who are restrained must be continuously monitored in accordance with federal, state, and regulatory agency guidelines (American Psychiatric Nurses Association, 2014). No part of a child’s body other than that which is necessary should be restrained. When infants have scalp vein infusions in place, such as for injection of a radioactive isotope for a nuclear medicine scan, for example, their arms may need to be immobilized so they do not touch the infusion site. Their trunk may need to be immobilized so they do not turn. Their lower extremities, however, do not need to be restrained so they can still actively kick and exercise. When a nurse or a parent is with a child, in most instances, all restraints can be removed. Various types of restraints commonly used are described in Table 37.1 and shown in Figure 37.1.

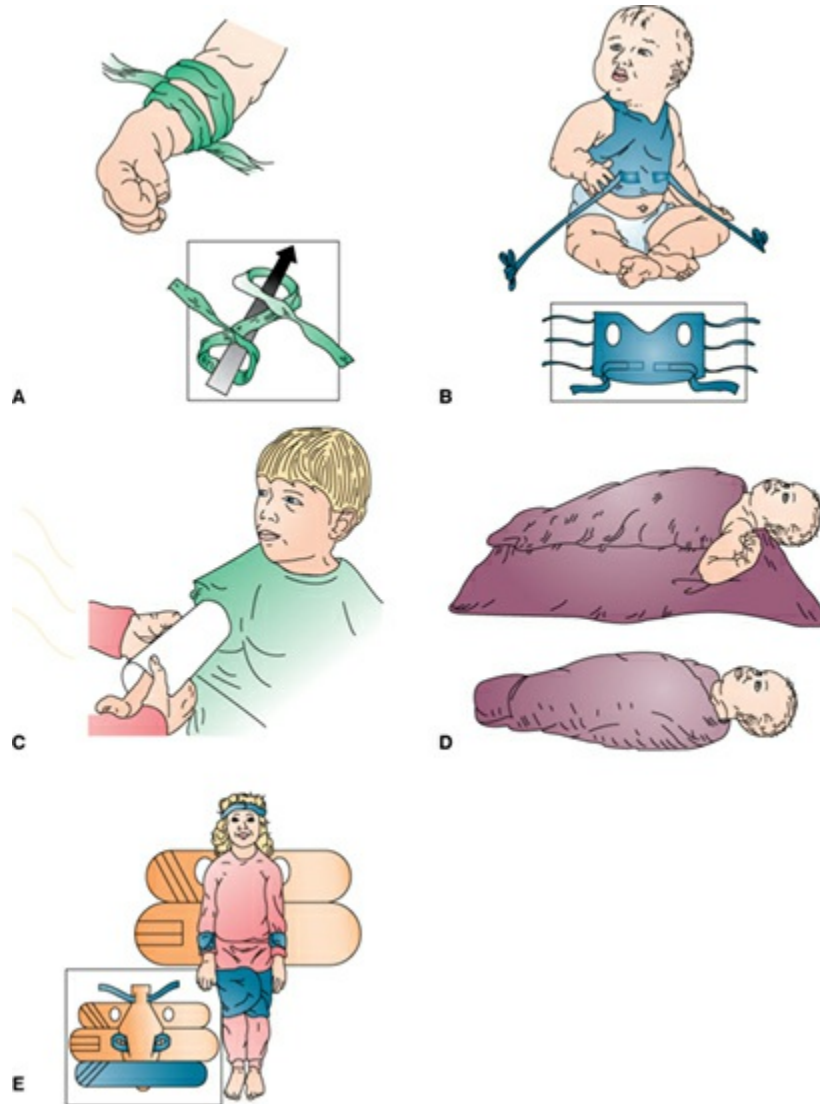

**TABLE 37.1 SAFETY WITH RESTRAINTS**

Type of Restraint	Purpose	Method
Wheelchairs and carts	Promote safety while transporting children to and from a healthcare facility procedure department.	For a wheelchair, use a vest restraint. Attach straps to the frame of the wheelchair with enough slack so the child has some mobility. For a cart, fasten a restraining belt and raise the side rails.
		Even with restraints in place, never leave a child unattended in hallways outside departments in a wheelchair or on a cart. Not only is this unsafe because the child may attempt to get down from the cart or wheelchair but also the anxiety of waiting in a strange department for

		a procedure without a support person with them may be too acute for young children to handle.
Clove-hitch restraints	Secure one arm or leg for a procedure, such as an intravenous infusion.	Use disposable restraints, gauze, or soft muslin tape. Soft muslin tape “gives” a little if the child exerts pressure against it so it will not pull too tight and reduce circulation or cause pain. Tie the restraint as shown in <a href="#">Figure 37.1A</a> .  If a child struggles against restraints, fold several layers of soft gauze around the wrist or ankle under the restraint. Secure the restraint to the underpart of the bed. Never tie restraints to side rails; when a side rail is lowered, it will jerk the child’s arm or leg and possibly cause an injury.  Release arm and leg restraints whenever someone can be with the child to keep the limb in the desired position.
Jacket restraints	Restrain children younger than 6 months in a supine position.	Fasten the ties at the back of the jacket. Tie strips attached to the sides of the jacket under the mattress to keep the child in one position (see <a href="#">Fig. 37.1B</a> ). Assess that the restraint is not pressing against the neck or could be causing interference with a child’s airway.
Elbow restraints	Prevent children from touching the head or face (e.g., following facial surgery).	Dress the baby in a long-sleeved shirt to prevent irritation from the restraint. Slip a commercial restraint such a NoNoSleeve up over the infant’s arm and secure it by the Velcro strips (see <a href="#">Fig. 37.1C</a> ). Assess the infant’s fingers to ensure the sleeve is not too tight that it interferes with circulation.
Mummy or blanket restraints	Temporarily immobilize young children for a procedure involving the head, neck, or throat (e.g., during insertion	Use this only for the duration of the procedure because it is a total body restraint. Follow the steps shown in <a href="#">Figure 37.1D</a> . If the child is exceptionally strong, a few safety pins can be used to hold the restraint even more firmly in place. For the infant who needs continuous observation for respiratory function, fold the mummy

of a nasogastric tube or blood drawing).

restraint so the chest is exposed. For newborns or infants, use a Papoose Board, a commercial restraint used in the same way as a full or mummy restraint (see [Fig. 37.1E](#)).

**Figure 37.1** Types of restraints. (A) A clove-hitch restraint. (B) A jacket restraint. (C) A NoNoSleeve or commercial elbow restraint. (D) A mummy restraint. (E) A Papoose Board.

## PROVIDING CARE AFTER PROCEDURES

After a procedure, assess how well a child reacted to the procedure by both observation and history. Allowing children to explain what happened helps them retrace the procedure in their mind so they can conquer their fear of it. Fill in gaps in information as necessary to improve a child's perception of the procedure. Provide therapeutic play, as necessary, to help reduce anxiety (see [Chapter 36](#)).

If tissue samples are obtained during a procedure, such as bone marrow aspiration,

send the specimen to the proper laboratory for analysis as soon as possible. Guard against specimens being dropped or improperly labeled.

If moderate sedation was used, children may be discharged home or to an inpatient hospital unit as early as 30 minutes after the procedure if they are awake and oriented; have a patent airway; respiratory status is without retraction, stridor, or wheezing; and oxygen saturation is 95% or greater on room air. Blood pressure, heart rate, and respiratory rates should be age-appropriate, and the child should be reasonably free of pain. Using a postanesthesia score sheet (Fig. 37.2) is an effective method to rate recovery from anesthesia and to document that all criteria are met.

Postanesthesia Assessment		
Activity:	Description:	Score:
Activity	Able to move four extremities	2
	Able to move two extremities	1
	Able to move no extremities	0
Respiration	Regular, able to deep breathe/cough	2
	Dyspnea, limited and obstructed breathing	1
	Apneic	0
Circulation	BP within 20 mmHg of preprocedure	2
	BP within 20–25 mmHg of preprocedure	1
	BP 25 mmHg above or below preprocedure level	0
Level of consciousness	Awake, alert	5
	Drowsy, but easily aroused	4
	Stupor, aroused by vigorous stimuli	2
	Responds to pain only	1
	No response to pain	0
Skin color	Preprocedure color, warm, dry	2
	Pale, dusky, blotchy, clammy	1
	Cyanotic, diaphoretic, cold	0
Ambulation	Ambulates with minimum help	5
	Ambulates with minimum support	4
	Unable to ambulate	2

**Figure 37.2** A postanesthesia recovery score. A passing score is at least 10 with a level of consciousness score no lower than 4. (From Tolia, V., Peters, J. M., & Gilger, M. A. [2000]. Sedation for pediatric endoscopic procedures. *Journal of Pediatric Gastroenterology and Nutrition*, 30[5], 477–485.)

Parents often have questions about what care their child will need after they return home after having moderate sedation. Tips for parents about this are highlighted in [Box 37.3](#).

### BOX 37.3

#### Nursing Care Planning Based on Family Teaching

## CARE AFTER MODERATE SEDATION

**Q.** Felipe’s mother says to you, “If my son receives moderate sedation for his MRI, what special care will he need when he comes home?”

**A.** Here are some tips to help you:

- Most children sleep for at least an hour after leaving the healthcare facility. Some feel sleepy for the remainder of the day.
- Do not allow the child to walk alone for at least 4 hours. The child may suddenly feel dizzy and fall without warning.
- Wait until getting home to give the child something to eat or drink to avoid car sickness because moderate sedation may cause children to feel nauseated more easily than usual.
- For the first 12 hours, do not ask him to do any activity that requires alertness, coordination, or balance, such as riding a bicycle, swimming, or doing homework because the sedative can affect coordination and balance.
- Remember that the child may forget things readily for the rest of the day. This forgetfulness should go away, however, after a night’s sleep.
- Moderate sedation may cause children to behave in unexpected ways, such as losing self-control or becoming very emotional. By the next day, the child’s usual behavior should return.
- Give infants clear liquids (e.g., water, apple juice, tea) after getting home. Wait approximately 30 minutes to make sure the child does not choke or vomit. Then, breast milk, formula, or other foods may be given.
- Wait approximately 30 minutes after the child is able to tolerate oral fluids. If there is no vomiting or choking, the child can be given food.
- Call your primary care provider if the child has pain or recurrent vomiting or if any of the effects mentioned last for more than 12 hours.

### *QSEN Checkpoint Question 37.1*

#### **SAFETY**

The nurse restrains Felipe to obtain a blood sample from his hand. The nurse determines which method of restraint is best?

- a. Asking his mother to hold him tightly on her lap
- b. Applying a jacket restraint to confine his body
- c. Asking a fellow nurse to hold his hand firmly
- d. Using a mummy restraint so he can’t be hurt

*Look in Appendix A for the best answer and rationale.*

## Measuring Vital Signs

Vital signs for children consist of temperature, pulse, respiratory rate, blood pressure,

and pain assessment. All vital signs need to be recorded conscientiously and with knowledge of the child's underlying condition so they can be meaningfully analyzed. Be especially alert that assessing any of these measures is not enough; if they are abnormal or if a child has pain, a measure to relieve the problem needs to be initiated. Average pulse rates, respiration rates, and blood pressures for children of different ages, because these differ according to the size and age of the child, can be viewed at <http://thePoint.lww.com/Flagg8e>. Pain assessment and management is discussed in Chapter 39.

## TEMPERATURE

A normal temperature is not a specific number but instead can range from 97° to 100.4°F (Wycoff, 2009). Common temperature values in children are the same as in adults: axillary, 97.6°F (36.5°C); oral or tympanic, 98.6°F (37.0°C); and rectal, 99.6°F (37.6°C). Thermometers that assess the temporal artery temperature are ideal for assessment in children because they register within 2 seconds and therefore cause less fear. Kemp (2013) put forth a position statement that “temperatures taken with temporal artery thermometers correlated with rectal temperatures better than axillary and tympanic membrane thermometry” (Batra & Goyal, 2013) (Fig. 37.3A).

**Figure 37.3** Temperature taking. **(A)** Temporal artery thermometer. (Image Point Fr/Shutterstock.com) **(B)** Axillary temperature.

In newborns, take the temperature using the temporal artery thermometer instead. Taking a temperature rectally increases the risk of damaging their fragile rectal mucosa with a thermometer ([Fig. 37.3B](#)). Children receiving chemotherapy have fragile rectal mucosa as well and so should not have their temperature routinely assessed using the rectum.

For temporal artery thermometer use, gently position the probe flush (flat) on the center of the forehead, midway between the eyebrow and the hairline. Press and hold the SCAN button. Lightly slide the thermometer across the forehead keeping the sensor flat and in contact with the skin until you reach the hairline ([Exergen, 2014](#)).

For a tympanic temperature recording, straighten the ear canal by pulling down on the earlobe in a child younger than age 2 years and pulling up on the pinna of the child older than age 2 years. Insert the tip of the tympanic thermometer gently into the child's ear canal directing the sensor beam toward the center of the tympanic membrane. Even if the child has earwax, tympanic membrane temperature is not affected, so the reading

is consistently accurate within seconds. By 4 years of age, children are usually old enough to close their mouth sufficiently for oral temperature recording by use of an electronic thermometer.

For an axillary recording, place the tip of an electronic thermometer in the axilla and hold the child's arm down to the side to keep the thermometer firmly in place until it registers. For the rare occasions when a rectal temperature must be taken, insert the electronic thermometer only to the length of the tip (0.5 in.) in infants, and not over 1 in. in older children, and hold it in place for 5 minutes.

## PULSE RATE

As children grow older, the heart rate slows and the range of normal values narrows. If possible, measure a child's pulse rate while the child is at rest. An apical pulse (i.e., listening at the heart apex through a stethoscope) is taken in children younger than 1 year of age because their radial (i.e., wrist) pulse is too faint to be palpated accurately. In an infant, the point of maximum intensity, or the point on the chest wall where the heartbeat can be heard most distinctly, is just above and outside the left nipple (i.e., just lateral to the midclavicular line at the third or fourth intercostal space). This point gradually becomes more medial and slightly lower up to 7 years of age. By 7 years of age, it is at the fourth or fifth interspace at the midclavicular line as in adults. For greatest accuracy, count the pulse rate for 1 full minute.

### *Concept Mastery Alert*

By the time a child reaches school age, the radial pulse may be used for measuring pulse. In infants younger than 1 year of age, the apical pulse is used.

## RESPIRATORY RATE

Respirations also should be measured before an infant is disturbed because the respiratory rate increases with crying. If possible, count the infant's respirations while the infant is being held by their parent or lying quietly in a crib before lowering the side rail. For a child, count the respirations when they are seated in a parent's lap. Infants tend to breathe with their abdominal muscles so it is just as accurate to take respirations by counting movements of the abdomen as it is to count chest movements. Again, for greatest accuracy, count respirations for 1 full minute.

## BLOOD PRESSURE

Beginning at 3 years of age, children should have their blood pressure measured at every office visit ([National Heart, Lung, and Blood Institute, 2005](#)). Offer an age-appropriate explanation of the procedure, especially to young children, because wrapping their arm and feeling the pressure applied can be frightening if they are not prepared for it.

Systolic pressure in children is read as the manometer pressure is dropping and at the point where the first sound is heard. The point at which the sound disappears is considered the diastolic pressure. Blood pressure can be difficult to measure in infants because the cuff used must be no more than two thirds and not less than one half the length of their upper arm; a wider cuff gives a lower reading and a narrower cuff gives a higher reading (Fig. 37.4). Doppler ultrasound blood pressure, which bounces high-frequency sound waves off blood moving through a vein, is especially effective when continuous monitoring is necessary for infants because it can be set to record at specified times and the result is obtained so much faster. If a Doppler lead is placed over an artery, either the movement of the blood (i.e., pulse wave) or its tension (i.e., blood pressure) can be registered on a digital readout or monitor print or the sound of the pulse waves can be broadcast for auscultatory assessment.

**Figure 37.4** Blood pressure measurements are essential during routine health assessments and before diagnostic or therapeutic procedures. Here, a nurse assesses a child's blood pressure during a routine examination. (XiXinXing/Shutterstock.com)

Preschoolers and school-age children enjoy watching the digital readout numbers, so digital recording also works well with these age groups. Direct measurement (i.e., intra-arterial monitoring by an indwelling catheter into the radial or femoral artery) is used

with children who are critically ill and is described in [Chapter 41](#).

If a child's arms are not free for blood pressure recording, blood pressure may be recorded by wrapping a cuff over the thigh and palpating or auscultating the popliteal pulse behind the knee or at the ankle. In infants younger than 1 year of age, the thigh and arm blood pressure should be equal. In children older than 1 year of age, the systolic pressure in the thigh tends to be 10 to 40 mmHg higher, whereas diastolic pressure remains the same. If the thigh blood pressure reading is lower than that in the arm, coarctation of the aorta or an interference with circulation to the lower extremities may be the cause and should be addressed immediately.

When assessing blood pressure, pay attention to the pulse pressure—the difference between systolic and diastolic readings—in addition to the actual numbers because both an unusually wide (more than 50 mmHg) or narrow (less than 10 mmHg) range may suggest congenital heart disease. An abnormally narrow pulse pressure, for instance, is a sign of aortic stenosis. An abnormally low diastolic pressure (causing a wide pulse pressure) occurs with patent ductus arteriosus.

## Reducing Elevated Temperature in Children

Fever is such a common symptom in children that reducing temperature, or giving a parent instructions on how to reduce a child's temperature at home, is a common intervention with children.

### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for hyperthermia related to illness or interference with temperature regulation from medication or surgery

**Outcome Evaluation:** Child's tympanic temperature returns to 98.6°F (37°C) within 2 hours.

Because the temperature-regulating mechanism in children is immature, fever tends to be more marked than in adults, and may even be out of proportion to the seriousness or extent of their disease. A high temperature occurs because a child's temperature-regulating point (set point) has been elevated. The child's temperature, therefore, cannot be reduced until the set point returns (or is returned) to normal.

Acetaminophen (Tylenol) and ibuprofen (Motrin or Advil) are excellent antipyretics and are often initiated when a child has a fever of more than 101°F (38.3°C). It is important to counsel parents that fever in children does not typically last long and is a means by which the body tries to protect itself by fighting off illness ([Box 37.4](#)).

**IBUPROFEN (ADVIL, MOTRIN)**

**Action:** used to reduce inflammation, fever, and mild-to-moderate pain

**Pregnancy Risk Category:** B; D if used in last trimester

**Dosage:** (for fever or pain) individually based on child's weight, not over four doses in 24 hours

**Possible Adverse Effects:** gastric upset, headache, dizziness, nausea, occult blood loss, prolonged bleeding, peptic ulceration ([Karch, 2015](#))

**Nursing Implications**

- Use with caution in children who have gastrointestinal irritation because ibuprofen causes gastric irritation.
- Encourage fluid intake; ibuprofen may cause renal failure if child becomes dehydrated.
- Administer this medication with food or drink to minimize gastrointestinal irritation.
- Do not give to infants younger than 6 months of age without healthcare provider's approval.
- Always use the measuring device supplied by the manufacturer, not a kitchen spoon, for dosage accuracy.

Acetaminophen in a dosage of 10 to 15 mg/kg every 4 to 6 hours to treat fever in children is safe and effective. It is estimated that 80% of children will have a decrease in temperature within the first 30 to 60 minutes after administration. Ibuprofen in a dosage of 10 mg/kg every 6 to 8 hours is as effective as acetaminophen and may have a longer effect on lowering body temperature; however, ibuprofen should not be given to infants younger than 6 months of age ([Sullivan & Farrar, 2011](#)).

Caution parents also to never give acetylsalicylic acid (aspirin) to children with fever because aspirin is associated with Reye syndrome, a severe neurologic disorder (see [Chapter 49](#)).

Many parents dress febrile children warmly in flannel pajamas to keep them from “getting a chill.” This actually increases the child's temperature and does not prevent the shaking, trembling reaction that comes with a high fever. In addition to antipyretic administration, suggest parents dress children with a fever in lightweight clothing. They can remove all clothing but the diaper from an infant. Placing a cool cloth (not ice) on a child's forehead often feels comforting and can help prevent a headache. Sponging children with ice water used to be prescribed on a routine basis to reduce fever, but the practice may lead to extreme chilling and shock to an immature nervous system and has little advantage over the use of oral antipyretics.

## Common Diagnostic Procedures

Diagnostic and therapeutic procedures used with children vary depending on a child's condition and age but are similar to those used with adults. Blood, urine, and stool studies are commonly prescribed. Respiratory illnesses require special procedures and are discussed in [Chapter 40](#). Biopsies (i.e., surgical procedures to remove tissue for examination) are done to detect malignancy and are discussed in [Chapter 53](#). Stress or exercise testing for cardiovascular pathology is discussed in [Chapter 41](#).

### ELECTRICAL IMPULSE STUDIES

As their name implies, **electrical impulse studies** are those that include electrical conduction. Children need special preparation for studies such as electrocardiograms (ECGs) ([Fig. 37.5](#)) or electroencephalograms (EEGs) because they have been warned not to play with electric wires and so may worry about being burned or electrocuted. You can assure a child the electricity passes from their body to the machine, not the other way around. Except for electromyelograms (i.e., study of the conduction paths of the spinal cord), you can also assure them these tests are painless. The electrodes are attached to the body by paste or sticky tape, which is easily removed afterward.

**Figure 37.5** Administering an electrocardiogram (ECG). Children can be assured this is a painless procedure. (© [Fotosearch.com.](#))

### X-RAY STUDIES

A variety of X-ray studies are used to inspect internal aspects of the body, such as bony structures. These range from simple flat-plate views to more complicated computed tomography scan or studies using contrast dye.

#### Flat-Plate X-Rays

X-rays are used to diagnose and evaluate the progress of illnesses as well as assess the placement of apparatuses such as gastrointestinal feeding tubes. As a rule, children accept X-rays without protest because the X-ray machine can be compared with a camera, an instrument with which they are familiar (Fig. 37.6). A lead apron and thyroid shield are used on portions of the body where X-ray exposure is not needed. Parents and healthcare providers who remain in the room during an X-ray should be provided with safety equipment such as a lead apron. Remove any objects that contain metal because they may obscure the image.

**Figure 37.6** Positioning of a child for an X-ray.  
([iStock.com/xavierarnau](https://www.iStock.com/xavierarnau))

### **Dye Contrast Studies**

To visualize a body cavity, radiopaque dye may be swallowed, instilled by enema, or administered intravenously and then revealed by X-ray. Caution the child who is asked to drink barium for a gastrointestinal study that even if flavored, it does not taste terribly good (more like warm thick milk). Always check the child's allergy status before administering anything that they have to ingest or be injected with. Evidence exists of a nonspecific cross-reactivity between contrast material sensitivity and allergy to seafood as well as other foods (Harrison, 2013). The frequency of allergic-like and physiologic adverse events related to the intravascular administration of iodinated contrast media (ICM) is low and has decreased considerably with changes in the use of ionic high-osmolality contrast media (HOCM) to nonionic low-osmolality contrast media (LOCM) (American College of Radiology, 2016). As the contrast dye is injected, the child may feel a hot flush, a sensation that can be frightening if the child is unprepared for this. Try not to use the word *dye* when describing a contrast medium to prevent young

children from worrying they will be dyed like an Easter egg or will *die*. Use the phrase *special medicine* instead.

Children easily grow bored during this type of procedure because of the time involved waiting for the contrast medium to reach and outline the specific organ to be studied. Have the child take along an activity to the exam room to make the time pass faster. Maintaining NPO status may also be difficult for lengthy procedures. Ensure that parents understand children do not “radiate” X-rays or radioactivity after the procedure, so they will not be afraid to hold a child closely for comfort.

## Computed Tomography

**Computed tomography (CT)**, more commonly known as a CT or CAT scan, is an X-ray procedure in which many views of an organ or body part are obtained to represent what the organ would look like if it were cut into thin slices. As with any X-ray, dense structures appear white and less dense structures appear gray to black on the films.

The procedure may include injection of an iodine-based radioisotope contrast medium. If this is necessary, the study may be referred to as **positron emission tomography (PET)** or **single-photon emission computed tomography (SPECT)**.

A CT scanner is a large machine with a hole, or short tunnel, in the center. A moveable examination table slides into and out of this tunnel. In the center of the machine, the X-ray tube and electronic X-ray detectors are located opposite each other on a ring, called a gantry, which rotates around the patient ([Fig. 37.7A](#)). It’s important for children to lie still during the procedure to avoid creating artifacts on the film. Sedation may be needed to aid in the procedure. You can assure parents that although the radiation exposure from CT scans occurs over a long period of time, such low doses are used that the actual exposure is comparable to a regular X-ray. Radiation dose from CT procedures varies from patient to patient. The particular radiation dose will depend on the size of the body part examined, the type of procedure, and the type of CT equipment and its operation ([U.S. Food and Drug Administration, 2016](#)).

**Figure 37.7** Some procedures are potentially frightening because of the size of the machinery used. **(A)** A computed tomography (CT) scanner. (From Michelle Del Guercio/Photo Researchers, Inc.) **(B)** A magnetic resonance imaging (MRI) scanner. (© [Fotosearch.com.](#))

## INFORMATICS

Felipe's mother is relieved that he does not need an MRI because she tells the nurse she "would not have not allowed that." What would be the nurse's best response to her?

- a. "MRIs are almost never used for children under 4 years so you don't have to worry."
- b. "Aren't you prepared to take some risks to ensure Felipe's well-being?"
- c. "If, at any point, Felipe does need an MRI, be prepared to change your mind."
- d. "What is the reason you wouldn't have allowed an MRI for your son?"

*Look in [Appendix A](#) for the best answer and rationale.*

## Magnetic Resonance Imaging

**Magnetic resonance imaging (MRI)** combines a magnetic field, radio frequency, and computer technology to produce diagnostic images that aid in the diagnosis of disorders such as the cause of renal or brain pathology. The child lies on a moving pallet that is pushed into the core of the machine, where the magnet is housed ([Fig. 37.7B](#)). When the magnetic field surrounding the child is turned on, it causes tissue atoms to line up in a parallel fashion. As radio waves are turned on and off, the atoms change position. This change is sensed and converted into a visual display on a computer screen ([Delso, Ter Voert, & Veit-Haibach, 2015](#)).

The procedure has an advantage over X-rays in that it has no apparent ill effects, it can reveal astonishingly clear structural defects in soft tissue, and, if a contrast medium is required, it is not iodine based, so the danger of a reaction is minimal. Because metal may deflect the magnetic waves, children with a metal prosthesis or metal dental braces are poor candidates for the procedure. Hairpins and eye makeup (which often has a metallic base), watches, or other jewelry should be removed. Remove any metal from the child's hospital gown, which may include metal snaps.

When the radio waves are turned on and off during the procedure, a booming noise can be heard. Prepare children for this sound (which is often compared with the sound of drums) as well as the feeling of claustrophobia they may experience. Except for cranial exams, headphones can be provided to decrease the noise. Because the total procedure (excluding cranial examinations) may take up to 45 minutes, sedation may be indicated so they can lie quietly for this length of time and not skew the images recorded. [Box 37.5](#) depicts an interprofessional care map for a child having a cranial MRI exam.

### BOX 37.5

## Nursing Care Planning

## AN INTERPROFESSIONAL CARE MAP FOR A CHILD IN NEED OF DIAGNOSTIC TESTS

Felipe is a preschooler who is scheduled to have a computed tomography study for a possible head injury.

**Family Assessment:** Child lives with single-parent mother and younger sibling in two-bedroom loft in refurbished inner city warehouse. Mother is a commercial artist. Rates finances as “healthy.”

**Patient Assessment:** Child was playing at community playground with day care staff. Was pushed off top of slide by another child. Fell approximately 6 ft onto his head and sustained brief loss of consciousness. Brought to emergency department by rescue. Temperature (T) = 100.6°F tympanic; Pulse (P) = 90; Blood pressure (BP) = 100/65 mmHg. Crying from pain in neck and upper back.

“He’s upset because of being bullied at school and he’s afraid of the dark. What will this exam be like and how can we make sure he will be safe?”

**Nursing Diagnosis:** Anxiety (child and parent) related to necessary diagnostic procedure

**Outcome Criteria:** Mother listens to explanation of advantages of computed tomography (CT) scan for diagnosis of brain, neck, or spine injury. Voices agreement to allow procedure. Helps prepare child for anxiety-filled experience.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Take history to assess if child has change of behavior from usual.	Review with parent that traumatic events can affect all body systems.	Head injury, if severe, can affect vital signs and cognitive processing.	Parent states she feels child is reacting as usual except for neck pain.
<i>Teamwork and Collaboration</i>				
Nurse/primary care provider	Assess if further neurologic consultation will be necessary following physical and neurologic exam.	Consult as necessary with neurologist about child’s condition and continued care based on CT findings.	A 6-ft fall could cause considerable intracranial swelling or bleeding.	Neurologist on call completes necessary consult and any needed additional procedures.
<i>Procedures/Medications for Quality Improvement</i>				
Nurse/pain	Ask child to rate	Explain CT	Moderate	Consent for

management team	pain using faces scale.	procedure to parent and child. Assist with moderate sedation.	sedation will allow child to sleep during an otherwise frightening procedure.	moderate sedation is obtained. Sedation is used during procedure without complications.
-----------------	-------------------------	---	---	---

*Nutrition*

Nurse	Assess last time child ate or drank.	Keep child nothing by mouth (NPO) prior to procedure.	Moderate sedation can cause aspiration in children with a full stomach.	Child remains NPO until postprocedure.
-------	--------------------------------------	---	---	--

*Patient-Centered Care*

Nurse/nurse practitioner	Assess parent's understanding of the need and technique of CT scan.	Fill in gaps of knowledge for parent about procedure.	A well-informed parent is able to make well-informed decisions about care.	Mother states she understands why procedure is needed.
--------------------------	---	---	--	--

*Psychosocial/Spiritual/Emotional Needs*

Nurse	Assess if child is still frightened from bullying episode at playground.	Review with child that bad things can happen to good people.	Discussion of an injury can help to relieve guilt and increase self-esteem.	Child discusses what happened; states he knows incident was not his fault.
-------	--	--	---	--

*Informatics for Seamless Healthcare Planning*

Nurse/primary care provider	Assess if parent understands importance of assessing child's respirations and pulse every 4 hours after return home.	Review with parent technique for respiration and pulse assessment.	A decreasing pulse or respiratory rate can indicate increased intracranial pressure.	Parent confirms she will be able to take vital signs accurately; will notify emergency department if vital signs vary from norms given to her
-----------------------------	--	--	--	---

### What If... 37.2

**Felipe's mother repeats to the nurse that he is very frightened of dark places. Knowing this, how would the nurse best prepare him for a CT scan?**

## ULTRASOUND

**Ultrasound** is a painless procedure in which images of internal tissue and organs, such as the appendix, are produced by the use of sound waves ([RadiologyInfo.org](http://RadiologyInfo.org), 2015). Because it is noninvasive, children accept ultrasound easily and may even enjoy watching the oscilloscope screen during the procedure. Alert a child that the clear gel, which is applied to the skin over the body part to be studied, may feel cool and sticky. Compare the transducer that is used on the body surface to pick up internal images to a television camera so it is not viewed as something strange ([Fig. 37.8](#)). Explain that the ultrasound procedure is not an X-ray, so they can remain in the room to comfort their child during the procedure. Because ultrasound appears to have no long-term effects, it can be repeated over and over for serial determinations.

**Figure 37.8** Ultrasound can be potentially frightening for children unless they receive good preparation because they don't understand the concept of sound waves. (© iStockphoto/Thinkstock.)

## NUCLEAR MEDICINE STUDIES

**Radiopharmaceuticals** are radioactive-combined substances that when given orally or by injection, flow to designated body organs. When a scintillation machine (a form of

Geiger counter) is passed over the organ where the radiopharmaceutical has collected, the pattern of the collected material outlines the organ. The pattern can then be reproduced as a screen image or a photograph.

Parents may worry that a child will be harmed by exposure to a radioactive substance (Adelstein, 2014), and although this procedure exposes the patient to low levels of ionizing radiation, the risk is minimal when used judiciously. Within the media are a number of reports about the medical use of radiation and the risk of neoplasm development. It is important to effectively communicate with families and patients about the medical use of radiation, the level of radiation exposure, and its potential risks (World Health Organization [WHO], 2016).

## DIRECT VISUALIZATION PROCEDURES

Direct visualization procedures involve the observation of an internal body cavity by way of a thin tube inserted through a body surface opening. Types of direct visualization include endoscopy, bronchoscopy, and colonoscopy.

### Endoscopy

**Endoscopy** involves the use of an endoscope, which is passed through the mouth, to examine the gastrointestinal tract and has become a common method of diagnosis for gastrointestinal disorders in children. The procedure is also used as an emergency measure to remove foreign objects such as quarters or toys swallowed by children. When first developed, endoscopes were straight and stiff metal instruments, so their use was limited. Currently, they are made up of fiberscopes, which are extremely flexible and easily maneuvered, so these examinations are not nearly as uncomfortable as before.

The thought of having a tube passed down the throat can be very frightening. Even after children understand what the procedure will consist of, they can still be very uncomfortable at the thought of a tube being passed into them. Before the procedure, children must remain on an NPO status for between 4 and 6 hours. They will need a sedative or moderate sedation so they can lie quietly for the time required. Good support during both the anxious time waiting for the procedure and during the procedure is crucial. Ask whether the child can have a digital photograph taken during the procedure to keep as a scrapbook souvenir.

Because the endoscope is passed through the throat, edema of the throat may occur from the pressure on the esophagus and pharynx. This means that the child requires close observation afterward for at least an hour to confirm that the edema is not interfering with respirations or causing discomfort. Observe closely the first time the child drinks after the procedure to ensure that the gag reflex is intact despite throat edema or the effect of a local pharyngeal anesthetic that may have been sprayed into the throat before the procedure.

## Bronchoscopy

**Bronchoscopy** is the direct visualization of the larynx, trachea, and bronchi through a lit, flexible, fiberoptic tube (i.e., a bronchofiberscope) that is passed through the naris or trachea. The procedure is used with children who have aspirated a foreign object, to instill certain medications, or to take culture and or biopsy specimens (Singh & Singhal, 2015). Typically, the throat is sprayed with a local pharyngeal anesthetic to numb the area. Moderate sedation is then administered, and continuous monitoring of vital signs is standard care. Different types of bronchoscopes are used depending on the age of the child and/or the size of the endotracheal tube being used. Procedural complications are not common but may include compromise to the airway such as hemorrhage, pneumothorax and airway edema. After the procedure, continue to assess the child's respiratory function and airway patency. Postprocedure complications may include bronchospasm, stridor, desaturation, or respiratory distress. Observe children carefully the first time they drink after the procedure to assess that their gag reflex is intact and they do not choke.

## Colonoscopy

**Colonoscopy** is an endoscopic examination of the large intestine with a flexible fiberoscope that is inserted through the anus and advanced as far as the ileocecal valve. Air is then infused to expand the bowel walls for good visualization. The technique allows the colon walls to be visualized; if abnormalities are found, photographs can be taken for analysis. It is used to diagnose inflammatory bowel disease or to obtain biopsies if a malignancy is suspected.

Before the procedure, children are given a clear liquid diet for about 24 hours and then they are asked to drink an isotonic saline laxative that causes fluid diarrhea so their bowel is clean for the procedure. It can be difficult for younger children to drink as much of the laxative solution as is needed so their bowel is cleared completely of stool (Elitsur, Butcher, Vicki, et al., 2013). Playing games such as Simon Says can be helpful to gain their cooperation. If a child cannot swallow all the laxative, a saline enema may be necessary. Moderate sedation is used during the procedure to reduce discomfort.

Postprocedure, children may pass a great deal of flatus in the first 12 hours because of the air introduced during the procedure. If the procedure was done on an ambulatory basis, children are discharged about 2 hours after the procedure (but they are kept NPO during that time to allow the bowel to have a brief rest). Provide parents with instructions on what observations they should make and report if they occur after they return home, such as abdominal pain, blood in stool, weakness, or pallor (signs of bowel bleeding) especially if a polyp was removed or a biopsy specimen was obtained. Even with moderate sedation, colonoscopies are difficult procedures for children to accept. Give generous praise afterward for their cooperation with both the preparation for the procedure and the actual procedure.

## ASPIRATION STUDIES

**Aspiration studies**, which are the removal of body fluids by such techniques as lumbar puncture or bone marrow aspiration, are always anxiety-causing procedures. The size of the needle that will be used can be frightening to parents and children alike. Children may need a sedative or moderate sedation so that they remain still during the procedure. Support and restrain children by talking and using touch as appropriate. Assess for bleeding at the puncture site after the procedure and apply pressure as needed to halt bleeding completely. After a lumbar puncture, remind children to remain quiet and with their head flat to help prevent a postdural puncture headache (see [Chapter 49](#) for specific procedural details).

## Collecting Specimens for Analysis

The collection of body fluids, secretions, and excretions is a collaborative nursing function essential to the complete assessment of a child. Elements of these fluids are measured by a variety of means; findings can be used to help diagnose an illness, evaluate the progress of a condition, or evaluate a child's response to therapy. As with all procedures, use standard infection precautions regardless of the source from which the sample is taken. Ensure precautions are maintained through the entire process, from obtaining, transporting, discarding, or storing specimens.

## OBTAINING BLOOD SPECIMENS

Having a blood specimen taken can be terrifying for a child. For many children, their past experience with losing blood has involved a nosebleed or a cut knee and the discomfort or pain they felt. They have also had injections for immunizations, so they know that injections sting. Putting the two experiences together makes collecting a blood specimen an extremely terrifying process. For these reasons, prepare children both before and during the procedure. Patient immobilization is crucial to the safety of pediatric and neonatal patients undergoing phlebotomy ([WHO, 2010](#)). When feasible, blood specimens should always be obtained away from a child's bedside to keep the room and bed as a "safe" area. Applying a Band-Aid afterward to cover the needle site provides physical as well as psychological support.

### Venipuncture

For very small infants, the usual sites for venipuncture (entrance into a vein) are the same as for adults: the superficial veins of the dorsal surface of the hand or the antecubital fossa. In a few instances, the jugular or femoral vein can also be used. In nonemergent situations, apply an anesthetic cream such as EMLA (eutectic mixture of local anesthesia) before venipuncture to reduce pain (see [Chapter 39](#)) and liberally use distraction techniques such as using toys with flashing lights, blowing bubbles, or playing a game for toddlers and asking distraction questions or playing a movie for

school-age children (Stevens & Marvicsin, 2016).

Offer children a simple explanation of the procedure in terms they can understand: “I need to take some blood from your hand. First, I’ll put some cream on your skin so when I come back to take the blood in a little while, you’ll feel only a pinprick because of the cream.” Let the child know you understand how difficult it is to agree to the procedure. Try not to say “drawing blood” because this sounds as if you’re proposing an activity with crayons, not a procedure that will cause discomfort (Box 37.6).

### BOX 37.6

#### Nursing Care Planning Tips for Effective Communication

Felipe is a 4-year-old who is going to have several diagnostic studies. He’s coloring a picture when you approach him to obtain a blood specimen for electrolyte levels.

*Tip:* Carefully explain what you need to do and why it is important. It is easy to forget that what a word means to you may not be interpreted the same way by a young child.

**Nurse:** Hi, Felipe. I see you are coloring a picture, can you tell me about it?

**Felipe:** It is a birthday card for my grandma.

**Nurse:** I am sure she will like it. Remember when we used this syringe and tubing to check on your blood last week? I need to do another check today. We can’t see inside your body, and by checking your blood, we can see if you are getting better. Which arm would you like me to use today?

**Felipe:** Use this one [holds out left arm]. I need this one [indicates right arm] to color with.

**Nurse:** You can squeeze this ball with your other hand while I clean off your arm with the (alcohol) pad. Let’s count to 10 together. If you hold real still I will be finished by the time we get to 10 [counts to 10 together]. You did great. I know it hurt for a second. Would you like to pick out a sticker?

Preschoolers may worry that they will lose all their blood during the procedure because they have no concept of how much blood their body contains. Many children younger than school age may have to be restrained for blood sampling because no matter how cooperative or brave they might be initially, the minute they see the needle, they can be too overwhelmed with fear to hold still.

#### *QSEN Checkpoint Question 37.3*

#### EVIDENCE-BASED PRACTICE

One of the biggest problems with trying to reduce pain from a procedure such as a venipuncture or an injection is that anesthetic creams do not take effect until 30

minutes to an hour. To test whether commercial devices called a J-tip (a needle-free device for subcutaneous delivery of lidocaine) and the Buzzy (a cooled, vibrating device that uses gate control to minimize procedural pain) could serve as an effective distraction technique to immediately reduce pain, researchers prospectively investigated patients aged 1 month to 21 years. Participants were enrolled in phase 1 (J-tip only) and then phase 2 (Buzzy and J-tip) for analgesia prior to venipuncture or IV start. Results revealed that patients who received either intervention reported lower scores on pain scales during venipuncture or IV start than the group receiving no analgesia (Kearl, Yanger, Montero, et al., 2015).

Based on this study, the next time Felipe needs to have blood drawn, the nurse's best action would be which of the following?

- a. Assessing Felipe's pain and anxiety levels before and after venipuncture
- b. Explaining that venipuncture feels much the same as a mild bee sting
- c. Planning a distraction technique for him that his mother thinks would be effective
- d. Explaining to Felipe that an attempt will be made to distract him before performing the procedure

---

*Look in Appendix A for the best answer and rationale.*

## Capillary Puncture

Capillary blood heel or fingertip punctures are often obtained for glucose and hematocrit determinations. Apply an anesthetic cream before the procedure to reduce discomfort if needed; however, be careful when applying this to a finger that the child doesn't lick this off and anesthetize their tongue or throat. Use the side of the finger, not the center, for the puncture to reduce discomfort afterward; for heel punctures, use the lateral aspect of the heel to avoid striking the medial plantar artery or the periosteum of the bone (Fig. 37.9). Comfort the child afterward because fingertip punctures seem minor but can be more painful than a venipuncture afterward.

In many settings, laboratory analysis such as glucose level can then be completed immediately using a commercial meter (a point-of-care test).

**Figure 37.9** Sites for a capillary blood heel puncture. Choose a site to the right or left on the heel to avoid the medial artery.

**QSEN Checkpoint Question 37.4**

**PATIENT-CENTERED CARE**

Felipe will be having a fingertip puncture for serum glucose. The nurse determines which instruction is best to empower him before the procedure.

- a. “It won’t hurt a bit; it’s only a small finger prick.”
- b. “Why don’t you choose which finger you’d like me to use.”
- c. “Most other boys your age don’t mind this at all.”
- d. “Make sure you hold still, otherwise you won’t get a special treat.”

Look in [Appendix A](#) for the best answer and rationale.

**OBTAINING URINE SPECIMENS**

Depending on the type of test required, urine may be collected with a usual voiding, after the external meatus has been cleaned (i.e., a clean-catch specimen), by catheterization, or suprapubic aspiration. A specimen may require a single specimen or collection of all the urine voided within a 24-hour period.

**Routine Urinalysis**

Routine urinalysis requires only a single voided specimen. The specimen will then be analyzed for appearance, glucose, specific gravity, and microscopic analysis. Specimens must always be collected in sterile containers to prevent contamination.

## The Infant and Toddler

An infant or a child who has not been toilet trained cannot be expected to urinate on command; thus, a collecting device must be attached to the genitalia to collect their next voiding. Contamination rates for bagged specimens are high; thus, a bagged specimen should not be used for urinary tract infection (UTI) diagnosis. If the bagged specimen is negative for bacteria, the possibility of a UTI diagnosis is low (Kim & Koo, 2015).

For girls, wash the perineum to remove any fecal matter and then rinse with water and dry the site where the collecting device will be attached to ensure good adherence. For boys, wash the penis and rinse and thoroughly dry the same way. Maintain dry skin that is free from powder, lotions, and oils (Fig. 37.10A). Apply the adhesive side of the collection device firmly and smoothly to the skin (any folds or wrinkling will cause leakage) to cover the urethral opening.

If an infant attempts to loosen the collector, cover the device with a diaper to keep it out of reach. Otherwise, leave the device visible so that it can be observed for urine output. Offer the child something to drink to encourage voiding. Most infants void shortly after a feeding, so if the collector is applied just before a regular feeding, voiding will probably result soon afterward. Remove the collector as soon as the infant voids and transfer the specimen to a specimen cup by cutting a bottom corner of the bag.

**Figure 37.10 (A)** A urine collector for infants. The trick to making the collector adhere is to make certain the child's skin is dry. **(B)** Testing specific gravity of urine with a refractometer. The advantage of this is that only one drop of urine is required.

Urine may be aspirated from diapers for tests such as specific gravity, dipstick protein, pH, or glucose (Fig. 37.10B). Current disposable diapers, however, are

designed to trap urine in the material so effectively, they can make it impossible to squeeze out a specimen. Placing cotton balls inside the diaper can be a help because these can be squeezed for additional urine.

### The Preschooler and School-Age Child

It may be difficult to obtain routine urine specimens from preschoolers or toilet-trained toddlers because they can void only when they feel a definite urge to do so, not on command. Another problem is language. It is not unprofessional to use words such as “pee-pee” if this is what the child will understand. Provide a potty chair if one is available; if not, put a urine collection cap device on a toilet. A generally successful approach with a child this age is to act as if voiding is not a difficult procedure. Offer the child a glass of water or other fluid and ask a parent to reinforce the request to void so that the child knows a parent approves. A school-age child is usually able to void when asked, although the child may find it more difficult than the adult.

### The Adolescent

Adolescents are usually knowledgeable and cooperative about providing urine specimens. As with adults, give them a clean specimen container and tell them what is needed. Unless they have voided recently, they usually are able to void on command. Remember, however, that adolescents are concerned and self-conscious about body functions and therefore are often reluctant to carry a urine specimen through a crowded waiting room to the desk area. They may be too self-conscious to void if they know someone is nearby, for example, just outside a curtain waiting for them. Send them to a nearby bathroom with a closed door, or leave the area to give them privacy. Collect the specimen from them immediately so they do not have to carry it themselves.

Some adolescents are suspicious that a urine specimen is being requested for drug testing. Providing a good explanation of its actual purpose relieves this fear. If you are in doubt regarding whether the fluid returned to you is urine, not water, assess its specific gravity. Water has a specific gravity of 1.000; urine will have a specific gravity more than this (1.003 to 1.030).

Adolescent girls may be embarrassed to mention they are menstruating so be sure to ask an adolescent girl about this before she voids. To prevent having a urine specimen contaminated by menstrual blood, which changes the specific gravity, protein, and red blood cell analysis, ask the girl who is menstruating to wash her perineum well with soap and water and rinse and dry it to remove menstrual blood.

### **Twenty-Four-Hour Urine Specimens**

Although a urinalysis of a single urine specimen will indicate the presence of substances such as protein or glucose, a 24-hour urine specimen may be necessary to determine how much of a substance is excreted during a full day (quantitative analysis). To begin a 24-hour urine collection, ask a child to void (with an infant, attach a collecting bag and

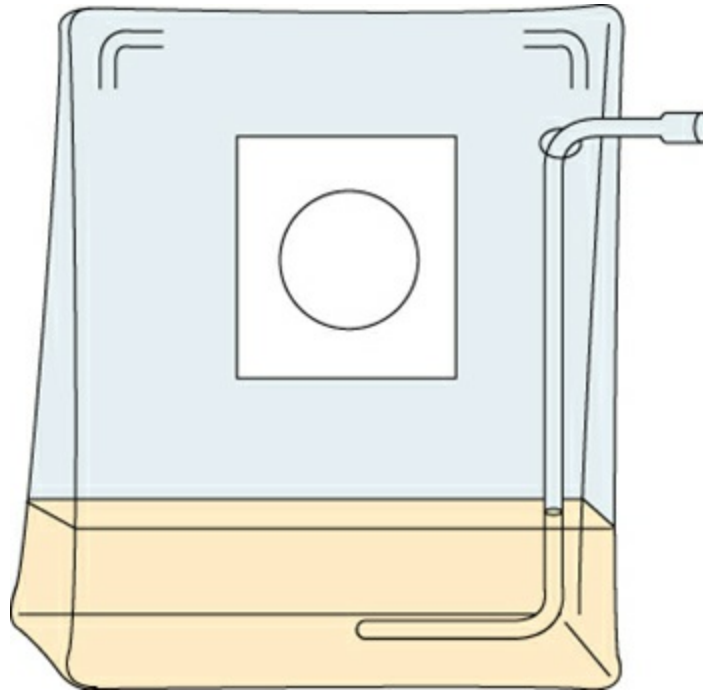

wait for the child to void). This specimen (i.e., the discard specimen) is discarded so that a specific time for the ensuing collection is known. If the urine collection was started early in the morning and this first specimen was counted as part of the collection, the urine collected during the next 24 hours would include urine that had been forming all night, resulting in an approximately 32-hour collection period that would distort the analysis.

Record the start of the collection period as the time of the discarded urine. Save all urine voided for the next 24 hours and place it in one collection bottle. Have the child void (or watch for an infant to void) at the end of the 24-hour period and add the final specimen to the collection bottle. Record the time of the collection as being from the time of the discarded urine to the final specimen added to the collection.

For an infant, use a 24-hour rather than a single specimen urine collector. These types of collectors, however, will adhere for this length of time only if a child's perineum is thoroughly dry at the time of application. Also, before applying the collector, apply tincture of benzoin or a commercial product to make the skin somewhat tacky and to help the collector firmly adhere to the skin. After the collector is applied, place the infant in a semi-Fowler's position, if possible, to encourage urine to flow freely into the collector. It may be necessary to place a diaper on the infant to keep the apparatus out of sight. Make certain the tubing from the collector is pinned out of the infant's reach or the infant may pull the collector free. Provide activities for the child and make sure the parents understand they can pick up infants and hold them during this time as long as they take care not to kink or pull the tubing.

To keep the bacterial count to a minimum, 24-hour collection containers are generally kept on ice; after each voiding, pour the new specimen into the larger container, which is kept refrigerated for the 24-hour period and until it can be transported to the laboratory for analysis. Because a preservative (considered a hazardous chemical) is added to the large container for some types of collections, instruct older children to void into a smaller container and then add their urine to the large container, or never void directly into the chemical-added container. Appropriate warning labels should be visible on the container to alert anyone handling the container. The Material Safety Data Sheet (MSDS) should be included with the handling instructions.

With active infants, fitting them with a colostomy bag applied to cover the urinary meatus may be more effective than using a collector with tubing because this allows them more mobility (Fig. 37.11). For this, puncture a small hole in the corner of the top of the colostomy bag. Insert a small feeding tube through this into the bottom of the bag and then apply the bag to the child's perineum. When the child voids, attach a syringe to the feeding tube and aspirate the urine. Transfer the specimen to the collection bottle. For the active toddler, this collector may be the only type that is acceptable to obtain a day-long specimen.

**Figure 37.11** A 24-hour urine collector made from a colostomy bag. When the infant voids, the bag fills with urine, which can be aspirated from the bag by the inserted feeding tube.

### Clean-Catch Specimens

A **clean-catch urine specimen** is ordered when urine is needed for urinalysis and culture. The objective is to obtain urine that is uncontaminated by external organisms, such as skin flora, which would increase the organism count of the urine. Specimens used for protein or blood analysis may be ordered as clean-catch specimens because this careful cleaning also reduces the possibility that vaginal or foreskin (in uncircumcised males) secretions, which contain protein or blood, could be added to the specimen.

The technique for obtaining a clean-catch urine specimen from an older child is the same as that for an adult (see [Chapter 11, Box 11.6](#)). Some modifications are necessary for the young child or infant because it is not always possible to obtain a midstream urine specimen from young children. For girls, clean the labia from front to back using a cleansing pad or cotton balls saturated with the agency's designated cleaning solution. For boys, clean the tip of the penis using a cleansing pad or cotton balls saturated with the agency's designated cleaning solution.

To collect a specimen from a young child, ask the child to void. During the child's voiding, ask the parent to collect a "midstream" sample into a sterile container provided.

Clean-catch urine specimens have a major advantage over bladder catheterized specimens: They are not invasive, so they carry no risk of introducing a bladder infection, and if clean-catch specimens are obtained with care, they practically eliminate the need for catheterization. A clean-catch specimen with a bacterial colony count of more than 50,000 colony-forming units per milliliter is considered a positive specimen, or evidence that a UTI exists ([AAP, 2011](#)).

To confirm that school-age children and adolescents understand the procedure, have them repeat the instructions you gave to them and then send them to a nearby bathroom to carry out the procedure by themselves.

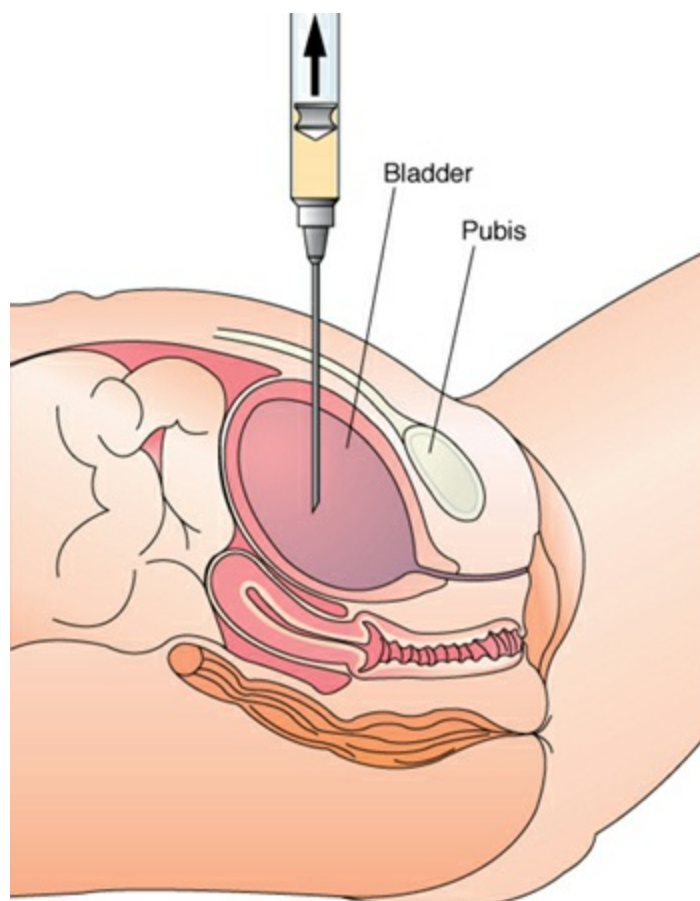

### Suprapubic Aspiration

Suprapubic aspiration is the withdrawal of urine from the bladder of a child who is not old enough or in some other way cannot cooperate enough so that a clean-catch or catheterized specimen can be obtained. Suprapubic aspiration has an advantage for uncircumcised boys with phimosis, or girls with labial adhesions in whom catheterized specimens are more technically challenging to obtain (Schmidt & Copp, 2015). The procedure is done by inserting a sterile needle into the bladder through the anterior wall of the abdomen. Suprapubic aspiration is usually done by primary care providers, although nurses in specialty units may also perform this procedure. A successful suprapubic aspiration depends on the following steps:

1. Apply EMLA cream to lessen the discomfort 30 minutes to 1 hour before the procedure.
2. Secure a sterile syringe and needle and designated antiseptic solution.
3. Clean the anterior abdominal wall with the antiseptic.
4. Block the urinary meatus by pressure from a gloved finger to confine urine in the bladder.
5. Insert the needle on the syringe just above the pubis into the bladder.
6. Aspirate urine through the needle into the syringe, then withdraw the syringe and needle.
7. Comfort the infant or child afterward because the sight of the needle is frightening, it may cause some pain, and some restraint is necessary.

Withdrawal of urine by suprapubic aspiration is effective because the bladder is the most anterior of abdominal organs and, when distended with urine, is easily accessible just under the abdominal wall (Fig. 37.12). However, the needle can cause a bladder spasm and can produce a moment of sharp discomfort as the needle is inserted. Explain the necessity of the procedure to parents, specifically why the urine specimen is needed and the reason for the method being used, as they may not be familiar with this procedure. A suprapubic or catheterized urine sample with greater than 50,000 colony-forming units per milliliter indicates the presence of a UTI.

**Figure 37.12** A suprapubic bladder aspiration. The full bladder is easily accessible by an abdominal puncture.

### **Catheterization**

Bladder catheterization is accomplished most easily in infants and young children if a small (#5 or #8) feeding tube is used instead of a urinary catheter because such a thin tube passes readily through the meatus of even an infant. Before beginning catheterization, assess the urinary meatus in girls as it is not as readily observable in infants and young children as it is in adult women. For uncircumcised boys, gently retract the foreskin until the urinary meatus is visualized. Like any invasive procedure, explain to parents how it is performed and why the procedure is needed. If a parent is present, ask the parent to assure the child it is all right for you to touch his or her perineum or penis because he or she may have been told many times not to allow strangers to touch these areas. Distraction techniques such as blowing bubbles or imagery may help the child to relax. Offer support and praise to the child for submitting to the procedure and, afterward, for their cooperation (even if they were not cooperative).

### **OBTAINING STOOL SPECIMENS**

Stool specimens are frequently obtained to be analyzed for blood, bacterial or viral infections, or ova and parasites. Ask children who are toilet trained to use a potty seat or

to place a collector cap device on a toilet. Transfer the specimen to a laboratory collection cup using tongue depressor blades. To obtain a specimen from a child who is not toilet trained, scrape stool from a diaper using tongue depressor blades and place it in a stool collection cup. Some stool specimens need a preservative added to the container. If it is important to keep urine from contaminating the stool specimen, place a separate urine collector bag on the infant. Ask an older child to void first into the toilet and then defecate into the potty seat or collection device.

Specimens should be sent to the laboratory promptly so they do not dry and have to be collected a second time because most children need at least 24 more hours to produce a stool specimen. If the stool specimen is for ova and parasites, do not refrigerate it because refrigeration destroys the organisms to be analyzed.

### *QSEN Checkpoint Question 37.5*

#### **TEAMWORK & COLLABORATION**

Felipe needs to have a 24-hour urine specimen collected and this will require the nurse to coordinate care with nurses on subsequent shifts. To ensure accurately timed collection, when would the nurse identify the collection's start point?

- a. The time you discard the first void
- b. The first time he voids in the morning
- c. A set time, which is most often 0700
- d. At the time of his first void after the discarded urine

*Look in Appendix A for the best answer and rationale.*

## **Assistance With Elimination**

Two aspects of intestinal elimination that require special care are administration of enemas and ostomy care.

### **ADMINISTERING ENEMAS**

Enemas are rarely used with children unless they are used as therapy for fecal impaction, Hirschsprung disease, a part of preparation for surgery, or a diagnostic test. If an enema is necessary, offer a careful explanation of what the child can expect.

Commercial enemas, such as Fleet enemas, are not routinely administered to children younger than 2 years of age because of the harsh action of the sodium biphosphate and sodium phosphate they contain. Tap water is not used either because, as it is not isotonic, it causes a rapid shift of fluid in body compartments, possibly leading to water intoxication. Although a solution of milk and molasses may be used in an emergency department to relieve a fecal impaction, normal saline (0.9% sodium chloride) is the usual solution used. It can be made by parents at home by adding 1 teaspoonful of salt to 1 pint (500 ml) of water.

As the sizes of children's bowels vary greatly, the usual amounts of enema solutions

used are:

- Infant: less than 250 ml (exact amount should be stipulated by primary care provider's prescription)
- Preschooler: 250 to 350 ml
- School-age child: 300 to 500 ml
- Adolescent: 500 ml

For an infant, use a small, soft catheter (#10 to #12 French) in place of an enema tip to prevent rectal trauma. Lubricate the catheter generously with a water-soluble lubricant and insert it only 2 to 3 in. (5 to 7 cm) in children and only 1 in. (2.5 cm) in infants. If using an enema bag, hold the solution container no more than 1 ft above the level of the sigmoid colon (12 to 15 in. above the bed surface) so the solution flows at a controlled rate. If a child experiences intestinal cramping, clamp the tubing to halt the flow temporarily and wait until the cramping passes before instilling any more fluid. An older child can be instructed to take deep breaths to reduce guarding of abdominal muscles and to help the cramping sensation pass. The amount of solution used in infants is so small that this is not usually a problem.

Until late school age, children cannot retain an enema as adults can (rarely more than 5 to 10 minutes). For this reason, ensure that the bathroom the child will use is available before administering the enema.

Infants and children up to ages 3 or 4 years cannot retain enema solutions at all, so hold the buttocks together for a short time to prevent immediate expulsion of the solution, or pad the edge of a bedpan so it is not cold or sharp, and rest their pelvis on it following the procedure. Elevate the child's upper body by placing a pillow under the upper body for better positioning and comfort. If the enema solution is to be retained, such as an oil solution, hold the child's buttocks together for a count of 10 after administration.

After any type of enema administration, praise a child for cooperating. Allow a preschooler an opportunity for therapeutic play because this is a frightening, intrusive procedure.

## PROVIDING OSTOMY CARE

An ostomy is a surgically formed opening from an internal structure to the surface of the body. Ostomies in newborns are created in the gastrointestinal system to relieve bowel obstruction caused by conditions such as ileal atresia, necrotizing enterocolitis, and imperforate anus. In older children, gastrointestinal ostomies are constructed for conditions such as inflammatory bowel disease, Crohn disease, and ulcerative colitis (Crohn's & Colitis Foundation of America, 2014). If an ostomy is created in the ileum (i.e., an ileostomy), the stoma is located on the right side of the abdomen and drains liquid stool, which is extremely irritating to the skin because of the digestive enzymes it contains. If an ostomy is created in the sigmoid portion of the bowel (i.e., a colostomy), the stoma is on the left lower abdomen and passes normally formed stool (Fig. 37.13).

**Figure 37.13** Different sites for ostomies. **(A)** A double-barrel colostomy. **(B)** A single-barrel colostomy.

An ileostomy requires the use of a collecting ostomy appliance to contain acid stool and to prevent excoriation of the abdominal skin. Older children also may use an appliance with a colostomy. For an infant with a colostomy, parents may choose (with support and advice) to use an appliance or just apply a diaper.

Two basic problems commonly arise when using an ostomy appliance with an infant: It may be difficult to locate one small enough to contain liquid drainage without leaking, and the skin under the appliance may become extremely irritated. Consulting with a wound ostomy continence nurse (WOCN) can be helpful to resolve these problems. As a rule, clear plastic, ringless colostomy bags are more easily cut to fit the size of the stoma and the contour and size of an infant's abdomen than bags with a ring attached. When using a commercial skin sealant to harden the skin surrounding the stoma, apply it according to the brand directions and allow it to dry. If a spray is used, protect the infant's face so that the infant does not inhale the solution. Tuck the chosen stoma collection appliance inside the diaper to help keep the infant from pulling it loose.

Check the appliance or bag for collecting stool at least every 4 hours. To protect the underlying skin, do not remove a self-adhering bag if it is full but drain collected stool from the bottom of the appliance into a basin or paper cup for disposal. To reduce odor, flush the appliance bag with a warm water and soap solution, using a bulb-type syringe (an Asepto syringe), and rinse with clear water. The collection bag may stay in place for as long as 1 week if properly secured. To remove a bag that was placed with a sealant, use the designated solvent to prevent pulling or harming the underlying skin. After removal, wash the skin with soap and water or the solvent can become an irritant. Because most infants enjoy tub bathing, a long, soaking bath is an excellent way to loosen an adherent appliance.

If a parent chooses not to use an appliance, stool will be discharged onto the abdomen three or four times a day, similarly to the usual newborn or infant stool pattern. Wash and dry the stoma and surrounding skin area well after defecation. Follow your agency's protocol for skin care, such as applying karaya powder or a skin

protection cream. Apply ample absorbent gauze (fluffed) and an absorbent pad over the stoma. Secure in place with nonadhesive tape or a binder. Without an appliance in place, stool is kept from touching the skin only by the protection of the ointment and frequent changing of the dressing, so assess for stool about every 4 hours. Turning an infant from side to side after every feeding can be helpful in keeping stool from flowing continuously to one side. Leaving the abdominal skin exposed to air for at least 1 hour per day also helps protect skin integrity.

Reassure parents caring for an infant with an ostomy that little is different from usual because all parents must change their infant's diapers frequently and clean the diapered area. Discuss with parents that the stoma has no nerves, so a parent can feel free to wash it without hurting the child and that compression against the stoma will not cause a child pain so the parent can feel comfortable placing an infant on the abdomen or holding the infant closely against his or her body for comfort.

Colostomies are rarely irrigated in children. On occasion, to prepare a child for second-stage abdominal surgery, irrigation of the "blind-end" bowel (i.e., the bowel between the rectum and colostomy) of a double-barreled colostomy may be prescribed daily to keep it lubricated and to maintain bowel tone. The exact amount of fluid to be used should be specified by the primary care provider; typically, the amount is small in infants, only 40 to 100 ml. Normal saline (0.9% sodium chloride) should be used in place of tap water, which could lead to water intoxication because tap water is not isotonic.

Children who have had a colostomy since infancy adapt well to having it because they have never known another method of defecation. Suggest that parents begin toilet training for urine control at the usual time (2 to 3 years of age). In contrast, school-age children often have a great deal of difficulty adjusting to a new colostomy. Encourage children to perform complete self-care as soon as possible to develop early independence. Preschool children usually benefit from therapeutic play that helps them work through their feelings about a colostomy. Provide some time for older children to discuss concerns about being accepted by others and how to answer questions from other children about a colostomy. Adolescents with a colostomy may have questions regarding sexuality and need reassurance that this should not interfere with intimate relationships.

## Nutritional Care

Almost all illnesses affect the nutritional and fluid balance status of children; therefore, assessment of these areas sheds a great deal of light on their general health. If a child is not able to take in oral food, supplementation by enteral feeding, gastrostomy, or total parenteral nutrition can be ordered, depending on the child's need for nutrients.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for imbalanced nutrition, less than body requirements, related to chronic illness

**Outcome Evaluation:** Skin turgor remains good; no signs of dehydration are present; child gains a minimum of 1 lb weekly as evidence that nutritional need is being met.

Supplying adequate nutrition includes a variety of measures such as measuring fluid intake and output and administering supplemental methods of feeding.

## MEASURING FLUID INTAKE AND OUTPUT

Fluid is an essential element of nutrition because it cannot only supply water but also be a source of calories and vitamins. Children with a myriad of conditions such as vomiting, diarrhea, burns, hemorrhage, dehydration, cardiac and kidney disease, draining wounds, gastrointestinal suction, edema, or receiving diuretic or intravenous therapy need to have fluid intake and output measured and recorded in order to assess for fluid balance.

### Fluid Intake

Estimating the intake of infants who are formula fed is simply a matter of estimating the kind and amount of fluids that were swallowed. Intake in breastfed infants is merely recorded as “breastfed for however minutes.” If it is necessary to estimate the amount more closely than this, an infant can be weighed before and after a feeding. The difference in weight (measured in grams) is calculated to establish the number of milliliters of breast milk ingested (1 g = 1 ml).

With preschool children, record fluids ingested during snacks as well as meals because children this age may drink more with snacks than with meals. At approximately 10 years of age, children can be depended on to record their own intake as long as they have a list of how many milliliters are contained in each glass or cup they swallow (an average cup is 150 ml; a glass, 180 ml). Remind them that soup, flavored frozen ice such as popsicles, gelatin, sherbet, and ice cream are liquids (they liquefy at room temperature so should be counted as fluid).

### Fluid Output

A single episode of vomiting is common in childhood and, because it is self-limiting, usually requires no special treatment. Extensive vomiting, however, can lead to dehydration and/or electrolyte imbalance. Measuring the amount a child vomits (i.e., emesis) can be challenging if it spills onto clothing or bed linen. When this happens, estimate the amount in relation to the amount of food or fluid the child recently ate; include the number of episodes, a description of the color of the vomitus (e.g., red or black may contain blood; green may contain bile), and whether it was composed of clear fluid or undigested food. Remind the child’s parents or the child of the importance

of noting the amount if more vomiting occurs; supply a graduated measuring container at the child's bedside.

Diapers can be readily used as a method of measuring urine output. Weigh a diaper before it is placed on an infant and record this weight conspicuously (e.g., mark it on the front of the plastic covering with a ballpoint pen). Reweigh the diaper after it is wet and subtract the difference to determine the amount of urine present. This difference will be in grams but because 1 g = 1 ml, the amount can be recorded in milliliters. In infants who have liquid stools, it is difficult to separate stool from urine because these blend together in a diaper. Separate urine from stool by applying a urine collector to the infant; check it frequently for filling.

Girls often void along with bowel movements when they use a toilet, which means that a urine specimen is easily lost or a stool specimen is contaminated with urine. To separate urine from bowel movements, teach older children to void first before trying to move their bowels.

## ENTERAL FEEDINGS

Enteral feedings, also called nasogastric or orogastric tube feedings, are a common means of supplying adequate nutrition to an infant who is unable to suck (or who tires too easily when sucking) or to an older child who cannot chew or swallow. Enteral feedings have the advantage over parenteral (i.e., intravenous) nutrition because they preserve the stomach mucosa and also decrease the risk of intravenous infiltration or infection. Parents who care for children at home find them easy to manage and so express high satisfaction with the method (López, Pedrón-Giner, Martínez-Costa, et al., 2015). In infants, such feedings may be referred to as *gavage feedings* (Box 37.7 and Table 37.2).

### BOX 37.7

#### Nursing Care Planning Using Procedures

#### INITIATING AN ENTERAL FEEDING FOR AN INFANT

**Purpose:** To supply nutrition by an enteral tube

Procedure	Principle
1. Loosely swaddle the infant using a mummy restraint.	1. Mummy or blanket restraints effectively contain arms and legs without causing any unwarranted pressure on the infant.
2. Measure the space from the bridge of the infant's nose to the earlobe then to a point halfway between the xiphoid process and the umbilicus using a #8 or #10 feeding tube. If	2. Measuring the tube ensures it will be long enough to enter the stomach. If a tube is passed too far, it will curl and end up in the esophagus; if not passed far enough, it will also be in

the child is older than 1 year of age, measure from the bridge of the nose to the earlobe to the xiphoid process (Fig. A).

the esophagus. Both situations could lead to aspiration of the feeding.

3. Mark the tube at the measured point with a small clamp or piece of tape. Lubricate the tip of the catheter with water.
3. Water lubrication helps the tube pass through the esophagus without trauma. Don't use an oil lubricant because, although the tube is going to be passed into the stomach, occasionally it can unintentionally pass into the trachea. Oil left in the trachea could lead to lipoid pneumonia, a complication an infant already burdened with a disease may not be able to tolerate.
4. Pass the catheter with gentle pressure to the point of the clamp or tape. If the catheter is inadvertently passed into the trachea rather than the esophagus, the infant usually will cough and become dyspneic. If this happens, withdraw and replace the catheter.
4. Using gentle pressure helps to ensure comfort and safety.

5. Assess the catheter for position (confirm that it is not in the trachea) before administering a feeding (see [Table 37.2](#)).
6. Aspirate stomach contents to assess amount. If the amount aspirated is small (a few milliliters), merely replace it at the beginning of the feeding. If large (large is determined by comparing it to the care provider's nutrition prescription), replace it through the tubing and reduce the amount of the feeding by that amount.
7. After being certain the catheter is in the stomach, attach a syringe or special feeding funnel to the tube. Elevate the infant's head and chest slightly to encourage fluid to flow downward into the stomach.
8. Add the specific kind and amount of feeding prescribed to the syringe or funnel and allow it to flow by gravity into the infant's stomach. Don't elevate the syringe end of the tube more than 12 in. above the infant's abdomen ([Fig. B](#)).
5. Assessing for proper placement helps to ensure the feeding will enter the stomach, not the infant's respiratory tract.
6. Assessing stomach content amount aids in determining if the previous feeding was absorbed. Replacing stomach secretions rather than discarding them helps prevent electrolyte loss.
7. Elevating the infant's upper body allows the feeding to flow by gravity.
8. Excessive elevation can cause the feeding to flow too quickly, filling the esophagus and increasing the risk for aspiration. Hurrying feedings by using the plunger of the syringe or a bulb attachment for more pressure also can lead to aspiration.

9. Offer a pacifier (nonnutrient sucking) during the feeding if the infant appears to enjoy this.
9. Nonnutrient sucking can help satisfy the infant's normal need to suck, which would otherwise go

- |  |   |
|--|---|
| <p>10. When the feeding has passed through the tube, reclamp the tube securely and gently and rapidly withdraw it.</p> <p>11. If the tube is to remain in place, flush it with 1 to 5 ml of clear water and cap it.</p> <p>12. If the tube is to be left in place, tape it below the nose and to the cheek. Do not tape it to the forehead.</p> <p>13. Burp the baby after an enteral feeding the same as you would after bottle or breastfeeding. If a parent is present, encourage him or her to do this.</p> <p>14. Unswaddle and place the infant on the right side with the head slightly elevated or hold and rock the infant in this position.</p> <p>15. Assess that the infant appears comfortable. If a parent observed the procedure, answer any questions or concerns.</p> | <p>unsatisfied with enteral feedings.</p> <p>10. Clamping the tube before it is withdrawn is important to prevent any milk remaining in the tube from flowing out as the tube is removed, thereby reducing the risk of aspiration.</p> <p>11. Flushing a tube helps prevent plugging of the tube with the feeding solution. Capping a tube helps to prevent air and bacteria from entering.</p> <p>12. Taping a tube to the forehead can put pressure on the anterior naris, leading to ulceration.</p> <p>13. Burping helps to prevent air accumulation and regurgitation of the feeding. Encouraging parental participation aids in promoting close contact, which is essential to the baby's development.</p> <p>14. Placing on the right side helps the feeding solution enter the pyloric valve, thus promoting stomach emptying.</p> <p>15. Assessing the infant after the feeding aids in outcome evaluation. Helping parents feel comfortable with alternative feeding methods can promote bonding with the infant.</p> |
|--|---|

**TABLE 37.2 METHODS TO DETERMINE FEEDING TUBE PLACEMENT**

<b>Method</b>	<b>Considerations</b>
1. If an X-ray is obtained to document correct tube placement, measure the length of the tube evident at that time. Remeasure the length of tube before a feeding to document that the tube has not pulled out or advanced	This system has inherent problems because it requires an X-ray and does not verify that the tube is actually in the stomach, but it can be used if it is healthcare policy.

further.

- |  |   |
|--|---|
| 2. Attach a syringe to the end of the tube and aspirate stomach contents. Test for pH (below 7 is acidic), which reveals the tube is in the stomach. | In most instances, stomach contents aspirated this way are returned to the stomach before the feeding; in small infants, the amount of stomach contents is subtracted from the prescribed amount of feeding. Because stomach contents are highly acid, discarding them at each feeding could lead to alkalosis. |
| 3. Inject 5 ml air into the feeding tube and listen over the stomach with a stethoscope to the sound of injected air.                                | The injected air is heard as a whistling or growling sound. Do not use an adult-size stethoscope on small infants to listen for it; the diaphragm of the stethoscope will be partially over lung, and where one is hearing the air injection is unknown.  |

Whether enteral catheters should be passed through the nares or the mouth is controversial. Because newborns are obligate nasal breathers, passing a catheter through the nose may obstruct their breathing space, and repeated insertion of a nasal gastric tube can cause inflammation and obstruction of the nose; thus, most tubes are inserted orally in small infants ([Vermilyea & Goh, 2015](#)).

Orogastric insertion can also decrease the possibility of striking the vagal nerve in the back of the throat and causing bradycardia. For older children, insertion through a nostril is often more comfortable. To prevent irritation or ulcer formation from the tube rubbing against the tip of the nose, always tape nasogastric tubes to the child's cheek rather than the forehead to secure it in place.

Because tubes are radiopaque, their placement or that they extend into the stomach can be confirmed by X-ray. [Table 37.2](#) describes other methods to use before a feeding, verifying that the tube is not in the trachea or has pulled out so is actually just resting in the back of the throat.

Although children with long-term neurologic disabilities may have enteral tubes left in place for continuous feedings administered by an enteric feeding pump, most children are generally offered bolus or intermittent feedings at what would be a usual meal time, rather than continuous infusions, to more closely mimic a normal feeding pattern. The nutrition formula infused should be at room temperature to prevent chilling the child. Before a feeding, elevate the child's upper trunk 30 to 40 degrees (i.e., a semi-Fowler's position), so the fluid will flow downward into the stomach and not upward into the esophagus, possibly causing aspiration into the trachea. For infants, you can do this by holding the infant in your lap or placing the infant in an infant seat. For an older child, use pillows or elevate the head of the bed. For small infants, it is often necessary to aspirate stomach contents before a feeding because this reveals whether an infant is absorbing the quantity of fluid given as well as confirms the tube's placement is in the

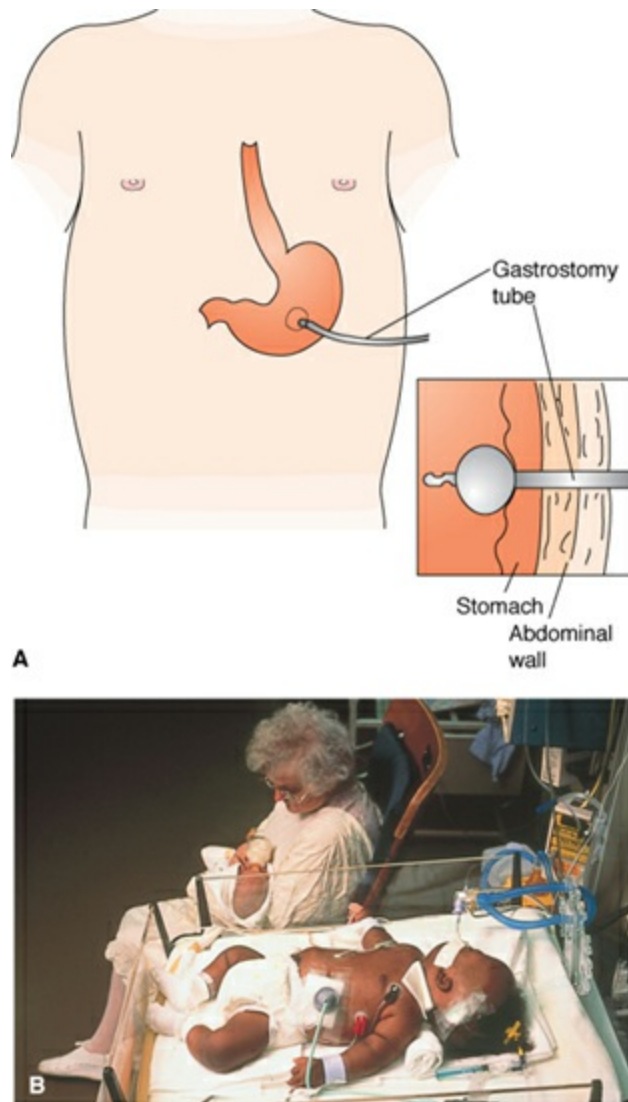

stomach. After noting the amount and type of fluid aspirated, unless prescribed otherwise, replace this fluid so the child does not lose the electrolytes or stomach enzymes it contains.

Following this, to administer a feeding, attach a syringe to the tube and allow the specified amount of nutrition formula to flow by gravity into the tube. Do not use the barrel of the syringe to force the feeding forward in order to prevent reflux and possible aspiration. Most infants enjoy having a pacifier for nonnutritive sucking during a feeding. This action helps to maintain or strengthen the sucking reflex for later when the child returns to oral feedings.

At the end of the feeding, flush the tube with 1 to 5 ml of water to clear it of the feeding solution, prevent blockage, and maintain patency. Keep the child's head elevated for at least 1 hour after a feeding to help prevent esophageal reflux. Provide mouth care at least twice a day to encourage salivation in children who are receiving nasogastric tube feedings; otherwise, their mouths can become dry and prone to the formation of mucosal ulcers.

## **GASTROSTOMY TUBE FEEDINGS**

A gastrostomy tube is one inserted under regional anesthesia through an abdominal puncture site into the stomach and used for nutritional formula feedings (Fig. 37.14). The method may be necessary for children who cannot swallow, have an esophageal stricture, or who need long-term enteral feedings (Vermilyea & Goh, 2015). The tube used in children is usually an indwelling urinary catheter (i.e., a Foley catheter) rather than a true gastrostomy tube because these are smaller in size, can be removed easily, and changed should they become plugged. In addition, the balloon used to secure the tube is small enough so it does not obscure and fill the small stomach space. As with nasogastric feedings, gastrostomy feedings should be at room temperature to prevent chilling and given at spaced times to simulate meal times. Aspirate for stomach secretions to assess absorption and placement before the feeding and then allow the formula to flow by gravity only, not forced. If a child has had esophageal surgery, suspend the unclamped tube in an elevated position after the feeding because leaving the tube unclamped and elevated this way ensures that if the child should vomit, vomitus will be evacuated from the stomach by the tube rather than past new sutures in the esophagus. Cover the open end of the tube with a clean piece of porous gauze to reduce bacterial colonization.

**Figure 37.14** Children who are ill often need supplemental feedings by nasogastric or gastrostomy tube feedings. **(A)** Internal placement of a gastrostomy tube. **(B)** An infant with a gastrostomy tube in place. (From W. McIntyre/Photo Researchers, Inc.)

Because infants who are fed by gastrostomy tube miss the pleasure of sucking the same as those fed by nasogastric tubes, offer a pacifier to suck on during the procedure unless contraindicated.

The biggest problem with managing gastrostomy tubes is they may not fit snugly, so formula or irritating gastric secretions can leak around the tube onto the abdominal skin. At least daily, wash skin around the tube with soap and warm water, removing any drainage and/or crusting. Once clean, make sure site remains clean and dry. A dry gauze dressing may be used. If a gastrostomy tube remains in place for a long period of time, the tube can move into the duodenum through the pyloric sphincter and cause obstruction. Observe and report any vomiting, abdominal distention, or brown or green tube drainage, which could be duodenal secretions that would suggest the tube has moved. Stomach secretions are acidic, and duodenal secretions are alkaline. Therefore,

testing residual aspiration fluid before a feeding to see that it is acid is a guarantee the tube is in the stomach. Also, putting a mark on the tube with an indelible pen lets you check that the tube has not migrated further into the gastrointestinal tract but is remaining securely in place.

Tubes are replaced approximately every 6 weeks. To replace a tube, deflate the catheter balloon by withdrawing the water in it and then gently pull the tube free. Insert a clean catheter into the stomach opening approximately 1 in. beyond the balloon and then inflate the balloon with 2 to 4 ml water. Apply skin protection and tape the tube into place.

Help parents to view gastrostomy feeding as merely an alternative way of feeding rather than a totally different one. Provide opportunities for parents and caregivers to participate and learn the feeding procedure. Assess whether they are comfortable with the procedure before the child is discharged from the hospital. Reinforce with them the understanding that it does not hurt their child to have pressure put against the tube so they do not worry about holding their child snugly.

If a child is going to need gastrostomy feedings for an extended time, a gastrostomy button will usually be implanted for easier stomach access, to prevent skin irritation, and to prevent ulceration of the stomach mucosa from the internal balloon (Fig. 37.15). For feeding with a button in place, a catheter is inserted through the device for a feeding and removed following the feeding. Advantages of gastrostomy buttons are the cosmetic benefit because only a small access device is visible instead of a bulky tube, and there is a lessened incidence of skin irritation.

### *What If... 37.3*

**The child in the hospital room next to Felipe has a gastrostomy button in place, with which she will be discharged. Her mother tells the nurse she's going to take her daughter to a restaurant as soon as they are discharged because she thinks "eating out" is an excellent way to teach table manners. What patient education would the nurse provide?**

**Figure 37.15** Placement of a gastrostomy button.

## TOTAL PARENTERAL NUTRITION

**Total parenteral nutrition (TPN)**, or nutrition administered intravenously, has become one of the most important therapies for children who have gastrointestinal illnesses that prevent proper absorption of basic caloric or fluid requirements or respiratory illnesses that make infants too exhausted to suck.

### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Imbalanced nutrition, less than body requirements, related to malabsorption of nutrients

**Outcome Evaluation:** Skin turgor is supple; signs of dehydration are not present; child loses no weight during therapy; intestinal cramps and distention lessen.

Traditional intravenous therapy contains fluid, electrolytes, and sugars but not protein and fat, ingredients which are essential for the maintenance and growth of body tissues. With TPN, all of a child's nutritional needs can be met by a concentrated hypertonic solution containing glucose, vitamins, electrolytes, trace minerals, and

protein. An intralipid solution (emulsified fat able to be administered intravenously), given once or twice per week, supplies needed fatty acids. Children with chronic diarrhea or vomiting, inflammatory bowel disease, bowel obstruction, anorexia, or extreme immaturity are examples of children who benefit greatly from TPN.

TPN solutions may be administered via a central intravenous access site or via a peripherally inserted central venous catheter (PICC line) (Corkins, Griggs, Groh-Wargo, et al., 2013). If a central access site is chosen, a catheter is inserted through the right external jugular vein into the superior vena cava, or directly into the subclavian vein under strict aseptic conditions (see Chapter 38). The catheter is secured at the site of insertion with sutures and covered with a sterile dressing to help reduce bacterial invasion. A major vein of this type is chosen to avoid inflammation reactions and resulting venous thrombosis from the high-caloric and high-osmotic fluid that will be infused.

The TPN solution is prepared by the pharmacy under sterile conditions according to prescription. A Millipore filter, which removes small particles in the solution that might cause an embolus to form, is inserted into the tubing. Because the solution is concentrated, it is administered by means of a constant infusion pump so the rate can be governed. As a general rule, if the rate should fall behind, do not increase it the next hour to make up the amount of fluid, as serious cardiovascular overload could result because the fluid is so concentrated.

Infection is a major danger of TPN because the solution is a perfect medium for the growth of bacteria or *Candida* organisms. The dressing over the insertion site and the intravenous tubing need to be changed every 48 hours or as needed according to the Centers for Disease Control and Prevention (CDC) *Guidelines for Prevention of Intravascular Catheter-Related Infections* (O'Grady, Alexander, Burns, et al., 2011). Do not use the tubing for obtaining blood or for adding medications (unless a double-barreled tube is used) because such processes have the potential to introduce infection. Use sterile technique to change both the bags of solution and the dressing so infection is not introduced. Inspect the insertion site at the time of a dressing change for indications of local infection, such as redness, tenderness, or discharge because infection at the insertion site can lead to a serious sepsis or thrombosis.

A second major problem that can occur with TPN is dehydration. This occurs because a TPN solution contains approximately twice the amount of glucose normally administered in an intravenous solution to ensure that the amino acids in the solution will be used for protein synthesis, not for energy. Dehydration can occur when the kidneys recognize the amount of glucose in the bloodstream as excessive and begin to reduce it by excreting it (the same phenomenon that leads to high urine output in persons with diabetes mellitus). Before TPN is started and during the administration, test urine for glucose and specific gravity with each voiding. If two or more consecutive samples indicate a 3+ or 4+ glucose level, either the rate of the infusion or the amount of glucose in the solution may need to be decreased or insulin may need to be added to the solution to counteract the excess glucose. Generally,

decreasing the concentration of glucose and then gradually increasing it again allows the child's body to adjust to the glucose overload without problems.

After the first few days of TPN, a rebound effect (e.g., the child's body produces increased insulin) may cause hypoglycemia. A urine sample that suddenly is negative for glucose after several serial specimens have been highly positive and, therefore, is not necessarily an encouraging sign; rather, it may be a warning the child's glucose level has become dangerously low. The TPN solution should never be discontinued abruptly but rather should be gradually tapered, or hypoglycemia could also occur. If a TPN catheter is accidentally pulled out by a child, notify the child's primary healthcare provider immediately and apply pressure to the insertion site to halt bleeding. The child must be immediately assessed for the effect of loss of blood and closely observed for signs of hypoglycemia (e.g., lethargy, lack of motor coordination, fidgeting, seizures). Parents need to be alerted to these steps if managing a child with parenteral nutrition on home care.

Remember that, to a child, eating is more than a means of receiving nourishment; it is also a means of receiving comfort and love. Even though children are able to voice the reason they must have TPN and appear to understand they are receiving all the needed nutrients by infusion, they still may miss eating food and the natural social interaction that comes with it. While in a hospital, they may be upset by the smell of food from a hospital unit kitchen or by the fact playmates have to leave to eat a meal. Finding an activity for a child receiving TPN while other children eat, such as helping to check unit supplies or stamping laboratory slips, can be helpful to supply the interaction a child misses. When feasible, help parents arrange for special times each day with the child to make up for the time normally spent interacting at meals.

Some children tolerate TPN better if they can be allowed chewing gum or occasional hard candy; advocate for these as necessary. Remind the child to continue tooth brushing twice a day to keep oral mucous membrane healthy because he or she is not chewing. An infant may enjoy the sucking pleasure from a pacifier.

### *QSEN Checkpoint Question 37.6*

#### **QUALITY IMPROVEMENT**

Felipe's primary healthcare provider asks the nurse to keep as accurate a record as possible of Felipe's intake and output while he is undergoing diagnostic testing. Felipe vomits without warning on his gown and the floor. How should the nurse document this form of output to ensure an accurate assessment?

- a. Estimating the amount of emesis and describe the character in his health record
- b. Describing the event in Felipe's health record and note that it was not possible to gauge the quantity
- c. Weighing his soiled gown and compare the weight to a clean gown of the same size

d. Asking his mother to approximate the amount that he vomited

*Look in Appendix A for the best answer and rationale.*

## Hot and Cold Therapy

Children who sustain muscle sprains or undergo procedures such as bronchoscopy or tonsillectomy may have cold applications prescribed to prevent swelling or edema, help control hemorrhage, or provide an analgesic effect. Ice packs are left in place for about 20 minutes. To prevent frostbite, never place an ice pack directly on the skin; instead, insert a towel between the pack and the skin. Document the type of application, duration of the therapy, and the condition of the skin before and after the treatment.

Local application of heat may be prescribed to relieve congestion and pain by increasing circulation through vasodilation and muscle relaxation (Box 37.8). Heat may also be prescribed to help resolve superficial inflammation and hasten the formation and drainage of abscesses or absorption from subcutaneous tissue if IV fluid infiltrated. It is important to not leave either hot or cold compresses in place continuously or a rebound effect that blocks their effectiveness may occur. Always assess the skin before and after the treatment to determine that tissue damage (e.g., a burn) did not occur from treatment. If you are using a heating pad to maintain warmth in a young child, set the temperature dial and then tape it in place so the child cannot spin the dial and increase the temperature beyond a safe level.

### BOX 37.8

#### Nursing Care Planning to Empower a Family

#### GUIDELINES FOR HOT AND COLD APPLICATIONS WITH CHILDREN

**Q.** Felipe's mother tells you, "I need to apply cold compresses to my child's head to help with his headache. How do I do this?"

**A.** When applying any type of hot or cold therapy such as cold or warm compresses, use the following guidelines:

- Apply neither heat nor cold for longer than 20 minutes unless prescribed because after that time, the vasoconstriction caused by cold and the vasodilatation caused by heat begins to reverse.
- When using electrical sources of heat with toddlers and preschoolers, never make a game of plugging in and pulling out the apparatus that makes the light come on or a dial glow. Otherwise, the child may play with it after you leave.
- Supply a special activity for a child to enjoy while a hot or cold application is in place (e.g., playing a board game, reading a story to the child), so that the procedure is not viewed as a chore but as a pleasant time to look forward to.
- Put tape on the gauge of an electric appliance at the point where you want it, so

that you will be able to tell if the child changes the setting.

- To determine that solutions or heat sources are not too hot, always test them with your inner wrist or the dorsal surface of your hand before applying them to the child.
- Do not apply ice packs or ice directly to the skin. Cover the pack or ice with a towel or other cover such as dish towel to prevent frostbite and cell damage from cold.
- Be cautious using heat or cold applications with a child who is receiving an analgesic because the child's perception of heat or cold may be reduced and the site could easily be burned.

## Wound Care

Children frequently have a dressing or bandage put in place to cover a surgical incision or sutured laceration. Such dressings are the same as those used with adults except in size, material, and methods used to secure them. Keeping a dressing dry to avoid introducing infection to the wound in infants and toddlers who are not toilet trained can be a major problem if the dressing is near the diaper area. In many instances after surgery, collodion (i.e., a clear substance similar to nail polish) or other commercially available "wound glues" are used to cover the incision because these solutions not only replace stitches but also keep the incision line from coming in contact with urine or feces. These materials allow good visualization of the healing surface as well because they are clear. Assure parents that such a covering is adequate and actually preferable if the incision is in the groin such as from a hernia repair. They are also preferable if an incision or laceration is on the face because they tend to heal with less scarring than if sutures were used.

If a gauze dressing is used near the diaper area, it can be covered with plastic and held in place with nonadhesive, waterproof tape to protect it from becoming soiled. When cutting plastic to cover a dressing, do not leave an extra piece behind in the crib because a child could pull this over the head and suffocate.

Occlusive dressings (e.g., hydrogel sheets, hydrocolloids, polyurethane films) are dressings especially designed to keep a healing surface clean and dry. Apply and remove these according to each product's directions or agency policy to protect irritating the skin underneath.

Apply Band-Aids generously after venipuncture or finger punctures because young children find bandages comforting and accept them as a "badge of courage."

Use nonadhesive tape (e.g., silk, paper) or secure a dressing with a nonadhering bandage (Kling) or roller gauze instead of adhesive tape to protect sensitive skin. Don't be surprised to see a young child pull a dressing loose and inspect what is underneath. Do not discourage children from looking at their incision during dressing changes. Even if the area looks raw and unhealed, it may look better than what the child envisioned was under the dressing.

### *What If... 37.4*

**The nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to diagnostic or therapeutic procedures in children (see Box 37.1). Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Felipe’s family and that would advance evidence-based practice?**

## **KEY POINTS FOR REVIEW**

- Preparing children for procedures reduces anxiety. Prepare a child and parents by trying to relate a procedure to something a child is already familiar with, such as comparing an X-ray machine to a camera.
- Include parents in both the planning and implementation of care because parents can reinfect children with fear if their own fear is uncontrolled. Try to give explanations on two levels: “I’m going to change the dressing on her suture line” for a parent; “I’m going to put a clean bandage on your tummy” for the child.
- Minimize the number of painful procedures; for instance, combine blood sampling procedures, if possible.
- Perform any procedures that will cause pain in a treatment room or away from the child’s bedside so the bed remains a “safe” place.
- Perform treatments without chilling or exposure. Respect modesty even in very young children.
- Allow a child to voice anger or fear of a procedure. Provide therapeutic play after a procedure to help reduce these reactions.
- Children feel more secure with adults who are confident in their actions. Practice as necessary the steps of a procedure before you begin so you can demonstrate confidence and skill.
- Once you have announced that a procedure needs to be done, proceed to do it; waiting for something to happen is often as stressful as actually having it done.
- Involve children in procedures to implement care that not only meets QSEN competencies but also best meets a family’s total needs. Allow a child to examine electrodes or apply gel for electrode contact before a procedure, for example. Give children a portion of an ECG strip as a badge of courage after the procedure, or let children apply their own adhesive bandage.
- Praise children for cooperation even if none was visibly obvious. For painful procedures, any behavior short of hysterical screaming counts as cooperation.
- Following the use of moderate sedation, observe children carefully until they are fully awake. Check for the return of the child’s gag reflex before offering any fluids to minimize the risk of aspiration.

- Help make feeding by a route such as a gastrostomy tube as close to normal as possible by talking to the child to simulate mealtime conversation and socialization.

### CRITICAL THINKING CARE STUDY

Donald Kohl is an 8-year-old whose father has brought him to the emergency room because he has been vomiting all morning and, over the past hour, has developed sharp pain in his right lower abdomen. You need to schedule him for an ultrasound to rule out appendicitis. Because Donald's parents are divorced and the father is not the custodial parent, he phones Donald's mother. She screams at him for being completely incompetent at child care and tells him, "Don't you dare sign anything until I can get there."

1. Because it will take a minimum of 45 minutes for Donald's mother to arrive, you are concerned that a long delay in having the ultrasound could be a significant threat to Donald's health because, if he has appendicitis, his appendix could rupture during that time. Would you ask the father to sign the permission despite his wife's opinion or wait for the mother to arrive?
2. Donald has had three X-rays over the past year because he broke his right tibia in an auto accident due to a combination of him not having his seatbelt fastened and his father's unsafe driving. His father asks you, in light of the radiation Donald has already received over the past year, whether an ultrasound will be safe for him.
3. You talk to Mrs. Kohl on her cell phone while she is in her car and she says it will be all right if you draw blood for a white blood count on Donald. As he's already anxious, would it be more important to apply anesthetic cream to his venipuncture site to help reduce pain or obtain the blood sample immediately?

## Nursing Care of a Family When a Child Needs Medication Administration or Intravenous Therapy

*Terry, an 8-year-old with Down syndrome, is brought to the emergency department by her parents because she has pain in her ankle. She is diagnosed with osteomyelitis, a bone infection. When you give her a tablet of acetaminophen (Tylenol) for pain, she spits it out. She does the same when you repeat with a second tablet. Her mother tells you Terry can't swallow pills. Her father tells you, "You'll have to give her an IV."*

*Previous chapters described the difficulty children may have adjusting to illness and also diagnostic and therapeutic procedures that are frequently used with children. This chapter adds information about techniques for administering medication and intravenous (IV) therapy to children. Because therapy for almost all illnesses today involves some form of medicine or IV administration, and safe medication administration is one of the most important parts of a child health nurse's role, this information is pertinent to the care of almost all children.*

**What would be an effective method of administering acetaminophen (Tylenol) to Terry if she cannot swallow pills?**

### KEY TERMS

**absorption**  
**distribution**  
**excretion**  
**intermittent infusion devices**  
**intracath**  
**metabolism**  
**pharmacokinetics**  
**vascular access ports (VAPs)**

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe common methods of medication and intravenous (IV) therapy used in the health care of children.
2. Identify nursing contributions in achieving Healthy People 2020 goals related to medication and IV therapy.
3. Assess the developmental stage and knowledge level of children and adolescents before beginning administration of medication or IV therapy.
4. Formulate nursing diagnoses related to medication or IV therapy with children.
5. Identify expected outcomes to meet the needs of children receiving medication or IV therapy as well as manage seamless transitions across healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing interventions specific to pediatrics related to medication and IV therapy and children.
8. Evaluate the effectiveness and achievement of expected outcomes for a child receiving medications and/or IV therapy.
9. Integrate knowledge of medication and IV therapy using the nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

Most adults immediately grasp that taking a medicine you offer them will be important to relieve whatever symptoms they are experiencing from an illness. Because children do not necessarily have this same level of understanding, they may resist taking medicine unless its importance is thoroughly explained to them and the medication is given to them by a method that best meets their preference and developmental stage. Many children do not have enough coordination to swallow tablets or pills until they are 6 or 7 years of age, and many adolescents still “don’t like pills.” This might mean getting a child to agree to try an oral medication only if it is furnished in a liquid or meltaway form. Almost all children fear intrusive procedures. This can make them forcibly resist accepting medication given by a rectal, nasal, intramuscular (IM), or IV route. Cognitive impairment, physical challenges, or developmental delay in a child may further complicate medication administration. Because children range in size from as small as 1 lb (0.5 kg) if preterm to more than 200 lb (90.9 kg) by late adolescence, there is no “standard” dose of medicine for children. Therefore, medications in children are dosed according to body weight (milligrams per kilogram) or body surface area (BSA) (milligrams per square meter). Before calculating the dose, weight must be converted from pounds to kilograms (1 lb = 2.2 kg). In addition, children have differing

abilities to metabolize and excrete medications and have difficulty reporting adverse effects of medicine as accurately as adults. This can make it difficult to determine whether side effects or adverse effects are occurring. All these things make medicine administration for children one of the most challenging interventions in nursing (Walsh, Mazor, Roblin, et al., 2013). The 2020 National Health Goals that address this area of child health practice are shown in Box 38.1.

### BOX 38.1

#### Nursing Care Planning Based on 2020 National Health Goals

When administering medicine to children or teaching children and parents how to take or give medicine, remember that medicines can be as dangerous in overdoses as they are helpful in the correct doses. They can be ineffective if a dose is inadequate or missed. Drugs also must be stored safely to avoid poisoning. National Health Goals that speak to medicine administration include:

- Reduce emergency department (ED) visits for medication overdoses among children less than 5 years of age from 32.8% to a target level of 29.5%.
- Increase the proportion of at-risk adolescents aged 12 to 17 years who, in the past year, refrained from using alcohol for the first time from 85.8% to a target level of 94.4%.
- Reduce the proportion of adolescents reporting the use of alcohol or any illicit drugs during the past 30 days from 18.4% to 16.6%.
- Reduce the past year nonmedical use of any psychotherapeutic drug (including pain relievers, tranquilizers, stimulants, and sedatives) from 6.1% of persons aged 12 years and older to 5.5% (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by educating parents about safe drug storage (locked in elevated cabinets) and teaching children and parents about effective nonpharmacologic ways to relieve stress or anxiety to help reduce drug dependence.

#### *Nursing Process Overview*

#### FOR A CHILD NEEDING MEDICATION/INTRAVENOUS THERAPY ASSESSMENT

Because children vary so greatly in size and individual need, administering medication to children begins by assessing the child's weight in kilograms so that weight-based dosing can occur. For some medications, such as chemotherapy, height and weight are both used to calculate dosage (body surface area dosage). Also crucial to the assessment is the child's developmental age. This is important because it reveals if a child can swallow oral medicine or will be able to use such self-

medication methods as patient-controlled analgesia (PCA); in addition, it will help you determine which site would be best for an IM or IV injection. Also assess the child's chronologic age and cognitive level to aid in planning the level of explanation that will be needed. An assessment of the child's past experience with taking medicine will help to determine the child's response to medication administration. The family's access to care and financial means to purchase the medicine can help predict whether the child will actually receive the medicine. Following the administration of the medicine, careful observation must continue to determine whether the medication is having its desired effect or whether any adverse effects are occurring (Yin, Dreyer, Moreira, et al., 2014).

### **NURSING DIAGNOSIS**

Common nursing diagnoses related to medicine administration vary widely. Some examples include:

- Disturbed sleep pattern related to timing of medication administration
- Deficient knowledge related to action and side effects of medicine
- Fear related to IV administration of medicine
- Discomfort related to side effects of medicine
- Health-seeking behaviors by parent related to desire to learn more about different types of medicine available for the child's illness

### **OUTCOME IDENTIFICATION AND PLANNING**

Planning the administration of medicine for children involves the same safe rules of administration as those for adults. Additional consideration is necessary at each step because determining the right form and route of medicine, such as liquid or capsule and oral or IM, varies so widely. Establishing a dose that is accurate for the size of the child can involve recalculating the dose using a milligram per kilogram formula or a nomogram that shows body surface area. The schedule for administration must be not only one that is effective for the drug's action but also one that will not interfere with school activities, eating, or sleep.

Explain to children the effects that can be expected from any medicine. Be certain to give this explanation at an age-appropriate level and be sure it is consistent with any prior explanation that a parent or other healthcare provider has supplied. Refer families to online resources for further information when appropriate (see [Chapter 36](#)).

### **IMPLEMENTATION**

Interventions related to medication and IV therapy with children include both administering medicine to ill children as well as teaching parents and children how to continue to take the medicine when at home or at school. As long as the child is uncomfortable or has definite disease symptoms, parents tend to give medicine conscientiously. However, when symptoms fade, a child returns to school, or the family returns to its busy everyday schedule, it is easy for parents to forget to give medicine. This can leave children open to a recurrence of the condition or symptoms,

such as pain or recurrent infection, because the organisms causing the illness were only suppressed, not killed. The classic example is strep throat—the child feels better, the medicine is stopped before completed, and, in the worst case scenario, rheumatic fever may result, possibly causing damage to the heart valves (see [Chapter 41](#)). Helping parents fill out administration schedules to post in a readily visible location, such as on the refrigerator or a bathroom mirror, or leaving reminder messages on their smartphones can be as important as explaining the drug's action to help ensure all doses of medicine will be given.

### OUTCOME EVALUATION

Expected outcomes associated with medication administration should ensure that a child receives the medicine as prescribed and that the medicine has the desired effect. Specific examples suggesting outcome achievement include:

- Child states she understands she must continue to take thyroid hormone for a lifetime.
- Parents list the adverse effects of prescribed drug and state the telephone number they will call if adverse symptoms occur.
- Parents demonstrate the correct dose using the medication delivery device (oral syringe) that they will use at home.
- Adolescent describes an administration program that includes four doses daily but allows time for sports activities after school.
- Adolescent states he realizes his prescribed medicine is for his illness alone so it or other medicines in the family medicine cabinet are not to be shared with friends.

## Medication Administration

Medications in children are given by a variety of routes: orally, intranasally, transdermally, topically, rectally, and via injection (subcutaneous, intradermal, IM, IV, intraosseous, or epidural) or by inhalation. Epidural administration is described in [Chapter 16](#) because this route is also frequently used with women in labor. Inhalation techniques are discussed in [Chapter 40](#) with respiratory illnesses.

Administering drugs safely requires knowledge of **pharmacokinetics**, or the way drugs are absorbed, distributed throughout the body, metabolized, inactivated, and excreted.

### PHARMACOKINETICS IN CHILDREN

The four basic processes of absorption, distribution, metabolism, and excretion determine the intensity and duration of a drug's action. The immaturity of body systems in children (and especially in newborns) plays a major role in drug action throughout each of these processes ([Reed & Bestic, 2014](#)).

## Absorption

Drug **absorption** (the transfer of the drug from its point of entry in the body into the bloodstream) is influenced by the route of administration as well as by the concentration and acidity of the drug. Some routes of administration in children are limited and so are rarely used. For example, children younger than school age usually cannot hold tablets under their tongue for sublingual administration; they tend to swallow them instead. The small muscle size of young children limits sites for IM injection. Transdermal patches can be easily removed by infants. The gastrointestinal system may be so immature at birth that gastrointestinal absorption can be ineffective. Vomiting and diarrhea, frequent symptoms of childhood illnesses, also interfere with absorption because a drug does not remain in the gastrointestinal tract long enough to be absorbed.

## Distribution

**Distribution** refers to the movement of the drug through the bloodstream to a specific site of action. Children tend to have more fluid held in interstitial spaces and less in intracellular spaces than adults, so drugs may not be distributed as quickly as in adults. Many drugs are distributed bound to serum albumin (which is manufactured by the liver), so adequate albumen must be present for the drug to reach its site of action. This binding action limits the amount of free drug in the circulation, thereby providing protection against toxic levels of a drug. As free drug is used, the bound drug is released to maintain a therapeutic level. Newborns with immature liver function may not have enough serum albumin to transport drugs readily. This is particularly true if elevated bilirubin levels are present because bilirubin is also carried by serum albumin. Bound to serum albumin this way, bilirubin is harmless. In free form, however, it can leave the bloodstream and enter other body tissues. If it enters the brain cells, it destroys their ability to function (acute bilirubin encephalopathy). If a newborn who has a high level of bilirubin from destruction of fetal hemoglobin receives a drug such as a sulfonamide that competes for albumin binding sites, a large quantity of bilirubin may be left unbound and the infant may develop acute bilirubin encephalopathy or may not receive benefit from the sulfonamide because it cannot be carried to the infection site. In addition, newborns have sluggish peripheral circulation, so distribution to arms or legs in children this young may not be effective. Any child with cardiovascular disease also may have limited distribution of drugs because of general poor circulation.

## Metabolism

**Metabolism** involves conversion of the drug into an active form (biotransformation) or into an inactive form (inactivation). Because a child's basic metabolic rate is faster than that of an adult, certain drugs are metabolized more rapidly in children. This means that the drug must be administered more frequently to a child to maintain effective drug levels than it would be in adults. Whether drugs are coadministered can also make a difference because this could cause the drugs to metabolize more quickly or more

slowly than usual. Some drugs, such as the salicylates and chloramphenicol, are metabolized directly by liver enzymes. Because liver enzymes are not fully developed in newborns, these drugs cannot be metabolized and so can reach toxic levels rapidly. Older children with liver disease who have impaired liver enzymes also have a decreased ability to inactivate or transform drugs (Thakkar, Salerno, Hornik, et al., 2017).

## Excretion

**Excretion** (the elimination of raw drug or drug metabolites, a process that largely prevents properly administered drugs from becoming toxic) is potentially limited until about 12 months of age, when kidney function becomes mature. If a child has kidney disease, excretion potential is limited at any age. A few drugs, such as digoxin, are excreted in bile. Most newborns have sluggish bile formation, so excretion of these drugs is questionable. Monitoring intake and output is important in children receiving drugs to be certain urine excretion or an outlet for drug metabolites is adequate.

### QSEN Checkpoint Question 38.1

#### INFORMATICS

After Terry receives an antibiotic, her body must distribute it to the site where it will act. Which assessment parameter addresses her body's ability to distribute a drug?

- Terry's renal function
- Terry's arterial blood gases
- Terry's plasma protein levels
- Terry's gallbladder function

*Look in Appendix A for the best answer and rationale.*

## ADVERSE DRUG EFFECTS IN CHILDREN

Children respond to drugs in much the same way as adults, but they may experience unique or exaggerated side effects because of immature liver function or rapid metabolism during periods of rapid growth. The newborn may suffer adverse effects from drugs taken by the mother prenatally or from drugs transferred in breast milk.

## SAFE STORAGE OF DRUGS

Because young children do not appreciate that overdoses of medicine can be serious and even fatal, they may self-administer additional doses of medicine resulting in toxic levels of medications. This can occur with prescription medications, over-the-counter medication, and even alternative/complementary medications (Schoenewald, Ross, Bloom, et al., 2013).

Adolescents can deliberately take extra doses of drugs such as steroids or pain medicine, hoping for an added effect. Oxycodone (OxyContin), for example, is an

analgesic that may be prescribed for adolescents and also is frequently abused by them. Methylphenidate (Ritalin), administered to children with attention deficit hyperactivity disorder, is a second prescription drug that may also be frequently abused (Albertson, Chenoweth, Colby, et al., 2016).

Adults always need to be certain to store medicine in a safe place. Because poisoning from medicine is a frequent type of poisoning in preschool children, children's medicine—whether prescription, over-the-counter, or alternative/complimentary—should be secured in a *locked* and safe place.

In most homes, this is in a locked medicine cabinet or a locked drawer above the height their child can reach; a motivated toddler can climb so well that just placing medicines “out of reach” is not sufficient. Remind parents that most childhood poisonings occur when a family is under stress because, during these times, the family may forget usual procedures and leave medications unlocked or within reach. Be certain to teach parents that they should never take medicine in front of children; children may imitate this action with the parent's medication when the parents are out of sight. Another caution is not to pour or prepare medicine in the dark. Because almost all medicine bottles dispensed from local pharmacies look and feel the same, it is easy to pour the wrong liquid, extract the wrong pills, or read the bottle instructions incorrectly without adequate light. Teaching parents the importance of reading over-the-counter medication labels for proper dosing and frequency is critical.

Remember that these same rules apply in a healthcare setting. Medications left at a bedside table in the hospital or on a medication cart could be easily accessible to an unsupervised toddler or preschool child walking around.

## **THE SAFE ADMINISTRATION OF DRUGS**

Administering drugs safely to children requires that you first determine that you are giving the right drug (and right drug form) to the right child, in the right dosage, and by the right route, at the right time, for the right action. Afterward, you observe for the right response and use the right documentation. You also need to ensure that the parents or child have the right information about the medicine.

### **Right Medication/Right Drug Form**

Most medication errors are made in situations where multiple medications are being administered in a fast-paced environment. Intensive care units and emergency departments, therefore, are the highest areas at risk for medication errors, often because of interruptions during the medication administration process (Frith, 2013). Errors can occur because prescribers may write a prescription using either generic or trade names. It is the responsibility of the person administering the medication to identify the correct brand or generic equivalent. As the number of medicines available increases yearly, so does the possibility that two drugs will have similar names. These factors make identifying the correct drug and form critical.

### *What If . . . 38.1*

**Terry's father tells the nurse that Terry is such a "picky eater" that she rarely eats a full meal. When should he give Terry a medicine that should be taken with a meal?**

### **Right Patient**

When asked what is their name, children cannot be depended on to reply with their correct name. Anxious to please, a preschooler will answer the question, "Are you Johnny Jones?" with "yes." He may also, however, agree with any other name you propose. School-age children who want to avoid taking a medicine may deny they are the person whose name you called. To prevent these types of errors, never ask children their names for identification. Instead, read or scan the bar code on their identification arm bands and compare them with the medication sheet or electronic record. In ambulatory care settings or homes, ask a parent to confirm the child's identity; to include the child, ask for their date of birth (or their age for younger children).

### **Right Dosage**

The correct dosage of most drugs for children is based on weight. However, for drugs such as chemotherapy, the dosage is based on a body surface, which requires height and weight (Fig. 38.1). To calculate surface area using such a chart, find the child's height in the left column (e.g., 40 cm); next, find the child's weight in the right column (e.g., 20 kg). Hold a ruler or straightedge to connect the two points. The mark at which the ruler crosses the center column is the child's body surface area (e.g., 0.38 m<sup>2</sup>). Before administering any medication to a child, confirm that the dose prescribed is correct for the child's weight or the child's body surface area. Take and record height and weight measurements conscientiously at health visits or on hospital admission (or daily, if important, during an admission) to obtain this information for dose calculation.

**Figure 38.1** A nomogram to estimate body surface area. To use such a chart, draw a line from the child’s height to the child’s weight. The point at which it crosses the middle line is the child’s surface area.

Adult patient providers often use the *Physicians’ Desk Reference* (PDR Staff, 2013), but child health nurses need to use drug manuals made specifically for children’s dosing. Every child health unit or clinic should have a pediatric drug reference, such as *The Harriett Lane Handbook* (Branden & Flerlage, 2014) to help determine safe drug doses. Neonatal units often use a manual, especially for neonates and premature infants, called *Neofax* (Thompson Reuters Clinical Editorial Staff, 2013).

Using child or neonatal references that are weight based rather than age based is important because a 3-year-old who weighs only as much as a 1-year-old needs a dose of an antibiotic consistent with that given to a 1-year-old (not the child’s actual age); a 12-year-old who is obese may need a dose greater than the average 12-year-old. This is exactly why weight-based dosing is used. If a prescribed dose does not conform to a child’s weight, recheck the dose for accuracy with the prescriber before it is administered because preventing medication errors in children is everyone’s

responsibility (Lan, Wang, Yu, et al., 2014).

Although most medication on hospital units is supplied by the pharmacy in unit doses, nurses may still need to occasionally calculate fractional dosages (Box 38.2). When talking to parents about giving medicine, stress that if a medicine comes supplied with a dosing cup, it is best to use that to measure the correct dose. If there is no dosing cup, then an oral medicine syringe or dropper are the next best methods to measure liquid medicine because the “teaspoons” in their kitchen drawer are rarely exactly 5 ml. If they do not have any of these measuring devices, encourage them to use cooking measuring spoons for more accurate dosing (Yin et al., 2014).

## BOX 38.2

### Nursing Care Planning Based on Responsibility for Pharmacology

To calculate a fractional drug dose use the formula:

$$\frac{\text{Strength Desired (D)}}{\text{Strength You Have (H)}} \times \frac{\text{Quantity Desired (QD)}}{\text{Quantity You Have (QH)}} = \text{Answer}$$

For example, you have a prescription for 90 mg acetaminophen. Acetaminophen is supplied as 125 mg drug in 5 ml liquid. Using the formula:

$$\frac{90 \text{ mg (D)}}{125 \text{ mg (H)}} \times \frac{\text{QD (what you are asking)}}{5 \text{ ml (QH)}} = ?$$

Cross multiply:  $125 \text{ QD} = 450 (5 \times 90)$

Dose ordered = 90 mg divided by what you have on hand (how the medication is available) 125 mg times quantity (5 ml)

$$\frac{90 \text{ mg}}{125 \text{ mg}} \times 5 \text{ ml} = 3.6 \text{ ml}$$

## Right Route and Time

Possible routes of administration for medicine in children are discussed in the following sections. Each of these methods requires special techniques because most children do not enjoy taking medicine and need support during administration. Proper spacing of time between doses is also necessary for accurate medication uptake, but choosing the right time of day for parents to give medicine (e.g., planning doses for 11 pm and 7 am instead of 8 pm and 4 am) can positively impact the ability of a family to successfully complete the medication as prescribed.

## Right Information and Documentation

Because so many medications are advertised on television or in magazines, many

parents and children are already aware of drug names and the action of individual drugs before they are prescribed. However, because the information provided may be limited, they also may have misconceptions about a particular drug. Be certain when giving medicine to a child or handing a prescription to a parent that you review the drug's purpose and action, when and how it should be taken, and any side or adverse effects the parent or child should be aware of. Ask them if they have any questions (Box 38.3). Remember that people under stress do not retain information easily, so although the prescriber may have reviewed this information with parents when the prescription was written, reinforcement may be necessary. Children as young as 5 or 6 years of age are able to identify adverse or side effects, so be certain your explanation of drug action includes them as well. Correct documentation assures other healthcare providers that a drug was administered and allows for continuity of care (Buchholz, 2016).

### BOX 38.3

#### Nursing Care Planning to Respect Cultural Diversity

Assessing children's and families' health beliefs and attitudes toward Western medicine is important because attitudes are not consistent across cultures. In some cultures, it is more acceptable to utilize an herb or a home remedy than a prescribed medicine. Because of this, a family may accept a prescription but then not fill it or hesitate to administer the medicine. An herbal remedy they use may duplicate or counteract a prescribed medicine's effect. Socioeconomic factors affect medicine administration as well because medicine is expensive and difficult to afford for many families who do not have health insurance.

As part of health histories, always ask if a child commonly takes any type of herbal or home remedy or if the child has been given anything specific for the present illness. Because medicine is expensive, when discussing a prescription with parents, ask them whether they have insurance and can fill their child's medications in a timely manner. Educate the family on the action and side effects of the medication and explain to them to contact their provider if the child's condition does not improve or if the child experiences any side effects or complications. Such inquiries allow parents to say they have questions about the medicine or are uncertain whether they should give it because of a cultural belief.

#### *QSEN Checkpoint Question 38.2*

#### **SAFETY**

The nurse gives acetaminophen (Tylenol) to Terry in the emergency department and she has no ID band currently in place. The nurse determines which identification method is best?

- a. Asking her what her name is
- b. Stating a need to know her name

- c. Asking a parent to provide two identifiers (name and date of birth)
- d. Asking to see her school student card

---

*Look in [Appendix A](#) for the best answer and rationale.*

---

## **ORAL ADMINISTRATION**

Children younger than 3 years of age are unable to swallow pills. However, the ability of children to swallow pills varies from one child to the next and is not age-dependent. Typically, children older than 9 years of age can be offered tablets; however, some adolescents are not capable of swallowing tablets. The best practice is to ask the child and parent whether they are able to swallow tablets before offering the tablet form of the medication. Most oral medications for young children are available in liquid, chewable, or meltaway forms (Buchholz, 2016).

In infants, oral medication can be given with a medicine dropper or a unit-dose oral syringe (without a needle). Never give medicine with the child lying completely flat; otherwise, a child could choke and aspirate. Instead, gently restrain the child's arms and head by holding the child against your body with the head raised. A crying child is already opening his or her mouth for you; otherwise, gently open the mouth by pressing on the child's chin or gently squeezing the child's cheeks. Be certain the end of the syringe or dropper rests at the side of the infant's mouth to help prevent aspiration (Fig. 38.2). Press the bulb of the medicine dropper or use the plunger of the syringe so that the fluid flows slowly into the side of the child's mouth. An infant also may be given fluid from a small spoon. Allow the fluid to flow a little at a time so that the child has time to swallow between small sips. Because oral solutions are pleasantly flavored, most infants resist the first drop but then suck the remainder of the medicine into their mouth.

**Figure 38.2** To administer oral medicine with a syringe, place the medicine at the side of the child's mouth. Note that infants should be positioned at least at a 45-degree angle.

Restraining the child while giving a medicine may cause them to be frightened afterward or for future administration. Take the time to sit and comfort the child afterward (or let a parent do this). These actions are as important as checking the correct dosage of the drug because promoting the child's psychological well-being is crucial.

Preschoolers and early school-age children respond well to rewards such as stickers or small prizes each time they take their medicine. For older children, hand them the cup of liquid or tablet medicine and offer them a favorite fluid to swallow (Box 38.4). If a child has difficulty swallowing tablets, some pills can be crushed or added to a teaspoonful of applesauce or a flavored syrup. If pills are not to be chewed (e.g., capsules, enteric coated tablets), be certain to tell the child not to chew them.

#### BOX 38.4

#### Nursing Care Planning to Empower a Family

## GUIDELINES FOR ADMINISTERING ORAL MEDICATION

**Q.** Terry's mother tells you, "All my children fight me anytime they need to take medicine. How can I get them to take medicine without a battle?"

**A.** The following guidelines can often help make the task a bit easier:

- Do not say, "*Can* you drink this for me?" If an adult seems unsure whether children can do a task, children can develop grave doubts themselves or they may just not want to and say "No."
- Do not say, "*Will* you drink this for me?" This leaves a child the opportunity to say no and creates the awkward position of having to admit the child really does not have a choice in the matter; the child must take the medicine.
- State firmly, "It's time for you to drink your medicine now." Give the child a secondary choice to allow a sense of control: "It's time to drink your medicine now; do you want milk or water to swallow after it?" is a suitable choice, assuming both milk and water are compatible with the medication.
- Never refer to medicine as candy. If they think it is candy, children may help themselves to fatal amounts of medicine when everyone's back is turned.
- Do not use reward systems to persuade children to take medicine. Bribing may work for one dose, but when a second dose is due, the child will ask for a bigger bribe; for a third dose, an even bigger one. At some point (generally reached quickly), it is impossible to supply such large bribes, and therefore, it is impossible to gain the child's cooperation.
- Do not threaten. Statements such as "Take this quickly or I'll ask the doctor to make it into a shot" are not appropriate or therapeutic.
- Children expect honesty from adults; therefore, do not lie about the taste of medicine. If in doubt about the taste, taste it (with the obvious exception of drugs such as digoxin). Most children's medicines are artificially flavored with raspberry, orange, or cherry syrup, so they do not taste bad.
- If a medicine tastes bitter, mix it with a spoonful of strained applesauce or a teaspoonful of flavored syrup. Do not mix medicine with a full jar of baby food or put it into a bottle of milk or juice because the child will then have to eat the entire jar of food or drink the entire bottle to get all of the medicine. As a rule, encourage children to take liquid medicine straight and then follow it with a pleasant-tasting drink to take away any bitter taste. You could offer the choice of taking it in a syringe or a medicine cup to provide some control.
- If a medicine is supplied in tablet form, you could crush or dissolve it in with syrup or applesauce for a better taste if appropriate. Be certain before removing the particles from a capsule that the medicine will work properly when not in capsule form: Some are encapsulated to keep them from dissolving in the stomach and to bring them into the intestine, where they have a therapeutic effect. The same precaution must be followed when giving enteric coated tablets.

- Never leave medicine by a child’s bed or chair for the child to take “in a minute” or “after your shower.” The child may become involved with another activity “in a minute” and will not take it or a smaller child could find the medicine appealing and swallow it.

Some children may be old enough to swallow tablets but have never done it before. To let them practice learning how to do this, give them small bits of ice to use for practice; these melt rapidly and so do not stick in the back of the throat or esophagus. Tell the child to put the ice on the back of the tongue, tip the head slightly to the side, take a sip of water, and swallow the water. Give generous praise for learning this new skill. Another useful technique to help the child learn to swallow pills is to push them into a teaspoonful of ice cream or pudding. Children tend not to chew this type of food; rather, as they swallow the pudding, they also swallow the pill. If using this technique, push the pill into the ice cream or pudding in front of the child so it’s obvious what you’re doing. The intent is not to hide the pill or fool the child but to help the child learn to swallow the medicine (Box 38.5).

### BOX 38.5

#### Nursing Care Planning Tips for Effective Communication

You want to give acetaminophen (Tylenol) to Terry, 8 years old, to help relieve her pain.

*Tip:* In this scenario, the nurse explains the advantage of taking the medicine and conveys an expectation of cooperation. Avoid making requests, commands, or threats. Instead, allow a secondary choice (such as a choice of beverage) by offering the child a sense of control while at the same time preventing the child from saying “no” to the primary request.

**Nurse:** I have your medicine, Terry. Swallow these for me.

**Terry:** No. My ankle is too sore.

**Nurse:** That’s why I want you to swallow the pills. It’ll take away the hurt.

**Terry:** I’d rather get a shot; my ankle is so sore.

**Nurse:** This type of medicine has to be swallowed. Do you want orange juice or apple juice to drink with them?

**Terry:** Orange juice.

**Nurse:** Good. Take a big swallow and they’ll be gone.

#### *QSEN Checkpoint Question 38.3*

#### TEAMWORK & COLLABORATION

Although Terry is 8 years old, she doesn't know how to swallow pills. If the nurse needs to delegate the administration of an oral medication to a licensed practical nurse, what instruction would the nurse provide to her colleague?

- a. "Draw a picture of a child swallowing medicine and talk about it."
- b. "Tell the child that all medicines taste sweet so she'll take it readily."
- c. "Give the child a small ice chip to use to practice swallowing."
- d. "Tip the child's head forward to avoid the possibility of choking."

---

*Look in [Appendix A](#) for the best answer and rationale.*

---

## INTRANASAL ADMINISTRATION

Because nasal drops and sprays are easy to administer, more medications are supplied in these forms every year (Del Pizzo & Callahan, 2014).

Drugs are well absorbed across the nasal mucosa, so this route is an effective means of drug administration and can be a route for important and even life-sustaining drugs. Having medication sprayed or dropped into the nose can feel very uncomfortable and frightening for a child. The child's developmental stage will determine how to best approach administration of an intranasal medicine. Utilizing resources such as parents, Child Life (specialists trained to support children in hospitals), or the child's nurses can make the experience less traumatic.

The following suggested techniques can be used: Turn the child or ask the child to turn onto his or her back. A school-age child can extend the head over the side of the bed so that it is lower than the trunk. Preschoolers generally are too frightened by this strange position and do better with a pillow under their shoulders so that their head extends over the pillow and rests downward. Infant may need to be restrained in a mummy restraint for nose drop administration if they struggle to keep the syringe or dropper away from their nose (see [Chapter 37](#) for a discussion of appropriate restraints).

Instill the appropriate number of drops into one nostril. Turn the child's head to the side—to the left after the left nostril, to the right after the right nostril—so that the medicine stays in the nose longer. If the child is a preschooler or older, ask him or her to further "sniff" the medicine so that it goes far back into their nose. If a child gets up immediately, the medicine will flow out and will be less effective. Therefore, have the child remain in the head-flat position for at least 1 minute to be certain the medicine remains in contact with the mucous membrane of the nose. Praise the child even if the child did not cooperate fully because it lets child know that you understand how hard it was for the child to stay still while the medicine was instilled. Children over about age 6 years may be able to use nasal sprays competently after they have been introduced to the technique. Acknowledge that spraying a liquid into the nose is uncomfortable because it tickles or causes a sneezing sensation. Have the child sit or stand upright, hold the spray bottle upright with the tip just inside one side of the nose, and gently squeeze the spray bottle. In most instances, a child should then tip the head to the side (the right side for the right nostril, the left side for the left nostril) or sniff, depending on

the bottle instructions, for best absorption. The administration is then repeated for the second nostril.

Spray bottles should be individually prescribed for children and should not be used by any other child to prevent the spread of disease organisms.

## OPHTHALMIC ADMINISTRATION

Eye medications, in particular, antibiotics to treat eye infections, are administered by being dropped into the conjunctival sac of the eye (Shaw, 2016). This type of administration, like nose drops, is frightening for children because the eyes are a sensitive area and a natural reflex occurs to avoid contact with the eyes. Also, children know that getting something such as dust in their eye can be very painful. As a result, infants and preschoolers generally may need to be restrained for eye drop administration. Always prepare the child first, with a developmentally appropriate explanation. Place the child on his or her back. Open the eyes of infants and preschoolers by gently but firmly pressing on the lower lid with the thumb and on the upper lid with the index finger. A school-age child or adolescent will open their eyes cooperatively, but you may need to rest a hand on the eyelid to keep the eye open long enough for the drug to be administered (Fig. 38.3). Be certain your fingernails are cut short to avoid scratching the child's cornea.

**Figure 38.3** Administering eye drops.

Instill the correct number of drops into the conjunctiva of the lower lid. Allow the eyelid to close. Avoid placing the drops directly on the cornea because that can be painful. To prevent the conjunctiva from drying, do not hold the eyelids apart any longer than necessary. After the child has blinked two or three times, allow the child to

sit up. Do not forget to give praise for his or her cooperation after administration is complete.

To instill an ophthalmic ointment, apply a fine line of the ointment along the inside rim of the conjunctival sac, working from the inner to the outer eye canthus; be careful not to touch the tube to the eye. Always work from the inner to the outer canthus because if the eye is pus filled, applying medication under pressure toward the midline could force pus across to the other eye or down into the lacrimal duct. Eye medicine should be individually prescribed and not used by other children because if even the tip of the dropper or tube touches the conjunctival sac, it is contaminated with body fluid or microorganisms.

## OTIC ADMINISTRATION

Otic administration refers to administering medicine, primarily drops, into the ear canal. Like other forms of medicine, this is difficult for children to accept because they have been told many times not to put anything into their ears. Also, because ear drops are generally administered for an earache, which is sharp, excruciating pain, a child may worry having medicine put into the ear will make the pain even worse. In addition, a child's inability to watch what is happening may contribute to the child's fear. It is important to be honest with the child and provide information that is developmentally appropriate.

Ear drops must always be used at room temperature or warmed slightly because cold fluid may exacerbate pain and may also cause severe vertigo as it touches the tympanic membrane.

Turn the child or ask the child to turn onto his or her back or use restraint as necessary. Turn the child's head to one side ([Fig. 38.4](#)). The slant of the ear canal in children is shown in [Chapter 50](#). If the child is younger than 2 years of age, straighten the external ear canal by pulling the pinna down and back. If the child is older than 2 years of age, pull the pinna of the ear up and back. Instill the specified number of drops into the ear canal. Hold the child's head in the sideways position to ensure the medication fills the entire ear canal. Praise the child for cooperating during this difficult procedure ([AAP, n.d.](#)).

**Figure 38.4** Administering ear drops. For the child older than 2 years old of age, the pinna of the ear is pulled up and back.

### *Concept Mastery Alert*

In order to straighten the ear canal in children older than age 2 years, the pinna of the ear is pulled *upward* and back. In children younger than age 2 years, the pinna is pulled *downward* and back.

## **RECTAL ADMINISTRATION**

In certain circumstances, administering medication to children through the rectum is recommended. Rectal administration not only assist in absorption across the mucous membrane of the intestine but also avoids the danger of aspiration in certain situations such as seizures or when a patient is unconscious (Jannin, Lemagnen, Gueroult, et al., 2014). Rectal administration may also be used to give a drug such as acetaminophen (Tylenol) to young children who are unable to swallow oral medicine or to those who are vomiting. This method may be difficult for children due to its invasive nature; therefore, it is not a major route of administration. Moreover, absorption rates vary widely, so dosing is inconsistent. Because the child cannot see what is happening during rectal administration, and what parents discuss with them about “safe touching” and private body parts, a child can be easily frightened by this procedure. Show the child the medication so the child can be certain that it is not an injection.

Also given by this route are rectal suppositories and retention enemas. Many suppositories are supplied already lubricated. If not, add a drop of water-based lubricant such as K-Y Jelly to the tip. Use a glove and insert the suppository gently but quickly beyond the rectal sphincters (approximately 0.5 in. or as far as the first knuckle of your

little finger for infants and approximately 1 in. or as far as the first knuckle of your index finger for older children). Withdraw your finger and press the child's buttocks together and hold for a count of approximately 10 or until the child's urge to evacuate the suppository passes.

If the medication is to be administered by a retention enema to a young child, follow enema administration procedure and volume ordered by the prescriber. Press and hold the child's buttocks together to prevent the expulsion of the medication, using a distraction technique or any developmentally appropriate method while administering an enema. Keep in mind that any invasive procedure is particularly threatening to a child.

### *What If... 38.2*

**Terry's mother tells the nurse her child's school has a "no drug" policy, so Terry will not be able to take her oral antibiotic at school. What would the nurse advise her to do?**

## **TRANSDERMAL/TOPICAL ADMINISTRATION**

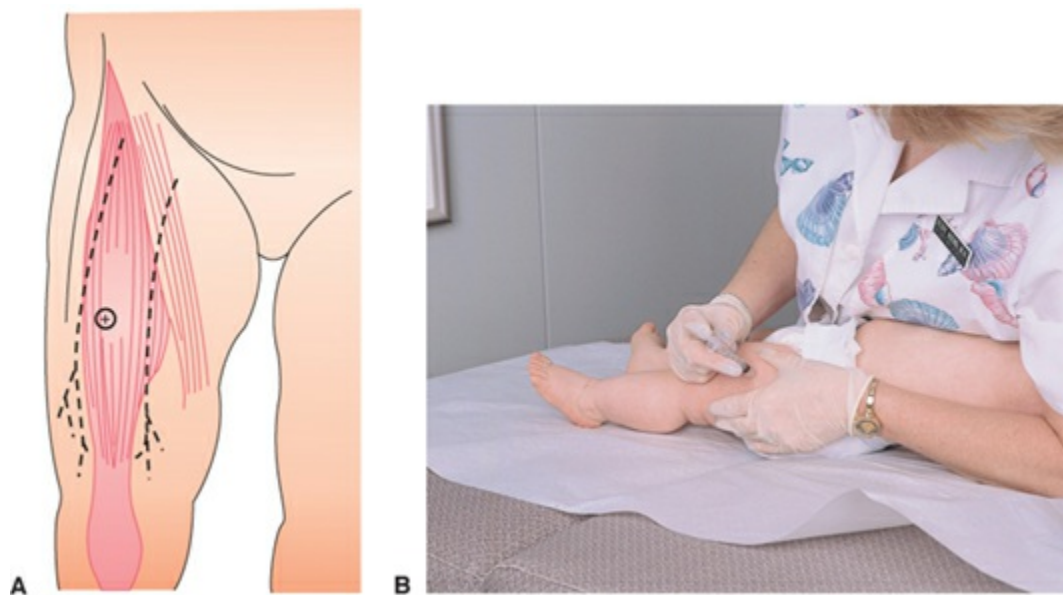

Children sometimes require administration of topical creams or lotions for skin irritation or to relieve itching or dryness. Most children are more tolerant of this type of application because it may provide immediate relief of symptoms. Older children may be able to assist with topical applications with your supervision. Be certain they wash their hands afterward so they do not lick any extra off their fingers and inadvertently take it orally.

Transdermal patches are an effective and pain-free route of administration of medication absorbed through the skin. The child's skin should be dry and intact at the site where the patch will be applied. Apply a patch over the trunk or a major muscle, not on distal extremities, for best absorption. Assess the skin under the patch every time a patch is changed to be certain the site is not becoming irritated because an irritated site might alter absorption. If possible, change the site every time a new patch is applied to decrease the possibility of irritation to the skin from the patch and clean the area of the skin before application.

Young children tend to remove transdermal patches the same as they do Band-Aids because of normal curiosity about what is underneath. Putting clothes on the young child immediately so the patch is out of sight is helpful. Assess infants carefully to be certain they have not pulled off the patch and are chewing on it because this can lead to drug toxicity. Be certain as well that patches applied to children wearing diapers are not placed where a leaking diaper could wet the patch and irritate the skin or dilute the medicine.

## **INTRAMUSCULAR AND SUBCUTANEOUS ADMINISTRATION**

IM injections are rarely prescribed for children admitted to the hospital because many children do not have sufficient muscle mass for easy deposition of medication and they are also painful. However, IM injections may be used in an emergency department and are commonly used for immunization. For IM injections in infants, the preferred site for administration is the vastus lateralis muscle of the anterior thigh (Fig. 38.5). Use the lateral aspect rather than the medial portion because this site is not as tender and should cause less pain. Using the gluteal muscle in children younger than 1 year of age is to be avoided due to the risk of damage to the sciatic nerve. Figure 38.5 shows an effective restraining technique for giving injections to infants. In older children, as in adults, the deltoid muscle (Fig. 38.6A) or a ventrogluteal site (Fig. 38.6B) should be used.

**Figure 38.5** (A) For infants under walking age, use the vastus lateralis muscle for intramuscular injections. (B) The technique for administering an intramuscular injection to an infant. Note the way the nurse uses her body to restrain and stabilize the infant.

**Figure 38.6** Sites for intramuscular injection. **(A)** In older children, the deltoid muscle is an acceptable site. **(B)** A ventrogluteal site may also be used in older children. Place the heel of the hand on the greater trochanter and the index finger angled toward the child's anterosuperior iliac crest, spreading the middle finger along the crest posteriorly. The triangle formed by the space between the index and middle fingers is the correct site.

Injecting an infant or child while he or she is sleeping should be avoided because they will be awakened and may be terrified of being attacked. Instead, play with the infant until they are awake, and depending on the developmental stage of young children, you may provide a short explanation immediately prior to injection. Be honest and do not make promises you cannot keep, such as telling the child it will not hurt. To reduce pain, ask for a prescription anesthetic cream to be applied to the injection site 30 minutes before the injection (see [Chapter 39](#)).

When giving injections, once you have described to the caregiver the drug's purpose and what you are going to do, do not delay the injection further because the anticipation the child may feel while waiting can be worse than the actual injection. Give the injection quickly, always keeping in mind safe technique. Remember to aspirate (if indicated). Massage the area briefly after the injection to help ensure absorption of the medication, although rubbing may be painful. Statements such as "Don't cry" while you

give an injection are not therapeutic. When children feel pain, they should be allowed to cry. Acknowledge that an injection may be painful and that it is “okay to cry or even scream” when they feel pain from the insertion of the needle. Squeezing a hand or a stuffed animal, singing a song, or counting may help with pain tolerance and/or distraction during an injection.

If necessary, ask for help in restraining a child when giving an injection to ensure safe administration. Evaluate children individually, however; school-age children may take pride in their ability to lie still and would not appreciate being restrained. Always hold and comfort a young child, or encourage parents to do so, after an injection or any other painful procedure.

Record the site of any injection while documenting the medication administration, so that sites can be rotated for better absorption. For subcutaneous injections, use the same injection sites, the lateral aspect of the thigh or upper arm, and inject the vaccine at a 45-degree angle.

If children are going to receive a series of injections, you can teach them distraction techniques, for example, imagery (e.g., thinking of the needle as a long thin rocket ship landing on their arm to help reduce apprehension). The distraction techniques used will depend on the developmental stage of the child (see [Chapter 39](#)).

### **Subcutaneous Pump Infusion**

Continuous subcutaneous pump infusion using a medication pump is the administration of a medication by the constant infusion into the subcutaneous tissue ([Peters, Mount, Huggins, et al., 2013](#)). Continuous pump infusions supply a constant level of medicine to sustain consistent blood levels. The disadvantage of the technique is that a child must be careful to protect the catheter at the insertion site from being dislodged.

With a subcutaneous infusion pump, the drug is delivered by the pump via a medicine-filled syringe. The site chosen is usually the abdomen because this both protects the pump and allows it to be out of sight. Insulin (see [Chapter 48](#)), heparin, and deferoxamine (Desferal), a chelating agent to remove stored iron from children with hematology disorders (see [Chapter 44](#)), are drugs often prescribed for use with infusion pumps.

The hub of the medicine-filled syringe is attached to a small tube with the needle attached at the distal end. The syringe is then clamped to the pump, the skin site is cleaned with alcohol, and the needle is inserted at a 45-degree angle (the usual subcutaneous insertion technique). The needle is typically retracted, leaving a small catheter in the subcutaneous tissue, which is taped in place before the pump is turned on (see [Chapter 20](#), [Fig. 20.5](#)).

The insertion site should be changed every 3 days to reduce the possibility of infection. The pump should be removed before showering so it doesn't get wet, although the catheter can remain in the subcutaneous tissue. For swimming or tub bathing, the entire pump, syringe, tubing, and catheter should be removed and then replaced again immediately. Pumps may not be advocated for children who are not yet

toilet trained because it's important to keep the pump and insertion site away from an area that could be soiled with urine or stool.

Older children, like adults, often worry at first that the pump will fail to operate, so they check frequently to be certain the syringe is emptying. With small children, cover the pump with clothing to prevent them from touching or trying to inadvertently manipulate the syringe. Careful monitoring of the patient's response to the medication is necessary for at least the first several days so that dosage adjustments can be made as necessary (Pozzilli, Battelino, Danne, et al., 2016).

## Autoinjection Syringes

Some medicines, such as insulin, come prepared in autoinject syringes that children are able to use to self-inject as soon as they are about 5 or 6 years old. Such injectable syringes have advantages in that they are prefilled with the correct amount of medicine, the needle is small, and the spring that causes the needle to inject the medication acts quickly, reducing pain during injection. You may need to remind preschool children not to play with the syringe or school-age children not to use it as a weapon against their friends or they could unintentionally inject them with the medicine. The use of EpiPens, which are filled with epinephrine (used to counteract anaphylactic reactions to allergens), is described in Chapter 42.

### QSEN Checkpoint Question 38.4

#### QUALITY IMPROVEMENT

Suppose Terry, 8 years old, needs to have ear drops administered. If the nurse consults the unit's policies and procedures, the nurse should expect which directive?

- Have the child self-administer the drops to give the child a sense of control.
- Refrigerate the drug for at least 30 minutes so it numbs the ear canal.
- Pull the pinna of the child's ear down to straighten the canal.
- Keep the child's head turned to the side to help retain the drops.

Look in Appendix A for the best answer and rationale.

## Intravenous Therapy

In the past, IV therapy was used extensively as a rapid means of hydrating children who were dehydrated as a result of diarrhea. Today, oral rehydration therapy is most often used in this case (Powers, 2015). IV therapy is a fast and effective means of maintaining fluid and electrolyte balance, producing therapeutic levels of drugs quickly, to provide nutritional support and offer blood or blood product replacement, so it still has a common place in children's care. The amount, type, and rate of IV fluids for children are prescribed carefully to prevent fluid overload. IV fluid may be infused into a peripheral vein, a central venous access device, or a peripherally inserted central venous catheter (McNab, 2016).

Despite its common use, IV therapy with children is not without problems. Because children move about a great deal and tend to remove bandages, all IV access sites must be assessed at least hourly for signs of infiltration. With movement, peripheral IV catheters can poke through fragile veins, central access devices can become dislodged, and ports can disconnect from the internal tubing, especially with the activity level of most children. Carefully inspect sites in order to identify any swelling or disconnections.

Infection is another problem associated with IV access. If a line becomes infected, it is usually removed, which may involve surgery for a centrally placed device. To avoid infection, insertion sites must be changed using a sterile technique as well as be carefully monitored. Keeping an IV site wrapped with something such as Kling gauze may help protect a curious toddler from removing the dressing and disrupting the site. However, remain vigilant about removing the gauze to inspect the site frequently if the gauze covers the insertion site.

## DETERMINING FLUID AND CALORIC NEEDS OF THE CHILD

IV fluid administered to children and infants must be isotonic (exerts the same osmotic pressure as their bloodstream) to prevent the destruction of red blood cells or the development of water intoxication. The use of isotonic fluid prevents fluid shifting from the bloodstream into interstitial tissue (as would happen if the IV fluid were hypotonic) or fluid shifting from interstitial tissue into the bloodstream (as would happen if the IV fluid were hypertonic). A 0.9% sodium chloride (0.9% sodium chloride is normal saline solution) is the IV fluid most commonly used in children because it is isotonic (Powers, 2015). Dextrose 10% in 0.9% sodium chloride or mannitol solution are examples of a hypertonic solution that might be used to cause fluid to shift into the bloodstream to relieve cerebral edema for a child with a head injury.

It is important to understand the principles of IV therapy, including the fluid and caloric needs of children (which differ significantly from those of the adult), to protect against overhydration, underhydration, or electrolyte imbalances such as hyponatremia (Powers, 2015).

Table 38.1 shows a typical method of calculating fluid requirements for children. Fluids administered using this table should ideally contain at least 5% dextrose, 0.9% saline, and 20 mEq potassium per liter so nutrients for energy and electrolytes are also replaced. For example, according to Table 38.1, a child weighing 45 kg would need 2,000 ml of a maintenance solution. A flow rate would be calculated for this amount (2,000 ml fluid in 24 hours = 83 ml/hr).

**TABLE 38.1 CALCULATING FLUID REQUIREMENTS FOR CHILDREN**

Body Weight	Fluid Requirement per 24 Hours
Up to 10 kg	100 ml/kg
11–20 kg	1,000 ml + 50 ml/kg for each additional kilogram over 10 kg

More than 20 kg 1,500 ml + 20 ml/kg for each additional kilogram over 20 kg

## OBTAINING VENOUS ACCESS

The needle size for IV therapy varies depending on the solution and the rate at which it will be administered. Commonly used needle sizes include 22 gauge, 24 gauge, 25 gauge, or 27 gauge.

Sites frequently used for IV insertion in young children or infants include the veins on the dorsal surface of the hand or on the flexor surface of the wrist. Leg and foot veins also may be used. In infants, another site is a scalp vein over the temporal area. Seeing IV fluid infusing into a scalp vein can be frightening for parents because it looks like a much more serious procedure than an infusion administered into a hand. You can explain to parents that scalp vein infusion is just another site to use to administer fluid or medicine to infants and ultimately might cause the least discomfort for their child because needles there do not infiltrate readily (Box 38.6). If any hair will be shaved away to place such a needle, ask parents if they wish to save the child's hair because this may be baby's first haircut.

### BOX 38.6

#### Nursing Care Planning Using Procedures

### INITIATING A SCALP VEIN INFUSION IN AN INFANT

**Purpose:** To provide a route for intravenous therapy

© Lesha Photography

#### Procedure

1. Apply an anesthetic cream to the chosen site.
2. In about 30 minutes (the time for the anesthetic cream to take effect), adequately restrain the infant using a mummy restraint.

#### Principle

1. An anesthetic cream decreases discomfort.
2. Restraining the infant promotes safety. Trying to hold the infant's arms and legs still without a restraint can be exhausting. Utilize Child

- |   |  |
|---|--|
| <ol style="list-style-type: none"> <li>3. Press the child's head to the side and hold it firmly in that position, with one hand on the occiput and the other securing the front of the head. Be certain the hand resting over the child's face does not obstruct the child's breathing.</li> <li>4. Lather the site over the temporal bone with a cleaning solution and carefully shave the hair. Ask parents if they want to save the clippings of hair if it is their child's first haircut. Assure them the hair will grow back in quickly.</li> <li>5. Place a rubber band around the infant's head at the level of the forehead.</li> <li>6. Wash the shaved area with an antiseptic solution.</li> <li>7. Insert a special small scalp vein needle or polytetrafluoroethylene (Teflon) catheter into a vein on her temple.</li> <li>8. Continue to hold the infant firmly until the needle is securely taped in place and until satisfied the infusion is running well.</li> <li>9. Cover the infusion needle with a clear dressing such as Tegaderm or OPSITE. Use a protective device, such as plastic shield, as needed to further protect the IV site from trauma.</li> <li>10. If necessary, use hand mitts to prevent the infant from touching the insertion site.</li> </ol> | <p>Life, if available, to assist with the procedure.</p> <ol style="list-style-type: none"> <li>3. This positions the child without interfering with respirations.</li> <li>4. The cleaning solution potentially reduces the possibility of nicks to the scalp. Hair removal allows a clear view of the insertion site and possibly reduces the risk of infection.</li> <li>5. A tourniquet is needed to dilate scalp veins.</li> <li>6. Washing the scalp further reduces the possibility of infection.</li> <li>7. Use of an appropriate insertion device establishes a fluid route.</li> <li>8. Securing the infant and device ensures an effective insertion site.</li> <li>9. Covering the site keeps the infant from dislodging the needle when the infant turns her head.</li> <li>10. Using hand mitts to protect the site is advised. Restraints are not recommended and only used as a last resort.</li> </ol> |
|---|--|

11. Spend some time comforting the child, talking and smiling, or lightly touching and stroking. Many infants enjoy sucking a pacifier or a bottle of glucose water during or after painful procedures; being held and rocked is the best comfort. Elicit the parents' support and institute principles of a traumatic care.

11. The infant may be frightened by the pinprick of the needle insertion as well as by having been held so firmly for a length of time.

Preschoolers and older children often express a preference regarding where they want an IV inserted. Offer a choice, if possible, or suggest the nondominant hand. Advocate for the child to ensure their wishes are respected.

Children who have IV infusions for long periods may require the placement of an **intracath** (a slim, pliable catheter threaded into a vein). The advantage of this type of device is that it cannot be dislodged as easily as a normally inserted IV needle, allowing a child the ability to move about more freely. For all children (including adolescents), IV infusions are sometimes secured in place with a small arm board. Without an arm board, it is easy to unintentionally and accidentally pull the catheter.

## **DETERMINING THE RATE AND AMOUNT OF FLUID ADMINISTRATION**

Because children's hearts and circulatory systems are smaller than those of adults, IV fluid must be infused at a slower rate to keep the child's cardiovascular system from becoming quickly overloaded. Therefore, just as in medication administration, supervising the amount of solution infused is critical. Infusion pumps are required in most settings for infants and children receiving IV fluids and when giving potent medications and always for small children because they regulate the flow accurately to a few drops per minute (Fig. 38.7). Overloading of IV fluid in infants and children can also be prevented by use of fluid chambers, devices that allow only 50 to 100 ml of fluid into the drip chamber at a time. With these in place, even if the pump fails, only the amount of fluid in the drip chamber will be infused.

**Figure 38.7** An infusion pump and calibrated infusion chamber are safety features used with children's intravenous infusions.

Another safety measure is the use of programmable infusion pumps that can be programmed to infuse fluids and medications in a prescribed rate. This allows for flow to be easily regulated and provides more accurate IV administration.

Keep a careful record of both the rate and amount of IV fluid administered to guard against fluid overload. At least once an hour, record the type and amount of fluid and the rate of flow (including the number of drops per minute). Signs of fluid overload are those of congestive heart failure and include coarse breath sounds and increased pulse rate and blood pressure. As the heart becomes overwhelmed by excessive fluid, blood pressure falls and signs of edema develop. In addition to observing for changes in vital signs such as these, assess intake and output per the following guidelines:

Infants = 2 ml/kg/hr

Children = 0.5 to 1 ml/kg/hr

Adolescents and adults = 40 to 80 ml/hr

It is difficult for children to lie still and wait for an IV infusion to finish (see [Box 38.7](#), an interprofessional care map for a child receiving intravenous medication). Try to provide children with quiet activities that will not interfere with the infusion. If a child will have medicine administration daily, help the child plan a special activity such as play a board game, listen to special music, or watch a favorite TV program, an activity reserved for only that time so IV infusion time is not seen as a dreaded activity. Be sure parents understand the importance of the IV therapy and help guard the infusion site while they are with their child. Infants who receive total fluids by IV infusion may enjoy sucking on a pacifier to fulfill their oral needs, ask the infant's mother if she would allow this, especially if the infant will return to breastfeeding soon.

**AN INTERPROFESSIONAL CARE MAP FOR A CHILD RECEIVING MEDICATION**

Terry is an 8-year-old with Down syndrome whom you meet in the emergency room. She has been diagnosed with osteomyelitis, a bone infection at her ankle. When you gave her a tablet of acetaminophen (Tylenol) for pain, she spit it out. Her mother tells you Terry cannot swallow pills. Her father tells you, “You’ll have to give her an IV.”

**Family Assessment:** Child is the youngest of four siblings. Lives with parents and other siblings in five-bedroom home on dairy farm. When asked about finances, parents state, “Fine, as long as people keep drinking milk.”

**Patient Assessment:** Child diagnosed with Down syndrome at birth; IQ approximately 60. Lacerated right foot on farm equipment in fall from hay loft 2 weeks ago. Laceration cleaned and bandaged by mother; not seen by healthcare provider. Today, wound has not healed, is open and erythematous; foot swollen; pain radiates up leg from foot. X-ray reveals abscess in bone. Child is so frightened by injections; she screams at the sight of any kind of needle. Placed on bed rest and prescribed an intravenous (IV) antibiotic and acetaminophen (Tylenol) and oxycodone for pain.

**Nursing Diagnosis:** Pain related to disease process (infection) in foot

**Outcome Evaluation:** Child rates pain on pain scale as 2 or below; cooperates with IV medication therapy to supply antibiotic and pain relief.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess what self-care measures child is able to complete by herself while on bed rest.	Explain to family that resting foot and maintaining IV therapy are crucial measures. Provide child with comfort and safety measures, age-appropriate diversional	Non-weight-bearing and antibiotic therapy will best cure the condition and relieve pain.	Child, nurse, and parent agree on plan of care for activities of daily living.

activities, and appropriate coverage of IV site to prevent dislodging.

*Teamwork and Collaboration*

Nurse/primary care provider	Assess if pain management team advice will be necessary.	Meet with pain consultant to discuss problem: Child is in pain but needs to remain still for IV therapy.	Sustained antibiotic therapy is necessary to treat bone infection; consultation can help avoid infiltration.	Pain management consultant meets with child and parent as appropriate; agrees on pain management plan.
-----------------------------	--	--	--	--

*Procedures/Medications for Quality Improvement*

Nurse	Assess if child has a preference for IV therapy site.	Begin IV therapy in nondominant hand if possible.	Allowing a child as much choice as possible helps to prevent a feeling of entrapment.	Parent will assist in keeping the child calm during the procedure.
-------	---	---	---	--

*Nutrition*

Nurse	Assess the child's food preferences to encourage eating.	Discuss with child and parent the importance of continuing nutrition while on bed rest. Suggest taking pain medication before meals.	Hospitalization can be a major stress to children. Pain can interfere with nutrition.	Child helps to choose foods from hospital menu that she would like to eat.
-------	--	--	---	--

*Patient-Centered Care*

Nurse	Assess if child has had experience with IV therapy in the past.	Review importance and plan for IV therapy with child and parents. Include	Knowledgeable patients and parents can aid in the success of therapy.	Child and parents state they understand why antibiotic and analgesia are needed and
-------	---	---	---	---

		child life as well as medical play as appropriate for development.		why administration method is required.
--	--	--	--	--

*Psychosocial/Spiritual/Emotional Needs*

Nurse	Ask child to rate pain by FACES Pain Scale hourly.	Discuss with family typical behaviors their child exhibits when in pain.	Important to ask the parent about their child's reaction to pain and specific behaviors that child displays. Pain relief can be adapted to child's specific needs.	Child and parent are satisfied with pain level. Pain is managed and child can participate in activities such as playing, eating, and sleeping.
-------	--	--	--	--

*Informatics for Seamless Healthcare Planning*

Nurse	Assess if parents have questions about child's care at home.	Explain the importance of continuing IV and then oral antibiotic. Practice swallowing pills with ice chips to ready child for oral administration.	Continuing antibiotic administration will be necessary to combat deep-seated infection.	Parents state they understand importance of continuing medicine administration. Keep follow-up visit for evaluation.
-------	--	--	---	--

**QSEN Checkpoint Question 38.5**

**EVIDENCE-BASED PRACTICE**

To investigate whether the viewing of cartoons can reduce the perception of pain in pediatric patients, younger children who presented to a major emergency department were randomized to watch a Barney cartoon in Spanish or English, and older children were randomized to view a Tarzan cartoon in either of the same two languages during painful procedures. Younger children were assessed 5 minutes before the procedure, during the procedure, and 5 minutes after the procedure using either a Poker Chip Tool or FACES Pain Scale. Older children were assessed at the same time interval using self-reporting and a visual analog scale. Results revealed children who watched

the cartoons rated their pain as significantly lower than those who did not watch the cartoons (Sahiner & Bal, 2016).

Based on the previous study, if Terry were watching television as the nurse approached her to insert an IV cannula, what would be the nurse's best action?

- a. Temporarily turning off the TV so she can clearly hear instructions
- b. Asking Terry's mother to turn the TV set to the cartoon channel
- c. Putting on an age-appropriate movie for Terry to watch
- d. Allowing Terry to continue to watch the current channel

---

## **Intravenous Medication Administration**

Medications may be added to an IV line as a small, one-time administration (bolus), a fluid chamber infusion, or by piggyback for larger children. As with any medication administration, identify the child before adding medicine to an IV line. Also ensure that the drug to be injected is compatible with the IV fluid being infused.

To administer medicine using a bolus technique, depending on what is available and the protocol at your facility, you may use a syringe pump for administering a medication or, if giving an IV push medication, clamp the IV tubing above the medicine port in the IV line, clean the port with alcohol, insert the needleless syringe filled with the prescribed medicine into the port, and inject the medicine slowly and gently based on the manufacturer's instructions. Once the medication has been given, remove the syringe and reopen the IV line immediately to allow the IV solution to flush the medicine into the child.

Currently, most intravenous fluids and medications are delivered using an infusion pump to ensure patient safety. Smart infusion pumps (SIPs) are equipped with safety features such as guardrails to alert nurses to specified parameters designated to prevent overdosing or to alert them of adverse drug interactions (Mason, Roberts-Turner, Amendola, et al., 2014).

For a piggyback infusion of medicine, medication is provided by the pharmacy prepared and diluted in small fluid-filled plastic bags. To begin a piggyback infusion, hang the piggyback bag, clean the medicine port on the IV line, and insert the piggyback system into the port. Lower the level of the main infusion bag and adjust the flow rate to that desired to allow the piggyback system to operate. As soon as the piggyback bag has emptied, elevate the maintenance bag of fluid again and make certain the IV line is flowing well and at the proper rate.

Analgesics are commonly administered to children either by intermittent IV administration or PCA pumps (Angheliescu, Faughnan, Oakes, et al., 2012; DiGiusto, Bhalla, Martin, et al., 2014). PCAs are set with lockout time intervals and are safe to use with children (see Chapter 39). When programmed, such pumps help protect against medication errors, but they still need to be monitored.

### What If... 38.3

**Terry's mother tells the nurse she does not believe in introducing any "foreign" substance into her child's body, so she does not want her to have IV medicine. How would the nurse counsel her?**

## USING INTERMITTENT INFUSION DEVICES

**Intermittent infusion devices**, sometimes called saline locks, are devices that maintain open venous access for medicine administration while allowing children to be free to move about without being restricted by IV tubing and pumps (Fig. 38.8). A vein on the back of the hand is generally chosen as the IV site. The saline lock is flushed as frequently as hospital policy requires to keep it patent. Be certain the tubing and stopper are both firmly secured to the wrist and, if necessary, an arm board is taped in place to remind the child to protect the site from trauma.

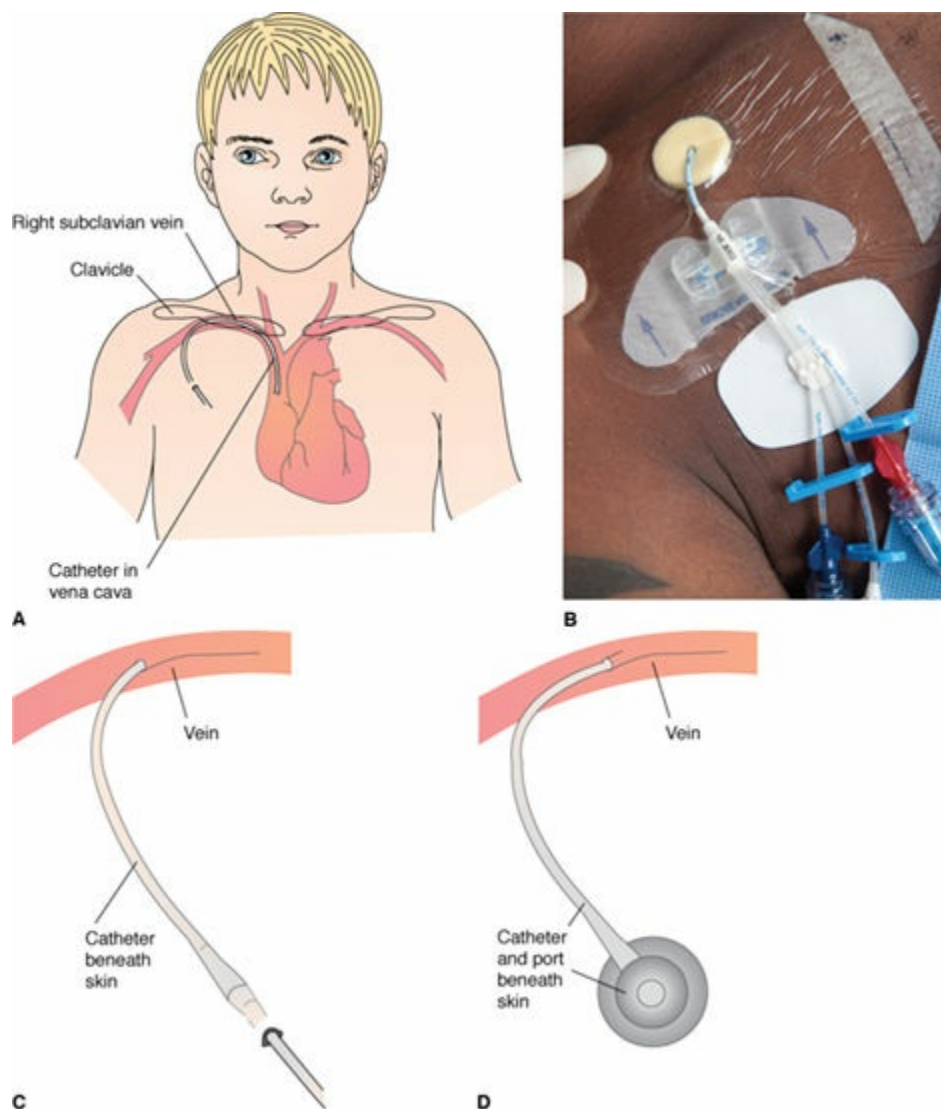

**Figure 38.8** An intermittent infusion device in place. Advocating for this type of apparatus increases mobility for parent and child. (From Ricci, S. S. [2017]. *Essentials of maternity, newborn, and women's health nursing* [4th ed.]. Philadelphia, PA: Wolters Kluwer.)

Children who are hospitalized or receiving home care for a long time and who need only IV medication, not additional fluid, are good candidates for such devices because IV medicine can be added to the site as needed without further venipunctures. Intermittent infusion devices also can be used if frequent venous blood samples are required because they can be used for blood draws. Similar devices may be inserted into arteries when arterial blood is required, for example, for the child who is having blood gases monitored frequently.

## USING CENTRAL VENOUS ACCESS CATHETERS AND DEVICES

Venous access for long-term IV therapy can be obtained using a tunneled catheter inserted into the vena cava just outside the right atrium; the catheter then exits the chest just under the clavicle for easy access (Fig. 38.9). Typical catheters used in this way include Broviac, Hickman, and Groshong types. Such catheters have a wrinkle-resistant fabric (Dacron) cuff that adheres to the subcutaneous tissue and helps to seal the catheter in place and keep out infection. These catheters are usually inserted in the operating room because tunneling under the skin is required and general anesthesia is preferred. These semipermanent catheters are used to administer bolus or continuous infusions of medications and fluid (Crocoli, Tornesello, Pittiruti, et al., 2015). Care of the catheter (depending on agency policy) consists of dressing changes over the exit site and periodically flushing the line with heparin or saline to ensure patency.

**Figure 38.9** (A) The insertion site for placement of a central venous catheter for intravenous infusion. (B) Changing a dressing for a central venous catheter. (From Lippincott Solutions. [n.d.]. *Critical*

Care [online module]. Retrieved from <http://lippincottolutions.com/specialties/critical-care>). (C) The central venous catheter beneath the skin. (D) A vascular access port (VAP) device beneath the skin.

Such catheters are advantageous because discomfort from further skin punctures is avoided. One disadvantage is that the catheter could become snagged on something and accidentally be pulled out. If this happens, it is an emergency situation because the child could lose an appreciable amount of blood from the point of entrance into the vena cava. Unless there is a waterproof dressing covering the insertion site, children with central venous catheters in place are usually not allowed to swim or take showers to avoid infection. Another disadvantage is the potential for profuse bleeding or air embolus if the IV tubing becomes disconnected from the catheter. Connections should be carefully secured and monitored. Infections must be prevented or the catheter will likely need to be removed.

**Vascular access ports (VAPs)**, also known as Infusaports or PORT-A-CATHs, are small plastic infusion devices that are implanted under the skin, usually on the anterior chest just under the clavicle, for long-term fluid or medication administration via bolus or continuous administration (see [Fig. 38.9D](#)). A small catheter threads from the port internally into a central vein. After skin cleansing, blood samples can be removed or medication can be injected by a needle inserted through the chest into the port. Puncturing the chest causes pain, so advocate for the child to receive a topical anesthetic at least 30 minutes prior to inserting the needle. Unlike the other types of central venous catheter that are visible outside of the chest, no dressing is required for these ports when they are not accessed with a needle. This allows for a full range of activities, such as showering and swimming. Be certain when accessing these ports to use only the needle supplied by the manufacturer because a regular needle tends to “core” or remove a small circle of the membrane over the port and destroy the integrity of the device. As with central lines, air emboli, bleeding from a disconnected line, and infection are major concerns with VAPs also.

Another type of IV access is peripherally inserted central catheters (PICC lines) for therapy ([Xiang, Li, Yi, et al., 2016](#)). These are advantageous particularly for home care because they can remain in place for up to 4 months without being changed. For this, a catheter is inserted into an arm vein (usually at the antecubital space into the median, cephalic, or basilic vein) and advanced until the tip rests in the superior vena cava. If a shorter catheter is used, the tip will rest closer to the head of the clavicle (a midline insertion).

Drugs commonly administered via PICC lines are antibiotics and analgesics. After medication is administered, the line is flushed with a small amount of a solution such as normal saline. The dressing over the insertion site is changed periodically according to agency policy.

Many parents seem more comfortable with this type of insertion than with a central

venous catheter because it appears so much more like a routine IV. Newborns can also have a catheter inserted into an umbilical vessel, with fluid and medications being administered by that route (see [Chapter 26](#)).

Remember that when caring for children with any type of central venous access systems, they all have the potential for hemorrhage, infection, air embolism, and thrombosis. Be certain to use strict aseptic techniques when changing the dressing covering the insertion site to prevent infections ([Cesaro, Cavaliere, Pegoraro, et al., 2016](#)).

### ***QSEN Checkpoint Question 38.6***

#### **PATIENT-CENTERED CARE**

Terry has her IV site changed to her dominant hand. Terry becomes agitated and begins to pull at her IV site. The nurse identifies which activity as best for her while her medication infuses?

- a. Listening to a story
- b. Playing kick ball in the hallway
- c. Playing Simon Says with her parents
- d. Building a tower in the play area with another child

*Look in [Appendix A](#) for the best answer and rationale.*

## **ADMINISTERING AN INTRAOSSEOUS INFUSION**

Intraosseous infusion is the infusion of fluid into the bone marrow cavity of a long bone, usually the distal or proximal tibia, the distal femur, or the iliac crest ([Reuter-Rice, Patrick, Kantor, et al., 2015](#)). Because the bone marrow communicates directly with the circulatory system, fluid reaches the bloodstream as quickly by this route as if it were administered intravenously. All fluids that can be administered intravenously, including whole blood or medication, can also be administered by this route.

Intraosseous infusion is used in an emergency when it is difficult to establish usual IV access or in a child with such extensive burns that the usual sites for IV infusion are not available. It is a temporary measure until a usual route of administration can be obtained because of the danger of osteomyelitis, a devastating infection with long-term effects to bone marrow. Intraosseous infusion is painful as the needle enters the bone marrow cavity. Prepare the child for this and offer support to both the child and caregiver.

The intraosseous needle may be inserted manually or using a power-assisted device, which is the preferred method for intraosseous insertion. Either way, identifying the correct anatomical landmarks for insertion is necessary. The following steps are used to initiate an intraosseous infusion:

1. The skin over the chosen site is cleaned as per protocol and anesthetized with a local anesthetic.

2. A small incision is made into the skin with a scalpel blade.
3. A large hypodermic or bone marrow needle is inserted through the incision into the cavity of the bone.
4. To ensure the needle tip has reached the bone marrow cavity, a syringe is attached to the needle and bone marrow is aspirated.
5. When bone marrow is obtained, the syringe is removed and IV tubing, including a filter and the fluid to be administered, is attached to the needle and opened to a gravity flow.
6. A dressing with additional antiseptic is then applied over the needle site.
7. A restraint is applied to the leg to help the child hold the leg still.

Tubing and dressings must be changed as per protocol (approximately every 48 hours for the tubing and approximately every 24 hours for the dressing), again, to reduce the possibility of infection. Assess for a distal pulse and adequate temperature and color of the leg every hour throughout the infusion to ensure there is adequate circulation to the extremity. To optimize assessment, place a pulse oximeter on a toe distal to the infusion and monitor waveform. If the needle should become dislodged, symptoms of circulatory impairment or pain and taut skin over the site occur.

Occasionally during fluid administration, a bone chip or thick marrow will occlude an intraosseous needle and slow the infusion. If this occurs, a stylet passed through the needle clears it and allows for continued fluid administration.

#### *What If . . . 38.4*

**The nurse is interested in exploring one of the 2020 National Health Goals with respect to the administration of medicine in children (see [Box 38.1](#)). Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Terry and her family and that would also advance evidence-based practice?**

### Unfolding Patient Stories: Brittany Long • Part 1

**Brittany Long**, a 5-year-old Black diagnosed with sickle cell anemia, is having an acute pain crisis, and her mother brings her to the emergency department (ED). Her last visit to the ED was 1 year ago when she was hospitalized for a vaso-occlusive crisis episode. How would the nurse prepare Brittany for insertion of an intravenous line and administration of intravenous fluids? How would the explanation differ for her mother? What nursing interventions safeguard the intravenous line and administration of fluids? (Brittany Long's story continues in [Chapter 56](#).)

Care for Brittany and other patients in a realistic virtual environment: *vSim for*

*Nursing* ([thepoint.lww.com/vSimMaternityPed](http://thepoint.lww.com/vSimMaternityPed)). Practice documenting these patients' care in DocuCare ([thepoint.lww.com/DocuCareEHR](http://thepoint.lww.com/DocuCareEHR)).

## KEY POINTS FOR REVIEW

- The effectiveness of medicines varies depending on the pharmacokinetics (absorption, distribution, metabolism, and excretion) of the drug.
- The principles of safe medicine administration for adults also apply to children: right medicine, right child, right dose, right route, right time, and right patient instructions.
- The correct drug dose in children is usually calculated according to the child's body weight. Body surface area, determined by using a nomogram or BSA formula, may also be used. The body surface area formula is based on height and weight for calculating medication dosages.
- Use adequate restraints as needed when giving medicine to be certain children will not inadvertently be harmed in the process.
- In children, the majority of medications are given orally or intravenously to avoid the discomfort of other routes. Subcutaneous pumps infuse medicine such as insulin.
- IV therapy may be administered peripherally or via a central venous access site. A scalp vein is a common IV site used for infants.
- An intraosseous infusion is used in an emergency when it is difficult to establish usual IV access or in a child with such extensive burns that the usual sites for IV infusion are not available.
- Teach parents safe actions for giving medicine at home so children can continue to receive accurate doses after hospital discharge and ensure they understand the importance of storing medications in a locked area; such thoroughness helps in planning care that not only meets QSEN competencies but also best meets a family's total needs.

## CRITICAL THINKING CARE STUDY

Casey is a previously healthy 4-year-old boy brought to the pediatric emergency room by his parents because he has diarrhea and has been refusing to eat today. He says his throat hurts too much for him to swallow and wants something to “stop the pain.” Upon examination, Casey is found to be mildly to moderately dehydrated. Pain medication (acetaminophen) and an oral rehydration solution (Pedialyte) are prescribed. His throat swab reveals he has a “strep throat,” so he is also started on a course of oral antibiotics.

1. Casey has been prescribed two oral medications plus an oral rehydration solution, yet one of his chief concerns is that his throat hurts too much for him to swallow. How would you approach this problem?
2. Suppose Casey vomits the rehydration solution so his primary care provider asks you to begin an IV infusion with him. How would you approach him to do this?

3. Casey has 2-year-old twin sisters and a new baby brother, 6 months old, at home. What would be important safety precautions to remind his parents about before he is discharged from the emergency room?

## Pain Management in Children

*Robin Harvey is a 3-year-old girl who was admitted to your hospital unit and has just returned from a bone marrow aspiration to rule out the possibility of leukemia. Robin received intravenous (IV) morphine sulfate during the procedure. Her mother asks you if Robin could have some more. "I know she's not having pain yet," her mother tells you, "But I want her to have something before the pain comes back."*

*Previous chapters described the growth and development of children and general care of ill children. This chapter adds information about the care of children when they need pain management. Such information builds a base for care and health teaching in a crucial area.*

**Is this mother's assessment or Robin's pain apt to be accurate or should you ask Robin herself about pain? Would anticipating pain in this way be the best intervention for Robin?**

## visceral pain

### OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the major methods and techniques of pain management for children.
2. Identify 2020 National Health Goals related to pain management in children that nurses can help the nation achieve.
3. Assess a child regarding whether pain management is needed or adequate.
4. Formulate nursing diagnoses for a child in pain.
5. Identify expected outcomes associated with management of pain in children as well as help families manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care related to a child in pain, such as suggesting an alternative therapy.
8. Evaluate outcomes for achievement and effectiveness of care for a child in pain.
9. Integrate knowledge of pain management in children with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

Pain is a difficult concept to define because it is a subjective symptom (experienced by the person), not an objective one (able to be determined using an objective scale), and is unique to each person. Because it respects children’s opinion of where and how much pain they feel, [McCaffery’s \(1979\)](#) classic description of **pain** is the one most useful to use with children: “The sensation of pain is whatever the person experiencing it says it is, and it exists whenever the person says it does.”

For children, because pain is such a different sensation than usual, pain is not only a hurting sensation but it can also be a very confusing one—the child did not anticipate the pain, does not have words to explain how it feels, and cannot always understand its cause. In addition, preschoolers and younger children lack an understanding of time, which makes it difficult to explain to them when the pain will go away. This can leave them feeling frustrated or angry while they wait for someone to give them relief.

Children’s perception of the situation influences their response to how much pain they feel. This means that children experiencing procedures that are less intrusive but who feel maximum anxiety from them may describe the degree of pain felt as more intense than they otherwise might have because of the accompanying anxiety ([Vervoort, Eccleston, Goubert, et al., 2010](#)).

Both helping children describe the type and extent of pain they are feeling and performing active interventions to relieve pain are some of the most important nursing roles in children’s care. Assessing for pain is so important that pain is often considered the “fifth vital sign” (Harrison, Elia, Royle, et al., 2013).

The 2020 National Health Goals that speak to pain management are shown in [Box 39.1](#).

### BOX 39.1

#### Nursing Care Planning Based on 2020 National Health Goals

Several 2020 National Health Goals speak directly to alleviating pain in several different areas:

- Reduce the proportion of patients suffering from untreated pain due to a lack of access to pain treatment.
- Reduce serious injuries from the use of pain medicines.
- Reduce the number of non–U.S. Food and Drug Administration (FDA)-approved pain medications on the market.
- Reduce deaths from the use of pain medicines ([U.S. Department of Health and Human Services, 2010](#); see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation reduce pain among children by active management of pain as well as by teaching children about the importance of avoiding painful unintentional injuries by the use of safety belts and bicycle helmets.

### *Nursing Process Overview*

#### FOR A CHILD IN PAIN

##### ASSESSMENT

Children, like adults, experience pain individually depending on the type and cause of the pain, their temperament, their previous experience with pain, and their expectation of relief. Infants and young children cannot verbalize what they are feeling and so have the most difficulty communicating how they feel.

Beginning as young as 3 years of age, children can indicate by pointing to a body part where they feel pain. They can also learn to express the degree of pain through a system such as comparing its intensity to a number of poker chips or drawings of faces. Older school-age children and adolescents can rate their pain on a scale of 0 to 10. Be aware that some children may be reluctant to admit pain because they are trying to be brave. Some may be reluctant to say they have pain because they are afraid they will receive a “shot” to relieve it, which will cause more pain. As a rule, it is most efficient to assess pain levels using an appropriate scoring tool along with a vital sign measurement.

##### NURSING DIAGNOSIS

Nursing diagnoses for children with pain focus not only on the pain but also on the stress, fear, or anxiety that pain produces. Examples of nursing diagnoses include:

- Pain related to an invasive procedure
- Fear related to anticipation of painful procedure
- Disturbed sleep pattern related to chronic pain
- Anxiety related to planned dressing changes that cause pain

### **OUTCOME IDENTIFICATION AND PLANNING**

The mark of efficient pain control is to anticipate when pain will occur and plan interventions to prevent it rather than let it occur and then relieve it. Three common reasons why nurses and other pediatric providers may not provide adequate pain relief to children include a belief that infants and young children do not experience pain, a fear children will become addicted to pain relief medications, and a fear of causing respiratory depression from analgesics. Infants and young children do experience pain, and there is little chance that children receiving opioids during a short hospital stay will become opioid dependent or that opiates cause greater respiratory depression in children than in adults (Fanning, Stucke, Christensen, et al., 2012). Refer parents to online resources for further information when appropriate (see Chapter 36).

### **IMPLEMENTATION**

Implementation for pain relief includes choosing the specific method of pain relief that is best for each child. Everyone involved in a child's care needs to be aware of the signs and symptoms that an individual child uses to express pain and specific ways that will help the child manage pain. If children are reluctant to admit they have pain because of the fear of receiving an injection, advocate for an oral form of analgesia or an intermittent IV infusion device or patient-controlled analgesia as appropriate options. Many parents are unsure about the safety of using strong analgesics for pain relief and so may give less than the prescribed dose. Therefore, regardless of whether they verbalize their concerns, educating parents about the need for pain relief, complications from undertreated pain, proper doses, and taking actions to involve them in the assessment and evaluation process are essential. Planning and assisting with complementary therapies is yet another area to consider.

### **OUTCOME EVALUATION**

An evaluation of expected outcomes is a key aspect of managing pain because no one pain relief measure is effective for everyone. After a child is given an analgesic, look for nonverbal clues, assess vital signs, and listen to the child's statements about pain to determine whether a drug was effective. Based on these findings, it may become clear that the technique of pain management being used may need to be modified or increased. A new technique may need to be added to the regimen so a child receives maximum pain relief.

Possible examples indicating achievement of expected outcomes include:

- Child states pain is now at a tolerable level that will not interfere with activity

or sleep.

- Adolescent says she has managed her fear through imagery.
- Child rates pain less than previously rated.
- Child describes ways he will help reduce pain when it returns.
- Child resumes age-appropriate behaviors following analgesia administration.

## The Physiology of Pain

As in adults, acute pain in children usually occurs for one of four reasons: reduced pH alterations which cause depletion of oxygen in tissues, pressure on tissue, external injury, or overstretching of body cavities with fluid or air. Chronic pain often involves irritation of nerves and/or tissue, which can occur with the pain of shingles, fibromyalgia, or other long-term injuries and irritations. The stimulus causing pain is not always visible or measurable. In addition, anxiety can lead to increased pain regardless of the physical stimuli.

Pain conduction consists of four major steps: transduction (sensing the pain sensation), transmission (routing the pain sensation to the spinal cord), perception (the brain interprets the sensation as pain), and modulation (steps the body takes to relieve pain).

Pain impulses join central nervous system (CNS) fibers in the dorsal horn of the spinal cord. Here, the impulses are projected upward to the brain, where they will be perceived as pain.

- **Acute pain** means sharp pain. It generally occurs abruptly after an injury. The pain of a pinprick is an example.
- **Chronic pain** is pain that lasts for a prolonged period or beyond the time span anticipated for healing. Acute pain usually causes extreme distress and anxiety; chronic pain can lead to depression and decrease patient's ability to achieve relief as the threshold to sense pain lowers and creates a "feedback loop" (Palermo, Eccleston, Lewandowski, et al., 2010). This is also referred to as **hyperalgesia** which is defined as an increased sensitivity to pain and is seen when patients have a heightened response to minimal painful stimuli.
- **Cutaneous pain** is pain that arises from superficial structures such as the skin and mucous membrane. A paper cut is an example.
- **Somatic pain** is pain that originates from deep body structures such as muscles or bones. The pain of a sprained ankle is somatic pain.
- **Visceral pain** involves sensations that arise from internal organs such as the intestines. The pain of appendicitis is visceral pain.
- **Referred pain** is pain that is perceived at a site distant from its point of origin. The pain of right lower lobe pneumonia, for example, is often first thought to be abdominal pain because the pain is referred or felt in the abdomen.

A child's **pain threshold** refers to the point at which the child first senses pain. This varies greatly from person to person and is probably most influenced by heredity. All

people also have a point above which they are not willing to bear any additional pain. This is a person's **pain tolerance**. Pain tolerance levels are probably most affected by cultural influences.

When pain is felt, the pituitary and hypothalamus glands both respond reflexively by releasing *endorphins* or polypeptide compounds that simulate opiates in their ability to produce analgesia and a sense of well-being. Children also consciously try to modify pain by physical actions such as shifting position or rubbing the body part.

Several theories have been proposed to explain the transmission of pain and how pain can best be managed. Of these, the gate control theory is the best known.

### ***QSEN Checkpoint Question 39.1***

#### **INFORMATICS**

Robin, 3 years of age, has just returned from having a bone marrow biopsy. The nurse documents the presence of which type of pain in Robin's electronic health record?

- a. Cutaneous pain
- b. Somatic pain
- c. Visceral pain
- d. Neuropathic pain

*Look in Appendix A for the best answer and rationale.*

## **GATE CONTROL THEORY OF PAIN**

The **gate control theory** of pain (Melzack & Wall, 1965) attempts to explain how pain impulses travel from a site of injury to the brain, where the impulse is registered. This theory envisions gating mechanisms in the substantia gelatinosa of the dorsal horn of the spinal cord that, when activated, can halt an impulse at that level of the cord. This prevents the pain impulse from being received at the brain level and interpreted as pain. Gating mechanisms can be stimulated by four techniques:

1. Cutaneous stimulation
2. Distraction
3. Anxiety reduction
4. Nerve blocks

Cutaneous stimulation (skin stimulation) has an effect because, when the peripheral nerves next to an injury site are stimulated, the ability of the A- $\delta$  or C fiber nerves at the injury site responsible for transmitting pain impulses appears to decrease. Rubbing an injured part such as a stubbed toe and applying heat or cold to the site are types of maneuvers that suppress pain because these actions activate the nearby peripheral fibers. This technique is especially effective with children because the rubbing is not only comforting from a physical standpoint but also conveys psychological warmth.

**Distraction** allows the cells of the brain stem that register an impulse as pain to be

preoccupied with other stimuli so a pain impulse cannot register. Having a child focus intently on an action or a thought or telling a child to say “ouch” while an injection is administered are common uses of this technique. For a child in pain after a procedure, a gift of a Mylar balloon or their favorite toy to hug can be wonderful distractions.

Pain impulses are perceived more quickly by the brain if anxiety is present. Therefore, any attempt to reduce a child’s anxiety as much as possible, such as teaching a school-age child what to expect with a procedure so there are no surprises, can help reduce the intensity of pain. In addition to teaching when something is going to happen, be certain you also teach when nothing is going to happen. Being told a clinic visit is just for a checkup and so will not involve painful procedures allows a child to relax and feel less anxiety.

The effectiveness of gate control theory techniques varies with a child’s age, ability to cooperate, degree of pain, and time allowed for learning and applying pain management techniques. Because memory may influence the sensation of pain (expecting to have pain produces anxiety, which increases pain), these techniques are best taught to children before they begin to have pain. In all instances, children should know to use them just before or at the moment they first feel the pain. If they wait until pain is intense, the pain may be so distracting that they cannot concentrate on using a technique. Children who were able to use a distraction technique in the past but can no longer do so need to be evaluated for what has changed. Is it their ability to cope with the pain or is the pain increasing in intensity?

## Assessing the Type and Degree of Pain

Pain assessment can be difficult with children not only because children have difficulty describing pain but also because some children will suffer with pain rather than report it, unaware that someone could make it go away. Other children may distract themselves by methods such as concentrating on play. Others may sleep, not from comfort but from the exhaustion caused by the pain. Cultural differences also influence how pain is expressed ([Box 39.2](#)). All of these factors can make using only subjective measures to assess pain, such as observation, misleading.

### BOX 39.2

#### Nursing Care Planning to Respect Cultural Diversity

Because children may have difficulty describing pain in a manner that adults can understand, it is difficult to assess the extent of their discomfort. Also, because pain is an individualized sensation, it may be experienced and expressed differently by different children. In some families, for example, pain may be expressed very openly and freely. In others, children are expected to be stoic about pain. The expression of pain is culturally determined in this way; therefore, two children who have the same degree of pain may express it very differently and it is important to be aware of these

differences when taking care of any patient.

Parents may be unclear and don't intervene with pain assessment or control because they assume healthcare providers are experts on pain control. Healthcare providers, on the other hand, may depend on parents to speak up if their child is in pain. Discussing how pain will be assessed, everyone's role, and what is available for pain relief clearly and openly early in a treatment program help ensure that these misunderstandings do not occur. Be certain that you also frequently reassess pain to be certain interventions such as the administration of an analgesic, distraction, or improved positioning are effective.

Keeping in mind each child's developmental level as well as chronologic age are important when assessing pain because assessment varies widely from that of a nonverbal infant to a very verbal adolescent (Box 39.3).

BOX 39.3

### Nursing Care Planning Using Assessment

#### ASSESSING A CHILD WITH PAIN

## THE INFANT

In the past, it was believed that infants do not feel pain because of incomplete myelination of peripheral nerves. Evidence-based practice has shown this not to be true because myelination is not necessary for pain perception.

A second argument in the past against needing to provide pain relief for infants was that they have no memory. It can be shown, however, that physiologic changes occur with pain even in preterm infants, so even with a lack of memory, it is clear that pain is experienced. Even newborns instinctively guard a body part by holding an extremity still or tensing the abdomen. Other clues are diffuse body movements; tears; a high-pitched, harsh cry; a stiff posture; alterations in facial expression such as eyes squeezed shut; a quivering chin; lack of play; and fisting (Schiavenato, Butler-O'Hara, & Scovanner, 2011). Perhaps, the chief mark in infants, however, is that when pain is present, they cannot be comforted completely. Preterm neonates particularly may have a difficult time organizing a distress response to cue a healthcare provider to the presence of pain. When working with any infant, be sensitive to situations that could cause pain

and try to reduce them to the maximum extent possible.

## THE TODDLER AND THE PRESCHOOLER

Determining when and how much pain is present continues to be difficult with toddlers and preschoolers because they may not have a word in their limited vocabularies to describe the sensation they feel because words such as “sharp,” “nagging,” or “aching” have little meaning until a child has experienced each type (Box 39.4). Parents often encourage children of this age to refer to pain as “my boo-boo” or to use other word such as “hurt” or “ouchie,” so children often are not sure if what you mean by the word “pain” (to be most accurate in assessment, use the child’s term for pain or teach the child that “pain” is the same as “boo-boo”). Children also can have difficulty comparing the pain they feel now to past pain (e.g., Is it better or worse?) because they have had so little experience with pain. For some toddlers, pain is such a strange sensation that aside from crying in response to it, they may react aggressively (e.g., pounding, rocking) as if to fight it off. They also may avoid being touched or held.

### BOX 39.4

#### Nursing Care Planning Tips for Effective Communication

Robin, 3 years old, has chronic leg pain from leukemia. You want to assess her level of pain.

*Tip:* When using pain rating scales, it’s critical to introduce them to children before surgery or before they have pain from procedures. This helps prevent situations where the child experiences both the pain and the rating tool as new all at once. It’s also important to give the correct instructions for standardized assessment tools, or the results will not be accurate. Mentioning a “shot for pain” can cause children not to report pain because they imagine the injection will cause even more pain rather than relieve it. In the following scenario, the nurse had already introduced Robin to the pain scale before her surgery so that that it wasn’t new to her.

**Nurse:** Robin? How are you feeling?

**Mrs. Harvey:** I don’t think she has any pain.

**Nurse:** Robin? Remember the faces we looked at this morning before surgery? I want you to use them to tell me how you feel. This one means “no hurt.” This one means “the most hurt you could have.” Point to the one that shows how much hurt you have.

**Robin:** (Points to the first face—the “no hurt” face.)

Preschool children can describe that they have pain but continue to have difficulty describing its intensity. They begin to use comforting mechanisms, such as gritting teeth, pressing a hand against a forehead, pulling on their ear, holding their throat, rubbing an arm, or grimacing, to control or express pain. Some preschoolers do not

think to mention they have pain because they believe it is something to be expected or, because of their egocentric thinking, they assume adults are already aware of their pain. They also may think pain is punishment for some act, so this is what they deserve. It is sometimes difficult to comfort children of this age during painful procedures by a statement such as “It’s only for a minute” because they do not yet have a perception of time.

Still, other behavior changes you may see in preschoolers are regression or withdrawal. To help evaluate if they have pain, ask yourself, “What would this child normally be doing?” (e.g., playing, eating, sleeping). Input from parents on how their child usually behaves can be valuable in an evaluation. If a trial dose of analgesia is used, you can then evaluate behavior changes after the dose is given. Children who resume their usual behavior after analgesia were probably in pain before the analgesia took effect.

## **THE SCHOOL-AGE CHILD AND THE ADOLESCENT**

Children who think concretely can have difficulty envisioning that a word like “sharp” applies both to knives and to the feeling in their abdomen. Because of this, they continue to have difficulty describing pain. They may also assume, like preschoolers, that you, as an authority figure, already know they have pain. In school-age children, guarding (tensing of body parts) is common. Sometimes, children can report they are fine while looking uncomfortable and being unwilling to move; as a nurse, you cannot always rely on what a child says; you have to read their body language, too.

Some children of school age will regress with pain such as returning to baby talk or lying in a fetal position. If pain will last only an instant, such as with an injection, children this age are old enough to control the pain through nonpharmacologic activities such as distraction techniques.

Children may be in middle school before they can understand how to use a numerical pain rating scale or that the scale intensifies from left to right. Doing preassessment work with them, such as giving them 10 different-sized triangles and asking them to arrange them from smallest to largest, is a good way to evaluate if they understand incremental measurements or “least to most” and are primed to describe pain intensity in a measurable way. A scale of 1 to 5 can be used in younger children if 1 to 10 seems overwhelming. If it seems clearer, you can turn a pain rating scale vertically so it measures bottom (little pain) to top (a lot of pain) to help a child learn incremental measurement.

Adolescents are able to use adult pain scales for assessment and also commonly use adult mechanisms for controlling pain such as grimacing or verbal outbursts. Some try to be stoic or not show pain in order to avoid stereotypes of “crybaby” or “chicken.” This tendency makes an assessment for body motions that could indicate pain, such as clenched hands, clenched teeth, rapid breathing, and guarding of body parts, doubly important to observe. This is also the age when concerns about addiction may begin to appear. A nurse can use this opportunity to discuss what it is adolescents may have

heard about pain medications, preconceived ideas about pain, and their risk for abuse of pain medications (see [Chapter 33](#)). It is important for a nurse to read both verbal and nonverbal cues from the patient when having these discussions.

## Pain Assessment

Common fallacies about pain in children are shown in [Table 39.1](#). Although monitoring for physiologic findings such as a change in pulse or blood pressure may give some indication that a child is under stress, these are not the most dependable indicators of pain because pain is a subjective symptom. Once children can speak, asking them to tell you about their pain (self-reporting or using a pain rating scale) becomes the most accurate method for assessment ([Downey & Zun, 2012](#)).

**TABLE 39.1 COMMON FALLACIES ABOUT PAIN IN CHILDREN**

Fallacy	Fact
Nurses can accurately estimate children's pain from their actions and so do not need to rely on children's self-reports.	Nurses commonly underestimate children's pain from physical appearance or activity.
Young children, particularly newborns, do not feel pain.	Newborns and children do feel pain.
A child who resumes usual activity or who sleeps cannot be in pain.	Some children distract themselves with play or music while in pain. They may sleep from exhaustion from the pain.
Because of the possible adverse effects, narcotic analgesics are too dangerous for young children.	In the proper dose, narcotics can be used safely with children, including low-birth-weight infants.
Experiencing pain will not harm an infant or young child.	Newborns with pain can become cyanotic and bradycardic; no one knows the psychological stress of pain at this age.
If children deny they are feeling pain, you should believe them.	Children may deny pain to avoid a procedure, such as an injection, which they view as more painful. They may be afraid, fearing that they are being punished, or believe others know how they feel.

A variety of pain rating scales have been devised to use with children. None have been proven to be consistently better than the others, mainly because both children and the type of pain they can be experiencing vary so much. As a rule, pick a well-

documented effective scale and urge your care team to use that consistently for each child rather than asking a child to adapt to different assessment techniques. Be sure to follow the specific instructions for that scale.

## THE PAIN EXPERIENCE INVENTORY

The Pain Experience Inventory is a tool consisting of eight questions for children and eight questions for the child's parents. It is designed to elicit the terms a child uses to denote pain and what actions a child thinks will best alleviate pain. Such a form can be used when a child is admitted to an acute care facility or on an initial home care visit (Box 39.5). If possible, it should be used before the child has pain.

### BOX 39.5

#### Pain Experience Inventory

##### QUESTIONS FOR THE CHILD

Tell me what pain is.

Tell me about any hurt you have had before.

What do you do when you hurt?

Do you tell others when you hurt?

What do you want others to do for you when you hurt?

What do you *not* want others to do for you when you hurt?

What helps the most to take away your hurt?

Is there anything special you would like me to know about you when you hurt? (If yes, have the child describe.)

##### QUESTIONS FOR PARENTS

Describe any pain your child has had before.

How does your child usually react to pain?

Does your child tell you or others when pain is experienced?

How do you know when your child is in pain?

What do you do for your child when your child is hurting?

What does your child do to help relieve pain?

Which of these actions work best to decrease or take away your child's pain?

Is there anything special that you would like me to know about your child and pain? (If yes, have the parents describe.) (Hester & Barcus, 1986)

## THE CRIES NEONATAL POSTOPERATIVE PAIN MEASUREMENT SCALE

The CRIES Neonatal Postoperative Pain Measurement Scale is a 10-point scale named for five physiologic and behavioral variables commonly associated with neonatal pain: C = crying; R = requires increased oxygen administration; I = increased vital signs; E = expression; S = sleeplessness (Krechel & Bildner, 1995) (Table 39.2).

**TABLE 39.2 THE CRIES NEONATAL POSTOPERATIVE PAIN MEASUREMENT SCALE**

		Infant's Score	
Assessment	0	1	2
Crying	No cry or cry is not high pitched.	Cry is high pitched but baby is easily consolable.	Cry is high pitched and baby is inconsolable.
Oxygen required for SpO <sub>2</sub> >95%	No oxygen required.	≤30% oxygen required.	<30% oxygen required.
Increased vital signs	Heart rate and blood pressure unchanged or less than baseline.	Baseline heart rate or blood pressure increased >20% of baseline.	Baseline heart rate or blood pressure increased ≥20% of baseline.
Expression	No grimace present.	Grimace alone is present.	Grimace and noncry vocalization grunt is present.
Sleepless	Infant has been continually asleep for past hour.	Infant has wakened at frequent intervals for past hour.	Infant has been awake constantly.
<i>Total infant score</i>			

SpO<sub>2</sub> = oxygen saturation.

From Krechel, S. W., & Bildner, J. (1995). CRIES: A new neonatal postoperative pain management score. Initial testing of validity and reliability. *Pediatric Anesthesia*, 5(1), 53.

Each area of concern is scored from 0 to 2. Infants with a total score of 4 or more are most likely to be in pain and need interventions to reduce discomfort. The scale cannot be used with infants who are intubated or paralyzed for ventilatory assistance because they would have no score for crying and because, if their faces are obscured, it is difficult to rate them for facial expression.

## THE COMFORT BEHAVIOR SCALE

The COMFORT Behavior Scale is a pain rating scale devised by nurses to rate pain in very young infants (Boerlage, Ista, de Jong, et al., 2012; van Dijk, Peters, van Deventer, et al., 2005). On the first part of the scale, six different categories (alertness, calmness/agitation, crying, physical movement, muscle tone, and facial expression) are rated from 1 to 5. The lowest score is 6 (no pain), and 30 is the highest (a great deal of pain). In addition to rating physical parameters, the infant is then observed for 2 minutes

and the evaluation of the baby's pain is documented on an analog (1 to 10) visual scale.

## THE FLACC PAIN ASSESSMENT TOOL

The FLACC Pain Assessment Tool is a scale by which healthcare providers can rate a young child's pain when a child cannot give input, there is a language barrier, or the child has a developmental delay. It incorporates five types of behaviors that can be used to rate pain: facial expression, leg movement, activity, cry, and consolability. Because a child does not provide active input, older children may prefer a pain rating system in which they actively participate.

## THE POKER CHIP TOOL

The Poker Chip Tool (Hester & Barcus, 1986) uses four red poker chips placed in a horizontal line in front of the child. The technique can be used with children as young as 4 years of age, provided the child has some concept of "more" or "less." To use the tool, tell the child, "These are pieces of hurt." Beginning at the chip nearest the child's left hand and ending at the one nearest the child's right hand, point to the chips and say, "This is a little bit of hurt, this is a little more hurt, this is more hurt, and this [the fourth chip] is the most hurt you could ever have." Then, ask the child, "How many pieces of hurt do you have right now?" Children without pain will reply they don't hurt; others will point to one of the poker chips. To gain more understanding of how much pain the child is feeling, clarify the child's answer by a follow-up question such as "Oh, you have a little hurt? Tell me about that." This is an effective tool for young children because the poker chips are concrete items and children are concrete thinkers (Fig. 39.1).

**Figure 39.1** Use a pain rating tool to assess children's pain. Here, a child points to the face on the circle that represents the degree of pain she is experiencing.

## WONG-BAKER FACES PAIN RATING SCALE

This scale consists of six cartoonlike faces ranging from smiling to tearful (Fig. 39.2). Explain to the child that each face from left to right corresponds to a person who has no hurt up to a lot of hurt (Wong & Baker, 1996). Use the words under each face to describe the amount of pain the face represents. Next, ask the child to choose the face that best describes the child's pain and record the number under the face the child chooses. The scale is popular with young children and can be used for those as young as 3 years of age (Pagé, Katz, Stinson, et al., 2012). The scale is widely used by healthcare providers because this appeal to children makes the evidence-based tool easy to use in practice.

**Figure 39.2** Wong-Baker FACES Pain Rating Scale. (Copyright 1983, Wong Baker FACES Foundation, [www.WongBakerFACES.org](http://www.WongBakerFACES.org). Used with permission. Originally published in Whaley & Wong's Nursing Care of Infants and Children. © Elsevier, Inc.)

## THE OUCHER PAIN RATING SCALE

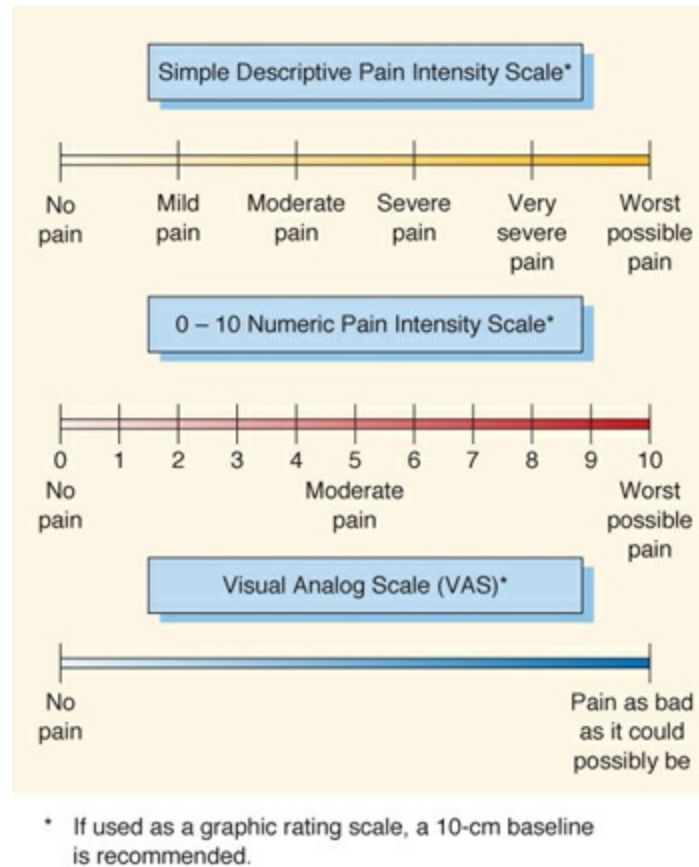

The Oucher Pain Rating Scale (Beyer, Denyes, & Villarruel, 1992) consists of six photographs of children's faces representing "no hurt" to "biggest hurt you could ever have." Also included is a vertical scale with numbers from 0 to 100. To use the photograph portion, point to each photograph and explain what each photo represents. Ask the child to point to the photo that best represents the child's degree of hurt.

To use the numbered scale portion, point to each section of the scale and explain that 0 means "no hurt," 1 to 29 means "a little hurt," 30 to 69 means "middle hurt," 70 to 99 means "big hurt," and 100 means "the biggest hurt you could ever have." Ask the child to point to the section of the scale that represents the present level of hurt. Children as young as 3 years of age can use the tool by pointing to the photograph that best describes their level of pain. If the child can count to 100 by ones and understands the concept of increasing value, the numbered scale can be used. The Oucher scale has White, Black, and Hispanic American photograph versions. If children are most comfortable with the tool, allow them to select the version they want to use or present the version that most closely matches the cultural characteristics of the child.

## THE NUMERICAL OR VISUAL ANALOG SCALE

The numerical or visual analog scale (Fig. 39.3) uses a line with end points marked "0 = no pain" on the left and "10 = worst pain" on the right. Divisions along the line are

marked in units from 1 to 9. Explain to children that the left end of the line (0) means that a person feels no pain. At the other end is a 10, which means that a person feels the worst pain possible. The numbers 1 to 9 in the middle are for “a little pain” to “a lot of pain.” Ask children to choose a number that best describes their pain. As soon as they can count and have a concept of “less to more,” children are ready to use a numerical scale. Be certain to show school-age children the scale; do not just say score your pain from 0 to 10. Until children reach late adolescence, they use concrete thought processes and so need the help of seeing the line to rate their pain best.

**Figure 39.3** Numerical and visual analog scales.

## THE ADOLESCENT PEDIATRIC PAIN TOOL

The Adolescent Pediatric Pain Tool (APPT) combines a visual activity and a numerical scale (Savendra, Tesler, Holzemer, et al., 1992). On one half of the form (Fig. 39.4) is an outline figure showing the anterior and posterior view of a child. To use the tool, tell a child to color in the figure drawing at the point where pain is felt. In addition, on the right side of the form, tell the child to rate the present pain in reference to “no pain,” “little pain,” “medium pain,” “large pain,” and “worst possible pain.” For a third activity, tell children to point to or circle as many words as possible on the form that describe their pain (words such as horrible, pounding, cutting, and stinging). The scale is suggested for use in children 8 through 17 years of age. Because many children younger than this age group need so much help reading and interpreting the multitude of

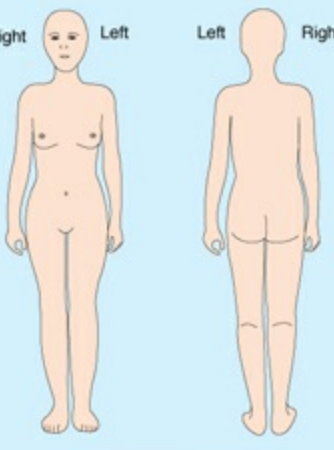

words that describe pain, it makes the form impractical for them. This is a useful tool for involving parents to talk with their child about pain. Reading the words together helps children examine the type, location, and level of pain they are experiencing. It also helps parents to better understand what their child is experiencing.

CODE \_\_\_\_\_

## LOGS AND DIARIES

Having children keep logs or diaries in which they note when pain occurs and the intensity of the pain each time it occurs can be useful for assessing children with chronic but intermittent pain. Examining such a diary not only reveals when pain occurs but also provides direction for pain management. For example, if the diary shows the child always awakens with pain in the morning, the child may need a longer acting analgesic to take at bedtime; if pain is worse during weekends spent at a grandparent's house, investigate whether something different is happening in that setting than at home that could be causing increased pain.

### What If... 39.1

The nurse asked Robin to color in a face on the FACES Pain Rating Scale

that best describes her pain, and she colored in all the faces. How would the nurse best assess Robin’s pain?

## Pain Management

Pain management techniques, like assessment techniques, vary greatly depending on the age of a child and the degree and type of pain a child is experiencing. Many healthcare agencies employ nurses specially prepared in pain management to serve on an interprofessional team of healthcare providers, including physicians, anesthesiologists, patient advocates, and wound therapy nurses, to plan individual pain management programs for children.

Children with chronic pain or pain not relieved with standard approaches may benefit from a referral to a pain management specialist or team because relief of frequent pain episodes or prolonged pain may require intense, consistent assessments and interventions, which are difficult to achieve in an acute care setting or during infrequent office visits. Whatever assessment tools or methods of pain relief are used, the staff should all become familiar and comfortable with their use, so interventions do not vary based on the healthcare provider.

A good rule for determining whether children need pain relief for a procedure is to remember that if the procedure would cause pain in an adult, it will also cause pain in a child. Many healthcare professionals such as physicians or X-ray or endoscopic assistants perform procedures with a child that could cause pain. Assist these team members in scheduling procedures at times when a child can be administered optimal pain relief. Help them institute nonpharmacologic measures of pain management such as distraction because often a combination of nonpharmacologic and pharmacologic methods work best (Pillai Riddell, Racine, Turcotte, et al., 2012).

General measures to alleviate pain based primarily on the gate control theory of pain management are summarized in [Box 39.6](#). [Box 39.7](#) shows an interprofessional care map for a child requiring pain management based on these guidelines.

### BOX 39.6

#### Nursing Care Planning Based on Family Teaching

##### PAIN MANAGEMENT WITH CHILDREN

**Q.** Mrs. Harvey asks you, “How can I be sure I can keep my daughter pain free after we return home?”

**A.** Here are some tips on ways to offer pain relief in addition to just giving medicine:

- Let the child know you want very much to try to take away the pain and so are happy to work with her to relieve it. Use a positive approach: “This medicine will take away your pain,” not “Take this and let’s hope it works.”
- Administer pain medication before pain becomes intense to help *prevent* pain

rather than just relieve it. If a child is in the hospital, inform the staff if a particular approach works or does not work.

- Never just give an analgesic. Make the child comfortable in ways such as straightening the sheets or offering a back rub.
- Ask your child about measures she thinks will be helpful, such as an additional pillow, the television turned on, or a favorite toy nearby.
- Help your child talk about and describe the pain she is experiencing. This can help make it more concrete and not as psychologically frightening.
- Relieve anxiety about other phases of life, if possible. Relaxation reduces muscle strain and tension that can add to pain.
- Offer emotional support. Pain never seems as bad when a support person is present. Reassuring your child that she is loved and that you will be there for her can be very comforting.
- Try not to use such statements as “Be a big girl” or “Stop crying” when a child is in pain from a procedure such as an injection. Say instead, “It’s all right to cry. I know it hurts,” to avoid shaming a child who cannot stop crying.

## BOX 39.7

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR A CHILD REQUIRING PAIN MANAGEMENT

Robin Harvey, a 3-year-old girl admitted to your hospital unit, has just returned from a bone marrow aspiration to rule out the possibility of leukemia. Robin received IV morphine sulfate during the procedure. Unfortunately, the bone marrow obtained for analysis is not adequate, so a repeat procedure is scheduled for 3 hours from now.

**Family Assessment:** Child is only daughter of two parents. Father works as a welder in a local steel mill; mother works part-time at a local convenience store. Family rates finances as “Doing good.”

**Patient Assessment:** A 3-year-old girl with a history of frequent nosebleeds, petechiae, and bruising admitted for diagnostic testing. First experience with hospitalization. Screams at the sight of a syringe and needle. Both parents at bedside talking with child. Child upset and crying, “Don’t let them hurt me!”

**Nursing Diagnoses:** Anxiety related to fear of the unknown and anticipation of painful procedure.

**Outcome Criteria:** Child identifies pain as no higher than 1 with Oucher Pain Rating Scale; exhibits few to no nonverbal indicators of pain; exhibits age-appropriate coping behaviors, including the use of one nonpharmacologic pain relief technique.

Team Member	Assessment	Intervention	Rationale	Expected Outcome
-------------	------------	--------------	-----------	------------------

## Responsible

### *Activities of Daily Living, Including Safety*

Nurse	Assess if IV morphine provided adequate pain relief for last procedure.	Review with parents the necessity for the repeat procedure and possible methods to help child with pain.	Being prepared for coming procedure can reduce anxiety in both parents and child.	Parents state they understand why repeat procedure must be done; are satisfied with repeat pain relief measures to be used.
Nurse	Assess vital signs and the child's present pain rating.	Engage the child in quiet activities for the first hour postprocedure.	The child is at risk for bleeding from the puncture site. Quiet activities reduce the risk for bleeding and also provide distraction.	Vital signs remain stable; pain rating is not more than 1 on child rating scale. Child colors quietly.

### *Teamwork and Collaboration*

Nurse/primary healthcare provider	Assess if pain management team member is available for consultation.	Consult with pain management team member for best pain relief for frightened preschool child.	Well-planned pain relief can best meet the needs of an anxious child.	Pain management team member meets with parents and child; determines best method of pain relief.
-----------------------------------	--	---	---	--

### *Procedures/Medications for Quality Improvement*

Nurse	Assess if repeat bone aspiration site is free of inflammation.	Apply anesthetic cream to aspiration site and cover with an occlusive dressing 1 hour before	Anesthetic cream helps reduce pain. An occlusive dressing enhances absorption and tissue	The child cooperates with application procedure. Occlusive dressing remains in place preprocedure.
-------	--	--	--	--

		scheduled procedure.	penetration.	
<i>Nutrition</i>				
Nurse	Assess when the child last ate.	Keep the child nothing by mouth (NPO) for 30 minutes preprocedure.	Nausea from heavy analgesia can lead to aspiration if stomach is full.	Parents state they understand temporary restriction for fluid.
<i>Patient-Centered Care</i>				
Nurse	Assess what the child and parents believe was most traumatic aspect of previous bone marrow aspiration.	Review with the child that a feeling of pressure with needle insertion will occur.	Anticipatory knowledge of events and feelings helps to prepare the child and aids in coping.	Parents state they feel prepared for new procedure; will support child through the procedure.
Nurse	Assess if pain assessment tool was used with child during previous procedure.	Introduce the child to Oucher Pain Rating Scale.	Introducing the child to the tool prior to the onset of pain minimizes anxiety and so can increase the tool's usefulness and accuracy in determining the level of pain.	Child rates her pain preprocedure to demonstrate she understands how to use the scale. Number sets a baseline for comparison postprocedure.
<i>Psychosocial/Spiritual/Emotional Needs</i>				
Nurse	Assess if the child has had experience with therapeutic play.	Provide opportunities for therapeutic play with a doll and syringe before and after the procedure.	Therapeutic play helps the child express her feelings about painful procedures and possibly reduces anxiety.	The child plays with doll and syringe under nurse supervision; does not demonstrate behavior suggestive of

extreme anxiety or  
fright.

### *Informatics for Seamless Healthcare Planning*

Nurse	Assess if the child is free of pain postprocedure and if parents received adequate information on the outcome of the procedure.	Ask the child to rate pain on the Oucher Pain Rating Scale; ask parents if they have received a procedure report and understand the results.	A postprocedure evaluation helps to meet further needs of the child and parents and improves skills of healthcare providers.	Child rates pain as 1 or below on a pain rating scale. Parents state they have results of the procedure and they understand the next step needed for diagnosis and treatment.
-------	---	--	--	---

#### *What If... 39.2*

**A colleague who works with the nurse says she doesn't want to use a self-report tool with Robin because she feels that such tools replace her nursing judgment. The nurse would like her to use one. How would the nurse best justify this view to her? What are the pros and cons of pain assessment tools?**

## Pharmacologic Pain Relief

Pharmacologic pain relief refers to the administration of a wide variety of analgesic medications. Many children need analgesic agents in addition to nonpharmacologic techniques for pain relief, especially for acute pain. Medications can be applied topically or given orally, intramuscularly, intravenously, or by epidural injection. As a rule, intramuscularly administered analgesia should be avoided in children because children dislike injections and have a limited number of adequate injection sites. Be certain children understand that it is acceptable to ask for medication for pain because they may not know they can do so unless this is stressed by healthcare providers. Be very careful when administering pain medications to children that even if you are hurrying to provide pain relief, you use all the usual medication safeguards because mistakes can have a very serious outcome. Always check medication doses in a pharmacology reference designed specifically for children or neonates (see [Chapter 38](#)).

### TOPICAL ANESTHETIC CREAM

To reduce the pain of procedures such as venipuncture, lumbar puncture, and bone

marrow aspiration, a local anesthetic cream that contains 4% lidocaine can be used (Jorge, Feres, & Teles, 2011; Poonai, Alawi, Rieder, et al., 2012).

The cream is applied to the skin, and the site is then covered with an occlusive dressing or plastic wrap to keep young children from wiping away or tasting the cream. The time needed for effect between different brands varies from 30 minutes to 1 hour and so must be applied within that time frame before an expected procedure (Box 39.8). Parents can apply anesthetic cream at home before bringing a child to a clinic visit for a procedure such as bone marrow aspiration to avoid a long waiting time (Fig. 39.5). Caution them not to allow their child to remove the dressing because the cream could anesthetize the gag reflex if eaten or cause eye damage if rubbed into the eyes. They are effective with procedures such as venipuncture, intramuscular (IM), or subcutaneous injections. They also can be used effectively for pain relief with circumcision (Rosen, 2010). EMLA cream, a combination of local anesthetics, is a popular cream used but has to be applied at least 1 hour before the procedure; however, it can be applied up to 3 hours before a procedure and still be effective. A newer compound, ELA-MAX (LMX), containing only lidocaine, takes effect in 30 minutes or less (Crowley, Storer, Heaton, et al., 2011). It can be purchased without a prescription but, as an over-the-counter medication, is often not reimbursed by insurance companies.

#### BOX 39.8

### Nursing Care Planning Based on Responsibility for Pharmacology

#### EMLA CREAM

**Classification:** EMLA (eutectic mixture of local anesthetics) is a topical anesthetic cream containing lidocaine and prilocaine.

**Action:** acts to anesthetize skin before potentially painful procedures (Karch, 2013)

**Pregnancy Risk Category:** B

**Dosage:** dollop of cream to intended skin site for at least 1 hour before procedure (2 to 3 hours before deeper procedures such as lumbar puncture or bone marrow aspiration)

**Possible Adverse Effects:** hypersensitivity and itching

#### Nursing Implications

- Explain to the child that the cream will help prevent pain during a procedure.
- Wash the site with soap and water; don't use alcohol because this removes body oil, which is necessary for the effective action of the anesthetic.
- Apply a dollop of cream to the intended site and cover with a transparent occlusive dressing at least 1 hour before the procedure. Do not rub cream into the skin.
- If the cream is to be applied at home, instruct the parents how to apply the cream and the occlusive dressing. Suggest the parents use plastic wrap for the occlusive dressing.
- Instruct the child not to touch the dressing while it is in place. If necessary, cover

the occlusive dressing with an opaque material to prevent the child from touching or playing with it.

- Just before the procedure, remove the dressing and then wipe the skin to remove the cream.
- Observe the skin. Look for reddened or blanched skin, which indicates that the drug has penetrated the skin.
- Do not use the drug for a child with a known history of sensitivity or allergy to local anesthetics such as lidocaine.
- The drug is not approved for use in infants younger than 1 month, although it is frequently used for circumcisions after research showed it was tolerated well by neonates for that procedure (Rosen, 2010).

**Figure 39.5** The local anesthetic cream can be applied to a child's hand and held in place with a transparent dressing at home prior to surgery. (© Sheldon Levis/Alamy.)

### *What If . . . 39.3*

**Robin is scheduled to have blood drawn at 10 AM and, to prepare her for this, the nurse applies an anesthetic cream, which takes an hour to be effective, at 9 AM. However, the technician who will take the blood arrives early. Would the nurse ask the technician to wait, or explain to Robin that the cream is not going to work?**

## **ORAL ANALGESIA**

Oral analgesia is advantageous because it is cost-effective and relatively easy to administer. Many analgesics are supplied in liquid form and flavored with cherry or grape syrup to disguise unpleasant tastes. Caution parents that even though such drugs taste sweet, they should never refer to them as “candy.” Reinforce with parents the need for proper storage (locked in a cabinet or out of the child's reach) because, otherwise,

children may help themselves to more of the pleasantly flavored “candy” when the parent leaves the room. Toxicity from too frequent or overly large doses of acetaminophen is the number one reason for poisoning in small children and can lead to severe liver damage in children (Karch, 2013). If swallowing pills or large volume of liquids is not an option, enterally dosed opioids can also be given sublingually or rectally, if appropriate.

Nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen or naproxen are excellent for reducing pain because, as their name implies, they reduce inflammation as well as pain in conditions such as sprained ankles or rheumatic conditions. Long-term administration of any NSAID can lead to severe gastric irritation, so this category of analgesics should not be used longer than prescribed. Help parents giving any analgesia around the clock for several days to make out a medication sheet to hang on their refrigerator door or some other method to remind them when the next dose will be due and alert them not to give drug doses too close together.

Children should not receive acetylsalicylic acid (aspirin) for pain relief, especially in the presence of flulike symptoms, because there is an association between aspirin administration and the development of Reye syndrome, a severe neurologic disorder (see Chapter 49).

For managing severe or acute pain, such as postoperative pain or the pain of a sickle-cell crisis, opioids, such as morphine, oxycodone, and hydromorphone (Dilaudid), are frequently prescribed. Because this class of drugs is also referred to as narcotics or opioids, parents may be reluctant to give their children these medications out of concern that their child will become addicted. Acknowledge their concern but reassure them the risk for addiction during short-term use is remote. Reinforce that the main concern is supplying adequate pain relief for their child. A reminder about the consequences of undertreated pain and a discussion about how anxiety can increase levels of pain may be helpful in the discussion as well.

### **QSEN Checkpoint Question 39.2**

#### **SAFETY**

Robin’s primary healthcare provider has prescribed both an oral analgesic and an IV antibiotic for her. What is the most important thing the nurse needs to know before safely administering these medications?

- a. Which medicine Robin’s mother prefers
- b. Robin’s weight and the recommended doses based on her weight
- c. Robin’s precise age because some medications are not prescribed for infants
- d. Robin’s ability to participate in nonpharmacologic interventions

*Look in Appendix A for the best answer and rationale.*

## **INTRAMUSCULAR INJECTION**

Although opiates are available as IM injections, analgesia for children is rarely given by this route because the number of suitable injection sites in children is limited, injections are associated with pain on administration, and such an injection can produce great fear in children. An IM injection also can lead to several risks, including uneven absorption, unpredictable onset of action, and nerve and tissue damage. As a rule, other routes are used whenever possible.

## INTRAVENOUS ADMINISTRATION

IV administration of analgesia, the most rapid-acting route, is the method of choice in emergency situations, in the child with acute pain, and in a child requiring frequent doses of analgesia but in whom the gastrointestinal tract cannot be used. Common opioids given by this route include morphine (no common brand name), fentanyl (Sublimaze), hydromorphone (Dilaudid), and methadone (no common brand name). In equianalgesic doses, they act very similarly. Fentanyl has a shorter duration of action than the others but works quickly and produces less side effects such as pruritus and vasodilatation. These features make it an ideal drug to use for short, painful procedures, such as debriding a burn or inserting a chest tube to relieve a pneumothorax.

Opiate analgesics can be given by bolus injection or by continuous infusion. If doses will be given periodically by an IV line, advocate for the use of an intermittent infusion device to avoid repeated venipunctures with each dose or the need for a confining IV line to be in place. If a child's pain is frequent or constant so a continuous IV line is necessary, advocate for a patient-controlled pump to offer the child a sense of control and rapid analgesia. As the child becomes able to take medications by mouth, oral forms of analgesics will then be administered. When switching from IV to oral medications, be certain the oral medication is supplied in an equianalgesic dose.

All opioids have the potential to decrease respiratory rate. Other side effects include nausea, pruritus, vasodilatation, cough suppression, urinary retention, and constipation. If toxicity with opioids should occur, low-dose naloxone (Narcan), an opiate antagonist, can be administered to counteract the effects. This low dose for side effect management is a different dose than the rescue dose needed for respiratory complications.

## PATIENT-CONTROLLED ANALGESIA

**Patient-controlled analgesia (PCA)** allows a child or a parent to self-administer boluses of medication, usually opioids, with an IV medication pump (see also [Chapter 16](#)). Children as young as 5 or 6 years of age are able to assess when they need a bolus of medicine and press the button on the pump to deliver the new dose through an established IV line. Parents or a nurse are able to administer a new dose to children younger than this as long as the child is awake. Morphine is a common analgesic used for PCA administration ([Anghelescu, Faughnan, Oakes, et al., 2012](#)). The pump is set with a lockout time so that after each dose, the pump will not release further medication even if the button is pushed again; because of this, children cannot overmedicate

themselves. If pain is constant, a continuous infusion should be used so that pain relief continues even while the child sleeps. The pump can still be programmed for bolus dosing to cover episodes of increased pain.

### *QSEN Checkpoint Question 39.3*

#### **PATIENT-CENTERED CARE**

Robin, 3 years old, received analgesia intravenously. Her mother has asked the care team if she would possibly be a candidate for PCA. What advantage of PCA would the nurse discuss with this mother?

- a. The child can gain a sense of control over his or her pain.
- b. The child can have his or her pain relieved without the risk of adverse effects.
- c. The child requires less nursing care in order to have his or her pain relieved.
- d. The child's pain will change from acute pain to chronic pain.

*Look in Appendix A for the best answer and rationale.*

## **CONSCIOUS SEDATION**

**Conscious sedation** refers to a state of depressed consciousness usually obtained through IV analgesia therapy (Havidich & Cravero, 2012). The technique allows a child to be both pain free and sedated for a procedure. Unlike the use of general anesthesia, protective reflexes are left intact and a child can respond to instructions during the procedure. The technique is used for painful procedures such as dental extractions, wound care, and bone marrow aspiration, as well as for magnetic resonance imaging and endoscopy, both of which require a child to lie still for a long period of time and can be potentially frightening. Drugs used for conscious sedation can be something as common as chloral hydrate or as involved as a sedative-hypnotic-analgesic combination, which relieves both anxiety and pain and depresses the child's memory of the event. In many healthcare settings, conscious sedation is administered and monitored by nurses specially prepared in the technique (Fig. 39.6).

**Figure 39.6** A nurse monitors the vital signs of a child who has received conscious sedation.

***QSEN Checkpoint Question 39.4***

**TEAMWORK & COLLABORATION**

Robin is scheduled for conscious sedation to have a repeat bone marrow aspiration. The nurse's colleague will accompany Robin and her mother to the procedure, and the nurse will subsequently join them and the other members of the care team. How should the nurse instruct colleagues to explain conscious sedation to Robin?

- a. "You'll be given a special medicine to knock you out."
- b. "I'll give you some medicine, but you will still be awake and feel everything."
- c. "Conscious sedation is an analgesic, not an anesthetic, method of pain relief."
- d. "I'll give you medicine so you'll be very sleepy but can still talk to me."

*Look in Appendix A for the best answer and rationale.*

**INTRANASAL ADMINISTRATION**

Intranasal administration is becoming an attractive way to dispense medicine for children because it's easy for parents to administer and the medicine absorbs well from the nasal mucous membrane. Influenza vaccine, for example, is now available in an intranasal form (Flood, Ryan, Rousculp, et al., 2011; Wolfe & Braude, 2010).

Midazolam (Versed) is a short-acting adjuvant sedative that can be administered intranasally by nasal drops or nasal spray before surgery or procedures such as nuclear medicine scanning (Karch, 2013). Because it has a very short duration of action, it may require repeat administration. Because it has no analgesic action, an analgesic should be administered concurrently if the procedure will be painful.

**LOCAL ANESTHESIA INJECTION**

Local anesthetics stop pain transmission by blocking nerve conduction of the impulse at the site of pain. Children receive local anesthetic injections, such as lidocaine, before procedures such as bone marrow aspiration, peritoneal dialysis, or suturing of lacerations. For many children, the sight of the anesthetic needle is so frightening that they cannot listen to the assurance that the momentary needlestick will actually prevent further pain. The use of an anesthetic cream before the injection can be helpful to relieve the needlestick pain and allow the anesthetic to numb the tissues to prevent pain (Crowley et al., 2011).

## EPIDURAL ANALGESIA

**Epidural analgesia**, an injection of an analgesic agent into the epidural space just outside the spinal canal, can be used to provide analgesia to the lower chest, abdomen, and lower body for 12 to 24 hours or longer if needed. An opioid, often combined with a long-acting anesthetic, is instilled continuously or administered intermittently by a catheter into the epidural space. Children who have orthopedic or chest surgery, for example, may have an epidural catheter inserted in the operating room and then continue to receive analgesia by this method to relieve postsurgical pain (Wu & Raja, 2011). This is a very effective route of analgesia for the postoperative child in the first few days after surgery. Because it is commonly used for childbirth, it is discussed further in Chapter 16.

Some parents may be reluctant to allow this type of analgesia because they equate it with spinal anesthesia, which they know can cause severe headaches. You can assure them that an epidural needle does not enter the cerebrospinal fluid, so spinal headaches are extremely rare.

## Nonpharmacologic Pain Management for Children

Nonpharmacologic pain relief measures (often called alternative or complementary therapies) can be used either independently or as complements to pharmacologic pain relief.

### DISTRACTION

Distraction techniques aim at shifting a child's focus from pain to another activity or interest (Fig. 39.7). Blowing soap bubbles, for example, could be used during an injection to accomplish this. If oral glucose is offered to infants during painful procedures, the pain they experience appears to be significantly less (Kassab, Sheehy, King, et al., 2011). It is hypothesized that drinking glucose not only serves as a distraction technique but also activates endorphins and produces a central analgesic effect (Harrison, Beggs, & Stevens, 2012). Breastfeeding may also be used in this way but is not advised to avoid the infant making an association between breastfeeding and pain. When helping parents choose a distraction technique such as blowing soap

bubbles with their child, be certain they do not interpret “distraction” as just talking to the child or suggesting a video game to divert attention. Although these are distractions, a distraction activity must require concentration; simple distractions can allow pain to break through.

**Figure 39.7** A parent using distraction (reading a book) as a pain management technique.

## SUBSTITUTION OF MEANING OR IMAGERY

**Substitution of meaning** or guided imagery is a distraction technique to help a child place another meaning (a nonpainful one) on a painful procedure (Kline, Turnbull, & Labruna, 2010). Children are often more adept at imagery than adults because their imagination is less inhibited. This technique works well with both quick, simple procedures such as venipunctures and chronic pain. Success with this technique requires practice, however, so it may have limited application in an acute care setting. As an example, a child could imagine a venipuncture needle as a silver rocket ship probing the moon or a submarine diving under the water to escape a torpedo just in time. Be certain a child thinks of a specific image. Help the child elaborate on the image to make it more concrete each time it is used by asking questions such as “What color is the rocket ship?” “Are there stripes on the sides?” and “What does the pilot look like?” This helps the child’s mind stay on the image and not the venipuncture pain.

### *QSEN Checkpoint Question 39.5*

#### **EVIDENCE-BASED PRACTICE**

Parents who are anxious may increase anxiety in their child during a painful procedure. To investigate whether parental anxiety affected their children, Evans, Payne, Seidman, et al. (2016) conducted a study involving 80 children, ages 8 to 29 years, experiencing pain. The study sought to identify whether variables such as solicitousness or overprotectiveness of the mother had an effect on the child’s pain. The children completed questionnaires measuring their pain and their parents’

solicitousness. Maternal anxiety predicted the boys' anticipatory anxiety and pain intensity. The same results were not conclusive for girls in relation to their mother's anxiety (Evans et al., 2016).

Based on the previous study, the nurse determines which action is best when Robert has his next bone marrow biopsy?

- a. Ask his mother if she and her husband would step outside the room.
- b. Suggest his mother just nod her head but not talk during the procedure.
- c. Ask his mother how best to draw Robert's attention elsewhere.
- d. Suggest that Robert's parents avoid the words "Don't worry" when talking.

---

*Look in Appendix A for the best answer and rationale.*

---

## THOUGHT STOPPING

**Thought stopping** is a technique in which children learn to stop anxious thoughts by substituting a positive or relaxing thought in its place. As with imagery, this technique requires practice before it can be used in a painful situation. It may be most helpful in relieving anticipatory anxiety, a negative force that not only increases a pain experience during a procedure but also makes the time before it full of anxiety as well. For this technique, help children think of a set of positive things about the approaching feared procedure. For a bone marrow aspiration, for example, this might include "It doesn't take long; my father will be with me; it's important to help me get better." Whenever children start to think about the impending procedure, they should stop whatever they are doing and recite the list of positive thoughts to themselves if others are present or out loud if they are alone or only important support people are present. Children can then return to a usual activity. Every time the anxious thoughts appear, however, a child should stop and recite the list again (Curtis, Wingert, & Ali, 2012).

Thought stopping is different from merely saying "Don't think about it." because the technique does not suppress thoughts; rather, it changes them into positive ones. It also gives children a feeling of control. The secret for success is for the child to use the technique every time the disturbing, anxious thoughts appear even if, at first, such thoughts crowd in as frequently as every few minutes.

## HYPNOSIS

Hypnosis is not a common pain management technique with children but can be effective if a child is properly trained in the technique (Kuttner, 2012). For best results, a child needs to train with a therapist before anticipated pain, so at the time of the pain, the child can produce a trancelike state to effectively avoid sensing pain.

## AROMATHERAPY AND ESSENTIAL OILS

Aromatherapy is based on the principle that the sense of smell plays a significant role in overall health. When an essential oil is inhaled, its molecules are transported via the olfactory system to the limbic system in the brain. The brain then responds to particular

aromas with emotional responses. When applied externally, the oils are absorbed by the skin and then carried throughout the body. Essential oils may be able to penetrate cell walls and transport nutrients or oxygen to the inside of cells. Jasmine and lavender are oils thought to be responsible for relieving pain (Miller, Jacob, & Hockenberry, 2011).

## **MAGNET THERAPY**

Magnet therapy is based on the belief that magnets can control or shift body energy lines to restore health or relieve pain. Magnets can be applied as jewelry or sewn into clothing or shoes. Although many people find relief from magnet therapy, the relief may be more of a placebo effect than an actual change in pain level (Lee & Raja, 2011). Copper also is believed to have pain-relieving ability and is often incorporated into rings and bracelets for this reason.

## **MUSIC THERAPY**

The use of music for calming or improving well-being can be effective for all ages of children or adolescents, even as young as preterm infants. It works to relieve pain because it can be relaxing and also serves as a distraction (Nguyen, Nilsson, Hellstrom, et al., 2010). A child who is “blasting” music from a phone or iPad may not actually enjoy hearing the music that loud but needs that level of distraction to feel free of pain.

## **YOGA AND MEDITATION**

Yoga, a term derived from the Sanskrit word for “union,” involves a series of exercises that were originally designed to bring people who practice it closer to spirituality. It offers a significant variety of proven health benefits, such as increasing the efficiency of the heart, slowing the respiratory rate, lowering blood pressure, promoting relaxation, reducing stress, and allaying anxiety. Exercises consist of deep-breathing exercises, body postures to stretch and strengthen muscles, and meditation to focus the mind and relax the body. Yoga may be helpful at reducing pain through its ability to create total relaxation and possibly through distraction or the release of endorphins (Evans, Moieni, Sternlieb, et al., 2012).

## **ACUPUNCTURE AND ACUPRESSURE**

Acupuncture involves the insertion of needles into critical positions (meridian lines) in the body to achieve pain relief (Chiou & Nurko, 2010). Acupressure involves applying deep pressure at the same points. Although acupuncture is almost painless, children can be very afraid of it at first because of the sight of the needles. This level of stress can make it not as attractive an option for pain management with children as acupressure. Children who consent to either technique, however, particularly those with chronic pain, report that the overall process is pleasant and the method offers relief from stress (Das, Nayak, & Margaret, 2011).

## CRYSTAL OR GEMSTONE THERAPY

Some people believe gemstones or crystals have healing powers when they are arranged in certain positions around the body. If these are being used, be careful when changing bedding or rearranging equipment in a child's room that you do not tip them over or move them. A child may feel they may lose their pain-relieving powers if placed in a different position (Zuzak, Bonková, Careddu, et al., 2013).

## HERBAL THERAPIES

Specific herbs are frequently used for relieving pain or for generally improving children's health. Some examples include chamomile tea (inflammation reduction), garlic (anti-inflammatory reduction, anticancer prevention), ginger (nausea or vomiting reduction), goldenrod (urinary tract inflammation reduction), or peppermint (abdominal pain relief) (Hunt & Ernst, 2011). Always ask when taking health histories if a child is being given any herbs to be informed about common herbs and to be certain what the child is receiving will complement, and not interfere with, the effects of prescribed pain medication.

## BIOFEEDBACK

Biofeedback is based on the theory people can regulate internal events such as heart rate and pain in response to a stimulus (Myrvik, Campbell, & Butcher, 2012). A biofeedback apparatus is used to measure muscle tone or the child's ability to relax. Biofeedback can be effective with adolescents but is less effective with school-age and younger children because they tend to resist the biofeedback information or cannot concentrate for long enough for training to be optimal. Although some children grasp the technique in one demonstration session, most need to attend several sessions to condition themselves to adequately regulate their pain response.

## THERAPEUTIC TOUCH AND MASSAGE

Massage is the use of rubbing or kneading of body parts to aid circulation and relax muscles. Therapeutic touch is the use of touch to provide comfort and relieve pain (Hall, 2012). Therapeutic touch is based on the principle that the body contains energy fields. When these are plentiful and arranged correctly, they lead to health; when they are in lesser supply, ill health results. Although therapeutic touch may serve as a form of distraction, proponents believe it is possible to redirect energy fields to increase the supply and the release of endorphins.

## TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION

**Transcutaneous electrical nerve stimulation (TENS)** involves applying small electrodes to the dermatomes that supply the body portion where pain is experienced (Ali, Drendel, Kircher, et al., 2010). When children sense pain, they push a button on a

control box, which then delivers a small electrical current to the skin. The principle underlying this technique is the same as rubbing an injured part or acupuncture—the current interferes with the transmission of the pain impulse across small nerve fibers.

TENS can be used to manage either acute or chronic pain. Some children (and parents) dislike TENS therapy because they are nervous about the electric current. Assure them that the current is a very mild one and will not harm their child. TENS is not recommended if the child is incontinent or has a wound that is likely to cause the electrodes to get wet. Skin should also be monitored for irritation from the TENS pads.

## HEAT OR COLD APPLICATION

Cold reduces pain by constricting capillaries and therefore reducing vessel permeability and edema and pressure at an injured site. After the first 24 hours of an injury, applying heat may be more helpful because this dilates capillaries, increases blood flow to the area, and again helps reduce edema.

### *QSEN Checkpoint Question 39.6*

#### **QUALITY IMPROVEMENT**

The algorithm on the pediatric unit for addressing pain in children includes teaching Robin guided imagery to help reduce pain. What is the rationale for using this technique to manage children's pain?

- a. Children's pain is generally not as acute as that of adults.
- b. IV pain relief is poorly distributed in children.
- c. Children's imaginations are at their peak in life.
- d. Children are typically more relaxed than adults.

*Look in [Appendix A](#) for the best answer and rationale.*

## Ongoing Pain Relief

Because of early discharge and the increased use of ambulatory surgery, many children return home on a pain management routine. Be certain children (and parents) are provided with support and follow-up to the extent necessary to continue adequate pain management in the home. Otherwise, the lack of pain relief at home can be overwhelming.

Either oral or IV analgesia can be administered by parents in a home setting. Be certain that parents have instructions on dosing, administration, frequency, expected outcomes, and expected level of relief. Provide them with the name and telephone number of a healthcare professional whom they can call if they have questions about pain management (Johnston, Barrington, Taddio, et al., 2011).

### *What If... 39.4*

**The nurse is interested in exploring one of the 2020 National Health Goals related to pain management and children (see Box 39.1). Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Harvey family and that would also advance evidence-based practice?**

## **KEY POINTS FOR REVIEW**

- Many children and infants are undermedicated for pain relief because of common misperceptions by healthcare personnel, such as infants do not feel or remember pain. Infants do experience pain and so need pain management the same as all other groups.
- Inviting parents and the child, if preschool age or older, to participate in assessment and pain management is an important aspect of pain therapy. It not only helps in planning nursing care that meets QSEN competencies but also best meets the family's total needs.
- Pain in children is best assessed by means of a standardized self-report tool such as the Poker Chip or Wong-Baker FACES Pain Rating Scale tools. Without self-report forms, both nurses and parents may underestimate children's pain.
- Many nonpharmacologic pain relief measures such as imagery, distraction, and TENS are available for children based on the gate control theory of pain management.
- Many children benefit from a combination of nonpharmacologic and pharmacologic methods of pain management such as an oral analgesic followed by a distraction technique.
- Anesthetic cream to help dull the pain of injections or other brief procedures can be helpful to allow for suturing or venipunctures. Think ahead to use these because a child has to wait 30 to 60 minutes to feel the anesthetic effect.
- Few analgesics are administered intramuscularly to children. For acute pain, IV administration has become the method of choice. PCA, a technique that gives a child a sense of control, can be used effectively with children.
- Conscious sedation is useful with potentially frightening procedures. With this, protective reflexes are left intact, and the child can respond to instructions during the procedure.

## **CRITICAL THINKING CARE STUDY**

Robert is a full-term male newborn. His parents are considering circumcision but are unsure of the procedure and the level of pain it will cause. Robert is a healthy newborn with no health issues that would contraindicate the procedure.

1. Suppose the doctor who comes to circumcise Robert doesn't like to use an

anesthetic for the procedure because it requires additional time. “I’ve done over a thousand of these,” she tells you. “Not one complained to me afterward about how much it hurt.” Because she supervises the births of only a few babies a year at your healthcare facility, would you try to change her opinion?

2. Suppose your healthcare setting policy requires an anesthetic cream to be used. What could you do for comfort for Robert over and above that?
3. Nurses often sit on institutional review boards (IRBs) to approve research protocols to be certain research respects patient safety and well-being. If you were a member of a hospital IRB, would you approve a study to investigate whether a new anesthetic cream or a placebo caused less pain in newborns having circumcisions?

UNIT 7

The Nursing Role in Restoring and  
Maintaining the Health of Children and  
Families With Physiologic Disorders

## Nursing Care of a Family When a Child Has a Respiratory Disorder

*Michael is a 6-year-old who is brought to the emergency department by paramedics who responded to an emergency call by his parents. The child is in respiratory distress, with obvious retractions, and he appears anxious. His parents say he has asthma and was petting a dog, to which he has a known allergy. He had several treatments with his rescue inhaler but is not improving. Michael is diagnosed with an asthma exacerbation and is treated in the emergency department.*

*Previous chapters described the growth and development of well children. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur when children develop respiratory disorders.*

**What emergency care does Michael need?**

### KEY TERMS

**adventitious breath sounds**  
**aspiration**  
**atelectasis**  
**clubbing**  
**cyanosis**  
**expiration**  
**hypoxemia**  
**hypoxia**  
**inspiration**  
**paroxysmal coughing**  
**percussion**  
**pneumothorax**  
**rales**  
**retractions**  
**steatorrhea**  
**stridor**  
**tachypnea**

tracheostomy  
tracheotomy  
vibrations  
wheezing

## OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe common respiratory disorders in children.
2. Identify 2020 National Health Goals related to children with respiratory disorders that nurses can help the nation achieve.
3. Assess a child with a respiratory disorder.
4. Formulate nursing diagnoses related to respiratory disorders in children.
5. Identify expected outcomes that address the priority needs of a child with a respiratory disorder to help him or her manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care for a child with a respiratory disorder.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of respiratory disorders in children with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to achieve quality maternal and child health nursing care.

Respiratory disorders are among the most common causes of illness and hospitalization in children (Witt, Weiss, & Elixhauser, 2014). Respiratory disorders range from minor illnesses, such as a viral upper respiratory tract infection (a common cold), to life-threatening respiratory tract disease. Because the level of acuity can change quickly, respiratory deterioration or compromise must be recognized and be responded to immediately.

Because respiratory disorders are such a common cause of childhood illness and hospitalization, 2020 National Health Goals have been established for children with respiratory illnesses (Box 40.1).

### BOX 40.1

#### Nursing Care Planning Based on 2020 National Health Goals

Because reducing the incidence of respiratory illness in children could greatly reduce

the number of emergency room visits and school days missed, a number of 2020 National Health Goals focus on respiratory illness prevention:

- Reduce hospitalizations for asthma in children under 5 years of age from a baseline of 41.4 out of 10,000 children to a target level of 18.1 out of 10,000 children.
- Reduce invasive pneumococcal infections in children younger than 5 years from 20.3 out of 100,000 children to 12.0 out of 100,000 children.
- Reduce the number of courses of antibiotics prescribed solely for the common cold from 1,728 out of 100,000 children to 864 out of 100,000 children.
- Increase the proportion of children 6 months to 2 years of age who are immunized yearly against seasonal influenza from 25% to 80%.
- Increase the proportion of children 2 to 4 years of age who are immunized yearly against seasonal influenza from 23% to 80% ([U.S. Department of Health and Human Services, 2010](#); see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help achieve these goals by teaching children ways to help avoid respiratory infections. Prevention strategies may include good hand washing and maintaining up-to-date immunizations.

### *Nursing Process Overview*

## FOR A CHILD WITH A RESPIRATORY DISORDER

### **ASSESSMENT**

Respiratory illness can begin as early as moments after birth if a neonate has difficulty initiating a first breath or establishing regular respirations. Rating a neonate using an Apgar score can help to quickly identify a newborn who may be experiencing respiratory difficulty at this early stage.

It is important to establish both the onset and duration of the problem so that its seriousness can be determined quickly. An infant who is having difficulty feeding because of nasal congestion or a child who cannot run with other children because of shortness of breath may be having complications from a respiratory problem.

A child admitted to the hospital with a respiratory disorder is usually in an acute stage of illness. A child's condition may worsen rapidly in the first few hours until a prescribed medication, such as an antibiotic or steroid bronchodilator, begins to take effect. Nursing assessment findings that show a child is developing tachypnea or retractions may be the first indication of a child's worsening condition.

### **NURSING DIAGNOSIS**

Nursing diagnoses established for children with respiratory disorders focus both on the alteration in mechanisms of breathing and on the emotional distress such problems can create. "Ineffective airway clearance" is a common diagnostic category used in this area. The problem may be characterized through presentations such as an ineffective/absent cough, nasal flaring, excessive sputum, or **adventitious breath**

**sounds** (extra or abnormal breathing sounds) (Pascoal, Lopes, da Silva, et al., 2016).

Examples of nursing diagnoses include:

- Activity intolerance related to insufficient oxygenation
- Fatigue related to impaired gas exchange
- Fear related to inability to breathe without effort
- Impaired gas exchange related to excessive mucus production
- Impaired social interaction related to difficulty in keeping up with physical activities of peers
- Ineffective breathing pattern related to decreased energy and fatigue
- Deficient knowledge related to the need for continued treatment

### **OUTCOME IDENTIFICATION AND PLANNING**

If a child is experiencing an acute respiratory problem, the expected outcomes and plan of care will focus on supporting the child and family through prescribed therapy and keeping caregivers informed about their child's health status and response to treatment. Caregivers of children with chronic respiratory conditions need to learn how to continue therapy at home. Helping families plan exercise programs and learn proper medication administration use and techniques are important nursing activities. Parents also need to understand that their approach to these programs must change as their child grows older. For example, with an infant, parents simply need to perform the prescribed procedures. As a child gets older, play can be incorporated to increase the child's engagement in and compliance with respiratory treatments. Adolescents should be involved in their own plans of care to increase compliance and engagement that are appropriate for their developmental level. School needs to be considered, developing plans of care that take into consideration the available resources (i.e., school nurses) and potential limitations posed by the school day.

### **IMPLEMENTATION**

Collaborative nursing interventions in the care of a child with respiratory dysfunction include suctioning to remove respiratory secretions, administering oxygen, and providing humidification. Various independent nursing interventions may be beneficial:

- Placing a child in an upright position to help the child cough more effectively and maintain a comfortable position
- Suctioning to remove nasal secretions
- Providing an interesting game to teach a child the importance of strengthening chest muscles
- Supporting a child and family through the anxiety created when a child is not breathing normally
- Teaching parents of a child with chronic respiratory dysfunction the basics of respiratory treatments such as percussion or chest physiotherapy techniques

All of these interventions require sound nursing judgment and skill to carry out or teach effectively.

## OUTCOME EVALUATION

An acute respiratory illness can be extremely frightening for parents as well as the child. Support, reassurance, and education are important components in successful home management.

Expected outcomes for a child with chronic respiratory disease will change as a child grows and develops and may be dependent on the diagnosis and prognosis of their illness. No matter what the specific concerns are, however, evaluation should always include examination of how well an individual child and his or her family as a whole have adapted to managing the limitations imposed by the disorder while maintaining a lifestyle that fosters growth and development for all family members.

Examples of expected outcomes that would indicate achievement of goals include:

- Infant, at 3 months of age, maintains respiratory rate of at least 30 breaths/min.
- Child describes a simplified program of school activities he or she will maintain to reduce fatigue.
- Child lists steps he or she will take if breathing becomes impaired while at school.
- Parents demonstrate correct techniques for performing respiratory therapy at home.
- For the allergic/asthmatic child, the child's pulse oximetry is maintained at 94% or above with minimal wheezing.

## Anatomy and Physiology of the Respiratory System

The respiratory system can be separated into two divisions: the upper respiratory tract, composed of the nose, paranasal sinuses, pharynx, larynx, and epiglottis, and the lower tract, composed of the bronchi, bronchioles, and alveoli. Through **inspiration** (breathing in), the respiratory system delivers warmed and moistened air to the alveoli, transports oxygen across the alveolar membrane to hemoglobin-laden red blood cells, and allows carbon dioxide to diffuse from red blood cells back into the alveoli. Through **expiration** (breathing out), carbon dioxide-filled air is discharged to the outside. Levels of oxygen and carbon dioxide in the lungs, blood, and body cells are shown in [Figure 40.1](#).

**Figure 40.1** Partial pressure of gas (millimeter of mercury [mmHg]) as measured in peripheral and systemic circulation. Because of the differences in partial pressure of the gases in the different areas,  $O_2$  moves from alveoli to pulmonary capillaries (i.e., the gas moves from the area of greater concentration to one of a lesser concentration). When it reaches the tissue capillaries,  $O_2$  partial pressure in cells is less, so  $O_2$  goes into the tissues and  $CO_2$  moves out.

## RESPIRATORY TRACT DIFFERENCES IN CHILDREN

Because the respiratory tract continues to mature during childhood, children have several important differences in respiratory anatomy and physiology from adults. The ethmoidal and maxillary sinuses are present at birth, but the frontal sinuses (the sinuses most frequently involved in sinus infection) and the sphenoidal sinuses do not develop until 6 to 8 years of age. Because there is such rapid growth of lymphoid tissue, tonsillar tissue becomes normally enlarged in early school-age children.

An infant's airway is shaped like a funnel, with the narrowest portion at the cricoid

cartilage rather than the vocal cords, as in an adult. The airway is narrower than in adults, increasing resistance if obstruction or swelling occurs, even with only small changes in the airway diameter. Infants have large occiputs when compared with an adult, which can obstruct the airway. Lying flat can put their head in a flexed position. Their tongues are large in proportion to the mouth and can more easily obstruct the airway. Infants have small nares and are obligate nose breathers until around 6 months of age. Therefore, nasal obstruction can contribute to significant respiratory distress.

The airway structures have greater laxity because of underdeveloped cartilage in the airway and a compliant chest wall that can contribute to airway obstruction and collapse.

A smaller amount of smooth muscle in the airway means that an infant does not develop bronchospasm as readily as an older child or adult. Therefore, **wheezing** (the sound of air being pushed through constricted bronchioles) may not be a prominent finding in infants even when the lumen of the airway is severely compromised.

## Assessing Respiratory Illness in Children

An assessment of respiratory illness in children includes history taking, physical examination, and possible laboratory testing. If the child is in acute distress, the interview and health history may cover only the most important details: when the child first became ill and what symptoms are present. It is important, however, to get as accurate a picture as possible because the problem could be the result of a variety of circumstances (Box 40.2).

BOX 40.2

### Nursing Care Planning Using Assessment

#### ASSESSING A CHILD FOR SIGNS AND SYMPTOMS OF RESPIRATORY DYSFUNCTION

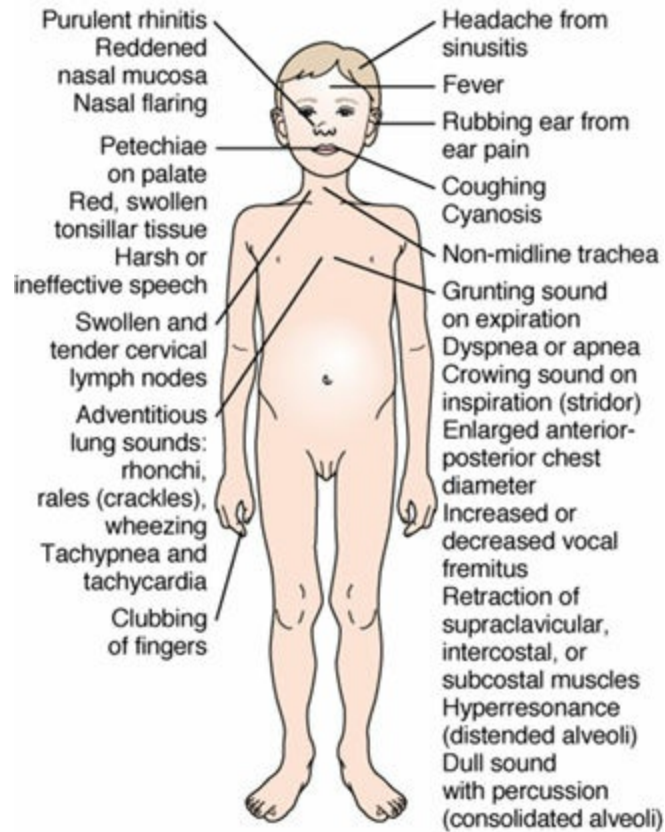

### History

*Chief concern:* Cough, rapid respirations, noisy breathing, rhinitis, reddened sore throat, lethargy, cyanosis, difficulty sucking, fever.

*Past medical history:* Poor weight gain, difficulty with respirations at birth, prematurity.

*Family history:* History of family member with asthma; other family members with respiratory infection.

### Physical examination

Symptoms of **hypoxemia** (deficient oxygenation of the blood), for example, are often insidious but can present with tachypnea (increased respiratory rate), decreased alertness, and decreased activity. Inability to feed because an infant cannot suck and breathe rapidly at the same time may be one of the first signs noted in the infant. Always ask about medication or homeopathic remedies used when obtaining a nursing history (Box 40.3).

### BOX 40.3

### Nursing Care Planning to Respect Cultural Diversity

Upper respiratory illnesses occur universally, making them a concern of parents the world over. Home remedies for such illnesses vary greatly, however. Hanging garlic around a child's neck is a frequent therapy in Mediterranean countries. "Cupping" or applying pressure to the back to "draw out" an infection (which leaves red circular ecchymotic marks on the child's back) may be used in Asian cultures. Although the

therapeutic value of these remedies may not be proved, it is important to the nurse–patient and nurse–family relationships to respect family traditions unless potential harm may be caused.

## PHYSICAL ASSESSMENT

A physical assessment of a child with a respiratory disorder includes generally observing the infant or child. Is he or she interactive, consolable, limp, or pale? This is followed by assessing the work of breathing. What is the child's position? Does he or she appear anxious? Does the breathing seem fast or slow? Do you see signs of respiratory distress such as retractions, nasal flaring, grunting, or gasping for breath? Breath sounds are best heard if a child is asleep or relaxed and is best done at the beginning of the physical exam, when he or she is most likely to be calm.

### Cough

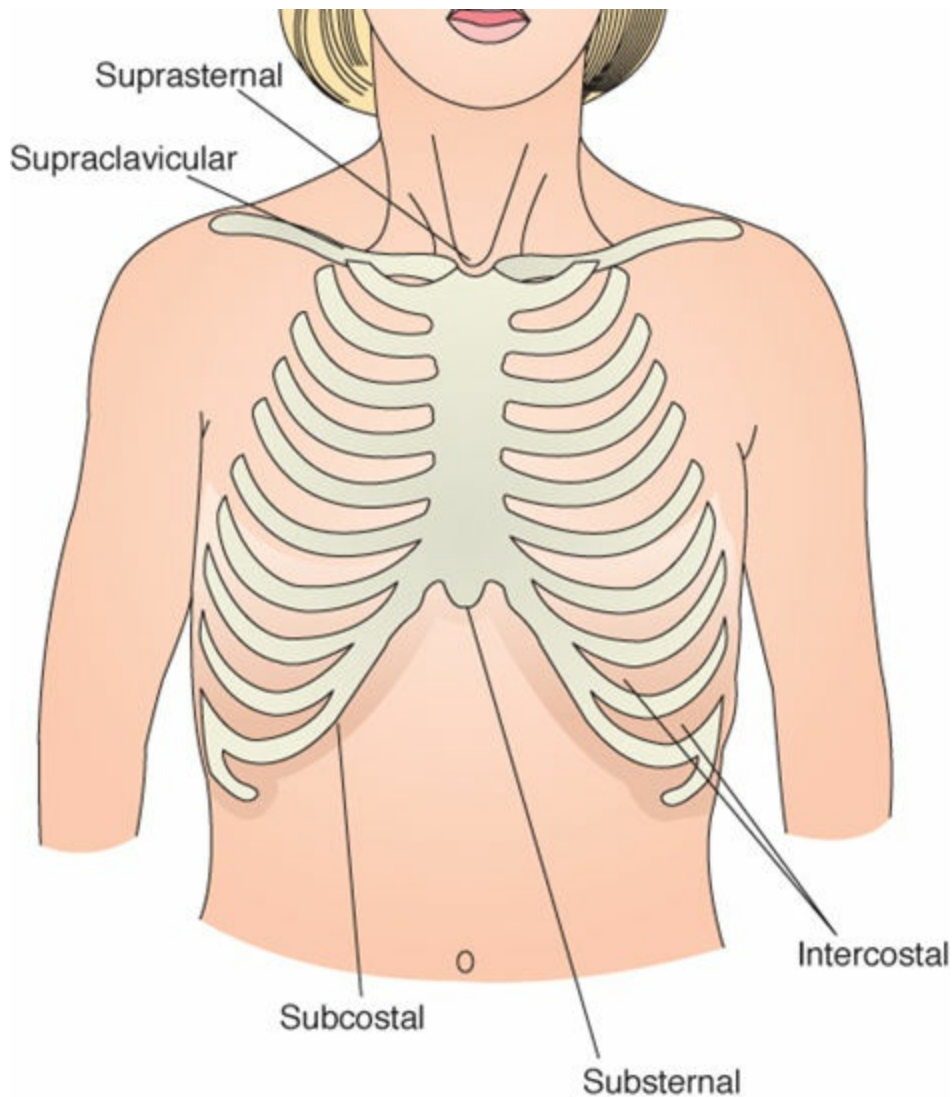

A cough reflex is initiated by stimulation of the nerves of the respiratory tract mucosa by the presence of dust, chemicals, mucus, or inflammation. The sound of coughing is caused by rapid expiratory air movement past the glottis. Coughing is a useful procedure to clear excess mucus or foreign bodies from the respiratory tract or as a response to gastric contents refluxed into the airway. **Paroxysmal coughing** refers to a series of expiratory coughs after a deep inspiration. Commonly, this occurs in children with pertussis (whooping cough) or in those who have aspirated a foreign body or a liquid they attempted to drink. Coughing can also be a symptom of underlying lung disease such as asthma or cystic fibrosis among others. Some children vomit after coughing episodes (posttussive emesis), and this may be initially attributed to a gastrointestinal illness.

### Rate and Depth of Respirations

**Tachypnea** (an increased respiratory rate) often is the first indicator of respiratory distress in young children. Assess not only the rate but also the depth and quality of respirations and other vital signs such as saturations, heart rate, and temperature.

### Retractions

When children must inspire more forcefully than normal to inflate their lungs because of an airway obstruction or stiff, noncompliant lungs, intrapleural pressure is decreased to the point that the intercostal spaces draw inward, creating **retractions** (Fig. 40.2).

**Figure 40.2** Sites of respiratory retractions.

### **Restlessness**

When children or infants have decreased oxygen in body cells (**hypoxia**), they can become anxious and restless. Be careful not to interpret the excessive movements of infants with respiratory distress as a sign that they are improving. Anxious or restless stirring may be a signal that respiratory obstruction is becoming acute or it may be one of the first signs of airway obstruction.

### **Cyanosis**

**Cyanosis** (a blue tinge to the skin) can indicate hypoxia. If children have a low unoxygenated red blood cell count (below 5 g/100 ml), cyanosis may not be apparent because there are not enough unoxygenated red blood cells to give the arterial blood its blue tinge. The degree of cyanosis present, therefore, is not always an accurate indication of the degree of airway difficulty.

Children increase respiratory effort in an attempt to supply more oxygen to tissues.

## Clubbing of Fingers

Children with chronic respiratory illnesses can develop **clubbing** of the fingers, a change in the angle between the fingernail and nail bed because of increased capillary growth in the fingertips (Fig. 40.3). The increased capillary growth occurs as the body attempts to supply more oxygen routes (more capillaries) to distal body cells.

**Figure 40.3** Clubbing of the fingers. (*Left*) The angle between the nail and digit is normally about 20 degrees in a child. (*Center*) Flattened angle represents early stage of clubbing. (*Right*) In advanced clubbing, the nail is rounded over the end of the finger. Note also that the distal phalanx is bulbous and of greater depth than the proximal portion of the finger (interphalangeal depth).

## Adventitious Sounds

Normal breath sounds are reviewed in [Chapter 34](#). Pathologic conditions cause adventitious breath sounds (extra or abnormal breathing sounds), which can be heard on lung assessment in children with respiratory disorders.

The **vibrations** produced as air is forced past an obstruction, such as mucus in the nose or pharynx, cause a snoring sound (*rhonchi*). If the obstruction is at the base of the tongue or in the larynx, a harsher, strident sound on inspiration (**stridor**) occurs. If an obstruction is in the lower trachea or bronchioles, an expiratory whistle sound (*wheezing*) occurs. If alveoli become fluid filled, fine crackling sounds (**rales**) are heard. Diminished or absent breath sounds occur when the alveoli are so fluid filled that little or no air can enter them.

## Chest Diameter

With chronic obstructive lung disease, children may be unable to exhale completely, thus allowing air to be chronically trapped in lung alveoli (hyperinflation). This produces an elongated anteroposterior diameter of the chest, sometimes termed a “pigeon breast.” There is an accompanying tympanic or hyperresonant (loud and hollow) sound heard on percussion (see later discussion on chest physiotherapy) over lung spaces.

## LABORATORY TESTS

Several laboratory tests can be used to confirm or rule out the presence of a respiratory

disorder and to help identify the cause and severity of the problem. These may include an analysis of arterial blood gases (Box 40.4), radiographs, nasopharyngeal culture, pulmonary function testing, or sputum analysis.

#### BOX 40.4

### A Quick Assessment of Arterial Blood Gases

Use a systematic format to assess arterial blood gases (ABGs) quickly:

1. Evaluate the pH: Normally, pH falls between 7.35 and 7.45. A pH below 7.35 denotes acidemia; one above 7.45 reflects alkalemia. If the patient has more than one acid–base imbalance at work, the pH identifies the process in control.
2. Evaluate  $\text{PCO}_2$ : The partial pressure of arterial  $\text{CO}_2$  ( $\text{PCO}_2$ ) normally ranges between 35 and 45 mmHg. A  $\text{PCO}_2$  greater than 45 mmHg indicates ventilatory failure and respiratory acidosis from  $\text{CO}_2$  accumulation. A  $\text{PCO}_2$  less than 35 mmHg indicates alveolar hyperventilation and respiratory alkalosis.
3. Evaluate  $\text{HCO}_3^-$ : A bicarbonate ( $\text{HCO}_3^-$ ) less than 22 mEq/L or a base excess (BE) less than  $-2$  mEq/L denotes metabolic acidosis. A bicarbonate level greater than 26 mEq/L or a BE greater than 2 mEq/L reflects metabolic alkalosis. If the two measurements conflict, the BE is the better indicator of metabolic status.
4. Determine which is the primary and which is the compensating disorder: Often, two acid–base imbalances coincide; one is primary, the other is the body’s attempt to return the pH to normal. When both the  $\text{PCO}_2$  and the  $\text{HCO}_3^-$  are abnormal, one denotes the primary acid–base disorder and the other denotes the compensating disorder.
  - a. To decide which is which, check the pH. *Only a process of acidosis can make the pH acidic; only a process of alkalosis can make the pH alkaline.* For example, if steps 2 and 3 indicate that the patient has respiratory acidosis and metabolic alkalosis and the pH is 7.25, the primary disorder must be respiratory acidosis. The remaining disorder is compensating for the primary problem.
  - b. When pH rises (becomes alkalotic),  $\text{PCO}_2$  decreases in amount (will be below 35 mmHg). When pH decreases (becomes acidotic),  $\text{PCO}_2$  increases (will be above 45 mmHg). When an opposite problem exists this way (pH increased;  $\text{PCO}_2$  decreased), the problem is respiratory in origin.
  - c. pH and  $\text{HCO}_3^-$  normally move in the same direction (when pH is elevated,  $\text{HCO}_3^-$  is elevated). When these two measurements correspond this way (pH decreased,  $\text{HCO}_3^-$  decreased), then the cause of the problem is metabolic in origin.
  - d. Three states of compensation are possible: *noncompensation*, reflected in an alteration of only  $\text{PCO}_2$  or  $\text{HCO}_3^-$ ; *partial compensation*, in which both  $\text{PCO}_2$  and  $\text{HCO}_3^-$  are abnormal and, because compensation is incomplete, the pH is

also abnormal; and *complete compensation*, in which both  $\text{PCO}_2$  and  $\text{HCO}_3^-$  are abnormal but, because compensation is complete, the pH is normal. To identify the primary disorder when compensation is complete, consider a pH between 7.35 and 7.40 indicative of primary acidosis and a pH between 7.40 and 7.45 indicative of primary alkalosis.

5. Evaluate oxygenation: Normally,  $\text{PO}_2$  remains between 80 and 100 mmHg. A  $\text{PO}_2$  between 60 and 80 mmHg reflects mild hypoxemia; between 40 and 60 mmHg, moderate hypoxemia; and below 40 mmHg, severe hypoxemia.
6. Interpret the findings: Your final analysis should include the degree of compensation, the primary disorder, and the oxygenation status (e.g., “partially compensated respiratory acidosis with moderate hypoxemia”).

### Pulse Oximetry

Pulse oximetry ( $\text{SpO}_2$ ) is a noninvasive technique for estimating arterial oxygen saturation ( $\text{SaO}_2$ ) either as a single measurement or via continuous monitoring. For the measurement, a sensor and a photodetector are placed around a vascular bed, most often a finger for a child or a foot for an infant (Fig. 40.4). Infrared light is directed through the finger from the sensor to the photodetector. Because hemoglobin absorbs light waves differently when it is bound to oxygen than when it is not, the oximeter can estimate the degree of oxygen saturation ( $\text{SaO}_2$ ) (Fig. 40.5) in the hemoglobin.

**Figure 40.4** Types of pulse oximetry probes include (A) infant continuous, (B) finger continuous, and (C) finger intermittent.

**Figure 40.5** The oxyhemoglobin dissociation curve.

One advantage of pulse oximetry is that it is noninvasive. A second advantage is that the continuous monitoring provided by a pulse oximeter allows you to modify your care appropriately. If an oxygen saturation level begins to fall while you are handling an infant, for example, you could immediately stop care until the infant's  $SpO_2$  again returns to normal. Inaccurate pulse oximetry readings can occur because of excess ambient light in the room, dark skin pigmentation, tissue perfusion, the child's movement, and various medical conditions. It is important to remember to always monitor a child's clinical condition, as normal pulse oximeter readings do not exclude the possibility of gas exchange problems or inadequate ventilation (Chan & Chan, 2013).

Pulse oximetry screening is recommended for all newborns prior to hospital discharge in order to increase the early detection of critical congenital heart disease.

**QSEN Checkpoint Question 40.1**

**EVIDENCE-BASED PRACTICE**

Epistaxis is a common condition encountered in pediatrics in children over the age of 2 years. Nasal infection and inflammation can be a common cause. Neoplasms and hematologic conditions are less common. In the initial assessment, if the child's

airway, breathing, circulation, and neurologic status are normal and there is no trauma, treatment can be provided at home. Just like with a wound that involves bleeding, pressure on the area will facilitate clotting and prevent further bleeding. Blood allowed to enter the stomach will most likely cause vomiting (Record, 2015). Improper home care can lead to continued epistaxis or repeated episodes.

Michael, a 6-year-old, has a nosebleed, and his parents cannot get it to stop. It has been on and off for the past 30 minutes. The child has congestion and a history of seasonal allergies. The parents have called their pediatric provider for assistance, and the advice nurse answered the call. Which action by nurse is best?

- a. Advise the parent to pinch the lower part of the nose (alae nasi) for 10 minutes without releasing pressure.
- b. Have Michael lean his head back to allow the blood to drain down the back of the throat.
- c. Have Michael blow his nose to remove any congestion and clotted blood.
- d. Have Michael stop the bleeding with ice packs applied to the face.

---

## Nasopharyngeal Culture

When done efficiently, nasopharyngeal cultures can provide valuable information about the microorganisms causing a disease. However, most children are terribly frightened by having something placed in their noses or throats and so may resist accordingly. Firm, calm support during the procedure is essential. Nose and throat cultures can reveal only the organisms present in the upper respiratory tract. As a result, they may not show organisms causing a lower respiratory tract infection. A throat culture will miss pathogenic organisms if the culture tip is not touched to the infected aspect of the pharynx.

## Sputum Analysis

Because they cannot raise sputum with a cough, sputum collection is rarely feasible in children younger than school age, unless collected from an artificial airway or tracheostomy tube. Older children, however, are able to cough and expectorate sputum. Teach them exactly what you want (a specimen of what they are coughing up, not just clearing from the back of their throat). Then, ask them to breathe in and out several times, cough deeply, and spit mucus they have raised into a sterile specimen container.

## DIAGNOSTIC PROCEDURES

In addition to cultures, several other diagnostic procedures are used to identify respiratory disorders in children. Many of these procedures are also used with adults, with modifications to account for the physical and developmental differences of children. Bronchoscopy (visualization of the bronchi through a bronchoscope) is discussed in Chapter 37.

## Chest Radiograph

Chest X-rays will show areas of infiltration or consolidation in the lungs; if a foreign body is opaque, an X-ray study will show its location. Chest X-rays are more limited in infants than in older children because infants cannot take a breath and hold it when instructed. It is therefore difficult to picture the lungs at their most expanded position. Many other modalities are available for evaluation of the respiratory tract, such as computed tomography (CT) and magnetic resonance imaging (MRI). Many factors need to be considered when deciding on other modalities, including cost, availability, and risks, such as the high amount of radiation exposure with CT and the potential need for sedation with MRI.

## Pulmonary Function Studies

The process of ventilation, or the work of breathing, involves three main forces: (a) an inertial force that must be overcome to change the speed and direction of air when the lungs change from exhalation to inhalation, (b) an elastic force to help the lungs expand with inhalation, and (c) the flow resistance force or resistance to the movement of air through the bronchial tree that must be overcome. Flow resistance must be at a minimum for best ventilation. It becomes increased when the bronchioles are narrowed or plugged with mucus. Pulmonary function tests measure the forces of inertia, elasticity, and flow resistance.

The alveoli of the lungs are never completely empty at the end of expiration because as the bronchioles collapse, they trap a residual amount of air in the alveoli. In contrast, alveoli are never completely filled on inspiration because their potential for expansion exceeds that necessary for good respiratory function. Children with obstructive respiratory conditions such as asthma or bronchiolitis have some difficulty moving air into the lungs, but they have even more difficulty moving air out of the lungs so greatly expand the size of the alveoli. Even if they do expire the same amount of air as the average child, they expire it over a longer period. Children with restrictive ventilatory disorders, such as neuromuscular disorders, have equal difficulty with inspiration and expiration.

Several lung capacity studies can be done to determine the degree of obstruction or restricted ventilation ability. For these studies, the child breathes into a spirometer, a device that records the force of air exchange.

Children younger than 6 years of age are usually unable to participate in pulmonary function tests because these tests require their cooperation and understanding of the test in order to get accurate results. This limits its use in young or early school-age children. Spirometry is the most common test of lung function in children and can be done in an office or specialty setting. It measures the amount of air that can be forced out of the lungs (peak expiratory flow) in a forceful breath. Peak flow is often measured using a handheld device (peak flow meter) and is a common way to measure respiratory impairment in the office and at home. It is commonly used in children with asthma to

assess impairment.

## Health Promotion and Risk Management

Several ways to promote respiratory health are available for parents and children. The common cold is the most frequent respiratory disorder seen in children and is spread through families easily. Teach children as young as toddlers to help avoid spreading colds by washing their hands, properly disposing of tissues, and blocking a cough by their shirt. Yearly influenza vaccination is recommended for all infants 6 months of age and older, ideally prior to the onset of active influenza in the community. Reducing respiratory irritation by reducing exposure to secondhand smoke can help prevent upper respiratory infections and can reduce the incidence of asthma attacks as well as otitis media (middle ear infections).

## Therapeutic Techniques Used in the Treatment of Respiratory Illness in Children

The primary goal of nursing interventions in the care of children with respiratory disorders is to maintain or reestablish adequate oxygenation, ventilation, and hydration. This may involve interventions aimed at clearing the airway, removing or loosening secretions. Particularly in young children, respiratory conditions may contribute to dehydration due to the inability to eat or drink due to fatigue, obstruction, or being obligate nose breathers.

### HOME TREATMENTS

Any irritation of the respiratory tract causes the production of large amounts of mucus. The amount produced can become so great that the natural mechanisms for clearing it (coughing and upward cilia action) are no longer adequate. If a child is breathing rapidly because of respiratory distress, the frequent passage of air over the mucus tends to dry it and make it more viscous, thus compounding the removal problem. Instilling saline nose drops or using saline nasal sprays can be effective at moistening and loosening dried mucus in the nose (Sylvester, Carr, & Nix, 2013).

### Humidification

Humidifiers are commonly used in homes for symptomatic relief of many common respiratory illnesses, although no research evidence supports their use. Humidifiers add moisture to a room by emitting a stream of fine droplets of water into the air, providing either a cool or a warm mist to the entire room. Caution parents when using a warm mist that a serious scald burn can result if children come into direct contact with the heated mist, so it should be kept out of a child's reach. Caution parents to clean humidifiers thoroughly after use to prevent the growth of mold and other contaminants in the

device. Humidifiers should not be used with children with asthma because this can cause symptoms to worsen.

## Inhalation Devices

Different types of inhalation devices can be used to deliver medication to the lower respiratory tract. Medication can be liquid or powder and delivered by pressure, nebulization, metered-dose inhaler, or breath actuation, depending on the illness being treated, the treatment setting, and the child's age.

Nebulizers are mechanical devices that provide a stream of moistened air directly into the respiratory tract. Most are handheld masks that fit over the nose and mouth and are attached to an electrical pump as a power source (Fig. 40.6). Metered-dose inhalers with valve holding chambers (also known as “spacers”) are at least as equally effective as nebulizers in the delivery of aerosolized medications (Mudd, Leu, Sloand, et al., 2015) and can be used with a mask or mouthpiece. Ultrasonic nebulization delivers minuscule droplets into the respiratory tract to moisten even the smallest bronchioles. Nebulizers also serve as an important means for the delivery of respiratory tract medications; medications such as antibiotics or bronchodilators can be combined with the nebulized mist and sprayed into the lungs. Young children often resist medication administration because of the need for a mask over the face. Distraction can be beneficial. It is important to monitor a child's respiratory status frequently and watch for common side effects of bronchodilators, such as tachycardia, nausea, and jitteriness.

**Figure 40.6** A child using a nebulizer. (Kleber Cordeiro/Shutterstock.com)

## Coughing

As a rule, encourage coughing rather than suppress it in children because it is an effective method of raising mucus. Changing a child's position and suggesting mild exercise or deep breathing are helpful techniques to initiate coughing. Cough and cold preparations are not recommended in children less than 6 years of age because of both the lack of evidence of their effectiveness and their potential harmful side effects.

### Mucus-Clearing Devices

A mucus-clearing device (a Flutter device) can be used to aid in the removal of mucus. This device looks like a small plastic pipe. A stainless-steel ball inside the device moves when the child breathes out, causing vibrations in the lungs (Fig. 40.7). This vibration helps loosen mucus so that it can be moved up the airway and expectorated. This device is used most frequently with children who have cystic fibrosis or pneumonia to help remove mucus from the lungs.

**Figure 40.7** (A) Flutter device. The metal ball (shown) is enclosed in the chamber and causes the vibration. (B) An adolescent using a flutter device.

### Chest Physiotherapy

Simply changing a child's position helps mucus to move, initiate a cough reflex, and be expelled and to prevent mucus from pooling in certain lung areas. If a child has a localized mucus problem, lying predominantly in one position can encourage drainage of that lung segment. When the child is repositioned and the mucus drains into new bronchi, this will often result in a cough from irritation caused by this new drainage.

Three techniques are involved with chest physiotherapy (CPT) to further loosen mucus for expectoration: postural drainage, percussion, and vibration. Each technique can be used alone, but they are usually more effective at moving mucus toward the main stem bronchus when performed together.

Although CPT is usually done by respiratory therapists, you will need to integrate the activity into care because CPT is best scheduled before meals or at least an hour after a meal so the subsequent coughing does not cause vomiting.

Common postural drainage positions for the infant are shown in Figure 40.8. An infant may be positioned on your lap, whereas a slant board or other surface is needed

for postural drainage with an older child. **Percussion** involves striking a cupped or curved palm against the chest to determine the consistency of tissue beneath the surface area. This technique causes a loud, thumping noise that sounds as if it hurts, but you can assure a child or parents it does not. In infants and some small children, a specialized device, a nipple, or a small oxygen mask may be used if the palm of the hand is too big (Fig. 40.9). These devices concentrate the motion and may increase the amount of mucus removed.

**Figure 40.8** Positions for bronchial drainage for major segments of all lobes in infants. This procedure is most readily performed with the infant in your lap, with your hand on the chest over the area to be cupped or vibrated. (A) The apical segment of left upper lobe. (B) The posterior segment of left upper lobe. (C) The anterior segment of left upper lobe. (D) The superior segment of right lower lobe. (E) The posterior basal segment of right lower lobe. (F) The lateral basal segment of right lower lobe. (G) The anterior basal segment of right lower lobe. (H) The medial and lateral segments of right middle lobe.

(I) The lingular segments (superior and inferior) of left upper lobe.

**Figure 40.9** Alternative percussion device. To assist with percussing an infant or small child, a nipple or mask such as that from a manual resuscitation bag may be used.

Vibration is done by pressing a vibrating hand against a child's chest during exhalation. Like percussion, it mechanically loosens and helps move tenacious secretions upward. Vibration also may be accomplished by a mechanical vibrator or a vibrating vest.

If a child is going to need continued CPT at home, one or both parents will need to learn the technique before their child is discharged so that it can be continued conscientiously. The technique is used most frequently with children with bronchiolitis or cystic fibrosis.

#### *What If... 40.1*

**Michael needs to cough to expectorate bronchial mucus but he refuses to try to cough. What are possible ways the nurse can encourage Michael to expectorate effectively?**

## **THERAPY TO IMPROVE OXYGENATION**

Improving oxygenation almost automatically relieves breathing distress.

### **Oxygen Administration**

Oxygen administration elevates the arterial oxygen saturation level by supplying more oxygen to red blood cells through the respiratory tract.

Nasal cannulas provide a concentration of approximately 50%, with an oxygen flow of 4 L/min. Most children do not like nasal prongs or catheters because they are intrusive. Assess their nostrils carefully when using these as the pressure of prongs can cause areas of necrosis, particularly on the nasal septum.

A snug-fitting oxygen mask (non-rebreather mask) is a method for supplying nearly 100% oxygen and is used in emergencies (Fig. 40.10). Masks, like prongs or catheters, are often not well tolerated by children because they tend to slip and obstruct their view.

**Figure 40.10** Types of oxygen administration include (A) simple oxygen mask, (B) nasal cannula, and (C) a rebreather mask (oxygen trapped in the bag increases the amount of oxygen available to the child).

Without proper humidification, oxygen dries mucous membranes and thickens secretions, compounding breathing difficulty. Oxygen, like any other drug, requires careful administration and a follow-up assessment. If concentrations are too low, oxygen is not therapeutic; in concentrations greater than those desired, it can be toxic. If newborns are subjected to oxygen concentrations over 100 mmHg for an extended time, retinopathy of prematurity can occur (see Chapter 26). In any child, administering oxygen concentrations of 70% to 80% for an extended period may lead to a thickening of the lung alveoli and a loss of lung pliancy (i.e., oxygen toxicity or bronchopulmonary dysplasia). For these reasons, oxygen should not be given in high concentrations for long periods without careful monitoring.

When caring for a child with any form of oxygen equipment, follow safety rules. Because oxygen supports combustion, keep open flames away from oxygen and minimize the risks of sparks. Because oxygen is humidified, the equipment is a good source of microbial contaminants and so should be changed according to your agency's policy to keep bacterial counts within safe limits.

## Pharmacologic Therapy

Children experience difficulty with exchange of air when their airways become obstructed because of unusual mucus production, bronchoconstriction, or inflammation. Several drugs may be used in children to reverse these processes. Nasal sprays such as normal saline can be administered to moisten and loosen nasal secretions. Antihistamines can reduce mucus production in the presence of allergies. Corticosteroids taken either orally or by inhalation can reduce airway inflammation. Brief use of nasal decongestants may be advised, but no data support the use of oral decongestants in children. Bronchodilators such as albuterol (Ventolin), terbutaline (Brethine), and levalbuterol (Xopenex) are examples of drugs used to open the lower airway. Antibiotics may be ordered if the illness is caused by a bacterial infection. Because so many different approaches are available to aid breathing, parents can be confused about the action of each medicine their child is prescribed. Caution them it is unsafe to give cough and cold medications to children younger than 4 years of age unless specifically prescribed by their healthcare provider because of the decreased breathing efforts these may cause ([Centers for Disease Control and Prevention, 2012](#)).

### Metered-Dose Inhalers

A metered-dose inhaler (MDI) is a handheld device that provides a route for medication administration directly to the respiratory tract. The child inhales while depressing a trigger on the apparatus. For successful use, children need to follow five general rules: shake the canister, exhale deeply, activate the inhaler and place it in their mouth as they begin to inhale, take a long slow inhalation, and then hold their breath for 5 to 10 seconds. Caution them to take only one puff at a time, with a 1-minute wait between puffs ([Berlinski, 2017](#)). Coordinating inhalation with MDI use can be difficult; therefore, use of an aerochamber (spacer) is generally recommended to prevent deposition on the posterior pharynx ([National Heart, Lung, and Blood Institute \[NHLBI\], 2007](#)) ([Fig. 40.11](#)). Younger children can use an MDI attached to an aerochamber with a mask. All children using inhaled corticosteroids need an aerochamber to prevent deposition of the medication in the mucous membranes of the mouth and pharynx, which can contribute to the development of thrush.

**Figure 40.11** (A) Many children use a metered-dose inhaler to administer a bronchodilator to themselves. Be certain children respect such medicine as medicine so they use sensible precautions. (B) Children need a “spacer” with inhalers.

### Incentive Spirometry

Incentive spirometers are devices that encourage children to inhale deeply to aerate the lungs fully or to move mucus. Although manufactured in different configurations, a common type consists of a hollow plastic tube containing a brightly colored ball or dome-shaped disk that will rise in the tube when a child inhales through the attached mouthpiece and tubing. The deeper the inhalation, the higher the ball rises in the tube.

Children need instruction on how to use this type of device because their first impression is that they should blow out against the mouthpiece rather than inhale (Fig. 40.12A). Incentive spirometry can be very effective with children because the device and procedure resemble a game more than an actual treatment.

**Figure 40.12** (A) Incentive spirometry is an appealing method to encourage children to aerate their lungs. (B) Encouraging children to

take a deep breath and try to blow a cotton ball across the table is also an entertaining way to help them fully expand their lungs.

## Breathing Techniques

Some children need exercises prescribed to help them better inflate or more fully empty alveoli. Blowing a piece of cotton or a plastic ball across a table, blowing through a straw, or blowing out with the lips pursed are effective techniques for better emptying alveoli (Fig. 40.12B). For best results, make these activities a game or contest rather than an exercise.

## Endotracheal Intubation

Endotracheal intubation (nasal or oral intubation) is a means of securing an airway in a child who is unable to oxygenate and/or ventilate adequately on his or her own. A tube is inserted into the trachea. The technique for this is discussed in Chapter 26, as this is the method used for newborn resuscitation. Because of risks of infection, injury, and impairment of mobility, endotracheal tubes (ETTs) cannot be left in place as a permanent solution. Children cannot speak while intubated and may need sedation. Supply those old enough to write with a pencil and paper for effective communication. Preschoolers can point to pictures to indicate what they need. Providing simple drawings or photos (a blanket, the television turned on, a urinal) to make needs known is helpful. ETTs are held in place by being taped to the face. Make sure tubes are carefully secured; otherwise, children can easily dislodge them.

ETTs may need to be suctioned using sterile technique in order to remove accumulated airway secretions. This should be done only as needed because it can have negative effects on children, including pain, infection, neurologic changes (due to increased intracranial pressure), bradycardia, and others.

A capnometer is a device that uses infrared technology and is attached to the distal end of the tube to measure the amount of CO<sub>2</sub> in exhaled breaths. By measuring the percentage of CO<sub>2</sub> in expired air, the arterial CO<sub>2</sub> (PCO<sub>2</sub>) can be estimated. This can help ensure correct placement of an ETT at the time of placement and for ongoing monitoring.

## Tracheostomy

A **tracheostomy** is an opening into the trachea to create an artificial airway. It is most often performed in infants who require prolonged ventilation but can provide a more stable airway in older children as well (Mitchell, Hussey, Setzen, et al., 2013). The procedure to create the airway is called a **tracheotomy**, and the resultant artificial airway is called the tracheostomy. Except in rare emergency situations, it is performed in a controlled setting in an operating room (Mitchell et al., 2013). Tracheostomy tubes come in different lengths and diameters (Fig. 40.13). Selection is based on a number of factors including the child's size, lung compliance, and developmental needs (such as

talking) (Mitchell et al., 2013).

**Figure 40.13** (A) Tracheostomy tubes: (*left*) a plastic tube, inner cannula, and obturator; (*right*) a plastic, cuffed tube. (B) The tracheostomy collar allows for humidification of inspired air or supplemental oxygen.

Humidification may be needed for some children and can be done with a tracheostomy collar or through the ventilator tubing, if a child needs mechanical ventilation. Parent education for tracheostomy care should start prior to placement and be reassessed prior to discharge. Tracheostomy tube ties should be used to prevent accidental dislodgment, the most common complication with tracheostomies (Mitchell et al., 2013). Stoma care is needed during the postoperative period. Cleaning is generally done with a cotton-tipped applicator and saline. Children will need

reassurance after tracheostomy tube placement.

## Suctioning Technique

Most tracheostomy tubes used with children today are plastic and have an inflatable cuff that helps to prevent dislodgment. Suctioning may be needed if secretions are seen or heard. The nurse should be prepared with appropriate equipment prior to suctioning, including a suction catheter, an appropriately sized bag-valve mask, an oxygen source, and a tracheostomy kit. Use sterile technique to prevent introducing microorganisms, although clean technique is generally taught to caregivers for home suctioning.

Tracheostomy tubes are held in place by cloth ties that fasten at the back of the child's neck. Change ties when they become soiled or loose and check them frequently to be certain they remain tied. Children may fuss with and untie such things, whereas adults will not. Assess that the ties not only fit snugly but also allow for one finger to be inserted underneath them so they do not rub and cause pain. For preschoolers or younger children, it is a good idea to cover the tracheostomy opening with a gauze square tied to the child's neck like a bib while they eat to prevent crumbs or spilled liquids from entering the tracheostomy opening.

Caution parents:

- Not to give their child small toys that could fit into the lumen of the tube and cause obstruction
- To keep the use of sprays such as room fresheners to a minimum so they won't be irritating to the exposed trachea
- To keep cold air from blowing against the tracheostomy opening because this can cause tracheal spasm (e.g., cover the child's throat with a loose fleece scarf when outside in cold weather)
- To inspect stuffed toys to be certain they are intact and do not shed (e.g., fur or stuffing could enter the tube)
- To supervise play with other children so they don't place anything in the tube. Stay with the child in the bathtub to be certain water does not splash into the tube.

When caring for children with tracheostomies, check on them frequently to assess for possible respiratory difficulty. Spend time playing with them or just sitting and rocking them so they can think of you in ways other than as the person who comes to suction them. If parents cannot stay with the child, assure them that you check on their child more frequently than what is necessary for suctioning alone, so they can feel confident if the child should have another episode of acute obstruction, someone will be nearby. If the tracheostomy tube is to be left in place after discharge from the hospital, be certain parents have enough experience with changing tubes if that will be necessary or suctioning so they can safely care for their child at home (Peacock & Stanik-Hutt, 2013).

Each child is considered individually with regard to when it is time to remove a tracheostomy tube.

Occasionally, a tracheostomy tube becomes dislodged. This can be a medical emergency in the immediate postoperative period, when the tract is not well formed, but not necessarily so after a tract is well established. Always keep a new tube and inserter (obturator) at the bedside so these are available if replacement is necessary. Slide the obturator into the tube and gently replace it in the tracheal opening. Remove the obturator and secure the new tube in place.

### Assisted Ventilation

When children cannot oxygenate and/or ventilate effectively, assisted ventilation may be necessary. Positive-pressure machines deliver moistened or nebulized air or oxygen to the lungs under enough pressure and with appropriate timing to produce artificial, periodic inflation of alveoli, and they rely on the elastic recoil of the lungs to empty the alveoli.

Noninvasive ventilation is the preferred method of ventilation with children, although if ventilation will be used for a prolonged period, children will usually require either a tracheotomy or endotracheal intubation (Fig. 40.14). Infants need a nasogastric tube inserted to prevent stomach distention from air entering the esophagus with a ventilator in place. Providing adequate nutrition may be a challenge, but enteric (nasogastric) feedings or total parenteral nutrition solves this concern. Providing a balance of rest, stimulation, and assurance for the child is a challenge for nursing personnel and parents.

**Figure 40.14** An infant with an endotracheal tube receiving assisted ventilation.

## LUNG TRANSPLANTATION

Lung transplantation is a possibility for children with a chronic respiratory illness such as cystic fibrosis (Vandemheen, Aaron, Poirier, et al., 2010). The transplant may involve a single lung or both lungs, or it can be done in conjunction with heart

transplantation if chronic respiratory disease has caused ventricular hypertrophy of the heart. The donor lung can be from a live donor or a cadaver.

As with any organ transplantation, children need continued immunosuppression therapy following a lung transplant to decrease cell-mediated immunity. Although this level of immunosuppression is the key to successful transplantation, it also makes posttransplant children susceptible to fungal, bacterial, and viral lung infections. In addition, families experience a tremendous psychosocial toll as they wait to see whether the new transplant will be rejected. With the transplanted lung in place, children may need to have CPT or use a portable spirometry device daily to help mobilize secretions resulting from loss of nerve innervation or a reaction to accumulating mucus in the transplant.

## Disorders of The Upper Respiratory Tract

The upper respiratory tract warms, humidifies, and filters the air that enters the body (Fig. 40.15). Because the structures of the upper respiratory tract constantly come into contact with a barrage of foreign organisms, including pathogens, this can lead to airway irritation and infection. Congenital malformations of respiratory structures also cause some upper respiratory tract disorders.

**Figure 40.15** Structures of the upper respiratory tract.

## CHOANAL ATRESIA

Choanal atresia is congenital obstruction of the posterior nares by an obstructing membrane or bony growth, which prevents a newborn from drawing air through the nose and down into the nasopharynx (Eladl, 2010). It may occur either unilaterally or bilaterally.

Newborns up to approximately 3 months of age are naturally nose breathers, so infants born with choanal atresia almost immediately develop signs of respiratory distress after birth as they attempt to breathe through their nose for the first time. Passing a soft #8 or #10 French catheter through the posterior nares to the stomach is a part of birthing room procedure in many healthcare facilities and confirms immediately that no atresia is present.

Choanal atresia can also be assessed by holding the newborn's mouth closed and then gently compressing first one nostril and then the other. If atresia is present, infants will struggle as they experience air hunger when their mouth is closed. Their color improves when they open their mouth to cry. Atresia is also suggested if infants struggle and become cyanotic at feedings because they cannot suck and breathe through the

mouth simultaneously.

The treatment for choanal atresia is either local piercing of the obstructing membrane or surgical removal of the bony growth. Because infants with choanal atresia have such difficulty with feeding, they may receive intravenous (IV) fluid to maintain their glucose and fluid level until surgery can be performed.

## **ACUTE NASOPHARYNGITIS (COMMON COLD)**

The common cold is the most frequent infectious disease in children. Toddlers can have as many as 10 to 12 colds a year. School-age children and adolescents have as many as 8 to 10 yearly because infection is spread so readily in classrooms. The incubation period for the common cold is typically 2 to 3 days, and most occur in the fall and winter, when respiratory viruses circulate.

Upper respiratory infections are caused by several viruses, most predominantly rhinovirus, respiratory syncytial virus (RSV), adenovirus, parainfluenza viruses, and influenza viruses. Children who are in ill health from some other cause, or who have a compromised immune system, are more susceptible than others to viral infection.

### **Assessment**

Symptoms begin with nasal congestion, a watery rhinitis, and a low-grade fever. The mucous membrane of the nose becomes edematous and inflamed, constricting airway space and causing difficulty breathing. Posterior rhinitis, plus local irritation, leads to pharyngitis (sore throat). As upper airway secretions drain into the trachea, this leads to a cough. Cervical lymph nodes may be swollen and palpable. Although fever typically lasts only a few days, respiratory symptoms generally last for about a week. Previous viral upper respiratory infections can be a precursor to development of a secondary bacterial infection in young children, such as ear infections.

### **Therapeutic Management**

No specific treatment is available for a common cold. Antibiotics are not effective against viral illnesses, unless a secondary bacterial infection is present. If a child has a fever that is causing discomfort, it can be alleviated by an antipyretic such as acetaminophen or ibuprofen. Help parents understand these drugs are effective only in controlling pain, discomfort, and fever symptoms; they do not reduce congestion or “cure” the cold. Children younger than 18 years of age should not be given acetylsalicylic acid (aspirin) because this is associated with the development of Reye syndrome, a potentially fatal neurologic disorder (see [Chapter 49](#)).

If infants have difficulty nursing because of nasal congestion, saline nose drops or nasal spray may be prescribed to liquefy nasal secretions and help them drain. Removing nasal mucus via a bulb syringe before feedings also allows infants to breathe more freely and be able to suck more efficiently.

Children’s cough and cold preparations are generally not recommended. Little

evidence indicates that oral decongestants relieve congestion to an appreciable degree with the common cold. Parents may use a cool mist vaporizer to help loosen nasal secretions if they wish. The efficiency of home vaporizers is questionable, however, and safe use of a vaporizer, including proper cleaning, must be stressed, or it can serve as a reservoir for microorganisms.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Parental health-seeking behaviors related to management of child's upper respiratory symptoms

**Outcome Evaluation:** Parents state intention to use cool mist vaporizer to loosen secretions, to encourage oral fluid, to administer an antipyretic to provide comfort, and to avoid cough medicine.

Care of the child with a cold is primarily supportive until the infection runs its course. Because they may have a loss of appetite, children may prefer simple liquids to solid food for the first few days of the illness. Parents generally ask whether children should remain on bed rest. Children characteristically restrict their activity when ill, so with acute cold symptoms, children often naturally curl up on the couch and sleep. One of the best ways parents can judge when children are improving is to note they have begun to increase their activity or are “acting like themselves” again.

A possible complication of a cold is otitis media (middle ear infection) because the common precursor for otitis media is a viral upper respiratory tract infection. Instruct parents about this possibility and the need to report symptoms suggestive of this infection, such as fussiness, irritability, sudden elevated temperature, and ear pain.

### *QSEN Checkpoint Question 40.2*

#### QUALITY IMPROVEMENT

Michael's history reveals he was born with choanal atresia. What assessment may be performed at birth to determine whether a newborn has this condition?

- Observe if the infant can breathe well while lying in a prone position.
- Close the infant's mouth and observe if he can breathe through his nose.
- Assess if the infant's palatine tonsils are blocking the back of the throat.
- Listen for the sound of either stridor or wheezing upon inhalation.

*Look in [Appendix A](#) for the best answer and rationale.*

## PHARYNGITIS

Pharyngitis is infection and inflammation of the throat. The peak incidence occurs between 5 and 15 years of age in winter and spring, with an incubation period of 2 to 5 days. It may be either bacterial or viral in origin. It may occur as a result of a chronic allergy in which there is constant postnasal discharge that results in a throat irritation.

### **Viral Pharyngitis**

The causative agent of pharyngitis is usually a virus. The symptoms are generally mild: a sore throat, fever, rhinorrhea, cough, and general malaise. On a physical assessment, regional lymph nodes may be enlarged. Erythema will be present in the back of the pharynx and the palatine arch. Exudate may or may not appear on the tonsils. Laboratory studies are generally not indicated.

If the inflammation is mild, children rarely need more than an oral analgesic such as acetaminophen or ibuprofen for comfort. By school age, children are capable of gargling with a solution such as warm water to help reduce the pain. Before this age, children tend to swallow the solution unless the procedure is well explained and demonstrated to them.

Because of throat pain, food intake may be diminished, so focus needs to be on adequate oral hydration.

### **Streptococcal Pharyngitis**

Group A  $\beta$ -hemolytic streptococcus is the organism most frequently involved in bacterial pharyngitis in children, particularly those between the ages of 5 and 15 years.

#### Assessment

Streptococcal infections are generally more severe and present more suddenly than viral infections. The back of the throat and palatine tonsils are usually markedly erythematous (bright red); the tonsils are enlarged, and there may be a white exudate in the tonsillar crypts. Petechiae may be present on the palate. A child typically appears ill, with a fever, sore throat, headache, stomach ache, and difficulty swallowing. Other respiratory symptoms are generally absent, such as cough, congestion, rhinorrhea, or conjunctivitis. A rapid antigen test and/or throat culture should be done to confirm the presence of the *Streptococcus* bacteria. These findings may vary depending on the child's age and make it difficult to distinguish it from a viral illness. Some children may develop a sandpaper-like rash (scarlatiniform rash) on the body.

#### Therapeutic Management

Streptococcal pharyngitis is treated with antibiotics, such as a penicillin or cephalosporin, along with supportive treatments such as those discussed for viral pharyngitis. Although rare, streptococcal infections can lead to acute rheumatic fever and glomerulonephritis if not treated. Antibiotic treatment may help decrease the occurrence of these diseases and shorten the duration of symptoms.

### **TEAMWORK & COLLABORATION**

Michael has had two recent streptococcal pharyngitis infections. Education on the importance of completing the full course of prescribed antibiotics is necessary to prevent which complication?

- a. Epiglottitis
- b. Dental abscesses
- c. Rheumatic fever
- d. Emphysema

*Look in Appendix A for the best answer and rationale.*

### **Retropharyngeal Abscess**

The retropharyngeal lymph nodes, which drain the nasopharynx, are located just behind the posterior pharynx wall. Although uncommon, an abscess can form in these lymph nodes and may constitute a medical emergency as it may impact the airway.

#### **Assessment**

The presentation may be a high fever, refusal to eat, and may drool because they cannot swallow saliva past the obstruction in the back of their throat. They begin to “snore” with respirations as the pharynx becomes further occluded. To allow themselves more breathing space, they may hyperextend the head, which is a very unusual position for infants.

A physical assessment may reveal swelling on one side of the neck but may require further evaluation with radiographs to further evaluate.

#### **Therapeutic Management**

IV antibiotic treatment and hospitalization is needed for these infants to monitor hydration and their respiratory status. Although some retropharyngeal abscesses will resolve with antibiotic treatment, some will need surgical drainage.

#### **Tonsillectomy**

Tonsillectomy is removal of the palatine tonsils. *Adenoidectomy* is removal of the pharyngeal tonsils. Frequent throat infections or tonsillar hypertrophy that cause breathing problems are common reasons for removal of the tonsils. Adenoids may be removed if they are so hypertrophied they cause obstruction or sleep apnea.

During a tonsillectomy, tonsillar tissue is removed by ligation or by laser surgery. Because sutures are not usually placed, the chance for hemorrhage after this type of surgery is higher than after surgery involving a closed incision. The danger of aspiration of blood at the time of surgery and the danger of a general anesthetic also compound the

risk.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for fluid volume deficit related to blood loss from surgery

**Outcome Evaluation:** Child's pulse and blood pressure remain normal for age; there is an absence of extensive bleeding; intake and output are within acceptable parameters.

Tonsillectomies are done as ambulatory or 1-day surgery following completion of a history and physical examination and laboratory tests, including bleeding and clotting times, complete blood count, and urinalysis. An important aspect of the presurgery assessment is to observe for loose teeth because, if present, these could be dislodged during surgery and aspirated. Make certain the presence of loose teeth is noted in the child's electronic record so the anesthesia provider can be aware of this.

Following surgery, observe vital signs carefully to make certain the child is not bleeding from the surgical site.

If hemorrhage should occur after tonsillectomy, it can be acute and intense. Because children swallow any blood that is oozing from the surgical site, a child can be bleeding heavily, however, and yet, little blood will be apparent. To detect if the child is bleeding, assess for subtle signs of hemorrhage, such as an increasing pulse or respiratory rate, frequent swallowing, throat clearing, or a feeling of anxiety. If you find that the surgical site is bleeding, elevate the child's head to reduce vascular pressure on the operative site and notify the child's primary care provider.

If children have no complications from surgery, are able to swallow fluids, and have voided, they are discharged later the same day of surgery. Be certain parents have received careful instructions concerning the danger signs to watch for during the first day home (e.g., frequent swallowing, clearing the throat, bleeding, increasing restlessness, severe pain). They are usually also advised to restrict their child's activity for a set period of time or until surgical follow-up (e.g., no gymnastics, no competitive sports).

**Nursing Diagnosis:** Pain related to surgical procedure

**Outcome Evaluation:** Child states level of pain is tolerable.

A tonsillectomy is an uncomfortable and painful procedure. Be certain children receive good preparation for both the procedure and for the sensations they will experience afterward. Some children develop a mild earache after surgery for the first week in addition to a painful throat, probably caused by shifting pressure on the eustachian tube.

Liquid analgesics are better tolerated than pills or tablets following surgery because they are easier to swallow. Rectal administration is a possibility for very young children. Offer instead frequent sips of clear liquid, popsicles, or ice chips. Avoid acidic and citric juices because these sting the denuded tissue. Carbonated beverages also can irritate unless they stand for a time to become “flat.” Avoid red fluid such as Kool-Aid, which, if vomited, could be mistaken for swallowed blood.

Children are then gradually advanced after 24 to 48 hours to a diet of soft foods such as gelatin, mashed potatoes, soups, and cooked fruits. Alert parents they should continue to eat only soft foods during the initial postoperative period (e.g., no toast crusts or other foods that could cause pharyngeal irritation if not chewed well). Be certain parents know whom they should call (clinic, hospital, or primary care provider) if they have a question or concern about their child’s condition or care.

## EPISTAXIS

Epistaxis (nosebleed) is extremely common in children and usually occurs from trauma, such as picking at the nose or trauma. Dry air can cause mucous membranes to become dry and be susceptible to cracking and bleeding. Nosebleeds may also occur after strenuous exercise, with hemolytic disorders, or may be associated with nasal polyps, sinusitis, or allergic rhinitis. Some families appear to show a familial predisposition to them.

Nosebleeds can be frightening. The fear, however, and the amount of blood that can be seen is generally out of proportion to the seriousness of the bleeding.

Keep children with nosebleeds in an upright position with their head tilted slightly forward to minimize the amount of blood pressure in nasal vessels and to keep blood moving forward, not back into the nasopharynx. Apply pressure to the cartilage on the sides of the nose with your fingers for about 10 minutes (Fig. 40.16). Make every effort to quiet the child and to help stop crying because crying increases pressure in the blood vessels of the head and prolongs bleeding. Discourage putting tissue in the nose or blowing the nose, as this may disrupt a clot that has formed. Prolonged or severe bleeding may need emergency intervention and packing. Chronic nasal bleeding may need investigation to rule out a systemic disease or blood disorder.

**Figure 40.16** Emergency therapy for a nosebleed is to sit the child up and apply pressure to the sides of the nose. (From Bowden, V. R., & Greenberg, C. S. [2014]. *Children and their families: The continuum of nursing care* [3rd ed.]. Philadelphia, PA: Wolters Kluwer.)

**QSEN Checkpoint Question 40.4**

**PATIENT-CENTERED CARE**

Michael's 4-year-old roommate in the care unit is scheduled for a tonsillectomy later today. The caregiver wants to know what types of food they can have at home for him after his tonsillectomy. Which of the following would be appropriate?

- a. Grilled cheese sandwich
- b. Tomato juice and pretzels
- c. Potato chips and dip
- d. An ice pop

Look in [Appendix A](#) for the best answer and rationale.

**SINUSITIS**

Sinusitis is infection and inflammation of the sinus cavities. It rarely occurs in children younger than 6 years of age because the frontal sinuses do not develop fully until that age. It can occur either as a primary infection or as a secondary bacterial infection from a viral upper respiratory illness. Children with bacterial sinusitis often have a preceding upper respiratory illness but have persistent or worsening symptoms of fever, nasal discharge, and cough that generally last for over 10 days (Wald, Applegate, Bordley, et al., 2013). Treatment for acute bacterial sinusitis consists of an analgesic for pain and an antibiotic for the specific organism involved.

## LARYNGITIS

Laryngitis is inflammation of the larynx, which results in brassy, hoarse voice sounds or the inability to make audible voice sounds. It may occur as a complication of pharyngitis or from excessive use of the voice, as in shouting or loud cheering. Sips of fluid (either warm or cold, whichever feels best) offer relief from the annoying tickling sensation often present.

## CONGENITAL LARYNGOMALACIA/TRACHEOMALACIA

Congenital laryngomalacia means that an infant's laryngeal structure is weaker than normal and collapses more than usual on inspiration (Adil, Rager, & Carr, 2012). This produces laryngeal stridor (a high-pitched crowing sound on inspiration) present from birth and possibly intensified when the infant is in a supine position or when sucking.

### Assessment

The infant's sternum and intercostal spaces may retract on inspiration because of the increased effort needed to pull air into the trachea past the collapsed cartilage rings. Many infants with this condition must stop sucking frequently during a feeding to maintain adequate ventilation and to rest from their exhausting respiratory effort.

### Therapeutic Management

Most children with congenital laryngomalacia need no routine therapy other than to have parents feed them slowly and provide rest periods as needed. The condition improves as infants mature and cartilage in the larynx becomes stronger at about 1 year of age. When parents wake at night and listen in a quiet house to the sound of stridor, it seems unbearably loud and can make it difficult for them to believe it is safe for them to care for the infant at home.

Be certain that parents know the importance of bringing the child for early care if signs of an upper respiratory tract infection should develop because, with this, laryngeal collapse will be even more intense and a complete obstruction of the trachea could occur.

## CROUP (LARYNGOTRACHEOBRONCHITIS)

Croup (inflammation of the larynx, trachea, and major bronchi) is a frightening illness in childhood, although complications are rare for caregivers. In children between 6 months and 3 years of age, the cause of croup is usually a viral infection such as parainfluenza virus.

### Assessment

With croup, children typically have only minimal signs at bedtime. Temperature is normal or only mildly elevated. They may develop a barking cough (croupy cough),

inspiratory stridor, and marked retractions from inflammation of the larynx, trachea, and major bronchi.

## Therapeutic Management

Cool moist air combined with a corticosteroid, such as dexamethasone, or racemic epinephrine, given by nebulizer, usually reduces inflammation and produces effective bronchodilation to open the airway. The provider may prescribe dexamethasone for home administration but racemic epinephrine needs to be administered in a healthcare setting.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Ineffective airway clearance related to edema and constriction of airway

**Outcome Evaluation:** Respiratory rate is not above 22 breaths/min; no cyanosis is present; PO<sub>2</sub> is 80 to 100 mmHg; and SaO<sub>2</sub> is over 95%.

Provide measures for a child to remain calm using distraction, toys, etc., while monitoring for respiratory changes through pulse oximetry monitoring and respiratory assessment.

Laryngospasm with total occlusion of the airway can occur if a child's gag reflex is elicited or when the child is crying. Therefore, *do not elicit a gag reflex in any child with a croupy, barking cough* and provide comfort to prevent crying.

Box 40.5 shows an interprofessional care map illustrating both nursing and team planning for a child with laryngotracheobronchitis.

### BOX 40.5

#### Nursing Care Planning

### AN INTERPROFESSIONAL CARE MAP FOR A CHILD WITH LARYNGOTRACHEOBRONCHITIS (CROUP)

Michael's 2-year-old neighbor is brought to the emergency department in respiratory distress. He has a sharp, barking cough and inspiratory stridor at rest. His breathing appears labored. He appears frightened and is tachypneic. His oxygen saturations are 85%. He is diagnosed with laryngotracheobronchitis (croup) and is admitted to the hospital for further monitoring and treatment.

**Past Medical History:** Mother received regular prenatal care beginning at 6 weeks; uncomplicated pregnancy. Full-term, spontaneous vaginal delivery, 38 weeks, birth weight 7 lb. Discharged at 2 weeks of age after surgical repair of choanal atresia. No

hospitalizations following newborn discharge; no known allergies to medicine. Allergic to seafood (hives) and has received all routine immunizations.

**Family Assessment:** The child lives with his parents in a four-bedroom home. He has two older siblings. Both parents work and are at the child's bedside. No smokers in household.

**History of the Present Illness:** 2 days of congestion and rhinorrhea. A fever started in the morning with decreased appetite and hoarse voice; no treatment tried; fussy and clingy.

**Physical Assessment:** Ill-appearing child with increased work of breathing; audible inspiratory stridor at rest. Temperature: 102.2°F (39.0°C), heart rate: 130 beats/min, respirations: 32 breaths/min, nasal flaring, and decreased air movement to bases of lungs. Barky sounding cough in room.

<b>Team</b>				
<b>Member</b>	<b>Responsible Assessment</b>	<b>Intervention</b>	<b>Rationale</b>	<b>Expected Outcome</b>
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess ability to maintain respiratory effort.	Place child in semi-upright position.	Upright position will facilitate optimal lung expansion.	Improved respiratory
Nurse	Assess degree of stridor/respiratory compromise.	Keep child calm; utilize distraction and decrease intervention.	Stridor can be worsened with agitation.	Decreased improved respiratory
<i>Teamwork and Collaboration</i>				
NP/MD/PA	Assess ability to maintain ventilation and perfusion.	Supplemental oxygen, steroids, inhaled medications	May improve oxygenation, decrease airway inflammation	Maintain/ventilatio perfusion
<i>Procedures/Medications for Quality Improvement</i>				
Nurse	Assess vital signs.	Antipyretics as needed	May decrease metabolic demand	Increased decreased rate
NP/MD/PA	Assess	Inhaled racemic epinephrine	Decreased	Decreased

respiratory status.	and/or	airway	breathing
	oral/intramuscular/intravenous	inflammation	improved
	steroids as indicated		oxygenat
			ventilatio

NP, nurse practitioner; MD, medical doctor; PA, physician's assistant.

### What If . . . 40.2

**Michael had loud stridor on admission. After oxygenation, suddenly no stridor is heard. How should the nurse respond?**

## EPIGLOTTITIS

Epiglottitis is inflammation of the epiglottis, which is the flap of cartilage that covers the opening to the larynx to keep out food and fluid during swallowing. Although it is rare, inflammation of the epiglottis is an emergency because the swollen epiglottis cannot rise and allow the airway to open. It occurs most frequently in children from 2 to about 8 years of age.

Epiglottitis can be either bacterial or viral in origin. *Haemophilus influenzae* type B has been replaced as the most common bacterial cause of the disorder followed by pneumococci, streptococci, or staphylococci. Echovirus and RSV also can cause the disorder. The incidence of epiglottitis has greatly decreased with the introduction of the *H. influenzae* type B vaccine.

### Assessment

Symptoms begin as those of a mild upper respiratory tract infection. After 1 or 2 days, as inflammation spreads to the epiglottis, the child suddenly develops severe inspiratory stridor, a high fever, hoarseness, and a very sore throat. Children may have such difficulty swallowing that they drool saliva. They may protrude their tongue to increase free movement in the pharynx.

If a child's gag reflex is stimulated with a tongue blade, the swollen and inflamed epiglottis can be seen to rise in the back of the throat as a cherry-red structure. It can be so edematous, however, that the gagging procedure causes complete obstruction of the glottis and shuts off the ability of the child to inhale. Therefore, in children with symptoms of epiglottitis (e.g., dysphagia, inspiratory stridor, cough, fever, and hoarseness), *never attempt to visualize the epiglottis directly with a tongue blade or obtain a throat culture* unless a means of providing an artificial airway, such as tracheostomy or endotracheal intubation, is immediately available. This is especially important for the nurse who functions in an expanded role and performs physical assessments and routinely elicits gag reflexes.

### Therapeutic Management

If cyanosis or respiratory distress is present, they need oxygen. IV fluids, an antibiotic, and establishment of an endotracheal airway are required to treat infection and maintain hydration.

**QSEN Checkpoint Question 40.5**

**SAFETY**

Michael has a barking cough, sore throat, and fever. The nurse wants to see whether his throat looks sore and swollen. What is the safest and most accurate way of performing this assessment?

- a. Gag Michael with a tongue blade so you can inspect his tonsils.
- b. Ask Michael to press down on his tongue with one of his fingers.
- c. Elicit a gag reflex using only one gloved finger.
- d. Ask Michael to open his mouth and then visually inspect his throat.

*Look in [Appendix A](#) for the best answer and rationale.*

**ASPIRATION**

**Aspiration** (inhalation of a foreign object into the airway) occurs most frequently in infants and toddlers. When a child aspirates a foreign object such as a coin or a peanut, the immediate reaction is choking and hard, forceful coughing. Usually, this dislodges the object. However, if the airway becomes so obstructed and no coughing or speech is possible, intervention is essential. A series of back blows or subdiaphragmatic abdominal thrusts may be used with children ([Figs. 40.17](#) and [40.18](#)).

**Figure 40.17** A subdiaphragmatic abdominal thrust on a school-age child used if back blows are not successful.

**Figure 40.18** (A) Back blows and (B) chest thrusts to relieve complete foreign body airway obstruction in an infant.

## BRONCHIAL OBSTRUCTION

The right main bronchus is straighter and has a larger lumen than the left bronchus in children older than 2 years of age. For this reason, an aspirated foreign object that is not large enough to obstruct the trachea may lodge in the right bronchus, obstructing a portion or all of the right lung. The alveoli distal to the obstruction will collapse as the air remaining in them becomes absorbed (atelectasis), or hyperinflation and pneumothorax may occur if the foreign body serves as a ball valve, allowing air to enter but not leave the alveoli (see later discussion on disorders of the lower respiratory tract).

### Assessment

After aspirating a small foreign body, the child generally coughs violently and may become dyspneic. If the article is not expelled, hemoptysis, fever, purulent sputum, and leukocytosis will generally result as infection develops. Localized wheezing (a high

whistling sound on expiration made by air passing through the narrowed lumen) may occur. Because this is localized, it is different from the generalized wheezing of a child with asthma.

A chest X-ray will reveal the presence of an object if it is radiopaque. Objects most frequently aspirated include buttons, bones, popcorn, nuts, and coins. Because objects such as those made of plastic, nuts, or popcorn cannot be visualized well on X-ray film, an X-ray study may be inconclusive. Foreign bodies may also lodge in the esophagus and cause respiratory distress because of compression on the trachea. Care must be taken when feeding young children to avoid potential choking/aspiration hazards. Popcorn, grapes, nuts, etc., can pose hazards. Additionally, children may aspirate on nonfood items such as toys, coins, etc.

### **Therapeutic Management**

A bronchoscopy may be necessary to remove the foreign body in the operating room. After a bronchoscopy, assess the child closely for signs of bronchial edema and airway obstruction that occur from mucus accumulation because of the bronchus manipulation. Obtain frequent vital signs (increasing pulse and respiratory rates suggest increased edema and obstruction).

Keep a child nothing by mouth (NPO) for at least an hour. Once a gag reflex is present, offer the first fluid cautiously to prevent additional aspiration. Cool fluid may feel more soothing than warm fluid and also can help reduce the soreness in the throat. Breathing cool, moist air or having an ice collar applied may further reduce edema.

## **Disorders of the Lower Respiratory Tract**

The structures of the lower respiratory tract are subject to infection by the same pathogens that attack the upper respiratory tract.

### **INFLUENZA**

Influenza involves inflammation and infection of the major airways. It is caused by the orthomyxovirus influenza type A, B, or C. It is marked by a cough and fever but may be accompanied by fatigue, body aches, a sore throat, and gastrointestinal symptoms such as vomiting or diarrhea. The disease spreads readily through a home or a classroom because children are contagious on the day before symptoms appear and for about the next 5 days. Young children are at highest risk of complications from the flu, in particular, children with chronic health conditions.

Oseltamivir (Tamiflu) may be prescribed for young children or children with risk factors such as cardiac or respiratory disease. To prevent the infection, children over 6 months of age should receive either the inactivated vaccine (given by injection) or the activated vaccine (given by a nasal spray). Because the influenza virus mutates yearly, the influenza vaccine is specific for only that year and must be readministered yearly.

## BRONCHITIS

Bronchitis (inflammation of the major bronchi and trachea) is one of the more common illnesses affecting preschool- and school-age children.

It is characterized by fever and cough, usually in conjunction with nasal congestion. Causative agents include the influenza viruses, adenovirus, and *Mycoplasma pneumoniae*, among others.

### Assessment

Children usually have a mild upper respiratory tract infection for 1 or 2 days, after which they develop a fever and a dry, hacking cough, which is hoarse and mildly productive and serious enough to wake a child from sleep. These symptoms may last for a week, although full recovery sometimes takes as long as 2 weeks.

On auscultation, rhonchi and coarse crackles (the sound of rales) can be heard. A chest X-ray will reveal diffuse alveolar hyperinflation and some markings at the hilus of the lung.

### Therapeutic Management

Therapy is aimed at relieving respiratory symptoms, reducing fever, and maintaining adequate hydration. An antibiotic will be prescribed if bacterial infection is suspected.

## BRONCHIOLITIS

Bronchiolitis is inflammation and edema of the fine bronchioles and small bronchi, usually due to a viral illness. The most common cause of bronchiolitis is the RSV, although a number of other viruses may also cause bronchiolitis (Florin, Plint, & Zorc, 2017). The infection occurs most often in the winter and spring and is the most common lower respiratory illness in children younger than 2 years of age, peaking in incidence between 3 and 6 months of age (Florin et al., 2017). It is the most common reason for hospitalization in infancy (Mahant & Parkin, 2016).

### Assessment

Typically, infants have several days of symptoms of a viral respiratory infection, such as congestion, rhinorrhea, and fever. This can progress to lower respiratory symptoms, including a cough, wheezing, and retractions. Infants can have variable presentation of respiratory distress. The diagnosis of bronchiolitis is typically made by a provider based on the history and clinical symptoms. Routine testing and radiographs are not indicated in typical cases (Florin et al., 2017).

### Therapeutic Management

For children with less severe symptoms, antipyretics, adequate hydration, nasal suctioning, nasal saline, avoidance of tobacco exposure, and home monitoring are

adequate. Hospitalization is warranted for children with severe illness, such as apnea, hypoxia, or dehydration, which may occur due to difficulty feeding.

Because RSV infection spreads readily from person to person and can survive on surfaces for extended time periods (>6 hours), infection control and hand hygiene is important to reduce the risk of transmission (Ralston, Lieberthal, Meissner, et al., 2014). Although fevers generally last for only the first several days of illness, respiratory symptoms can last for about 2 weeks (Florin et al., 2017).

Palivizumab, a monoclonal antibody, is recommended as prophylactic injection to prevent RSV during RSV season. Infants eligible for palivizumab are defined by specific qualifying criteria, generally defined by gestational age less than 29 weeks or less than 1 year of age with preexisting health conditions, such as chronic lung disease of prematurity or congenital heart disease (Ralston et al., 2014). Injections are given monthly during RSV season.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Caregiver anxiety related to respiratory distress in child

**Outcome Evaluation:** Caregivers state their anxiety level is tolerable as signs and symptoms of disease decrease.

Education as to the course of illness is important. Understanding signs that could indicate worsening illness, such as respiratory distress and dehydration are critical during care. Additionally, caregivers need to understand that the symptoms of bronchiolitis can continue for an extended period of time, although worsening symptoms (such as recurrence of fever after the first few days of illness) should be brought to medical attention to evaluate for secondary infection. Caregivers should understand that medications, such as antibiotics, have no role in treatment of viral illnesses.

## ASTHMA

Asthma is a chronic inflammatory disorder of the respiratory track and is the most common chronic illness in children (NHLBI, 2007). Typically, asthma presents before 5 years of age, although it may be difficult to make a definitive diagnosis in these early years. Many viral illnesses can present with symptoms that are similar and asthma and viral illnesses can trigger asthma symptoms, adding to the complexity of diagnosis. Asthma symptoms can be variable with each child with different triggers and clinical presentations. The severity of asthma in a child is dependent on risk factors, which include genetics as well as environmental exposures, such as allergens, stress, pollution, etc., that affect the body's immune responses (NHLBI, 2007).

When an allergen invades, mast cells release histamine and leukotrienes that result in diffuse obstructive and restrictive changes in the airway because of a triad of inflammation, bronchoconstriction, and increased mucus production. Most children with asthma can be shown to have allergy triggers. A primary irritant is environmental tobacco smoke. Other indoor allergens, such as mice and cockroaches, are common irritants. Outdoor irritants can include pollens, grasses, and pollution, among others. Viral respiratory illnesses are a common trigger for asthma exacerbations in children.

### **Mechanism of Disease**

Asthma primarily affects the small airways. The relationship of inflammation to airway hyperresponsiveness and airway obstruction contributes to clinical symptoms. This complex interplay of factors presents as recurrent wheezing, breathlessness, chest tightness, and coughing (NHLBI, 2007, p. 14).

### **Assessment**

The word *asthma* is derived from the Greek word for “panting,” a description of the child’s distress. Typically, an episode begins with a dry cough. Children then develop increasing difficulty exhaling as it becomes more and more difficult for them to force air through the narrowed lumen of the bronchioles that are not only inflamed and swollen but also filled with mucus. Typical dyspnea and wheezing (the sound caused by air being pushed forcibly past obstructed bronchioles) associated with the disorder begin. Wheezing is heard primarily upon expiration because the lumen of bronchioles are narrower during exhalation than inhalation, but it may be absent with severe asthma exacerbations.

### **History**

An assessment should include a thorough history of the development of a child’s symptoms; for example, what the child was doing at the time symptoms began, the child’s known asthma triggers, and what treatments were given. After the acute attack has passed, take time to ask a parent or the child to describe the home environment, including any pets, the child’s bedroom, outdoor play space, classroom environment, and type of heating in the house, to see whether more environmental control could reduce allergen triggers and future occurrences.

### **Physical Assessment**

In some children, the initial wheezing is evident only by stethoscope auscultation; in others, it is so loud it can be heard by simply listening.

Air-filled lungs are hyperresonant to percussion or they make a louder, more hollow noise on percussion than usual. With normal respiration, the inspiration phase of breathing is longer than the expiration phase. During an asthma attack, however, a child must work so hard to exhale due to air trapping that the expiration phase becomes

longer than the inspiration phase. Time the two phases to demonstrate this. Also, observe for retractions (the chest wall is drawn inward with breaths) because children have to use intercostal accessory muscles to achieve full breaths.

As constriction becomes acute, the sound of wheezing may decrease because so little air can leave the alveoli.

During attacks, children with asthma are generally more comfortable in a sitting or standing position rather than lying down and should be allowed to be in a position of comfort. If seated in a chair, they lean forward and raise their shoulders to give themselves more breathing space. Children who do agree to lie down are either at the end of an attack and beginning to feel less threatened by the dyspnea or are so exhausted by the paroxysms of coughing that they no longer have the strength to sit upright.

### **Pulmonary Function Studies**

Pulmonary function studies or spirometry can be helpful in evaluating children for asthma. Good pulmonary function depends on good ventilation (both drawing adequate air into the lungs and expelling it again), adequate transfer of gases across the alveolar capillary membranes, and adequate volume and distribution of pulmonary capillary blood flow to transport oxygen to body cells. In children with asthma, the vital capacity (i.e., the air that they are able to exhale) may be low or the capacity may be normal but because of narrowed bronchioles as a result of bronchospasm, the expiratory rate will be abnormally long (more than 10 seconds rather than the normal 2 or 3 seconds). This is often difficult to perform in young children because good understanding and effort is needed to effectively perform.

### **Peak Expiratory Flow Rate Monitoring**

Children with asthma may use a home peak flow meter daily to measure gross changes in peak expiratory flow and to help in planning an appropriate therapeutic regimen (Fig. 40.19). Children with asthma should be able to tell you their usual reading and personal best score.

**Figure 40.19** A child with asthma receives instructions on using a peak flow meter to track his peak expiratory flow readings on a daily basis. (From Lippincott Professional Development Collection. [n.d.]. *Pediatric Nursing Program* [online module]. Retrieved from <http://lippincottsolutions.com>)

To use a peak flow meter, a child places the indicator on the apparatus at the bottom of the numbered scale and takes a deep breath. The child then places the meter in his or her mouth and blows out as hard and fast as possible. The child then repeats this two more times and records the highest number achieved as the peak flow meter result. During a 2-week period when a child feels well, this should be done daily. The highest number achieved during this time is recorded as the child's personal best.

Children are assigned "zones" to help determine the level of severity of their symptoms at home. Each zone (green, yellow, or red) is associated with treatment recommendations. These may include options for inhaler use and guidelines for when to call their provider or seek emergency care.

### **Therapeutic Management**

According to the Expert Panel report (NHLBI, 2007, p. 35), the diagnosis and management of asthma involves four components: (a) measure of asthma assessment and monitoring, which involves history and physical examination and objective testing to determine asthma severity and control; (b) education for home self-management; (c) control of environmental factors that contribute to symptoms (i.e., allergens); and (d) pharmacologic therapy, defined as quick relief and long acting medications (see Chapter 42).

The primary goal in asthma management is the prevention of airway inflammation.

A child with mild intermittent asthma may be prescribed an inhaled short-acting  $\beta$ -agonist, such as albuterol, to take as needed, whereas children with persistent or severe symptoms will need an inhaled corticosteroid to take daily in order to prevent exacerbations (Box 40.6).

## BOX 40.6

### Nursing Care Planning Based on Responsibility for Pharmacology

#### FLUTICASONE PROPIONATE

**Classification:** Fluticasone propionate is a corticosteroid used as an oral inhalation for prevention of asthma symptoms.

**Action:** anti-inflammatory (bronchodilator)

**Pregnancy Risk Category:** C

**Dosage:** Dosages are based on asthma severity and whether a child has had previous bronchodilators or corticosteroid use; given via a metered dose inhaler with a valve holding chamber (spacer), twice a day.

**Possible Adverse Effects:** Dizziness, dysphonia, oral thrush, and dermatitis; potential for decrease in linear growth, headache, nausea, dry and irritated throat, cough, nasal congestion, epistaxis, sneezing

#### Nursing Implications

- Instruct parents and child that this drug is not effective in an acute attack.
- Advise parent to have child rinse their mouth (or take a drink if too young to rinse) after administration to prevent thrush.
- Caution child and parents to take the drug exactly as prescribed and to continue other prescribed medications.
- Instruct child and parents in the use of metered-dose inhaler for administration.
- Advise parent to continue this daily to prevent asthma exacerbations.
- Instruct parents and child to watch for a possible recurrence of asthma symptoms if dosage is decreased.

Other medications, such as leukotriene receptor agonists (e.g., montelukast), inhaled long-acting  $\beta$ -agonists, immunomodulators, and mast cell stabilizers, may be used for children with more severe asthma symptoms. Short courses (generally 2 to 5 days) or an oral corticosteroid may be prescribed during an acute exacerbation.

### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Fear related to sudden onset of asthma attack

**Outcome Evaluation:** Parents and child express confidence in their ability to prevent, recognize asthma symptoms, and intervene appropriately.

Asthma is a frightening disease and can have great impact on the child and family. Ongoing education is needed to recognize triggers, minimize exposure to triggers, manage medications, and ensure proper technique and use of inhaler.

**Nursing Diagnosis:** Health-seeking behaviors related to prevention of and treatment for asthma attacks

**Outcome Evaluation:** Parents and child accurately state triggers that cause an attack; and child correctly demonstrates breathing exercises, use of inhaler, and peak expiratory flow meter.

Children need to learn how to avoid possible triggers through environmental control. If foods are a trigger, children need to learn to be responsible for their own diets so they can avoid these foods. Children as young as 6 years of age can learn what foods they cannot eat and can take responsibility for telling a friend's parent or a schoolteacher that they must not eat certain foods. They must learn to use a metered-dose inhaler or nebulizer if prescribed. The goal of asthma management is to have symptom-free periods that allow optimal quality of life.

### **QSEN Checkpoint Question 40.6**

#### **INFORMATICS**

The nurse wants to teach Michael's 3-year-old roommate about peak flow testing. During this diagnostic test, what instruction should the nurse provide?

- "Hold your breath until I say and then cough forcefully."
- "When I put the meter in your mouth, take a big, deep breath."
- "I need you to blow out through the meter as hard and fast as you can."
- "Breathe like you usually do when I put the meter against your mouth."

*Look in Appendix A for the best answer and rationale.*

### **Unfolding Patient Stories: Sabina Vasquez • Part 2**

**Recall Sabina Vasquez** from **Chapter 35**, a 5-year-old diagnosed with asthma who uses an albuterol inhaler. What questions and assessments help the nurse evaluate her current respiratory status during a routine clinic visit? What methods can the nurse use to guide asthma management and determine how well Sabina's asthma is managed at home?

Care for Sabina and other patients in a realistic virtual environment: **vSim for Nursing** ([thepoint.lww.com/vSimMaternityPed](http://thepoint.lww.com/vSimMaternityPed)). Practice documenting these patients' care in DocuCare ([thepoint.lww.com/DocuCareEHR](http://thepoint.lww.com/DocuCareEHR)).

## STATUS ASTHMATICUS

Status asthmaticus is a severe and prolonged asthma attack that is not responsive to asthma therapy. It requires hospital evaluation and close cardiopulmonary monitoring.

### Assessment

A child with status asthmaticus is in acute respiratory distress. By definition, a child in status asthmaticus has failed to respond to first-line therapy (Pardue Jones, Fleming, Otilio, et al., 2015). Both heart rate and respiratory rate are elevated. The child's level of alertness and responsiveness may be altered, and they may appear anxious. Both oxygen saturation and  $PO_2$  are low;  $PCO_2$  is elevated because the bronchi are so constricted the child cannot exhale, resulting in  $CO_2$  accumulation. The rising  $PCO_2$  rapidly leads to acidosis. In contrast to the loud wheezing initially heard in an asthma attack, children with status asthmaticus may have so little air passing in or out of their lungs that breath sounds may be limited.

### Therapeutic Management

Continuous nebulization with an inhaled  $\beta_2$  agonist and IV corticosteroids may be necessary to reduce symptoms, along with oral or IV steroids, smooth muscle relaxers, and others. In severe attacks, endotracheal intubation and mechanical ventilation may be necessary to maintain effective ventilation and perfusion.

## PNEUMONIA

Pneumonia is an infection and inflammation of alveoli. It often has a bacterial or viral origin and is categorized as hospital- or community-acquired (Box 40.7). Pneumonia occurs most often in late winter and early spring. The differences between bronchiolitis, asthma, and pneumonia are summarized in Table 40.1. *Pneumocystis carinii* pneumonia, seen almost exclusively with HIV/AIDS infection, is discussed in Chapter 42.

### BOX 40.7

#### Nursing Care Planning Tips for Effective Communication

Michael's 3-year-old hospital roommate, B. J. Silver, has pneumonia, and you notice that his mother is visibly upset.

*Tip:* Be sure to explain to parents that pneumonia is serious, but with antibiotic treatment, it is not the fatal diagnosis it was years ago. Ask enough questions to be certain parents understand the probable outcomes.

**Nurse:** Is something wrong, Mrs. Silver? You seem upset.

**Mrs. Silver:** I didn't realize pneumonia was so serious until I talked to my mother.

**Nurse:** Pneumonia can be serious, but we are monitoring B. J. very closely.

**Mrs. Silver:** My mother told me my brother had pneumonia when he was a baby. Is this oxygen? My mother said to make sure B. J. is receiving oxygen.

**Nurse:** I know that pneumonia can be a scary diagnosis. Would you like to talk about B. J.'s treatment plan?

**TABLE 40.1** Comparison of Bronchiolitis, Pneumonia, and Asthma

Assessment	Bronchiolitis	Pneumonia	Asthma
Cause	Usually respiratory syncytial virus	Possibly bacterial (pneumococcal, or <i>Haemophilus influenzae</i> ), viral, or mycoplasmal; possibly secondary to aspiration	Hypersensitivity type I immune response
Age of child	Under 2 years	All through childhood	Onset: 1–5 years
Onset pattern	Follows an upper respiratory infection	Often follows an upper respiratory infection	Often triggered by respiratory infection; follows initiation by an allergen
Appearance	Fatigued, anxious, shallow respirations, increasing anteroposterior diameter of chest	Fatigued, anxious, shallow respirations	Wheezing, exhausted, frightened
Cough	Paroxysmal, dry	Productive, harsh cough	Paroxysmal, with thick mucus production
Fever	Low grade	Elevated	None
Auscultatory sounds	Barely audible breath sounds, rales, wheezing	Decreased breath sounds, rales	Wheezing, decreased breath sounds

### Pneumococcal Pneumonia

The onset of pneumococcal pneumonia is generally abrupt and follows an upper respiratory tract infection. In infants, the infection tends to be bronchopneumonia with poor consolidation. In older children, pneumonia often localizes in a single lobe with full consolidation. During the initial 24 to 48 hours of infection, children may have

blood-tinged sputum that transitions to a thick, purulent sputum.

### Assessment

Children may often appear acutely ill, with high fever, tachycardia, chest or abdominal pain, chills, and signs of respiratory distress. Breath sounds are often diminished, and crackles (rales) may be present. Dullness on percussion indicates total consolidation. Chest radiography will often reveal consolidation, and laboratory studies will indicate leukocytosis.

### Therapeutic Management

Pharmacologic management may include IV fluid therapy, antibiotics, and antipyretics (Bradley, Byington, Shah, et al., 2011). Oxygen saturation levels should be assessed frequently. Humidified oxygen may help labored breathing and prevent hypoxemia. CPT may be used to encourage the movement of mucus and prevent obstruction. Repositioning the child will prevent pooling of secretions.

### Chlamydial Pneumonia

*Chlamydia trachomatis* pneumonia, typically seen in newborns up to 12 weeks of age, is often contracted from contact with the mother's vagina during birth. Symptoms begin gradually with nasal congestion, a sharp cough, and poor weight gain. These progress to tachypnea and wheezing and rales on auscultation. A laboratory assessment will show elevated levels of IgG and IgM antibodies, peripheral eosinophilia, and antibodies to *C. trachomatis*. Antibiotics are often used for pharmacologic treatment.

### Viral Pneumonia

Viral pneumonia is generally caused by viral infections of the upper respiratory tract. Symptoms begin as an upper respiratory tract infection and may progress to diminished breath sounds and fine rales on auscultation. Antibiotic therapy is not effective against viral infections. Rest and antipyretics are used for treatment. Similar to bacterial pneumonia, fatigue often occurs following the acute phase of illness.

### Mycoplasma Pneumonia

Mycoplasma pneumoniae occurs more frequently in children over 5 years of age during winter months. Fever, cough, cervical lymphadenopathy, and rhinitis are common symptoms. Mycoplasma organisms are generally sensitive to erythromycin or tetracycline.

## ATELECTASIS

**Atelectasis**, the collapse of lung alveoli, may be a primary or secondary condition.

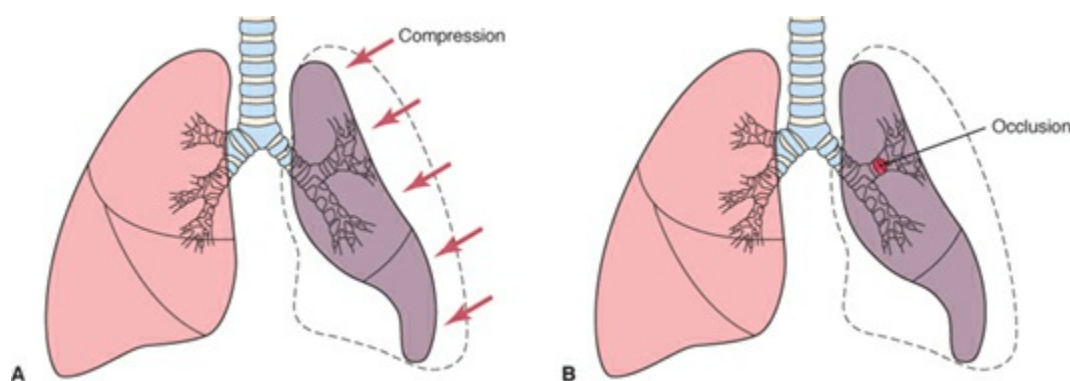

## Primary Atelectasis

Primary atelectasis is seen in preterm newborns with limited surfactant and poor respiratory strength or mucus or meconium plugs in the trachea (Dargaville, 2012).

Respirations become irregular, with nasal flaring and apnea. Respiratory grunting, caused by the glottis closing upon expiration, increases pressure in the respiratory tract and keeps alveoli from collapsing. Grunting may also be tiring to the newborn, resulting in hypoxemia, hypotonicity, and flaccidity. Therapy must be directed at the cause of atelectasis. Crying and administration of oxygen may aerate the alveoli and may decrease cyanosis.

## Secondary Atelectasis

Secondary atelectasis often occurs from a respiratory tract obstruction that prevents air from entering a portion of the alveoli (Federico, Kirby, Deterding, et al., 2011). As residual air in the alveoli is absorbed, the alveoli collapse. Causes of obstruction may include mucus plugs associated with chronic respiratory disease, foreign object aspiration, or pressure on lung tissue from outside forces, such as compression from a diaphragmatic hernia, scoliosis, or enlarged thoracic lymph nodes (Fig. 40.20).

**Figure 40.20** (A) Atelectasis caused by compression of lung tissue.  
(B) Atelectasis caused by obstruction.

Signs of secondary atelectasis depend on the degree of collapse. Asymmetry of the chest may be noticed as well as diminished breath sounds on the affected side. Tachypnea and cyanosis may be present. Chest radiography will show collapsed alveoli. Children with atelectasis are prone to secondary infection because mucus, which provides a good medium for bacteria, becomes stagnant without air exchange.

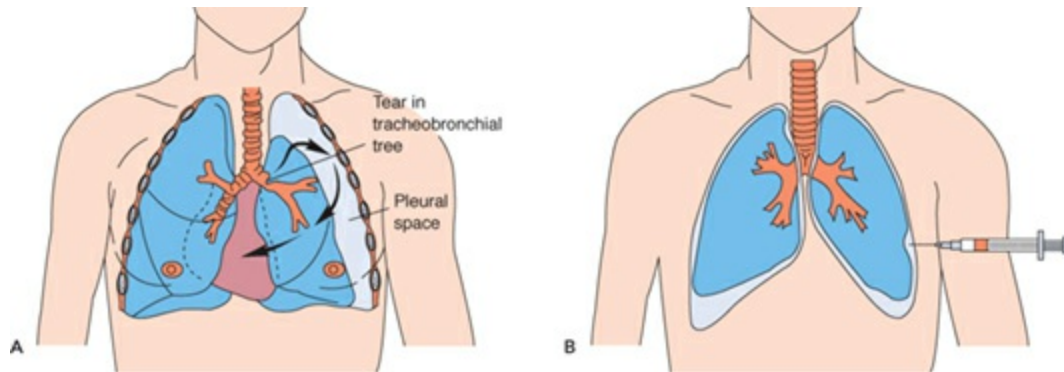

## Therapeutic Management

Atelectasis caused by inspiration of a foreign object will not be relieved until the object is removed by bronchoscopy. Atelectasis caused by a mucus plug will resolve when the plug clears up. The chest of a child with atelectasis should be kept free from pressure for optimal lung expansion.

A semi-Fowler's position generally allows for the best lung expansion because it lowers abdominal contents and increases chest space. Suction, CPT, and increased humidity may prevent further bronchial plugging.

## PNEUMOTHORAX

**Pneumothorax** is the presence of atmospheric air in the pleural space, causing atelectasis (Fig. 40.21). It can occur when external puncture wounds allow air to enter the chest (Janssen & Cardillo, 2011).

**Figure 40.21** (A) A pneumothorax. A tear in the tracheobronchial tree has caused air to move into the pleural space; the lung collapses and the mediastinum shifts to the unaffected side. (B) Aspiration of air from the pleural space allows lung to reexpand after a pneumothorax.

Pneumothorax occurs in approximately 1% of newborns often because of rupture of the alveoli from the extreme intrathoracic pressure needed to initiate a first inspiration. The infant will develop signs of respiratory distress. Auscultation reveals absent or decreased breath sounds on the affected side. Percussion may not be revealing. Despite the hollow air space, the chest may be hyperresonant because of the presence of increased air. A more revealing sign may be the shift of the apical pulse (mediastinal shift) away from the site of the pneumothorax. Chest radiography will show a darkened area of the air-filled pleural space.

A child with a pneumothorax needs oxygen therapy to relieve respiratory distress. A thoracotomy catheter or needle may be placed through the chest wall into the pleural space to remove accumulated air. In most children with pneumothorax, symptoms are relieved within 24 hours after suction initiation. The use of water-seal drainage with children is discussed in [Chapter 41](#).

If air in the pleural space is from a puncture wound such as a stab wound, cover the chest wound immediately with an impervious material, such as petrolatum gauze, to prevent further air from entering and to decrease the risk of atelectasis. The extent of symptoms and the outcome will depend on the cause of entry of air into the pleural space and its removal.

## BRONCHOPULMONARY DYSPLASIA

Bronchopulmonary dysplasia (BPD) is chronic lung condition that can occur in infants. The condition, frequently found in preterm infants who received mechanical ventilation for respiratory distress syndrome at birth, is thought to occur from a combination of surfactant deficiency, barotrauma, oxygen toxicity, and inflammation.

Infants may develop tachypnea, retractions, nasal flaring, tachycardia, and oxygen dependence. Auscultation reveals decreased air movement. Chest radiography may show areas of overinflation, inflammation, and atelectasis. As inflamed surfaces heal, the infant is left with fibrotic scarring.

The clinical course ranges from a mild need for increased oxygen, which gradually resolves over a few months, to a severe disease requiring chronic tracheostomy and mechanical ventilation during the first few years of life.

Administration of a corticosteroid to reduce inflammation and a bronchodilator by nebulizer can improve respiratory function. Infants need to be monitored carefully for nutrition and fluid intake, especially if they are ventilator-dependent.

## TUBERCULOSIS

Tuberculosis, caused by the bacterium *Mycobacterium tuberculosis*, is a highly contagious pulmonary disease that affects children worldwide (Winston & Menzies, 2012).

Children who are homeless, immunocompromised, or adopted internationally are at increased risk (Raviglione, Marais, Floyd, et al., 2012). The mode of transmission is inhalation of infected droplets, and the incubation period is 2 to 10 weeks.

In initial stages of infection, primary inflammation occurs and a slight cough develops. As the disease progresses, anorexia, weight loss, night sweats, and a low-grade fever may be present.

Leukocytes and lymphocytes invade the lung area to attack the tuberculosis organism and wall off the primary infection. The wall surrounding the bacteria then calcifies and confines the organism permanently. If the infection is unable to be contained, tuberculosis may spread to other parts of the body (miliary tuberculosis), such as bones, lymph nodes, kidneys, and the subarachnoid space (tuberculous meningitis).

### Assessment

All children living in high-risk areas should have a tuberculin test as part of basic preventive healthcare screening at 9 to 12 months of age and yearly thereafter. A Mantoux test, also known as a purified protein derivative (PPD) test, is administered by injecting 5 units of protein derivative vaccine intradermally, usually in the left lower arm. Assessment of the area 72 hours after administration is necessary to evaluate the level of reaction. A positive reaction, the formation of a 5- to 15-mm reddened induration, indicates the child has been exposed to tuberculosis or has developed

antibodies to the foreign products of the tuberculosis organism. Children with positive reactions need a follow-up chest radiograph. Skin testing should not be done on children who have a history of tuberculosis diagnosis because of the risk of intense reaction at the testing site. Additionally, a tuberculosis screening test should not be done immediately after administration of the measles, mumps, and rubella (MMR) vaccine because of the possibility of a false-negative result.

Tuberculosis may not be immediately evident on chest radiography. As local inflammation occurs, however, calcification and cloudiness in the inflamed area will be noticeable.

Sputum analysis, typically done for 3 consecutive days, is needed to confirm a diagnosis of active disease. Mucus should be expectorated from the lungs. Infants and children younger than 5 years of age do not expectorate sputum but swallow it; therefore, a gastric lavage may be necessary to obtain the specimen. Therapeutic play and support are helpful throughout the procedure.

## Therapeutic Management

Antituberculosis drugs include isoniazid, rifampin, pyrazinamide, and ethambutol (Getahun, Sculier, Sismanidis, et al., 2012). Dosage and frequency of pharmacologic therapy vary with history and clinical presentation and are often determined in consultation with an infectious disease specialist. In addition to drug therapy, children should ingest a diet high in protein and calcium. Children should have periodic chest radiographs to ensure the disease does not reactivate. Up-to-date vaccination is encouraged. Children may return to regular activities, including school, when drug therapy has been initiated and treatment compliance has been established.

### *What If . . . 40.3*

**Michael has a PPD test with a positive result. Would the nurse prevent him from playing with other children on the hospital unit? Why or why not?**

## CYSTIC FIBROSIS

Cystic fibrosis (CF) is an inherited disease of the secretory glands. The disease is characterized by a thick mucus secretions, particularly in the pancreas and the lungs, as well as electrolyte abnormalities in sweat gland secretions. An abnormality of the long arm of chromosome 7 results in the inability to transport small molecules across cell membranes, leading to dehydration of epithelial cells in the airway and pancreas.

CF is inherited from an autosomal recessive trait. It occurs in approximately 1 in 2,500 live births and is most often found in White children. Chorionic villi sampling or amniocentesis can be performed during pregnancy for early detection. Additionally, all newborns can be screened at birth (Laguna, Lin, Wang, et al., 2012).

Affected males may be unable to reproduce secondary to persistent plugging and

blocking of the vas deferens by tenacious seminal fluid. Affected females may have thick cervical secretions that limit sperm motility. Alternative insemination and in vitro fertilization are options for patients who desire to become pregnant.

### **Pancreas Involvement**

The acinar cells of the pancreas normally produce lipase, trypsin, and amylase—enzymes that flow into the duodenum to digest fat, protein, and carbohydrate. In patients with CF, these enzyme secretions may be so thick that they plug ducts, resulting in atrophy of the acinar cells and an inability to produce enzymes. The islets of Langerhans and insulin production are influenced much later because of their endocrine (ductless) activity.

An absence of pancreatic enzymes in the duodenum results in an inability to digest fat, protein, and some sugars. Bowel movements become large, bulky, and greasy (**steatorrhea**). An increase in intestinal flora and fat results in an extremely foul odor, and the increased bulk of feces often leads to a protuberant abdomen. Malnutrition occurs without therapy and may include emaciated extremities and loose skin folds on the buttocks. Fat-soluble vitamins, particularly vitamins A, D, and E, cannot be absorbed in the absence of fat absorption, resulting in vitamin deficiency.

Meconium in a newborn is normally thick and tenacious. In approximately 10% of children with CF, it may be so thick that it obstructs the intestine, known as meconium ileus. A newborn who develops abdominal distention with no passage of stool within 24 hours of birth should be evaluated further ([Wainwright, 2011](#)).

### **Lung Involvement**

The anteroposterior diameter of the chest becomes enlarged in CF. Thickened mucus pools in bronchioles and often results in frequent infections. Organisms most frequently cultured are *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *H. influenzae*. Atelectasis may occur as a result of absorption of air from alveoli behind blocked bronchioles. Clubbed fingers may occur because of inadequate peripheral tissue perfusion.

### **Sweat Gland Involvement**

Although sweat glands are not changed in structure, the level of chloride to sodium in perspiration is increased 2 to 5 times above normal, resulting in “salty” perspiration.

### **Assessment**

CF is typically detected at birth through screening tests. It may also be detected by documentation of chromosomal abnormality, abnormal chloride concentration in perspiration, absence of pancreatic enzymes in the duodenum, the presence of immunoreactive trypsinogen in the blood secondary to pancreatic obstruction, and pulmonary involvement.

CF may be suspected in a newborn who fails to regain normal birth weight within 7 to 10 days after birth. This occurs secondary to the infant's inability to absorb milk fat. Nurses should be concerned with poor weight gain or meconium ileus in a newborn. Children undiagnosed at birth may present with complaints of increased hunger and steatorrheic stools because these stool changes are inconsistent with simple colic.

Respiratory infections develop around 4 to 6 months of age, and wheezing and rhonchi are often heard on chest auscultation. The chest may be hyperresonant with percussion. Cough is a prominent finding by preschool, and clubbing of fingers may also be present during this time.

### *Sweat Testing*

Sweat testing detects abnormal salt concentrations. In this procedure, the paper is analyzed for sodium chloride content. A normal concentration of sodium chloride in sweat is 20 mEq/L; more than 60 mEq/L of sodium chloride is diagnostic of CF. Sweat tests are often not necessary because of advanced chromosomal testing.

### *Duodenal Analysis*

Duodenal secretions may be used to detect pancreatic enzymes and reveal the extent of pancreatic involvement. This is done by passing a nasogastric tube into the duodenum; secretions are then aspirated for analysis. The tube placement can be determined by pH levels. Secretions from the duodenum are sent to the laboratory for analysis of trypsin content, the easiest pancreatic enzyme to assay.

### *Stool Analysis*

Stool may be collected and analyzed for fat content and lack of trypsin of the stool.

### *Pulmonary Testing*

A chest X-ray generally confirms the extent of pulmonary involvement. Pulmonary function may be tested to determine the extent of atelectasis and emphysema.

### *Therapeutic Management*

Therapeutic management is a collaborative process to reduce the involvement of the pancreas, lungs, and sweat glands.

## **Nursing Diagnoses and Related Interventions**

**Nursing Diagnosis:** Imbalanced nutrition, less than body requirements, related to inability to digest fat

### Outcome Evaluation:

1. Adequate height and weight growth percentiles
2. Decrease in stool quantity
3. Absence of vitamin deficiency

Children are placed on a high-calorie, high-protein, and moderate-fat diet and receive supplementation with vitamins A, D, and E. Medium-chain triglycerides are more readily digested than other oils. During hot months of the year, extra salt may be added to food to replace that lost through perspiration.

Generally, infants with CF may be breastfed and also use supplementary formula. A high-protein formula is generally recommended as a supplement.

Children should take a synthetic pancreatic enzyme, pancreatic lipase, to replace the enzyme they cannot produce (Box 40.8). These synthetic enzymes are supplied in large capsules that must be opened for young children and added to a small amount of food. Enzymes should not be added to hot food because a large portion of enzyme activity can be destroyed. Additionally, enzymes should not be added to a bottle of formula. If the infant doesn't drink the entire bottle, they will not receive the total benefit of the enzyme. The use of pancreatic enzymes may decrease the size and foul odor of stool and also aid in weight gain. Adolescents may have difficulty eating adequate amounts to maintain weight because their growth requires additional caloric intake.

Children should be monitored for overheating because excessive loss of sodium and chloride may result in dehydration. Monitor heat exposure and offer water frequently.

### BOX 40.8

#### Nursing Care Planning Based on Responsibility for Pharmacology

### PANCRELIPASE (COTAZYM)

**Classification:** Pancrelipase is an enzyme replacement.

**Action:** used to aid digestion in children with cystic fibrosis (Berlinski, 2017)

**Pregnancy Risk Category:** C

#### Dosage:

- Children 6 months to 1 year of age: 2,000 units orally per meal
- Children 1 to 6 years of age: 4,000 to 8,000 units orally with each meal and 4,000 units with snacks
- Children 7 to 12 years of age: 4,000 to 12,000 units orally with each meal and with snacks

**Possible Adverse Effects:** nausea, abdominal cramps, diarrhea, hypersensitivity

#### Nursing Implications

- Administer the drug before or with meals and snacks. Instruct parents and child to do the same.
- Caution child and parents to avoid inhaling powder or spilling it on the hands because it may irritate the skin or mucous membranes.
- Do not crush or let the child chew the enteric form of the drug. Break open the capsule and mix with 1 teaspoon of food.
- Instruct the child and parents about possible adverse effects and encourage them to contact their healthcare provider should any become severe.

**Nursing Diagnosis:** Ineffective airway clearance related to inability to clear mucus from the respiratory tract

**Outcome Evaluation:**

1. Child's temperature is below 100.4°F (38.0°C).
2. PO<sub>2</sub> is 80 to 90 mmHg.
3. PCO<sub>2</sub> is less than 40 mmHg.
4. Oxygen saturation is 92% to 100%.

Pulmonary infection from plugged airways is common. It is important to keep bronchial secretions moist and flowing freely to encourage draining from the bronchial tree. This is done by frequent nebulization or aerosol therapy followed by chest physiotherapy. Frequent observation is necessary to monitor for respiratory distress. If a portion of a lung becomes obstructed from a mucus plug, a child can quickly experience respiratory distress.

The right side of the heart tends to enlarge in children with chronic respiratory disease because congestion in the lungs increases pressure in the pulmonary artery and right ventricle. After a period of stress or exercise, children may begin to show signs of cardiac failure because their already enlarged heart has inadequate compensation.

*Humidified Oxygen:* Oxygen is supplied to children by mask, prongs, ventilators, or nebulizer. Mist can be supplied by an ultrasonic compressor and delivered through a nebulizer mask.

*Aerosol Therapy:* Children may be given aerosol therapy by means of a nebulizer to provide antibiotics or bronchodilators. A mucolytic can be added to the mist to aid in diluting and liquefying secretions. Cough suppressants and codeine should be avoided because secretions must be removed to promote effective air exchange and prevent infection.

*Chest Physiotherapy:* Bronchial secretions may be so tenacious that children are unable to expectorate, even with liquefaction by mist or aerosol therapy. Chest physiotherapy, as often as three or four times a day, may aid in drainage secretion.

*Activity:* Encourage normal activities as tolerated. Children confined to a bed need

frequent position changes to encourage lung drainage and prevent skin breakdown over bony prominences. A superior position will encourage lung lobes to drain.

*Respiratory Hygiene:* Sputum may have a disagreeable taste or odor. Encourage adequate dental hygiene.

**Nursing Diagnosis:** Risk for impaired skin integrity related to stool acidity

**Outcome Evaluation:** Skin breakdown is not present. Rectal prolapse is not present. Stool may be irritating because of high fat content. Children who are not toilet trained should have diapers changed immediately to prevent skin breakdown.

Monitor for rectal prolapse due to weak musculature of the rectal area. Rectal prolapse appears as a bright-red mass protruding from the anal sphincter and should be replaced promptly to prevent a compromised blood supply. Prolapse occurs much less frequently in children who are receiving pancreatic enzymes than in those who are not because the incidence of rectal prolapse decreases with improved nutrition.

**Nursing Diagnosis:** Risk for compromised family coping related to chronic illness in a child

**Outcome Evaluation:** Family members state they have adequate resources to cope with diagnosis.

Family members assume a great deal of responsibility for the care of their child. Begin discharge planning and teaching when a child is first admitted to a hospital. Discuss changes that may be needed to successfully accommodate the child's therapeutic regimen. Encourage quarterly communication with the healthcare team to review individualized care plans and address barriers to CF care (Lahiri, Hempstead, Brady, et al., 2016).

*Adequate Rest and Comfort:* Any child with compromised lung function may have a degree of dyspnea that leads to exhaustion. Encourage periods of rest during the day, including before meals and prior to chest physiotherapy.

*Growth and Development:* Encourage age-appropriate activities. Children should attend regular school and participate in physical fitness, as much as possible, to encourage socialization with other children.

*Continuing Care:* Periodic health assessments and routine childhood immunizations, including annual influenza vaccination, are necessary. Children should receive the first dose of pneumococcal polysaccharide vaccine (PPSV23) at least 8 weeks after the last dose of pneumococcal conjugate vaccine (PCV13) (Lahiri et al., 2016).

Children with CF often report feelings of vulnerability and loss of independence due to their disease. Treatment management should include opportunities for shared decision making, control, and self-efficacy (Jamieson, Fitzgerald, Singh-Grewal, et al., 2014).

Adolescents with CF are candidates for lung transplants. Some of these are done

as lower lobe transplants from a living donor. A lung transplant is advantageous for children with CF because the new lung does not possess the defective gene, greatly improving life expectancy.

#### *What If... 40.4*

**A nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to respiratory disorders and children (see Box 40.1). What would be a possible research topic pertinent to these goals that would be applicable to Michael and his family and that would also advance evidence-based practice?**

### **KEY POINTS FOR REVIEW**

- Respiratory tract disorders tend to occur more frequently in children than adults because the lumens of children's bronchi are narrow and obstruction and infection are more likely to occur. Planning nursing care that includes assurance not only meets Quality & Safety Education for Nurses (QSEN) competencies but also best meets the family's total needs.
- Acute nasopharyngitis (the common cold) is the most common infectious disease in children. Treatment should include comfort measures.
- Tonsillitis is infection and inflammation of the palatine tonsils. Adenitis is infection and inflammation of the adenoid tonsils. Children with recurring infections may have their tonsils surgically removed.
- Laryngotracheobronchitis (croup) is inflammation of the larynx, trachea, and major bronchi. Epiglottitis is inflammation of the epiglottis. Both of these conditions can severely impair the airway. Children with epiglottitis should never be assessed for a gag reflex using a tongue blade because the elevated epiglottis can occlude the airway.
- Bronchiolitis is inflammation of the fine bronchioles.
- Respiratory syncytial virus (RSV) accounts for the majority of lower respiratory tract infections in young children. Infants with RSV infections must be observed closely for signs of increased respiratory distress.
- Asthma, a type I hypersensitivity reaction, is a diffuse and obstructive airway disease with wheezing as the most common symptom. Newer drugs such as leukotriene receptor antagonists and careful environmental control have aided in the management of asthma.
- Cystic fibrosis is a disease in which there is generalized dysfunction of the exocrine glands. This results in malabsorption and tenacious pulmonary secretions, leading to infections and poor nutrition. Lung transplantation may be used to replace the diseased lung tissue and to increase the child's life span.

## CRITICAL THINKING CARE STUDY

Amanda is a 14-year-old with chronic asthma whom you meet in the emergency room. She is allergic to cats, goldenrod, and tomatoes. She lives with her mother; her parents have been divorced for the past 6 months. This afternoon, she attended a birthday party for a school friend. As soon as she returned home, her respiratory rate increased, she gasped for breath, and she began wheezing. Her father, a fireman, whom she's been staying with for the weekend, came home from work still in his rubber coat and boots to bring her to the hospital. While you talk to him to obtain a history, he keeps glancing at his watch.

1. Amanda's father keeps looking at his watch while he waits for you to take vital signs on Amanda. When you ask Amanda if anything happened at the party she could identify as an asthma "trigger," she shakes her head rapidly. Would you want to ask her any more questions?
2. Amanda admits she doesn't take her medications regularly because it isn't "cool." What suggestions could you give her to make her feel better about taking medicine?
3. Amanda was suspended from school last month because she rang the fire alarm, and she is banned from entering her local convenience store because she was caught stealing candy from there. When you ask her why these things happened, she answers, "Because I have asthma." What questions would you want to ask her to see if she's using her illness as an excuse for bad behavior?

# 41

## Nursing Care of a Family When a Child Has a Cardiovascular Disorder

*Megan is a newborn who was born with a moderate-sized ventricular septal defect. Megan's parents will be taking her home this afternoon with follow-up in the pediatric cardiology office in 1 month. They tell you the cardiologist instructed them to "watch her carefully" during that time. "What does that mean?" they ask you. "Exactly what should we watch for?"*

*Previous chapters described the growth and development of well infants and children and care of children when ill. This chapter adds information about the child who is ill with a cardiovascular disorder and the stress that such a serious diagnosis places on families. Such information builds a base for care and health teaching for children with these disorders.*

**What advice would you offer Megan's parents?**

### KEY TERMS

acyanotic heart disease  
afterload  
cardiac catheterization  
cardiomyopathy  
congestive heart failure (CHF)  
contractility  
cyanotic heart disease  
diastole  
heart murmur  
preload  
systole  
vasculitis

### OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe common cardiovascular disorders of childhood.
  2. Identify 2020 National Health Goals related to children with cardiovascular disorders that nurses can help the nation achieve.
  3. Assess a child with a cardiovascular dysfunction.
  4. Formulate nursing diagnoses for a child with a cardiovascular disorder.
  5. Establish outcomes based on the priority needs of a child with a cardiovascular disorder that can help the family manage seamless transitions across different healthcare settings.
  6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
  7. Implement nursing care for a child with a cardiovascular disorder, such as teaching about the importance of taking prescribed medication.
  8. Evaluate expected outcomes for achievement and effectiveness of care.
  9. Integrate knowledge of cardiovascular disorders with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.
- 

Cardiovascular issues in children are complex, spanning the spectrum from congenital defects that may present at birth to acquired heart disease or late-onset inherited disorders. Severity, complexity, and presentation vary depending on the disorder and the child's age. The disorders may require episodic care or mandate life-long medical management by a specialist. Managing a child with a cardiovascular disorder is very challenging and requires the nurse to have an in-depth understanding of a multitude of disease processes, congenital heart defects, and treatment regimens as well as the ability to work with children of any age and families in varying states of emotional health.

Healthcare providers are not just better today at managing children with cardiovascular disorders, but they are also better at diagnosing these disorders. Genetic testing has allowed for families to test even asymptomatic children for an identified genetic syndrome based on familial patterns, including dysrhythmias, cardiomyopathies, Marfan syndrome, or long-QT syndrome. This ability to provide early diagnoses allows for enhanced therapeutic management and risk-reducing interventions, which may improve survival and provide a sense of empowerment for patients and their families.

Many heart-related problems can be prevented. Healthy People 2020 has identified several National Goals that address children's risk for preventable heart disease and other disorders secondary to hypertension, overweight, and obesity. Although it is not possible to prevent congenital heart disease, we can provide children and families with education and guidance in an effort to prevent disorders such as hypertension, obesity, and dyslipidemia, which are documented to have a negative impact on cardiovascular

health. Even in families with a predisposition for these disorders, education is imperative in guiding families to incorporate lifestyle changes into their daily routine.

**Box 41.1** depicts 2020 National Health Goals that address achieving cardiovascular health through health promotion and disease prevention, measures that can begin in childhood and adolescence.

#### BOX 41.1

### Nursing Care Planning Based on 2020 National Health Goals

Cardiovascular illness is a major health problem in adults. Because the illness and its effects can be prevented or at least minimized by instituting measures early in childhood, a number of 2020 National Health Goals address ways parents and children can modify nutrition or exercise to achieve better cardiovascular health:

- Increase the proportion of adolescents who meet current federal physical activity guidelines for aerobic physical activity (7 days/week) and for muscle-strengthening activity ( $\geq 3$  days/week) from a baseline of 21.9% to a target of 24.1%.
- Reduce the proportion of children age 2 to 19 years who are considered obese from 16.1% to 14.5%.
- Reduce consumption of calories from solid fats in the population aged 2 years and older from a mean 16.6% of total daily calorie intake to 14.2%.
- Reduce consumption of calories from added sugars from a mean 15.1% of total daily calories to 9.7% in the population aged 2 years and older.
- Increase consumption of dark green vegetables, red and orange vegetables, beans, and peas to the diets of the population aged 2 years and older from a mean 0.29 cups per 1,000 calories/day to 0.53 cup equivalent.
- Reduce the proportion of children and adolescents (ages 8 to 17 years old) with hypertension from 3.5% to 3.2% ([U.S. Department of Health and Human Services, 2010](#); see [www.healthypeople.gov](http://www.healthypeople.gov)).

There are many more goals at the Healthy People 2020 website that are specific to the health of children. Nurses can help the nation achieve these goals by educating parents and children at every encounter about the importance of reducing obesity and implementing exercise and nutrition programs for sound cardiovascular health. These are frequently difficult lifestyle choices, so the information must be reinforced with every encounter. Encourage families to make any changes as an entire family, not just make the changes only for the child. Although encouraging a low-fat diet, it is important for nurses to caution parents not to start their children on reduced-fat diets until they are 2 years old to allow for myelination of nerve cells. Children should also not be placed on a diet or limited caloric intake unless under the direction of a healthcare provider.

An important factor affecting the health care of children with cardiovascular issues

today is the increased life expectancies for children born with complex congenital heart disease and the decreased mortality experienced by children with a variety of disorders, including single-ventricle heart disease, cardiomyopathies, and dysrhythmias. Not only are traditional therapies more successful in children, but also pediatric patients of all ages now have greater access to a wide range of treatment options, including heart transplant, ventricular assistive devices, extracorporeal membrane oxygenation (ECMO), and nonsurgical catheter-based interventions. The ensuing pages provide a greater understanding of the pediatric cardiovascular system, the disease states that most frequently affect children, and management strategies to afford these children the best health possible.

### *Nursing Process Overview*

## FOR CARE OF A CHILD WITH CARDIOVASCULAR DISORDER

### **ASSESSMENT**

Assessment of a child with a cardiovascular disorder includes both careful history taking and physical examination because many signs and symptoms of cardiac complications in children can be subtle. A variety of studies such as echocardiography, electrocardiography, cardiac catheterization, and diagnostic imaging may be used to confirm a diagnosis, guide therapy, or determine the need for surgical intervention.

Although the diagnosis, management, and treatment of cardiovascular disorders in children has progressed exceptionally far in recent decades, these therapies and survival rates do not come without consequences. Children are living longer, but their lives can be very complicated. They can have health deficits that require long-term monitoring, and they frequently have many comorbidities such as poor feeding, reactive airway disease, or diminished cognitive abilities, all of which may require other medical treatments, medications, and intervention. When assessing children with an underlying cardiovascular disorder, you must incorporate a multisystem assessment into practice, as other systems may be directly or indirectly affected by the cardiac disorder.

Cardiovascular disorders are frightening for both children and parents, as even small children realize the importance of their heart to sustain life. For the families of children with a cardiovascular disorder, understanding the functioning of the heart and circulation is an important first step toward coping with the illness. You will need to be comfortable teaching about the underlying disorder, explaining diagnostic tests, and providing emotional support to children and their families throughout the assessment process.

### **NURSING DIAGNOSIS**

Nursing diagnoses associated with heart disease in children usually address the effect of compromised cardiac function or the impact a serious disorder can have on the child or parents. Examples include:

- Risk for ineffective peripheral tissue perfusion related to impaired myocardial function
- Decreased cardiac output related to altered cardiac anatomy, physiology, or altered cardiac rhythm
- Imbalanced nutrition, less than body requirements, related to increased metabolic demands of the disordered heart
- Deficient knowledge related to care of the child with a cardiac disorder
- Anxiety related to lack of knowledge about child's illness
- Anxiety related to lack of knowledge about caring for a child after surgery or a cardiac catheterization
- Risk for activity intolerance due to altered cardiopulmonary physiology
- Interrupted family processes related to stresses of diagnosis and care responsibilities
- Ineffective coping related to lack of adequate support people
- Impaired parenting related to inability to bond with a critically ill newborn

If the concerns in the latter three diagnoses are not identified at the time of diagnosis or when a child is ill, they may continue long after a child is treated and returns home. This can have negative consequences on the entire family and may affect parent-child bonding.

### **OUTCOME IDENTIFICATION AND PLANNING**

Nursing planning is essential to help parents and children understand heart anatomy because a sound knowledge base can help them understand the need for diagnostic testing, medication compliance, and ongoing follow-up. Additional teaching is necessary to prepare parents and children for procedures or surgery and recovery at home. Teaching parents to conscientiously administer cardiac medications is another area where planning plays an important role. Organizations that are helpful for referral are the American Heart Association (AHA; [www.heart.org](http://www.heart.org)), the Cardiovascular Disease Foundation ([www.cvdf.org](http://www.cvdf.org)), and the Congenital Heart Information Network ([www.tchin.org](http://www.tchin.org)).

### **IMPLEMENTATION**

Nursing interventions in the care of children with a cardiovascular disorder include teaching, providing an opportunity for children and their families to express fears about a child's illness and treatment plan, providing physiologic and psychological support such as comfort measures after surgery, and caring for a child during acute hospitalizations. An equally important role is teaching prevention of heart disease such as promoting a home environment free from smoke and encouraging a healthy lifestyle through exercise, maintaining an appropriate weight, and eating a low-fat diet.

### **OUTCOME EVALUATION**

Outcome evaluation should include both immediate and future outcomes for the child and family because cardiac disorders may be long term. Important short-term

outcomes involve receiving adequate support during procedures and treatment. If long-term care becomes necessary, evaluating the family's ability to think of their child not in terms of illness but in terms of wellness and providing opportunities for parents to express their concerns about their child's status are important.

The following examples suggest achievement of outcomes:

- The child demonstrates age-appropriate coping skills related to diagnosis and possible intervention.
- The parents demonstrate competence with procedures required for care of their child.
- The parents exhibit positive coping skills related to their child's diagnosis and the care required to foster optimal growth and development in their child.
- The parents verbalize positive thoughts about their child's future.

## Health Promotion and Risk Management

Because the risk factors that lead to adult heart disease (e.g., obesity, high cholesterol levels, and lack of consistent exercise) involve health habits that begin in childhood, prevention of cardiac disease has shifted from an adult focus to a child focus in the hope that early interventions will have a major impact on reducing the incidence of preventable heart disease in the next generation.

### RISK MANAGEMENT FOR CONGENITAL HEART DISEASE

The cause of congenital heart disease often cannot be documented, although some associations are seen with familial patterns of inheritance. Women need to enter pregnancy fully immunized to help prevent infection during pregnancy. Parents who have a family member who was born with a heart disorder need to be aware that other children born to them need to be carefully screened prenatally and at birth for a similar disorder.

### RISK MANAGEMENT FOR ACQUIRED HEART DISEASE

Acquired heart diseases in children that have identified risk factors include rheumatic fever, hypertension, and hyperlipidemia. Rheumatic fever is an autoimmune response that follows a group A  $\beta$ -hemolytic streptococcal infection. Ensuring that all children who have a streptococcal infection such as streptococcal pharyngitis receive adequate antibiotic therapy is essential in preventing the complication of rheumatic fever.

Although hypertension (elevated blood pressure) is associated with a genetic predisposition, other factors such as a high intake of sodium, lack of exercise, and obesity increase the chances a susceptible child will develop the disorder by late childhood (Riley & Bluhm, 2012). Hypertension leads to changes in the left ventricle if not well managed. Urging families to reduce their intake of processed foods and snacks can reduce salt intake in children. School nurses can play an important role in this effort

by monitoring the foods served daily in school cafeterias and advocating for more nutritious menus. Beginning when a child is 3 years of age, blood pressure should be included as part of routine assessment to detect as early as possible the development of prehypertension or hypertension ([Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents, 2011](#)).

Although the tendency toward hyperlipidemia is also inherited, a diet high in saturated fat has been implicated in the development of the metabolic syndrome. It is important that fat intake not be restricted in infants and toddlers because they need the fat for brain development. School-age children and adolescents, however, should reduce their fat intake to 30% of total calories (the same recommendation as for adults). Children from high-risk families (in which a family member has had an early [before the age of 50 years] myocardial infarction or hyperlipidemia) should be regularly screened for elevated cholesterol and triglyceride levels at routine healthcare visits ([Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents, 2011](#)). All families and children should be encouraged to participate in routine aerobic physical activity with daily limits on the amount of screen time, including television, phone, computer, social media, and/or games.

## **Nursing Care of the Child With a Cardiac Disorder**

Caring for a child with a cardiovascular disorder not only requires the nurse to have a strong understanding of the cardiac anatomy and various disease states but also requires a strong understanding of developmental levels and being comfortable working with children and families as they progress through a very stressful time, emotionally, socially, psychologically, and financially.

Most parents have many questions about how to care for a child born with heart disease. Encourage them to learn as much as possible about their child's disorder and give care to their newborn or child whenever they can while in the hospital, so they will feel more secure in caring for that child at home when there are limited resources. Be certain parents are aware that children with heart disease are different from adults with heart disease. They will not have the same degree of activity or intake restrictions, so parents should not unnecessarily limit their infant's activities or types of food. Caring for an older child who has any form of heart disease is equally challenging, as the children themselves can be very stressed or anxious. Offer support at all healthcare visits to help parents feel confident that they know the child's medication regimen and reinforce any signs or symptoms they should report immediately to the child's cardiologist or primary healthcare provider.

It has been noted that many of these children have an altered quality of life. Factors that affect quality of life most are parental support, lower socioeconomic status, limitations due to physical impairment, as well as the level of a child's baseline anxiety and depression ([Drakouli, Petsios, Giannakopoulou, et al., 2015](#)). These can not only affect that child's ability to live a "normal" life but also affect the family. Recent studies

have found the impact of an infant's congenital heart disease on the family is determined by both the child's medical condition and the family's psychosocial factors. Families with a poor social support network may have the greatest need for intervention. The financial burden can also be quite significant for families of children with a cardiac disorder, specifically complex congenital heart disease.

## Nursing Diagnoses and Related Interventions

Nursing diagnoses for children with cardiac disease need to address both physical and psychosocial care.

**Nursing Diagnosis:** Parental health-seeking behaviors related to desire to be informed about child's cardiac disorder

**Outcome Evaluation:** Parents accurately state the nature of their child's illness and unique needs of their child; parents state they will telephone or e-mail the child's cardiologist or primary healthcare provider if they have any questions or concerns.

**Provide or Review Information About Care.** Parents generally ask questions such as "Is it safe to let a baby with heart disease cry?" Crying for a few minutes while a parent warms a bottle or fully awakens at night to breastfeed will not harm the baby. If the child has no immediate needs to be met, such as hunger, cold, or a wet diaper, the child should be allowed to fuss so they can learn to self-soothe and do not become dependent on being held.

Another common question is "Does our child need special nutrition?" As with all newborns, breastfeeding is the preferred method of feeding, and the average infant with heart disease can be successful at this. Because some infants with congenital heart disease tire easily, they may require frequent small feeds or feeding with increased caloric density. Breastfeeding can be more tiring for an infant and may require a mother to pump breast milk so it can be fortified if necessary and fed with a bottle. Infrequently, a child may require a nasogastric or nasojejunal tube for feedings.

"How much activity can we allow the baby?" is another question that is often asked. Again, the answer to this depends on the type and extent of the heart disorder, but, as a rule, infants and young children naturally limit their own activity and stop when they are fatigued. Parents may need some guidance, however, in knowing when to set sensible limits. Encourage parents to observe their infant carefully so they can recognize the signs of respiratory distress or easy fatigability. Older children are usually encouraged to play as they desire and participate in physical education class, but varsity-level competition may require some restrictions, based on the cardiac disorder.

Although children with congenital heart disorders are usually followed by a cardiologist for health supervision, it's important they are also followed by a primary care provider so they receive routine childhood immunizations and health guidance. As a rule, parents need to bring infants and children with heart disorders for prompt treatment for minor illnesses, especially upper respiratory infections, as this may compromise their respiratory status to a greater degree than in children without underlying disease. Hydration must be closely monitored so dehydration does not occur. Baseline tachypnea will increase insensible water loss, so any changes to fluid intake due to illness or changes in metabolic demand may cause excessive fluid loss and dehydration.

***Review Steps for Follow-Up Care and Emergencies.*** Before parents leave the hospital with a newborn with a congenital heart disorder, be certain they have the name and number of the healthcare professional to call if they have a question about their infant's health. Be certain they also have an appointment for a first well-child visit with their primary care provider and an appointment with their specialist(s) so they can feel assured that the responsibility of caring for this child will not be theirs alone but will be shared with other healthcare personnel. If they are ever unsure of whether their child is ill or in distress, urge them to err on the side of caution by telephoning or bringing the child to their primary care setting. Everyone who cares for infants or children with heart disease appreciates the responsibility parents feel and the difficulty they can have in making health judgments about their child.

If you have any concerns, you should check with the family about transportation concerns; other persons to support the parents with providing care, especially when a parent must return to work; or financial concerns. Referring a family to a social worker or case manager before they are discharged may help ensure the child attends all necessary appointments, receives medications or special formulas, or receives home care support if needed.

Parents of newborns are frequently taught cardiopulmonary resuscitation (CPR) before they leave the hospital. Make sure all household members have an understanding of the newborn or child's needs, including feeding regimen, medications, and signs of distress. It is helpful if all adult household members can also learn CPR.

## The Cardiovascular System

The cardiovascular system consists of the heart, which acts as a pump; the blood, which provides the fluid and cells for transport of oxygen, nutrients, regulatory substances, antibodies, and the evacuation of waste products; and the blood vessels, which provide the means and routes for transport throughout the body. The system has a great capacity to adapt to changing body needs.

A thorough understanding of the fetal, newborn, and older child's cardiac anatomy

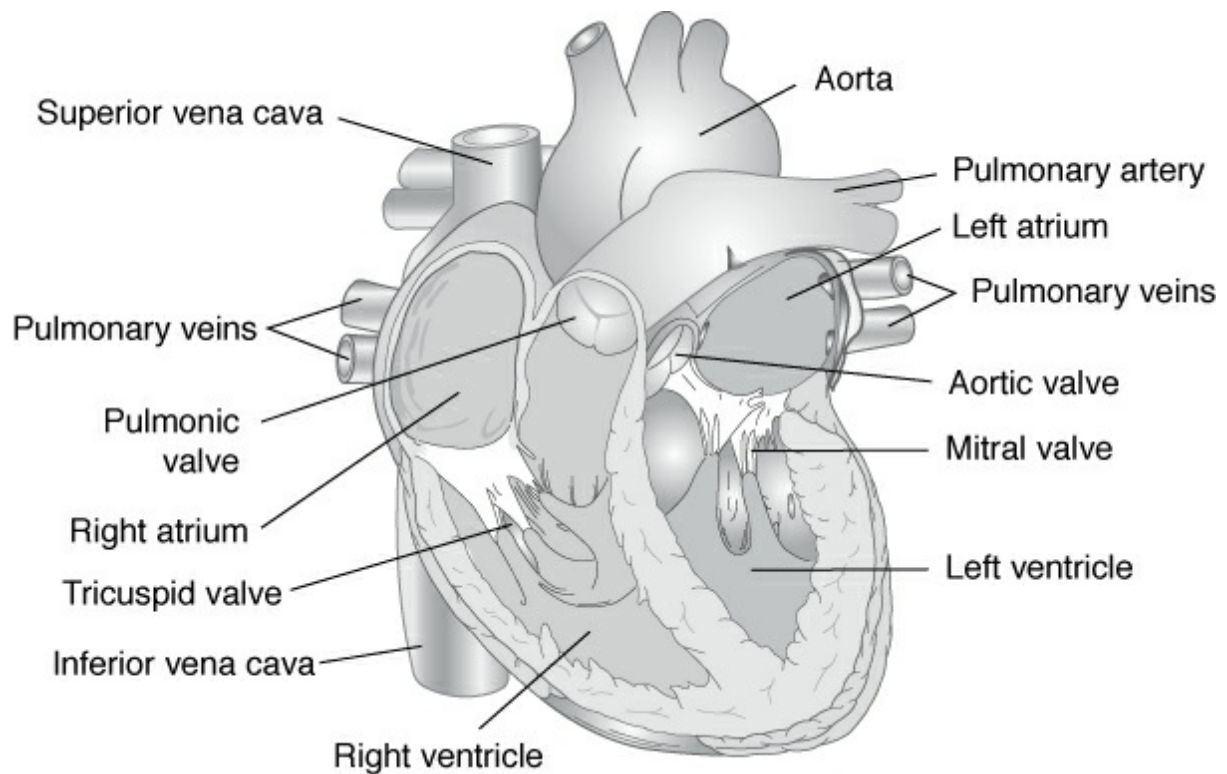

and physiology is essential when caring for children with a variety of heart diseases. It is necessary not only to provide optimal care but also to educate both the child and family so they understand the disease process and management strategies.

## **ANATOMY REVIEW**

Embryologic development of the heart is described in [Chapter 9](#); cardiac adaptations at birth are described in [Chapter 18](#). After the infant transitions from fetal circulation, the heart can be thought of as consisting of two pumps: one on the right side that pumps blood to the lungs, where it is oxygenated before returning to the left side of the heart, and one on the left side that moves the oxygenated blood to peripheral tissues through systemic arteries. After supplying nutrients and collecting wastes, the blood returns through the veins to the right side of the heart, where the cycle begins again.

### **Review of Normal Heart Circulation**

Deoxygenated blood returning from the upper body travels through the superior vena cava (SVC); that returning from the lower body travels through the inferior vena cava (IVC). This blood mixes in the right atrium and then goes through the tricuspid valve into the right ventricle. It then goes through the pulmonic valve and out the main pulmonary artery, continuing out the right- and left-branch pulmonary arteries to the lungs. Once the blood is oxygenated, it returns to the left atrium by way of four pulmonary veins. It then travels through the mitral valve, to the left ventricle, through the aortic valve, and out the ascending aorta ([Fig. 41.1](#)). It continues across the transverse arch and to the descending aorta. As it passes through the transverse arch, three vessels come from this area: the brachiocephalic (which branches into the right subclavian artery and the right common carotid artery), the left common carotid artery, and the left subclavian artery. When blood leaves the heart, it is fully oxygenated; when it returns, it has an average saturation of 75%.

**Figure 41.1** Anatomy of the normal heart. (From Troiano, N. H., Harvey, C. J., & Chez, B. F. [2012]. *AWHONN high-risk & critical care obstetrics* [3rd ed.]. Ambler, PA: Lippincott Williams & Wilkins.)

The coronary arteries come off the root of the aorta. Two coronary origins exist: the right coronary artery and the left coronary artery. The left coronary artery branches into the left anterior descending and the circumflex coronary artery. These vessels are perfused during diastole and provide oxygenated blood to the heart itself. This blood, once deoxygenated, returns to the right atrium by the coronary sinus vessels.

A strong understanding of fetal circulation is important to understanding congenital heart defects. While in utero, the lungs exhibit high resistance to blood flow due to their fluid-filled status and constricted pulmonary arterioles. The lungs do not perform normal gas exchange functions; rather, the placenta performs the actions of oxygenation and carbon dioxide removal for the fetus. Therefore, the fetus requires blood to be mixed in the heart in order to provide oxygenated blood to the body. Three fetal shunts exist to facilitate this circulation: the foramen ovale, the ductus arteriosus, and the ductus venosus.

As the highly oxygenated blood returns from the placenta through the IVC, 40% of the flow is directed across the foramen ovale into the left atria. The foramen ovale is a flapped opening between the atria that allows for this oxygenated blood to bypass the lungs and continue from the left atrium to the left ventricle and out the ascending aorta to the coronaries and upper body, which includes the brain.

The remaining IVC blood mixes in the right atrium with the deoxygenated blood

that has returned from the head and upper extremities via the SVC. This blood then passes through the tricuspid valve, to the right ventricle, and out the pulmonary artery. But because of the higher pulmonary pressures in comparison with the lower systemic pressures, almost 90% of blood flowing from the right ventricle bypasses the lungs via the ductus arteriosus. The ductus is a conduit connecting the pulmonary artery to the aorta at the level of the pulmonary artery bifurcation. It allows blood to bypass the high-pressure pulmonary system and travel directly out the aorta to the body. Only 10% or less of blood ejected from the right ventricle actually passes to the lungs for growth and development.

These two shunts, the foramen ovale and ductus arteriosus, are what allow most of the poorly saturated blood from the upper and lower body to reach the right ventricle and the more highly saturated umbilical venous return to reach the left ventricle.

The final fetal shunt is the ductus venosus. As blood returns from the placenta through the umbilical vein, some goes into the hepatic veins to the liver and slightly more than half passes through the ductus venosus into the IVC. This highly oxygenated blood that is directed to the ductus venosus is then preferentially guided to the foramen ovale, allowing this oxygenated blood to go directly to the left side of the heart and out to the body (Fig. 41.2).

**Figure 41.2** Fetal circulation. (From Sadler, T. W. [2010]. *Langman's medical embryology* [11th ed.]. Baltimore, MD: Lippincott Williams & Wilkins.)

The changes that occur at birth, including hormonal levels, oxygen tension changes, pressure changes, and blood flow, precipitate closure of these three shunts.

As amniotic fluid is absorbed in the lungs and they become a gas-filled system, pressures on the left side of the heart are now higher than on the right. As well, the volume of blood returning from the pulmonary veins directly to the left atrium significantly increases. These changes in volume and pressure allow for the flap of the foramen ovale to be pressed closed against the atrial septum immediately; over the ensuing weeks, the flap will become permanently closed.

The ductus arteriosus will begin to constrict immediately at birth due to changing oxygen tension levels, decreasing prostaglandin levels, and a drop in pressure within the lumen of the ductus caused by changes in pulmonary vascular resistance, ultimately closing completely within a few days at the latest. Factors such as prematurity, congenital heart defects, or persistent pulmonary hypertension can change the expected closure times for these two shunts.

Although the final shunt, the ductus venosus, will immediately see a significant reduction in flow with the elimination of umbilical–placental circulation, some portal venous flow continues through this vessel and will vary over time. Permanent structural closure is thought to occur within 2 to 3 weeks after birth.

Within a few days after birth and with no confounding factors, circulation will follow the same pattern as in an adult. It is important to note though that the pulmonary pressures in a newborn, although lower than systemic pressures immediately after birth, will continue to drop to their lowest level by approximately 4 to 6 weeks of age.

## ASSESSMENT

The heart is intricately involved with all other organs. Changes in the heart's function can affect multiple organ systems, and changes in other organs can be manifested in the cardiac system as well. Therefore, a cardiac assessment must begin with a complete health history and include a thorough physical examination.

### Health History

As a result of technologic advances in prenatal care, heart disease may be recognized early in fetal life. Used during pregnancy, fetal echocardiography can reveal details about heart anomalies as early as 18 weeks into a pregnancy, allowing providers to be prepared with appropriate personnel for safe, effective management of the child's disorder at the time of birth.

If heart disease was undetected in utero, some murmurs associated with abnormal circulation may not be detected until several weeks after birth as pulmonary pressures continue to drop. Half of all newborns with critical congenital heart disease, particularly

those with ductal-dependent defects, have no distinctive murmur, and in many cases, the symptoms of heart disease do not present until after hospital discharge. Universal screening with pulse oximetry testing in the newborn nursery is becoming the standard of care for newborns in the United States, with the goal of increasing the early identification of previously undiagnosed cyanotic heart disease.

A thorough child and family history is important to obtain. The history must include birth history with maternal and newborn issues noted. The pregnancy history will determine whether an intrauterine insult such as infections, medications, or drug use could have led to poor fetal formation. It is important, though, to understand that congenital heart disease has no one identified cause; many mothers who lead healthy lives and have healthy pregnancies may have a child with a cardiac disorder. The nurse must support the family and ensure they feel no guilt for the birth of a child with an anomaly.

Pertinent family history relative to the cardiac examination includes family members with cardiac disease before the age of 55 years, any episodes of sudden death, any other children born with heart problems, and any dysrhythmias. A family history is important for assessment because some heart disorders may have a polygenic inheritance pattern. Heart disorders also occur as an anomaly in chromosomal disorders such as Down syndrome, Turner syndrome, William syndrome, and DiGeorge syndrome. Therefore, if certain genetic disorders are noted, investigation into associated cardiac anomalies is necessary.

The child's current health status is important—not only their medical and surgical status, prior hospital admissions, and current medications but also their developmental level and timeline for attaining milestones. Some children may not be able to meet milestones on time because of their easy fatigability or extended hospital stays. Specific questions that indicate cardiac function focus on activity level, weight gain, and events such as chest pain or syncope. Remember, an infant's "activity level" is evaluated by how they feed: How long does it take? Do they take frequent rests? Do they become tachypneic, diaphoretic or show other signs of distress while feeding? These are indicators of an inability to meet the metabolic demands incurred while feeding and could be related to poor cardiac function. Older children will be assessed based on their ability to keep up with their peers during times of activity such as recess, gym class, or participation in sports.

It is important to note the child's height, weight, and body mass index (BMI), as well as their vital signs, specifically heart rate, respiratory rate, blood pressure, and oxygen saturation. You will plot the child's growth parameters on the appropriate growth charts and note any deviations from their standard curve. Many children with underlying cardiac diseases may not grow on a "normal" curve but will maintain their own version of a normal curve.

You must also know the normal ranges for vital signs for children of all ages in order to perform an accurate assessment.

## General Appearance

Once you have done a thorough review of the child's and family's history, you can perform a cardiac assessment. Upon entering a child's room, you should do a brief visual assessment. Does the child appear calm and comfortable? Is he lethargic? Is she in distress? What color are the child's extremities? You should also take time to interact with the child at a developmentally appropriate level before actually performing the physical examination. Taking a few minutes to play or talk with a child can gain the child's trust and allow for a more accurate, complete examination. Infants can sit with their caregiver to feel safe and comfortable. If they are sleeping, attempts should be made to not disturb them while performing as much of the physical exam as possible. Feeding infants while performing an exam may also help to keep them from becoming upset. Older children can be distracted with noises, songs, bubbles, or videos. They too should be allowed to stay with a caregiver to keep them feeling safe and unafraid.

Be certain to inspect the distal extremities for color and measure capillary refill time, as these are indicators of poor tissue perfusion. When pressure is applied to a nail bed, it will blanch white and then quickly return to pink in a child with good circulation and oxygenation. Normal capillary refill time is less than 2 to 3 seconds. In a child with poor tissue perfusion, the pink color returns more slowly.

The mucous membranes of the mouth are the most accurate site to assess for cyanosis, so always assess the buccal membrane and lips for a blue color as these are less likely to be affected by environmental temperature. Cool, cyanotic extremities in newborns is termed *acrocyanosis* and is a normal finding in the first 24 to 48 hours of life that should not be confused with cyanosis related to heart disease. Measuring an oxygen saturation will give a more accurate measurement of circulating oxygen levels.

## Physical Examination

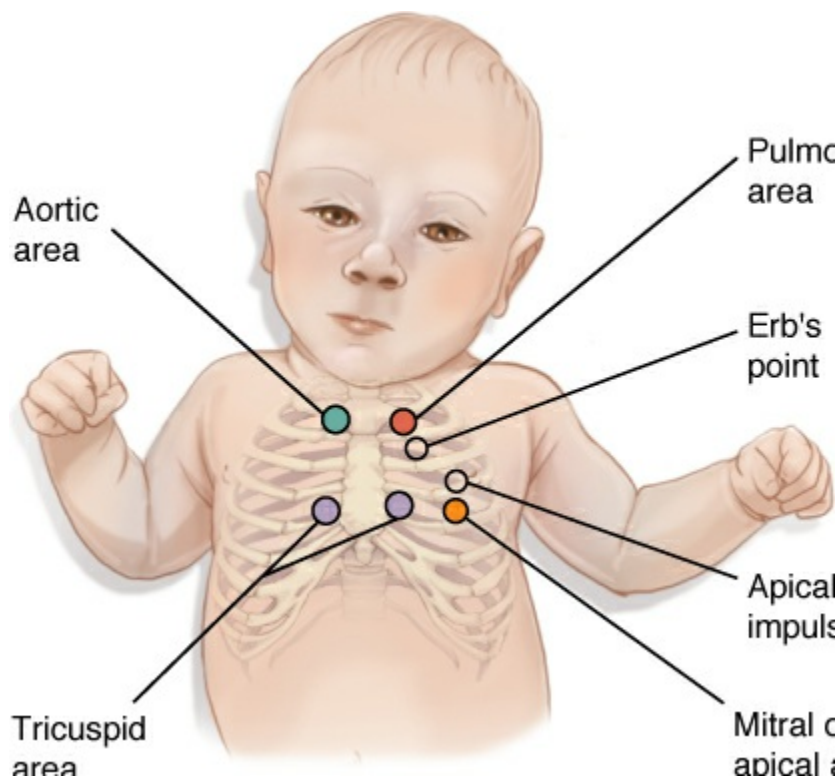

Before actually placing your stethoscope on the patient's chest, you should place your hand on the left side of the chest to evaluate for the apical impulse, thrills, lifts, or heaves. The apical point of maximal impulse (PMI) is normally located at the fourth or fifth intercostal space, on the midclavicular line in infants and children. Deviations in the PMI can be indicators of an enlarged heart due to illness, heart failure, or congenital heart defects.

A thrill is a vibration felt secondary to significant cardiac murmurs. It feels like the throat of a purring cat and occurs because of turbulent blood flow. A lift is a forceful cardiac contraction that causes the hand to move up. A heave is a very forceful cardiac contraction that actually causes the hand to move up and laterally.

Cardiac auscultation can be challenging in infants and young children because of their dislike of cold environments and strangers as well as fear of painful procedures such as immunizations that they come to associate with healthcare providers. A child who is ill is also more likely to be irritable and uncooperative. It is important for the room to be quiet and for the child to not speak during the examination. A pediatric-size

stethoscope is necessary in order to differentiate where abnormal sounds are heard. The stethoscope has a diaphragm for hearing high-frequency sounds and a bell to detect low-frequency sounds. As you are listening to heart sounds, focus on the “normal” sounds of S1 and S2, the opening and closing of the valves. Then, listen for other sounds beside those two. You must try to block out respirations and listen for several heart beats at each location. Auscultation should be performed in a systematic manner (Fig. 41.3). With the child in a sitting position (either alone or in a parent’s lap), you should start your assessment with the diaphragm of your stethoscope at the second intercostal space, at the right upper sternal border, then proceed to the second intercostal space at the left upper sternal border, and then continue listening down the left sternal border until you reach the fifth intercostal space. Once at this point, you should begin moving your stethoscope laterally, to the midclavicular line and out to the midaxillary line. After you have completed listening to the child’s chest, you should then listen to their left back, along the spine, starting at the scapula and progressing halfway down the back. Finally, the chest assessment should be completed once again with the child supine.

All children may not participate with such a thorough examination, but this is the ideal technique.

**Figure 41.3** Sites for cardiac auscultation. (From Stephen, T. C., Skillen, D. L., Day, R. A., et al. [2013]. *Canadian Jensen’s nursing health assessment: A best practice approach*. Philadelphia, PA: Lippincott Williams & Wilkins.)

## First Heart Sound

The first heart sound (S1) is produced by the mitral and tricuspid valve closing. Blood fills the ventricles, and as ventricular pressure exceeds atrial pressure due to the volume within, the mitral and tricuspid valves are forced close. At this time, the aortic and pulmonic valves are forced open and the ventricles contract, ejecting blood out the aorta and pulmonary artery. This action is termed **systole**.

### Second Heart Sound

The second heart sound (S2) is produced by closure of the aortic and pulmonic (semilunar) valves. After the ventricles contract and empty, the aortic and pulmonic valves close during ventricular relaxation. Relaxation of the heart is termed **diastole**.

The pulmonary valve normally closes after the aortic valve. During inspiration, the aortic and pulmonary valve components close approximately 0.05 seconds apart. This is termed a split-S2 and is a normal finding. Inspiration causes the intrathoracic pressure to become more negative which leads to an increase in venous return to the right heart and lowers pulmonary resistance. These actions prolong right ventricular systole and shorten left ventricular systole by reducing pulmonary venous return to the left heart. During expiration, the reverse occurs, so the S2 is noted as a single sound. A split-S2 can be very difficult to detect, especially in an infant with a rapid heartbeat or in an uncooperative child. On auscultation, the S2 component is not as crisp as S1; there is a subtle difference to the heart sound as the valves close at different times.

A very noticeable split-S2 or one that does not change with inspiration and expiration can be indicative of right heart volume overload, as seen with an atrial septal defect (ASD); this is termed a *fixed split-S2*.

### Third Heart Sound

The third heart sound (S3) is produced from the rapid filling of the ventricles in early diastole and is best heard with the bell of the stethoscope. This can be a normal sound in children and is likened to the rhythm of “Ken-tuc-ky” with the last syllable being the S3 sound. Some cardiac diseases are associated with this sound as well, especially those associated with myocardial dysfunction or volume overload conditions.

### Fourth Heart Sound

The fourth sound (S4) is produced by atrial contraction in late diastole and is always pathologic. It is heard best with the bell of the stethoscope and produces a gallop rhythm likened to “Ten-ne-see” with the first syllable being the S4 sound. This sound is noted in conditions associated with decreased ventricular compliance.

### Murmurs

**Heart murmurs** are defined as turbulent flow through an abnormal valve, vessel, or chamber. A murmur can be either innocent or pathologic. Innocent murmurs are not associated with any intracardiac disease, whereas pathologic murmurs are always

associated with a cardiac anomaly or altered cardiac function. Increased metabolic states that occur with anemia, fever, pregnancy, or anxiety can alter the characteristics of an innocent murmur.

When noting a murmur, you need to assess and document:

- Its position in the cardiac cycle (systole, diastole, continuous)
- Quality (harsh, soft, blowing)
- Pitch (high- or low-sounding noise)
- Intensity (loudness)
- Location (where it is heard best or the point of maximum intensity)
- Radiation (do you hear it elsewhere beside the maximum intensity area)
- Presence of a thrill (a palpable purring sensation)
- The response of the murmur to exercise or change of position

Systolic murmurs are graded on a scale of I to VI (Levine scale), whereas diastolic murmurs are graded on a scale of I to IV. [Table 41.1](#) notes this systolic grading scale. Grading a murmur as II or III is subjective based on the loudness of the murmur. You cannot give a murmur a grade of IV/VI just because it is exceptionally loud. To be graded IV/VI, the murmur must be associated with a palpable thrill. Murmurs graded at V/VI or VI/VI are fairly rare in pediatric patients.

**TABLE 41.1 LEVINE GRADING SCALE FOR SYSTOLIC MURMURS**

<b>Murmur Grade</b>	<b>Characteristic</b>
Grade I	Lowest intensity, difficult to hear
Grade II	Immediately audible but lower intensity
Grade III	Audible and louder than grade II
Grade IV	Murmur is readily noted; has an associated palpable thrill
Grade V	Palpable thrill; murmur can be heard with stethoscope partially lifted off the chest
Grade VI	Palpable thrill; loudest intensity; murmur can be heard with stethoscope raised above the chest

A systolic murmur can be either innocent or pathologic. A systolic murmur is heard immediately after the first heart sound and can continue for varying lengths of time depending on the defect. Common innocent systolic murmurs include the vibratory or “Still’s” murmur. This murmur is thought to be secondary to the blood coming into contact with bands of muscle in the left ventricle. This contact causes a low-frequency sound that has a musical quality to it. It is typically noted at the left mid-sternal area or left lower sternal border and does not radiate. It can be louder or heard for the first time if a patient is febrile or anemic, and it will change in intensity with position changes of the child (sitting to supine). This murmur is heard in 75% of all children but is typically

heard from 3 years old to adolescence.

Although innocent murmurs are of no consequence, parents need to be told when their child has one because this finding will undoubtedly be discovered again at a future health assessment or during periods of increased metabolic rate, such as a febrile illness or anxiety. Activities need not be restricted when a child has an innocent murmur, and the child does not require more frequent health appraisals. Be certain that parents understand that innocent murmurs do not turn into serious murmurs so parents do not view them as a prelude to heart disease. A murmur also does not mean their child has a “hole in their heart.” At future health assessments, parents may need to be reassured again that the murmur is innocent.

Another common innocent murmur of infancy is a pulmonary flow murmur. This murmur is secondary to the turbulent flow of blood through the slightly smaller branch pulmonary arteries and specifically through the left pulmonary artery by way of a more acute angle. It is a high-pitched, harsher murmur heard best at the left upper sternal border with transmission of sounds to the axillae and the left upper back area. This is typically noted after birth and should disappear by the time the child turns 6 months of age, as the pulmonary arteries have grown. If it is still noted at 6 months, the child should be referred to a pediatric cardiologist for further evaluation.

A diastolic murmur is heard immediately after the second heart sound and is always pathologic. It is associated most commonly with regurgitant aortic and pulmonic valves.

Continuous murmurs are also noted in children. A venous hum is an innocent continuous murmur heard most commonly in children 2 to 8 years of age. It is a low-pitched sound, noted typically at the right upper sternal border and is due to the flow of blood from the SVC into the right atrium. This murmur is heard when the child is sitting or standing but will change in quality if the child’s head is turned to the opposite side and will disappear completely if the child lies supine. A persistent patent ductus arteriosus will cause a continuous murmur that is considered pathologic. It is noted at the left upper sternal border or out to the left clavicular area and will not change in quality when the child changes position. See [Table 41.2](#) for a summary of innocent murmurs compared with pathologic murmurs.

**TABLE 41.2 COMPARISON OF INNOCENT AND PATHOLOGIC MURMURS**

<b>Characteristic</b>	<b>Innocent</b>	<b>Pathologic</b>
Timing	Systolic	Systolic or diastolic
Duration	Short	Longer
Quality	Soft, musical, twangy	Harsh, blowing, to and fro
Intensity	Soft	Soft or loud
Position in which heard	Can change in intensity with position changes	Does not change with position changes

## Diagnostic Tests

Many diagnostic tools can provide you with data regarding the heart and its function, health state, or structure. The diagnostic studies performed on a child with suspected heart disease vary with the specific disorder under investigation.

Teaching about tests such as an echocardiogram, electrocardiography, or cardiac catheterization, and providing psychological support to children and their families are two major responsibilities of nurses throughout the assessment process.

### Chest X-ray

Chest X-rays (CXR) provide an understanding of the heart's size and orientation, pulmonary blood flow, and any associated lung disorders, including fluid collections (effusions).

### Laboratory Testing

Basic lab work such as chemistry and hematology tests will provide insight into the child's electrolyte balance, hematologic state, and acid–base balance. Alterations in these can affect myocardial function. Specifically, potassium is lost with most diuretics; calcium is necessary for myocardial contractility and to prevent dysrhythmias; sodium is an indicator of fluid status; hemoglobin and hematocrit determine the need for blood transfusions; and coagulation studies (prothrombin time [PT], partial thromboplastin time [PTT], international normalized ratio [INR]) are imperative before and after cardiac surgery to prevent unnecessary bleeding.

If there are concerns for myocardial damage due to arrhythmia, inflammation, or infection, a specific isoenzyme of creatine kinase (CK), CK-MB, can be tested for along with troponin levels. These lab tests are specific for myocardial injury or damage.

It should be noted that cyanotic children may develop a degree of polycythemia over time as the body develops a greater number of red blood cells in an effort to provide more oxygen carrying capacity to the body. Newborns born at term may have elevated hemoglobin and hematocrit levels at birth and progress to their nadir (lowest blood count level) at 8 to 12 weeks of life as they transition from fetal hemoglobin production to adult hemoglobin production (Kett, 2012).

C-reactive protein (CRP) is an indicator of an active infectious process, and erythrocyte sedimentation rate (ESR) is an indicator of inflammation such as occurs with rheumatic fever, Kawasaki syndrome, or myocarditis (Xiu-Yu, Jia-Yu, Qiang, et al., 2010).

B-Type natriuretic peptide (BNP) is a substance secreted from the ventricles in response to changes in pressure that occur when heart failure develops and worsens. The level of BNP in the blood increases when heart failure symptoms worsen and decreases when the heart failure condition is stable. No heart failure is indicated by a level less than 100 pg/ml. This marker shows promise for the ongoing evaluation of a child's cardiac status.

Arterial blood gas testing provides information regarding the child's arterial acid–base balance (pH and base status), carbon dioxide, oxygen, and bicarbonate levels. This test requires access to an artery and is usually only performed in acute settings such as an emergency department or intensive care unit.

### Electrocardiogram

An *electrocardiogram* (ECG) is a written record of the electrical activity generated by the heart and provides information about heart rate, rhythm, state of the myocardium, presence or absence of hypertrophy (thickening of the heart walls), ischemia or necrosis due to inadequate cardiac circulation, abnormalities of conduction, or the effect of various drugs and electrolyte imbalances on the heart. Changes in the size or shape of the various waveforms may indicate chamber enlargement or poor function. If a child is experiencing an actual arrhythmia, it will be documented, but it will not capture intermittent events consistently. Details regarding ECG waveforms will be discussed with dysrhythmias later in this chapter.

### Holter/Event Monitor

A Holter monitor is worn for 24 hours and gives a complete account of every heart beat the child experiences. This allows for evaluation of average rate, rhythm, and frequency of ectopic beats. An event monitor is kept by the child for at least 30 days and can be triggered to record either automatically or manually, if the child experiences a sensation such as chest pain or palpitations. This allows for documentation of potential intermittent dysrhythmias such as supraventricular tachycardia. This data is then transmitted to a cardiologist for interpretation.

### Transthoracic Echocardiogram

An echocardiogram is a noninvasive ultrasound of the heart that gives detailed information about heart structure and function. For this, high-frequency sound waves, directed toward the heart, are used to locate and study the movement and dimensions of cardiac structures, such as the size of chambers; thickness of walls; relationship of major vessels to chambers; and the thickness, motion, and pressure gradients across valves. It can also evaluate velocity of blood flow through the heart, estimate pressures in the heart chambers and lungs, and provide three-dimensional images of structures. You can remind parents that echocardiography does not use X-rays, so it can be repeated at frequent intervals without exposing their child to the possible risk of radiation.

The use of a transesophageal echocardiogram (TEE) is another option to better evaluate the heart anatomy. In this imaging option, the TEE probe hangs in the esophagus immediately posterior to the heart and provides high-quality images of intracardiac structures because of the absence of interfering structures such as lung and bone. If a TEE is necessary, it will be done under moderate sedation or general

anesthesia because children will not tolerate a probe being placed down their esophagus while awake.

### Computed Tomography/Magnetic Resonance Imaging

These noninvasive imaging modalities provide very detailed images of the heart and chest structures and are typically used as an adjunct to echocardiography. Computed tomography angiography (CTA) of the cardiovascular system provides excellent anatomic imaging of the chest structures, including the coronary arteries, through the use of radiation. Although computed tomography (CT) is very brief, it does require a slower heart rate, and breath holding may be necessary to produce the best images. CT can be reconstructed to provide 3D images. Cardiac magnetic resonance imaging (MRI) can provide information regarding cardiac anatomy and function, blood flow measurement, tissue characterization, myocardial perfusion, and viability. An MRI does not provide radiation but is a much longer test and requires near stillness to be accurate. Many young children will require moderate sedation to successfully complete an MRI.

### Exercise Stress Testing

Exercise stress testing (EST) is used to evaluate a child's clinical condition during periods of increased myocardial demand, such as with exercise. Exercise testing can be accomplished with a treadmill, bicycle, or a 6-minute walk to increase the child's heart rate. The child's heart rate and rhythm are continuously monitored, and blood pressure is measured intermittently. It is also possible to perform pulmonary function testing before and immediately after exercise to evaluate lung capacity. Many children referred for an exercise stress test have complaints of shortness of breath, chest pain, or palpitations with exercise. EST is performed in an effort to recreate these symptoms and evaluate for any true cardiac involvement in producing these symptoms. Very young children (less than approximately 8 years old) may have difficulty performing an EST on a bicycle or treadmill because of the size of the equipment and reference values for the 6-minute walk continue to be validated for children and adolescents.

### Cardiac Catheterization

This procedure is invasive; catheters are inserted through a large vein and artery and floated into the heart. A cardiac catheterization allows for direct measurements of pressure as well as visualization of the heart and all blood vessels with the aid of a contrast medium. Cardiac catheterization uses fluoroscopy, which is a form of imaging that uses radiation to generate real-time moving images of structures.

Many corrective procedures can also be performed in the catheterization lab, such as atrial and ventricular septal defect closure, patent ductus arteriosus closure, or valve replacement. Care of a child after a cardiac catheterization will be discussed in greater detail later in this chapter.

## Systemic Assessment

As previously stated, a cardiac assessment cannot be performed isolated from other systems. The child's respiratory status must be evaluated for increased rate or work of breathing, which could be secondary to increased pulmonary blood flow due to a defect or congestive heart failure. Frequent upper respiratory tract infections can also occur and may be an indication of the need for corrective surgery. The abdomen should be palpated for liver size, as hepatomegaly is an indicator of poor right heart function. Urine output and feeding tolerance are also indicators of cardiac output. An infant should have approximately 6 to 8 wet diapers per day; older children should void several times daily, and the urine should be light in color. Edema from retained or excess fluid is a late sign of heart disease in children. If edema does occur, periorbital edema generally occurs first.

A child's neurologic status should be considered as a possible indicator of cardiac output. If a child is lethargic or not interactive, they may be fatigued or be experiencing poor tissue perfusion. Finally, distal extremities must be evaluated for capillary refill time, presence of palpable pulses, temperature, and color—all indicators of adequacy of cardiac output.

Performing an accurate, thorough cardiac history and examination of a child is imperative to understanding the child's health state, evaluating the effectiveness of treatment regimens, and educating families. You will need to practice these assessments, but in time, you will become confident and proficient.

## Congestive Heart Failure

Many cardiac disorders, including congenital heart defects, or acquired disorders such as cardiomyopathy or Kawasaki disease can manifest with either very subtle physical symptoms or symptoms of congestive heart failure with varying degrees of severity. It is important for you to understand the physiology behind the concept of heart failure and how children present when they are experiencing heart failure. Therefore, congestive heart failure is presented before further discussions about specific disorders because any myocardial dysfunction, regardless of etiology, can present with some degree of congestive heart failure.

To understand congestive heart failure, the nurse must first understand the components of adequate cardiac function. Cardiac output is the volume of blood pumped by the ventricles each minute. The formula for calculating cardiac output is heart rate multiplied by stroke volume. Stroke volume is affected by the following factors:

- **Preload:** the volume of blood in the ventricles at the point just before contraction; it is an indicator of circulating blood volume.
- **Contractility:** ability to modulate the rate and force of fiber shortening
- **Afterload:** amount of resistance met by the ventricles upon ejection
- **Compliance:** the ability of the ventricles to stretch and fill

Infants and children can easily modify their heart rate in an effort to increase cardiac output, but they are not as able to change their stroke volume. Much of the therapy for pediatric heart failure is aimed at altering those factors that affect stroke volume, in particular, reducing preload and afterload and increasing contractility to promote better cardiac output.

**Congestive heart failure (CHF)** is defined as the inability of the heart to supply adequate oxygenated blood to meet the metabolic demands of the body. Heart failure is a cluster of symptoms and physical examination findings that are secondary to an underlying process. The primary processes can be systemic or directly related to the heart. The most common causes of CHF in children are congenital heart defects that produce an excessive workload on the myocardium, cardiomyopathies due to metabolic disorders, infectious diseases, drugs, Kawasaki disease, and myocardial dysfunction after heart surgery. Regardless of the underlying etiology (inability to meet metabolic demands, decreased filling, or obstruction of flow), the outcomes are the same: Either one side or both sides of the heart are unable to pump effectively and will eventually fail if the root problem is not corrected.

When the heart begins to perform inadequately, several physiologic responses occur. The initial neurohormonal response to decreased cardiac output is peripheral vasoconstriction and fluid retention. The sympathetic nervous system provides a rapid response by increasing heart rate (chronotropy), stimulates myocardial contractility (inotropy), and promotes regional vasoconstriction. A longer term mechanism will occur with activation of the renin–angiotensin–aldosterone system (RAAS), which stimulates renal fluid retention to expand vascular volume. The body's goal is to maintain adequate blood pressure and circulating blood volume. Stroke volume and cardiac output initially improve, but because the underlying etiology of the poor cardiac output has not been addressed, the heart eventually becomes overloaded from the extra volume and cannot maintain adequate contractility against the increased afterload. In addition, the vasoconstriction and redistribution of blood flow to ensure adequate perfusion of vital organs (brain and heart) occur at the expense of skin, intestinal, and renal blood flow. This leads to lactic acidosis secondary to anaerobic metabolism, fatigue, an intolerance to oral intake, decreased urine output, and electrolyte imbalance.

## **ASSESSMENT**

Children in a state of heart failure, regardless of the underlying etiology, will initially present with similar clinical symptoms, such as tachycardia and tachypnea. Infants and young children may present with poor feeding and failure to thrive, whereas older children may complain of fatigue, exercise intolerance, and breathlessness. CHF is more difficult to detect in infants because it may be more subtle. The infant may be noted to have rapid respirations and to use accessory muscles of respiration. The infant will tire easily, may be diaphoretic, or may have difficulty sucking because of the dyspnea and the energy required to eat. A child may gain weight from fluid overload, but more frequently, an infant will lose weight because their caloric expenditure is greater than

the caloric intake.

Right-sided failure leads to hepatomegaly, increased venous pressure noted in jugular venous distention in older children, or periorbital edema. Left-sided failure results in increased pulmonary pressures, rales, tachypnea, and shortness of breath.

Regardless of age, but depending on the degree of heart failure and the amount of time the child has experienced the failure, the clinical examination may reveal hepatomegaly, a cardiac gallop, or an enlarged heart on chest radiograph, with or without pulmonary edema.

With left-sided heart failure, back pressure causes blood to accumulate in the pulmonary system, causing orthopnea (difficulty breathing except in an upright position because of increased pulmonary congestion). The child may demonstrate use of accessory muscles to support their breathing, which causes intercostal, substernal, and/or suprasternal retractions. The sound of rales (crackles) can be heard on auscultation. Left-sided CHF can ultimately lead to right-sided failure, as excessive pressure in the pulmonary system prevents blood from leaving the right ventricle.

Right-sided heart failure manifests with an enlarged liver, which is palpable below the costal margin. Periorbital edema may be noted as well as jugular venous distention in older children. Generalized edema may be noted, but this is uncommon in children (Box 41.2).

#### BOX 41.2

### Nursing Care Planning Using Assessment

#### ASSESSING A CHILD WITH CONGESTIVE HEART FAILURE

## THERAPEUTIC MANAGEMENT

Management of heart failure is twofold: (a) symptomatically manage the patient and (b) treat the underlying cause of the heart failure. Management in children is difficult because all therapies are based on adult heart failure studies and extrapolated to pediatric patients. It is difficult to study heart failure in children because of the heterogeneity of the patients and underlying disorders. Nevertheless, several pharmacologic agents are staples in heart failure management. As previously stated, the

goal is to decrease any fluid overload, enhance myocardial contractility, and decrease afterload in order to ensure adequate perfusion and decrease the work of the heart.

Be certain that outcomes established for the care of a child with congestive heart disease are realistic in light of the child's overall condition and are individualized for each child. Not all children may be able to attain "normal" vital signs, but they should be comfortable and be able to participate in their regular daily activities, regardless of the actual heart rate or respiratory rate. Interventions focus on helping support heart function and helping parents deal with this crisis until the child is stabilized and the underlying condition can be treated, if possible.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Altered cardiac output related to inadequate heart function

**Outcome Evaluation:** Child will maintain heart rate and blood pressure within normal limits; adequate tissue perfusion, as noted by capillary refill time less than 2 to 3 seconds and warm and pink extremities.

Digoxin may be used for its positive inotropic and negative chronotropic effects. It has been thought that the increased contractility would be beneficial, but this has not been consistently demonstrated in studies. Although the use of digoxin in adults fell out of favor after a 1997 study showed no improvement relative to placebo, it remains common in many pediatric centers for infants and children because of its historical physiologic benefit and symptom relief. Typically, the medication is used in oral form, and it is not routinely prescribed with a loading dose because of the potential side effects. It is rarely given in an intravenous (IV) form. Although digoxin has a narrow therapeutic window and toxicity can cause significant side effects, such as nausea and vomiting, dizziness, diarrhea, headache, arrhythmia, and bradycardia, levels are not routinely monitored. If dosing is appropriate for a patient's weight and electrolyte status (specifically potassium level) is normal, the digoxin is considered to be therapeutic. If a child is bradycardic for their age and the heart rate is not their normal baseline value, a provider should be consulted before giving the medication.

Many children are discharged to home on digoxin. Be certain that parents understand the drug's correct dose and frequency of administration, typically twice a day in young children and infants ([Box 41.3](#)). Have them demonstrate drawing up the correct amount of oral solution into a syringe. Make sure they understand they must use the same size syringe each time, as many parents may not understand the different volumes held by different syringes. Help them choose a specific time for administration to which they can adhere faithfully. Support them by making out a medication calendar or urge them to leave a reminder on their phone to help them

remember to give the drug. Parents must also be reminded to call for a refill *before* the medication actually runs out. As with all oral solutions, they are encouraged to draw up the medication away from the infant or child to prevent the bottle from getting knocked over and medication being lost.

### BOX 41.3

## Nursing Care Planning to Empower a Family

### GIVING DIGOXIN SAFELY AT HOME

**Q.** Megan’s mother says to you, “The doctor has prescribed our daughter digoxin to take at home. Are there any special things we should do?”

**A.** Use the following guidelines to ensure safe digoxin administration at home:

- Always use only a clearly marked syringe so the dose given is accurate and consistent.
- Do not change the amount or timing of the dose without specific instructions from your cardiologist.
- If you miss a single dose, give the next dose on time as prescribed. If you miss more than one dose, telephone your cardiologist for further instructions.
- Give digoxin 1 hour before or 2 hours after feeding to ensure complete absorption and to avoid a dose being lost if the infant spits up.
- If a dose is vomited, do not repeat the dose. Give the next dose at the scheduled time. If the child vomits the next dose, call your cardiologist as this could be a sign of toxicity.
- Keep the medication bottle away from the child. Draw up the dose away from the child and recap the bottle to prevent it from being knocked over and medicine being lost.
- Call your cardiology office for a refill several days before you actually run out of medicine so there is no lapse in medication availability.
- Direct the parents to NOT give their child any herbal supplements or other over-the-counter medications unless directed by their provider. Many supplements interact negatively with prescribed medications or we do not completely understand the interactions. Simple over-the-counter (OTC) medications such as acetaminophen or diphenhydramine (Benadryl) are typically safe, but it may be best to clear it with the provider before giving the first time.

Angiotensin-converting enzyme (ACE) inhibitors are another medication used in the traditional triad of pharmacologic management of pediatric heart failure. ACE inhibitors reduce afterload by blocking the conversion of angiotensin I to angiotensin II, a potent vasoconstrictor. They also block the activation of the RAAS and decrease adrenergic activity. This causes vasodilation, improves tissue perfusion, and reduces congestion by natriuresis. They have also been shown to reduce cardiac myocyte

remodeling by preventing fibrosis. Examples of such medications are captopril, lisinopril, and enalapril. All three are available as an oral solution. Care must be taken when planning a medication schedule for a patient on a diuretic and an ACE inhibitor. If the two medications reach peak effect at the same time, the child is at risk for hypotension. Therefore, the nurse must ensure the medications are given 1 to 2 hours apart in order to prevent this complication. ACE inhibitors can also cause a cough, which can be irritating and prevent further use of this category of medications.

Although evidence is lacking that beta-blockers reduce mortality in children with heart failure, the therapy continues to be used in an effort to affect the counter-regulatory features of CHF, specifically the activation of the sympathetic nervous system and the RAAS. Reduction in the RAAS reduces preload and then reduces ventricular wall stress and cardiomyocyte remodeling. Studies in children with a cardiomyopathy have shown an improvement in left ventricular function, improved exercise tolerance, and decreased need for heart transplantation with beta-blocker use.

Angiotensin II receptor blockers (ARBs) are a new group of agents being used very successfully in adults, with some sporadic use in the pediatric population. They act by inhibiting the RAAS, which decreases afterload and promotes reversal of ventricular remodeling with long-term use. Few data are available on the use of ARBs in children, so ACE inhibitors remain the preferred agent unless they are not tolerated. The use of one specific ARB, losartan, is noted in the literature, specifically in patients with Marfan syndrome or hypertension. Evidence in the adult literature show that losartan slows and reverses the dilation of the aortic root in this group of patients, but these results have not been consistently proven in the pediatric literature.

Other groups of medications belong to a category of inotropic agents that work directly on the heart and vasculature. These medications are administered through continuous IV infusions and are limited to intensive care settings. Common medications used in CHF include milrinone and dobutamine.

**Nursing Diagnosis:** Altered fluid balance, greater than body requirements due to poor myocardial function and fluid retention

**Outcome Evaluation:** Clear bilateral breath sounds, no clinical symptoms of respiratory distress (tachypnea, retractions), no peripheral edema, adequate urine output

Diuretics are routinely used to manage pediatric heart failure. The purpose of the diuretic is to increase the excretion of sodium and water, which in turn relieves the symptoms of fluid overload and congestion. Loop diuretics such as furosemide are usually first-line choice, as they block a large proportion of sodium reabsorption. The main complication associated with loop diuretics is hypokalemia. If the dose or frequency of the loop diuretic is significant and hypokalemia is a concern, either potassium supplements can be added, although they are not always well tolerated orally and can cause nausea or vomiting, or a potassium-sparing diuretic can be used, such as spironolactone, which by itself is not a potent diuretic but works

synergistically with a loop diuretic. Spironolactone is categorized as an aldosterone receptor antagonist that has been associated with improved mortality in adult studies. This effect is independent of the diuretic effect.

If a child has dyspnea, hypoxemia, or cyanosis, supplemental oxygen by way of mask or nasal cannula may be necessary. But oxygen is a medication and has a significant vasodilatory effect on the pulmonary vasculature. If a child has a cardiac defect that increases pulmonary blood flow, the use of oxygen will dilate the pulmonary bed further, leading to more pulmonary blood flow and worsening of respiratory compromise. Oxygen should not always be the initial response to low oxygen saturation in many children with congenital heart defects and symptoms of respiratory distress or compromise.

**Nursing Diagnosis:** Risk for imbalanced nutrition, less than body requirements, related to easy fatigability

**Outcome Evaluation:** Child maintains appropriate daily weight gain and percentile curve on individual growth chart.

Maintaining proper nutrition may be a problem for children with CHF because they tire so easily. Eating several small, high-calorie, high-fat meals daily is often less tiring than eating three large meals and still provides adequate nutrition. Calorie requirements may also be supplemented with protein shakes. It should be noted that the act of breastfeeding demands a significant amount of energy. Children with moderate heart failure may need for their mothers to manually express breast milk so they can feed by a bottle to conserve energy and allow for calorie concentration.

Regardless of fatigue, a child in heart failure has increased metabolic demands and calorie consumption and may require daily increased calories to meet those demands and ensure adequate weight gain.

**Nursing Diagnosis:** Fear related to child's ill appearance and possible disease outcome

**Outcome Evaluation:** Parents and child openly discuss fears and concerns, actively question, and express confidence in treatment plan and healthcare team.

Offer time to talk or use therapeutic play so the child can express his or her fears.

Parents of a child with CHF need assurance because they are typically very worried by their child's ill appearance, lack of weight gain, or inability to keep up with others. It is often helpful to point out subtle signs of improvement that they may not notice on their own, such as a slower, less distressed respirations or an increase in daily weight.

If the child will be cared for at home, review CPR to be certain parents know how to use this in an emergency. If a parent will be making more concentrated feeds for the child, be very thorough in reviewing this technique with them. Write out the directions; ensure they have the tools necessary such as measuring cups and are very comfortable making the feed. Alterations in the prescribed concentration of the feed

can cause serious complications such as seizures from hyponatremia or hypernatremia. Be certain they have a follow-up appointment with the cardiologist scheduled and a telephone number they can call if they have any concerns about their child's condition.

Box 41.4 shows an interprofessional care map illustrating both nursing and team planning for an infant with CHF.

## BOX 41.4

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR AN INFANT WITH CONGESTIVE HEART FAILURE

Megan is a newborn who was born with an AVSD and Down syndrome. She does not appear to have other medical issues. The family was not aware of this diagnosis prior to birth. The child is now 2 days old and is being prepared for discharge, but the parents have several questions.

**Family Assessment:** Child's parents were divorced 1 month ago; dual custody of infant granted. Child will spend weekdays with mother, weekends with father. Father is a city bus driver; mother is a paralegal. Father to pay child support; with child support, mother rates finances as "workable."

**Patient Criteria:** Two-day-old infant girl who appears pale, tachycardic, and tachypneic. Child born by vaginal birth; Apgar scores 9 and 8. Afebrile; heart rate is 150 beats/min; respirations are 36 breaths/min. Oxygen saturation via pulse oximetry is 96%. S3 heart sound noted. Lungs with mild rhonchi.

**Nursing Diagnosis:** Risk for activity intolerance due to altered cardiac physiology  
 Risk for altered nutrition due to increased pulmonary blood flow and increased metabolic demands

**Outcome Evaluation:** Child's vital signs remain within age-acceptable parameters; skin color pink and warm; breathing is comfortable with limited use of accessory muscles, lungs clear to auscultation, appropriate weight gain is followed.

Team Member Responsible	Assessment	Intervention	Rationale
-------------------------	------------	--------------	-----------

*Activities of Daily Living, Including Safety*

Nurse	Assess vital signs and heart and lung sounds, as prescribed. Monitor daily weight.	Frequent auscultation of breath sounds (BS) and evaluation of heart rate (HR),	The child's response to feeding and medications may vary as she grows so
-------	--	--	--

	Evaluate for increased work of breathing.	respiratory rate (RR), saturation Daily weight compared to previous day	frequent evaluation is necessary. Daily weights ensure adequate weight gain despite increased metabolic needs.
--	---	--	---

---

*Teamwork and Collaboration*

---

Cardiologist	Assess cardiac anatomy and function. Evaluate need for new or altered doses of medications.	Perform electrocardiogram (ECG) and echocardiogram routinely; assess child. Based on test results and assessment, determine need for medications to manage congestive heart failure (CHF).	Cardiac function may decrease over time if pulmonary pressures elevate or left heart dilates. Child may outgrow medications if weight gain is good.
--------------	--	---	--

---

*Procedures/Medications for Quality Improvement*

---

Pharmacist/nurse	Ensure medications are being given routinely and on schedule. Ensure timing and dosing of medications is safe.	Review all medications with family and confirm times given.	Managing CHF while the child grows and waits for surgery is dependent on the medications prescribed. Diuretics and angiotensin-converting enzyme (ACE) inhibitors
------------------	---	---	--

			should be scheduled several hours apart to prevent drops in blood pressure.
Nutritionist/cardiologist/nurse	Monitor weight gain. Assess electrolytes for hypokalemia.	Monitor weight daily at same time. Administer diuretics as prescribed.	Weight is an indicator of caloric intake and balance. Diuretics reduce edema which decreases respiratory effort. High or frequent doses of loop diuretics can cause potassium losses.
Nurse/respiratory therapist	Evaluate BS and work of breathing.	Assess BS and observe for increased work of breathing.	Atrioventricular septal defect (AVSD) can cause an increase in pulmonary blood flow which can cause congestion, rales, and ultimately changes in pulmonary pressures.

---

*Nutrition*

---

Nurse/nutritionist

Assess child's

Assist family

By

	intake for adequacy. Monitor weight gain.	with concentration of breast milk if necessary, as directed by nutritionist and provider. Encourage family to allow infant to rest during feedings.	concentrating the feeds, the infant can gain more calories in less volume which will then require less time feeding and less energy expenditure.
--	---	---	--

---

*Patient-Centered Care*

---

Nurse	Assess parents' understanding of child's condition.	Educate parents as needed about congenital heart disease and CHF. Ensure both parents have adequate quantities of medications and supplies.	Parents need an understanding of child's illness to respect need for rest and medications.
-------	---	---	--

---

*Psychosocial/Spiritual/Emotional Needs*

---

Social worker/nurse	Assess whether parents feel they have enough emotional support to care for an ill infant at home while waiting for cardiac surgery in a few months.	Discuss necessity for vigilance and keeping infant free of infection.	Respiratory infection could quickly worsen child's condition.
---------------------	---	---	---

---

### *Informatics for Seamless Healthcare Planning*

---

Nurse	Assess whether parents are familiar with cardiopulmonary resuscitation (CPR) technique for infants. Ensure all providers have contact information for parents.	Parents will watch CPR video and be trained in CPR per institution protocols. Obtain all phone numbers and e-mail addresses for parents to ensure successful communication.	Well-prepared parents can be lifesaving for a child with heart disease. Communication with providers is imperative for safety of the infant.
-------	--	---	--

### *QSEN Checkpoint Question 41.1*

---

#### **QUALITY IMPROVEMENT**

Children with CHF are often prescribed digoxin (Lanoxin). Knowing that this drug possesses a high risk of adverse effects if given incorrectly, the nurse provides educational materials to Megan’s parents. Which statement by Megan’s mother would alert the nurse that she has *not* received all the education that she needs?

- a. “I know the drug is thought to help Megan’s heart pump better.”
- b. “It’s important I give the exact dose every time.”
- c. “If I happen to miss a dose, I will not give double the dose at the next time.”
- d. “Nausea and vomiting are expected side effects for the first few weeks of treatment.”

---

*Look in [Appendix A](#) for the best answer and rationale.*

---

## **Congenital Heart Defects**

About 8% of term newborns and 9% to 10% of preterm infants are born with a congenital cardiovascular abnormality (Darst, Collins, & Miyamoto, 2012). Approximately 25% of defects can be considered complex, and one third will require

intervention during infancy. Twenty-five percent of neonates with congenital heart defects have other associated congenital anomalies. However, as a result of the advances in evaluation and treatment of these children, up to 85% of neonates born with congenital heart disease are expected to survive to adulthood.

Congenital heart defects can be classified in many ways based on embryologic formation, structure, or physiology. The defects in this chapter are categorized by physiology; this will help you understand the impact on the child, the symptoms that may be present, and the therapeutic regimens used. Defects are classified as “increasing pulmonary blood flow,” “decreasing pulmonary blood flow,” or “obstruction to systemic blood flow.” The final type of defect discussed is single-ventricle defects such as hypoplastic left heart syndrome. It is an extremely unique defect with very complex physiology and is discussed independent of the other defects.

When caring for a child with a congenital heart defect, it is important to remember normal physiology, as this influences blood flow. The right side of the heart is a lower pressure system than the left side of the heart. This pressure difference allows blood to flow from one chamber to another, specifically from an area of high pressure to an area of low pressure; the blood will always follow the “path of least resistance.” When venous blood from the right side of the heart mixes with blood on the left side, this is a “right-to-left” shunt that delivers deoxygenated blood to the body. Heart defects with this type of blood flow are termed **cyanotic heart disease**. If the blood shunts left to right, then oxygenated blood from the left side mixes with blood in the right side of the heart and goes back to the lungs again. This is called **acyanotic heart disease**.

## DEFECTS THAT INCREASE PULMONARY BLOOD FLOW

### Patent Ductus Arteriosus

A patent ductus arteriosus (PDA) occurs when this fetal shunt fails to close after several days of life. This remnant of fetal circulation remaining patent occurs more frequently in children born prematurely, with an incidence ranging from 20% to 60%. If a ductus arteriosus does not close after birth, it allows blood to flow from the aorta (area of high pressure) through the PDA and into the main pulmonary artery (area of low pressure). The shunted blood then returns to the left atrium of the heart and repeats the cycle. This extra blood flow increases pulmonary circulation. This is an acyanotic defect, as the blood flowing from the aorta is fully oxygenated (Fig. 41.4).

**Figure 41.4** Patent ductus arteriosus. (Asset provided by Anatomical Chart Co.)

### Assessment

This defect produces a systolic murmur early in life and a continuous murmur as the child ages. The murmur is noted at the second intercostal space, left upper sternal border, or out to the left clavicular area. If the defect is large enough, the flow to the lungs will be significant and can cause rales, congestion, increased work of breathing, difficulty feeding, or failure to thrive. Over time, the left heart can become dilated. The severity of the symptoms depends on the amount of blood shunting to the lungs. A PDA is confirmed with an echocardiogram.

### Management

Treatment for a PDA varies. Medical management of a PDA involves addressing the symptoms of the increased blood flow by prescribing a diuretic such as furosemide. The caloric concentration of the infant's feeds may need to be increased in an effort to help the child gain weight. If the child is experiencing significant manifestations of the increased pulmonary blood flow or if left heart dilation is noted from the extra blood flow returning to the left side of the heart, the child will be referred for PDA closure.

If the PDA is noted immediately after birth, indomethacin, a nonsteroidal anti-inflammatory and prostaglandin inhibitor, can be utilized to facilitate closure. This is usually given in three separate IV doses in the newborn nursery. In older children, a PDA can be closed in the cardiac catheterization lab with a device placed in the duct to occlude flow. Occasionally, a duct needs to be closed surgically either for a premature baby who is too small to undergo closure in the catheterization lab or due to other confounding factors. Surgical closure of a PDA is done via a left-sided thoracotomy incision and does not require cardiopulmonary bypass.

### **Atrial Septal Defect**

An ASD is created when a portion of the atrial septal tissue does not completely form. The defect can occur in any location along the septum, but most common is the *secundum* type defect that is located in the center of the atrial septum (Fig. 41.5). Other deficiencies of the atrial septum include a *primum defect* that is found low in the atrial septum near the IVC. Defects in this area are frequently associated with atrioventricular septal defects (AVSD) (discussed in detail later in this chapter). Another atrial defect is found high in the septum where the pulmonary veins enter the left atrium. These are *sinus venosus defects* and allow communication of one or more of the pulmonary veins with the right atrium.

**Figure 41.5** Atrial septal defect. (Asset provided by Anatomical Chart Co.)

Regardless of where the defect is located, the physiology is consistent. This is an acyanotic defect that allows blood to flow from the high-pressure left atrium to the low-pressure right atrium and continue out to the lungs. But because the atria overall have a lower pressure than the ventricles, the amount of blood flow through this defect is significantly limited. This means an ASD may not have a murmur associated with it; therefore, it may go unnoticed if no clinical symptoms exist. Regardless of the presence of a murmur, an ASD may have a fixed split-S2 heart sound.

### Assessment

If the defect is small, it may go undetected or, if noted, may cause no clinical concern and require no intervention. If the defect is large enough, a child may show symptoms of the ASD. The child will present with symptoms of pulmonary overcirculation, such as rales, congestion, tiring with activity, or poor weight gain. Over time, the right heart may also dilate as a result of the increased volume. Murmurs associated with an ASD are not related to flow through the actual defect, as the velocity through the defect is low. Instead, the murmur is related to the relative increased blood volume traveling

across the pulmonary valve. The turbulence created by the increased pulmonary blood flow produces a systolic murmur heard best at the left upper sternal border. An ASD is confirmed with an echocardiogram.

## Management

If an ASD was incidentally noted, is less than 5 mm, and is producing no clinical symptoms, it will not be closed. For clinically significant defects, management will be based on the child's age and the size of the defect. Medical management of the symptoms with diuretics will be attempted first in an effort to allow the defect to close spontaneously. Defects that remain 5 mm or greater with persistent shunting after an observation period should be referred for closure to decrease the incidence of supraventricular dysrhythmias and prevent pulmonary vascular disease. If the defect is 8 mm or larger with evidence of increased pulmonary blood flow, the child will be referred for closure immediately.

A secundum ASD is typically closed in the catheterization lab with a device that sits in the defect space. Sinus venosus and primum defects typically cannot be closed in the catheterization lab because of their anatomy and are referred for surgical closure. Surgical closure involves a median sternotomy incision and cardiopulmonary bypass. These children are typically home within 2 to 3 days of cardiac surgery.

## Ventricular Septal Defect

Ventricular septal defects (VSDs) are the most common defect found in children, either in isolation or combined with other defects. A VSD occurs when a portion of the ventricular septum does not completely close. VSDs may be single or multiple and are defined based on their anatomical location within the septum (Fig. 41.6).

**Figure 41.6** A ventricular septal defect. (Asset provided by Anatomical Chart Co.)

### Assessment

Regardless of the location or classification of the VSD, it is an acyanotic defect that allows oxygenated blood to flow from the left side of the heart to the right side of the heart. This increases pulmonary blood flow and ultimately increases the volume of blood returning to the left heart, causing left heart dilation over time. A murmur is always associated with a VSD because of the high velocity of flow through the defect, producing a harsh, holosystolic murmur noted at the left lower sternal border. The typical murmur of a VSD may not be heard at birth because the pulmonary vascular resistance is still high, which limits blood flow across the defect. As pulmonary resistance decreases over the first 4 to 6 weeks of life, the amount of shunted blood increases and produces an audible murmur. Symptoms associated with a VSD are similar to those found with a PDA or ASD and are determined by the size of the defect. A small defect may have a murmur but produce no clinical symptoms. If the defect is large enough, the increased pulmonary blood flow manifests as symptoms of CHF, such as tachypnea, poor feeding, or failure to thrive. The defect is confirmed with an echocardiogram.

## Management

The child may be medically managed to allow for spontaneous closure of the defect as the child grows. Some children will have an audible murmur but no symptoms of pulmonary overcirculation. These may be very small defects that will close spontaneously. If the child does exhibit signs of pulmonary overload, such as tachypnea, retractions, or rales, management will include use of a diuretic such as furosemide and possibly an increase in the caloric density of the child's formula or breast milk if there are concerns for poor weight gain. As previously stated, breastfeeding demands a significant amount of energy from the child, and mothers may need to manually express the breast milk so it can be fed through a bottle or nasogastric tube.

If closure does not occur over time in a symptomatic child, or if the child experiences persistent failure to thrive, depressed myocardial function, or dilation of the left heart, they will be referred for closure. Some types of VSDs can be closed in the catheterization lab; others are closed surgically. If a child has a small defect that is causing no clinical concerns, the defect does not need to be closed. VSDs are surgically closed through a median sternotomy (entering the chest cavity through the sternum). VSD repairs can be high risk for heart block depending on the location.

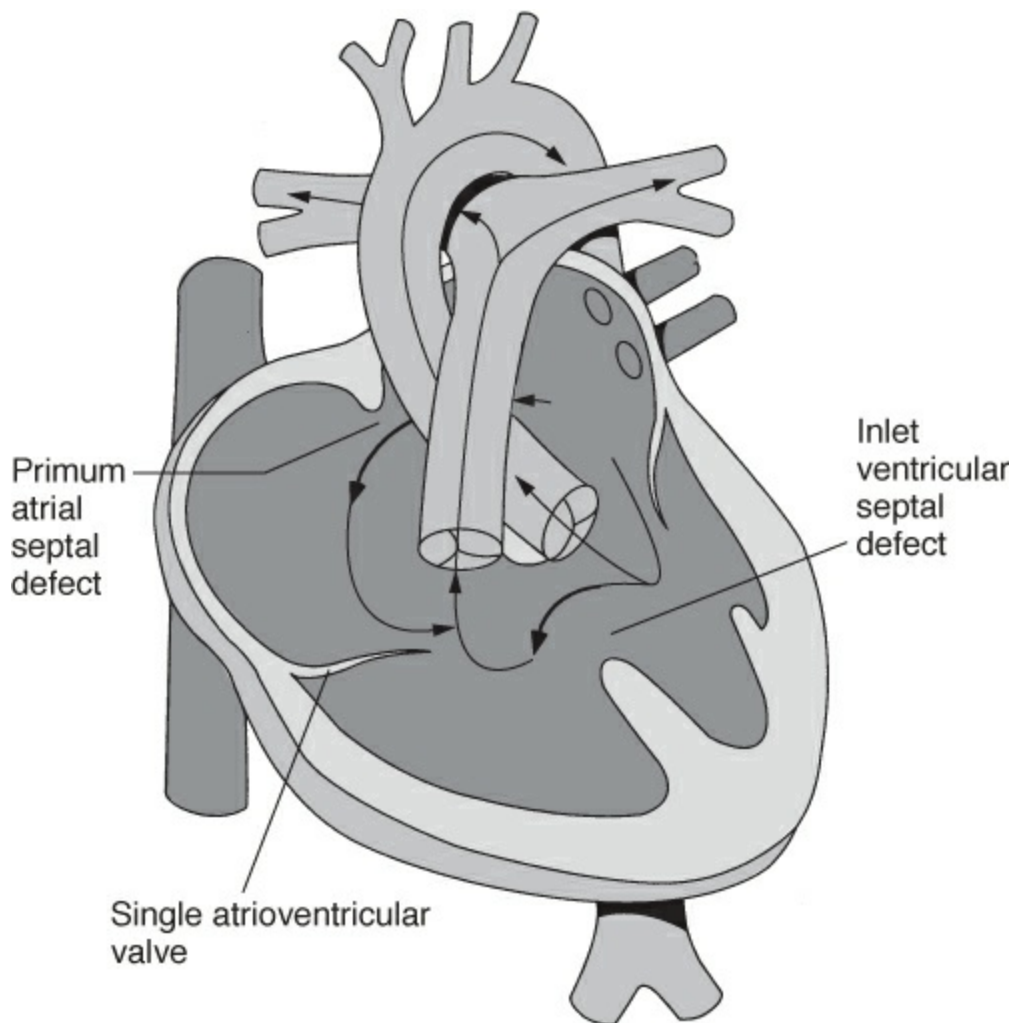

### *What If... 41.1*

**The nurse notices Henry, a 2-month-old with a VSD, is using his accessory muscles while breathing. His mother states he is always breathing like that and sometimes it gets worse when he eats, but she is not concerned because he is not turning blue. What reasons for concern might the nurse identify?**

## Atrioventricular Septal Defect

This defect comprises several congenital heart defects: a primum ASD, a high VSD, and failure of the tricuspid and mitral valves to develop and attach correctly (Fig. 41.7). Varying degrees of abnormality occur with this lesion, from mild septal defects to a complete lack of central septa with incompetent valves on both sides. In a complete AVSD, blood freely mixes between the right and left sides. As with other septal defects, pulmonary blood flow can be significantly increased, but a complete AVSD also allows for right-to-left shunting, which may lead to desaturation. This is not typically noted, though, as the blood will preferentially flow to the lungs (left-to-right shunting). The atria can become dilated through regurgitation of blood through the incompetent valves. Although rare in the general population, as many as 20% of children with trisomy 21 (Down syndrome) who have heart disease, have this type of congenital cardiac disorder (Kucik, Shin, Siffel, et al., 2013).

**Figure 41.7** Atrioventricular septal defect. (From Marino, B. S., & Fine, K. S. [2013]. *Blueprints pediatrics* [6th ed.]. Baltimore, MD: Lippincott Williams & Wilkins.)

### Assessment

The child can present with symptoms of CHF similar to those seen in other defects that increase pulmonary blood flow. Because the degree of increased pulmonary blood flow is excessive, these children can present with significant symptoms early on and are at risk for developing increased pulmonary vascular resistance that can be irreversible if it persists too long. The development of increased pulmonary resistance has been noted to occur more rapidly in children with Down syndrome, necessitating earlier repair in these children. Diagnosis is confirmed with echocardiography. A cardiac catheterization may be performed before surgical correction to measure pulmonary pressures and confirm reactivity with the administration of oxygen or nitric oxide, both of which should cause pulmonary pressures to decrease.

### Management

Management typically includes medications such as furosemide, digoxin, and an ACE

inhibitor like captopril or enalapril. These children may also require concentrated feeds to help maintain weight. Children with Down syndrome experience complications from the increased pulmonary blood flow earlier than children without Down syndrome, so they are typically referred for surgical correction by 3 months of age or earlier if the transthoracic echocardiogram demonstrates signs of increased pulmonary pressures. Children without Down syndrome are referred for repair by 5 or 6 months of age or as clinically necessary.

If the surgical repair needs to be delayed, a temporary measure to decrease the amount of pulmonary blood flow can be performed. This is called a pulmonary artery band, which is a band surgically placed around the pulmonary artery that constricts it to increase the resistance within the pulmonary artery, thus decreasing some of the overall pulmonary blood flow and preventing too much pulmonary circulation and long-term pulmonary vascular changes.

Surgical repair of an AVSD consists of closing atrial and VSDs and repairing the mitral and tricuspid valves to make them functional. It is important that the mitral valve be high functioning, as left-sided valve leakage is not tolerated by children; right-sided leakage is better tolerated. These children are at high risk for heart block after surgical repair. They will have a right bundle branch block on ECG with the VSD repair and may have persistent mitral valve dysfunction (stenosis or regurgitation) after surgery. If this progresses to severe dysfunction, further surgical intervention will be required. The goal is to repair the mitral valve so no stenosis and minimal regurgitation exist. If this cannot be achieved, an artificial valve will be placed.

### **Transposition of the Great Arteries**

This is the second most common congenital defect and is described as reversal of the great arteries. The exact etiology is not completely understood. All other intracardiac structures are normal, with VSDs noted in 50% of these infants. The resultant anatomy has the aorta coming off of the right ventricle and the pulmonary artery arising from the left ventricle. This results in essentially two separate circulations whereby the oxygenated blood returns from the lungs to the left atrium, to the left ventricle, and then proceeds back through the pulmonary artery and to the lungs again, whereas the deoxygenated blood returns from the body to the right atrium, the right ventricle, and proceeds back out the aorta, supplying deoxygenated blood to the systemic circulation (Fig. 41.8). The coronary arteries are positioned on the aorta coming off the right ventricle. Although not typically thought of as a defect that increases pulmonary blood flow, if the defect is undetected or monitored for a longer time, and there is an area that allows for mixing of oxygenated and deoxygenated blood, it is possible for the child to experience increased pulmonary blood flow.

**Figure 41.8** Transposition of the great arteries. (From Perrino, A. C., & Reeves, S. T. [2014]. *A practical approach to transesophageal echocardiography* [3rd ed.]. Philadelphia, PA: Wolters Kluwer.)

### Assessment

Transposition of the great arteries is a cyanotic defect noted immediately after birth. The infant is typically tachypneic, and a murmur may not be noted. Blood must mix to provide oxygenated blood to the systemic circulation. A prostaglandin E1 (PGE1) infusion is started immediately after birth to maintain patency of the ductus arteriosus and encourage mixing of blood. Side effects of a PGE1 infusion can include apnea and hypotension. Apnea occurs in 10% to 20% of patients with congenital heart disease and is more common in children weighing less than 2 kg. It is typically noted within the first hour of the infusion. The goal is to use the smallest amount of medication that keeps the duct open and has minimal side effects. It is best for the child to remain on room air, spontaneously breathing, but the staff must be prepared to offer ventilator support should a child stop breathing.

However, more effective mixing occurs through a patent foramen ovale (PFO). If

the PFO is in any way restrictive at birth, the opening will have to be enlarged at the bedside or in the catheterization lab through a balloon atrial septostomy. This entails a catheter being placed through the IVC up to the right atrium and floated across the foramen ovale. Once the catheter has crossed into the left atrium, a balloon is inflated at the end of that catheter, and the catheter is vigorously pulled back through the septum, effectively creating a larger ASD.

An echocardiogram will confirm this diagnosis. The echocardiogram will also delineate the coronary artery anatomy. Any deviations in this anatomy will impact surgical correction. A cardiac catheterization is not necessary for diagnosis unless the coronary arteries cannot be visualized by echocardiogram.

## Management

This defect requires surgical correction within the first 14 days of life to ensure the most positive outcomes. The repair, termed an *arterial switch or Jatene procedure*, includes dissecting both the pulmonary artery and aorta above their respective valves and switching the vessels to the appropriate location. The final component of the surgical repair is removing the coronary arteries from the base of the original aorta and surgically placing them in an appropriate spot on the new aortic root, now coming off of the left ventricle.

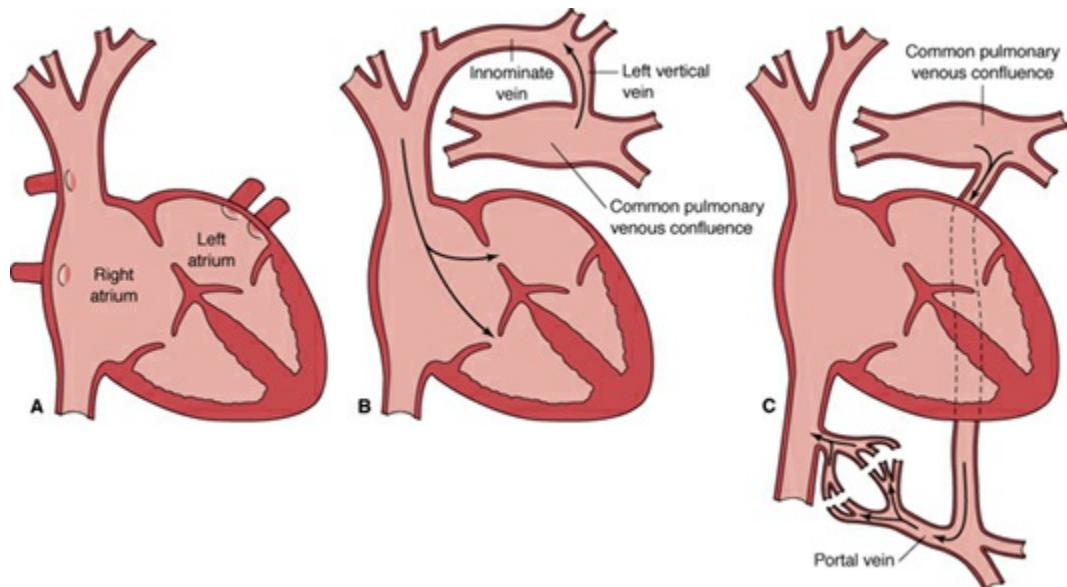

This surgery requires cardiopulmonary bypass, and the postoperative complications are similar to other surgeries. Reimplantation of the coronary arteries, however, produces other potential complications. If any narrowing or obstruction occurs at the site of the implantation, coronary blood flow to the heart can be compromised and produce ischemia. Infants may either manifest very poor myocardial function or S-T segment changes in leads V5 or V6 on the ECG. As well, any obstruction at the great artery suture sites may cause decreased cardiac output and impair ventricular function. This may occur immediately but is also seen frequently as a long-term complication for these children as they grow and the suture line narrows. They may also experience long-segment narrowing of the pulmonary artery as a result of manipulation of the vessel in the original surgery.

These children remain in an intensive care setting from birth until they undergo their corrective surgery. Nursing care before surgery includes ensuring their oxygen saturation remains normal for this defect, which is 75% to 85%; monitoring for signs of increased pulmonary blood flow; and supporting the family as they wait for their newborn to undergo heart surgery.

## **Anomalous Pulmonary Venous Return and Truncus Arteriosus**

Two rare, uncommon cyanotic defects are anomalous pulmonary venous return (APVR) and truncus arteriosus (TA). APVR is a result of failure of the pulmonary venous connections to unite with the left atrium in utero. Instead, they return to another vessel (left innominate, portal, or coronary sinus vein) or directly to the right atrium, and the

oxygenated pulmonary blood return drains back into the right side of the heart. This can be seen with one, two, or three of the veins (partial APVR), or all four veins (total APVR) (Fig. 41.9), draining to the venous side. Total APVR requires urgent surgical intervention. Partial PVR, if only one vessel, can be missed because it may cause no significant clinical effects.

**Figure 41.9** Total anomalous pulmonary venous return. **(A)** Partial anomalous pulmonary venous return (PAPVR). **(B)** TAPVR (supracardiac). **(C)** TAPVR (infradiaphragmatic). (From Nichols, D. G., & Shaffner, D. H. [2015]. *Rogers' textbook of pediatric intensive care* [5th ed.]. Philadelphia, PA: Wolters Kluwer.)

TA is characterized by a single arterial vessel that originates from the heart, overrides the ventricular septum, and supplies all of the systemic, coronary, and pulmonary blood flow (Fig. 41.10). The branch pulmonary arteries arise at some point along this large vessel. Truncus has four classifications, depending on where the pulmonary arteries arise from the truncal vessel. It occurs as a result of the great artery failing to divide in utero into two vessels, the pulmonary artery and the aorta. After birth, the truncus vessel arises from the ventricles; blood ejects and follows the path of least resistance to the pulmonary bed. This is a cyanotic lesion that also requires urgent surgery.

**Figure 41.10** Truncus arteriosus. (From Muscari, M. [2015]. *Lippincott review: Pediatric nursing* [5th ed.]. Philadelphia, PA: Wolters Kluwer.)

## DEFECTS THAT DECREASE PULMONARY BLOOD FLOW

### Tetralogy of Fallot

The prevalence of tetralogy of Fallot (TOF) in the United States is approximately 4 to 5 per 10,000 live births. This defect accounts for about 7% to 10% of cases of congenital heart disease and is one of the most common congenital heart lesions requiring intervention in the first year of life. TOF occurs equally among males and females.

This typically cyanotic defect is defined by four components: pulmonary artery stenosis, VSD, overriding aorta, and right ventricular hypertrophy (Fig. 41.11). The right ventricular hypertrophy is not an isolated problem but occurs secondary to the pulmonary stenosis.

**Figure 41.11** Tetralogy of Fallot. (From Kline-Tilford, A. M., & Haut, C. [2015]. *Lippincott certification review: Pediatric acute care nurse practitioner*. Philadelphia, PA: Wolters Kluwer.)

The degree of cyanosis is directly proportional to the degree of pulmonary stenosis. Pulmonary stenosis can be noted at several sites along this right ventricular outflow tract; most typical is subpulmonary valve stenosis with anomalies of the actual pulmonary valve also seen. Significant narrowing produces increased resistance to blood flowing through the pulmonary valve and out to the lungs. Because of this increased resistance, the blood will shunt right to left through the VSD because the VSD provides less resistance, and this deoxygenated blood travels directly out through the aorta into the systemic circulation. Children with minimal obstruction through right ventricular outflow tract may have normal systemic arterial oxygen saturations and are termed “pink” tetralogy patients.

### Assessment

These children will have a systolic murmur noted at the left upper sternal border; this murmur is due to the turbulent flow out the right ventricular outflow tract. The VSD murmur may not be noticed if the defect is large. Echocardiography will confirm the diagnosis. A cardiac catheterization may be necessary if the coronary arteries are not well visualized. There have been instances where one of the coronary arteries crosses directly over the pulmonary artery. If this occurs, the surgical plan will be altered so as not to damage the coronary artery.

Occasionally, the area below the pulmonary valve may spasm, thereby increasing

the resistance to flow through this area even more. This will cause a greater than usual amount of blood to shunt from right to left across the VSD, and the child will be more deoxygenated. This is termed a *hypercyanotic spell*, or a “tet spell.” The exact etiology of these episodes is unclear, although a number of mechanisms have been proposed, including increased infundibular contractility, peripheral vasodilatation, hyperventilation, and stimulation of right ventricular mechanoreceptors.

During a spell, the child becomes distressed and irritable, possibly without reason. This period of lower saturations is temporary and can be managed by the family by soothing the child if he or she is upset and bringing the child’s knees tightly to the chest in an effort to increase systemic vascular resistance. This increase in the pressure on the left side of the heart (the systemic side) will help force blood back through the pulmonic valve, thereby oxygenating more blood.

In a hospital setting, along with knee-to-chest positioning, blow-by oxygen can be beneficial to enhance circulating oxygen and possibly dilate the distal pulmonary bed. It will have no effect on subpulmonary spasm. The use of sedatives is controversial because they will dilate the systemic circulation, which may enhance right-to-left shunting, worsening the cyanosis. If needed, the use of alpha adrenergic agonists such as phenylephrine causes vasoconstriction and may facilitate more flow out the pulmonary artery.

If a child experiences a true hypercyanotic spell, the parents must notify their cardiologist, as this may be an indication that the child requires corrective surgery soon.

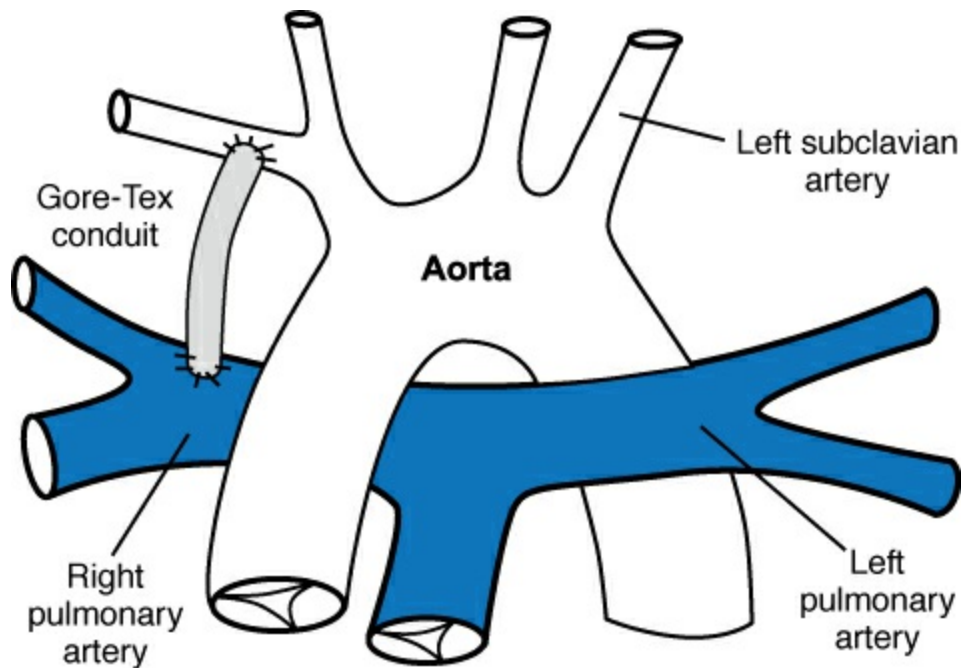

It is possible for children with a “pink” tetralogy anatomy to experience pulmonary overcirculation due to the VSD and have clinical symptoms similar to those previously discussed.

## Management

Children with TOF are generally medically managed and followed by a pediatric cardiologist. If they have trouble gaining weight or experience hypercyanotic spells, they will be referred for surgery. Repair is usually performed by approximately 3 to 6 months of age, regardless of the occurrence of spells. Surgical repair of this defect includes closure of the VSD and repair of the stenotic pulmonary valve and any associated right ventricular outflow tract anomalies. Postoperative concerns center on right ventricular function, adequacy of the pulmonary valve, and flow through the pulmonary artery. In some instances, the pulmonary valve cannot be saved and is completely removed. This creates a continuous, to-and-fro murmur noted at the left upper sternal border, with radiation throughout the chest. The valve will have to be replaced, typically during the child’s school-age years.

If the right ventricular outflow tract narrowing was extremely severe at birth, a child may be referred for a palliative procedure, which will allow for adequate pulmonary blood flow until the complete surgical repair can be performed. This palliative procedure is typically a modified Blalock-Taussig (BT) shunt, which is placement of a conduit (synthetic tube) between the subclavian artery and the pulmonary artery (Fig.

41.12). This allows for a stable source of pulmonary blood flow as blood flowing out of the aorta travels through the shunt and into the lower pressure pulmonary system to become oxygenated. This ultimately increases the amount of oxygenated blood mixing with the deoxygenated blood and increases saturation. These conduits are not made of viable human tissue, however, and will not grow with the child. This is a temporary measure until it is safe for the child to undergo open heart surgery.

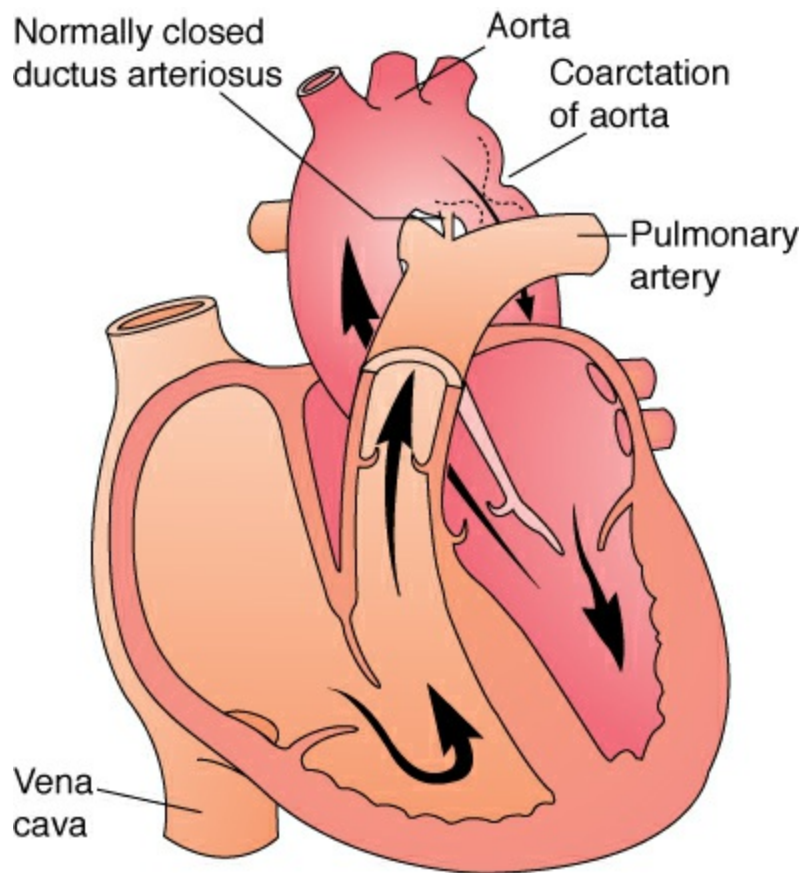

**Figure 41.12** Blalock-Taussig shunt. (From Tecklin, J. S. [2014]. *Pediatric physical therapy* [5th ed.]. Philadelphia, PA: Wolters Kluwer.)

## DEFECTS WITH OBSTRUCTION TO SYSTEMIC BLOOD FLOW

### Coarctation of the Aorta

This defect is typically located at the level of the ductus arteriosus insertion; the mechanism is thought to be migration or extension of ductal tissue into the wall of the fetal thoracic aorta, causing the tissue to constrict (Fig. 41.13). Aortic narrowing occurs across a spectrum that encompasses discrete thoracic lesions, long-segmental defects, tubular hypoplasia, and, rarely, coarctation in the abdominal aorta. Coarctation accounts for 4% to 6% of all congenital heart defects, with a reported prevalence of about 4 per 10,000 live births. It occurs more commonly in males than in females.

**Figure 41.13** Coarctation of the aorta.

### Assessment

The common coarctation of the aorta (CoAo) typically causes a discrete narrowing of the aorta. Frequently, children are not diagnosed with a coarctation until they grow and are noted to be hypertensive. The narrowed area is most frequently distal to the right subclavian artery, so the pressures before that area increase and refer out these vessels. This causes elevated blood pressures to be noted in the right arm. Occasionally, a murmur may be noted in these children. If the narrowing is significant, it can cause a systolic murmur heard along the left sternal border and the left midscapular area. This narrowing increases the resistance to the left ventricle and can lead to left ventricular hypertension and hypertrophy over time.

Coarctation noted in infancy is usually more critical and can produce heart failure within weeks of birth. These emergencies require immediate surgical intervention.

To further identify the presence of a coarctation defect, you must assess the patient for the presence of pulse equality in the upper and lower extremities. While a child is lying supine, the right radial and femoral pulses are palpated concurrently. The pulses in both areas should be felt simultaneously without delay. There should be no absence or weakness in the femoral pulses compared with the radial or brachial pulse.

Another method to evaluate for the presence of a significant coarctation is to obtain blood pressures in the right arm and either leg. If the correct cuff size is used for each

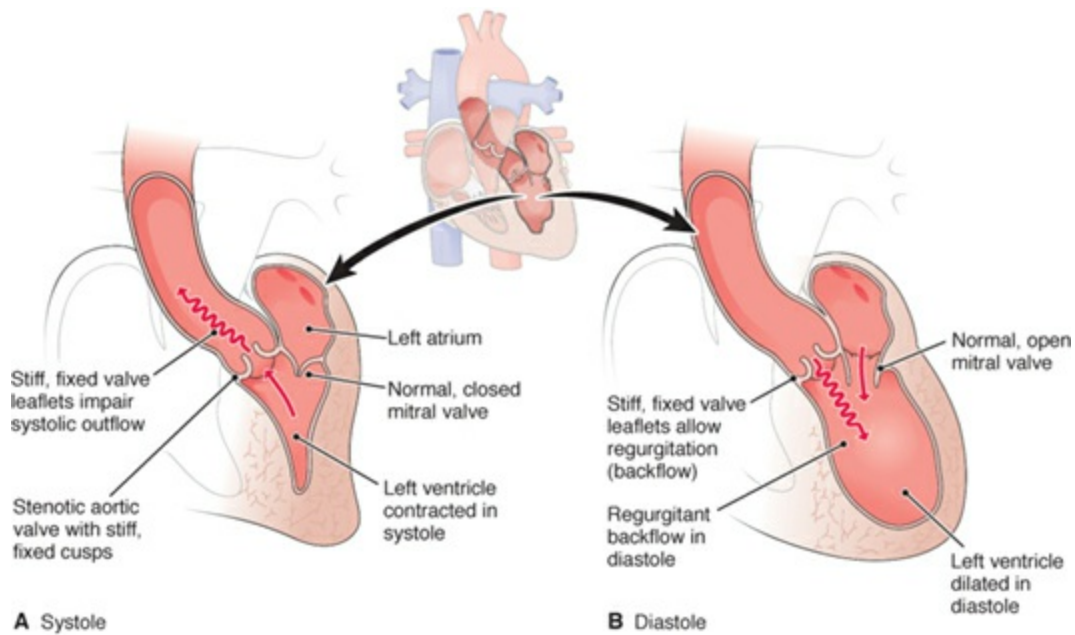

extremity and the child is demonstrating a similar behavior during both measurements (not crying for either reading), the pressures should be fairly equal, with the systolic pressure in the lower extremity reading slightly higher than that in the upper extremity. If the systolic pressure reading in the right upper extremity is 10 mmHg higher than that in the lower extremity, this is an indicator of potential CoAo and requires further evaluation. The exact location of the coarctation can vary but is rarely before the right subclavian branch off of the aorta. This is why using the right arm and any leg for blood pressure comparison is effective.

## Management

Echocardiographic evidence of a significant gradient across the narrowing, or any signs of left ventricular hypertrophy due to the increased resistance, are indicators for correction either by balloon angioplasty in the cardiac catheterization lab or by surgical intervention. Initial repair of a coarctation defect in the catheterization lab can be controversial, as some data do not support a long-term repair of the defect by this method. CoAo is surgically repaired through a left thoracotomy incision, usually with resection of the narrowed tissue and the remaining ends of the aorta sutured together (end-to-end anastomosis). Depending on the age of the child at the initial repair, recurrent narrowing frequently occurs at the surgical area as the child continues to grow. Future interventions with balloon dilation or stent placement are typically performed in the catheterization lab.

## Aortic Stenosis

Obstruction out the left ventricle can occur below the aortic valve (subvalvar), at the valve (valvar), or above the valve (supravalvar). These can be isolated abnormalities or occur with other defects. Regardless of the location of the restriction, the resultant physiology is the same. The narrowing prevents blood from passing freely from the left ventricle of the heart into the aorta. Because the heart must work harder to pass blood through the narrowed area, increased pressure and hypertrophy occur in the left ventricle (Fig. 41.14). If this pressure becomes severe, pressure in the left atrium will increase as well, resulting in back pressure through the pulmonary veins to the lungs, possibly causing pulmonary edema. Aortic stenosis accounts for about 10% of congenital cardiac abnormalities (Darst et al., 2012).

**Figure 41.14** Aortic stenosis. (From McConnell, T. H. [2014]. *Nature of disease: Pathology for the health professions* [2nd ed.]. Baltimore, MD: Wolters Kluwer.)

The most common location for obstruction is valvar aortic stenosis, which is typically associated with an abnormal, bicuspid aortic valve. In a bicuspid aortic valve, the leaflets are not properly divided into three. This allows for stenosis of the valve that progresses in severity in about 33% of cases. Bicuspid valves are frequently seen with other left-sided cardiac anomalies, especially CoAo.

### Assessment

Aortic stenosis eventually presents with a systolic heart murmur at the right second intercostal space, but the child may be otherwise asymptomatic. If the obstruction is severe, the child may experience chest pain with exercise. Aortic regurgitation is frequently associated with stenosis, so a diastolic murmur may also be noted. ECG may note left ventricular hypertrophy if the stenosis has been ongoing. Echocardiography will determine the exact location and severity of the narrowing as well as any impact on ventricular size and function.

### Management

Management of aortic stenosis is difficult and requires frequent and meticulous evaluation by a pediatric cardiologist. Stabilization with a beta-blocker or a calcium channel blocker may be necessary to reduce or prevent further ventricular hypertrophy. These children require routine echocardiograms and possibly cardiac catheterizations to best quantify the pressure gradient across the valve. More aggressive intervention is based on these pressure gradients. Typically, initial intervention is through balloon dilation in the cardiac catheterization laboratory. Surgical intervention may be necessary

for recurrent stenosis or ineffective balloon dilation.

## SINGLE-VENTRICLE DEFECTS

A variety of congenital abnormalities such as mitral atresia, aortic atresia, or pulmonary atresia with an intact ventricular septum result in a single-ventricle physiology. The resultant physiology and management strategies vary given each child's specific anatomy; it is not possible to address all of these permutations, but the basic conceptual understanding and management of single-ventricle defects is grossly the same.

This section discusses specifically hypoplastic left heart syndrome (HLHS), its anatomy, physiology, and management strategies (Fig. 41.15). HLHS is a rare disorder, accounting for only 1% to 3% of congenital heart disease, and is detectable on prenatal ultrasound. HLHS results when there is poor or no flow to the left ventricle, typically secondary to mitral or aortic stenosis or atresia. Because of the limited amount of blood in the left ventricle, it does not develop appropriately. The ascending aorta is also hypoplastic, and the coronary arteries are perfused through retrograde flow down the ascending aorta. A PFO will occur, although the atrial septum is thickened. In utero, the circulation is adequate to meet the needs of the developing fetus. But at birth, survival is dependent on a PDA. Infants are typically male, rarely premature, and have no other associated cardiac anomalies.

ASD = Atrial Septal Defect  
IVC = Inferior Vena Cava  
LA = Left Atrium  
LV = Left Ventricle  
PA = Pulmonary Artery

PDA = Patent Ductus Arteriosus  
PV = Pulmonary Vein  
RA = Right Atrium  
RV = Right Ventricle  
SVC = Superior Vena Cava

**Figure 41.15** Hypoplastic left heart defect. (From Bucklin, B. A., Baysinger, C. L., & Gambling, D. [2016]. *A practical approach to obstetric anesthesia* [2nd ed.]. Philadelphia, PA: Wolters Kluwer.)

At birth, this cyanotic defect has normal right-sided flow out to the lungs. Oxygenated blood returning to the left atrium mixes across the PFO. This blood mixes with the deoxygenated blood returning from the systemic circulation, and the resultant oxygen saturation is approximately 75%. When this blood is ejected from the right ventricle, it travels to the lungs, with a portion of it traveling through the PDA and down the descending aorta to supply the systemic and coronary circulation.

This is a ductal-dependent lesion; these children cannot survive without their ductus remaining patent until surgery can occur. For this reason, a PGE1 infusion is initiated immediately at birth to keep the duct from closing.

A balanced circulation must be maintained while the child awaits surgical palliation. When the right ventricle contracts, it is best for the blood to distribute evenly to the lungs and the systemic circulation. If resistance in the lungs decreases, this would increase the blood flow to the pulmonary circulation but effectively “steal” from the systemic circulation. Although the saturations would read as being higher, the child would begin to experience decreased cardiac output and tissue perfusion, which would lead to a state of metabolic acidosis. It is very difficult for these children to recover from a stressor such as this. Therefore, it is extremely important that you always recognize and understand that a saturation of 70% to 80% is normal for these children. Interventions such as oxygen aimed at raising the saturation would be detrimental to the child, as oxygen is a potent pulmonary vasodilator.

## **Surgical Management of a Hypoplastic Left Heart Syndrome Defect**

### **Norwood Procedure**

This surgery, which includes several components, is done within a few days of birth once the child is hemodynamically stable (Fig. 41.16).

- Dissection of the main pulmonary artery from the branch pulmonary arteries, which is then attached to the hypoplastic ascending aorta so there is one great vessel taking blood out of the heart (right ventricle) to the body and providing blood flow to the coronary arteries.
- Shunt placement, typically either a BT shunt or a Sano shunt. The BT shunt (as discussed previously for TOF) directs blood from the right subclavian artery to the branch pulmonary artery, whereas a Sano shunt is a conduit from the right ventricle to the branch pulmonary arteries. The purpose of both shunts is to allow for stable blood flow to the lungs.
- Ligation of the PDA
- Ensuring a widely patent atrial septum

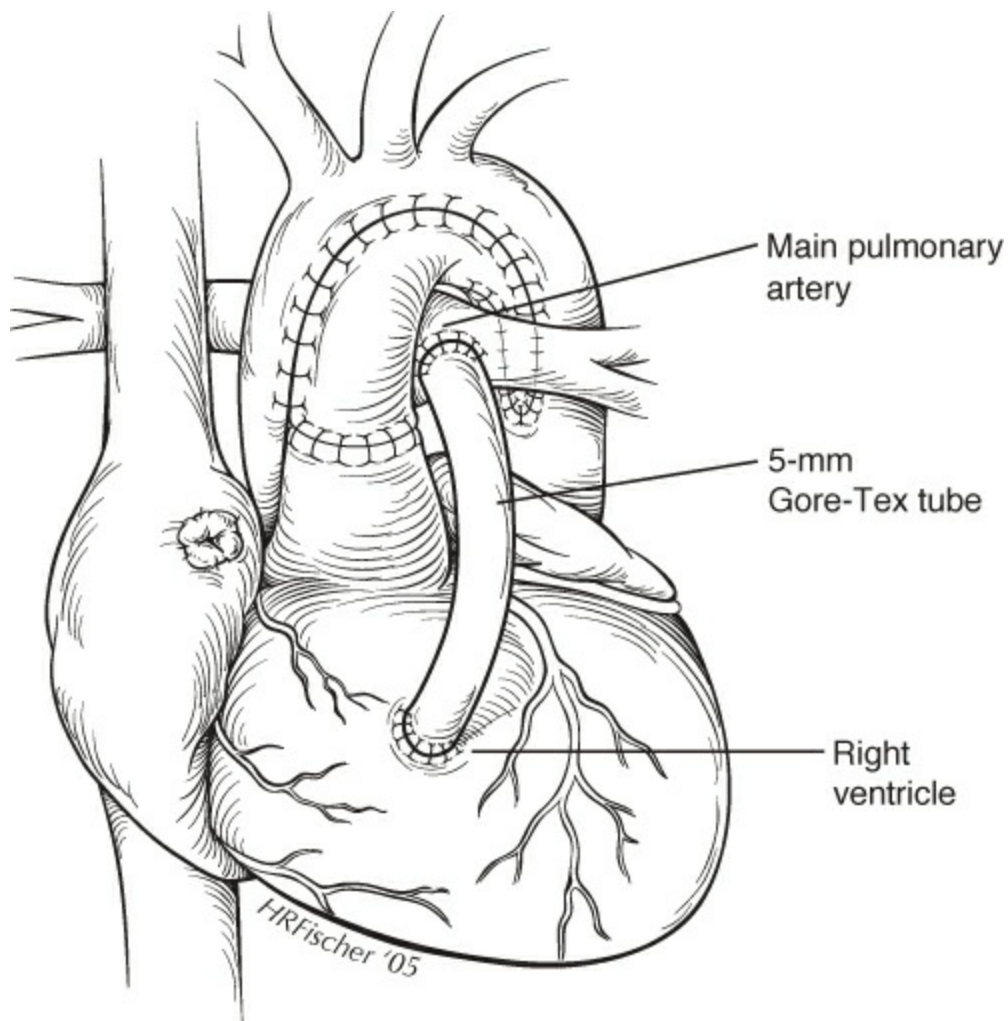

ASD = Atrial Septal Defect  
 BT = Blalock-Taussig  
 IVC = Inferior Vena Cava  
 LA = Left Atrium  
 LV = Left Ventricle

PA = Pulmonary Artery  
 PV = Pulmonary Vein  
 RA = Right Atrium  
 RV = Right Ventricle  
 SVC = Superior Vena Cava

**Figure 41.16** Modified Blalock-Taussig (BT) shunt with Norwood procedure. (From Bucklin, B. A., Baysinger, C. L., & Gambling, D. [2016]. *A practical approach to obstetric anesthesia* [2nd ed.]. Philadelphia, PA: Wolters Kluwer.)

Once this surgery is complete, all blood ejected from the right ventricle travels to the systemic circulation, with some blood shunted through the BT shunt or Sano shunt (Fig. 41.17) to the lungs to get oxygenated.

**Figure 41.17** Sano shunt. (From Kaiser, L., Kron, I. L., & Spray, T. L. [2013]. *Mastery of cardiothoracic surgery* [3rd ed.]. Philadelphia, PA: Wolters Kluwer.)

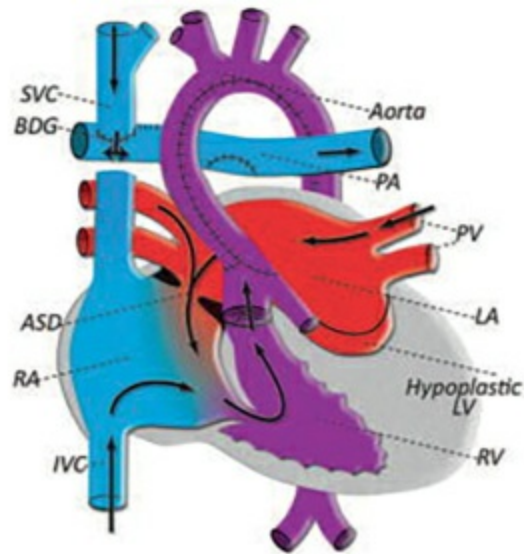

The time period before the Glenn shunt is performed has a high morbidity and mortality rate. These children are at high risk for sudden death due to dysrhythmias, inability to fight infection, or metabolic imbalance. These children must receive antiviral therapy for prophylaxis against respiratory syncytial virus (RSV) monthly during the season. An RSV infection can be lethal for these children.

### Bidirectional Glenn Shunt

This surgery is usually performed at approximately 4 to 6 months of age or when the child outgrows their previously placed BT or Sano shunt. The purpose of the shunt is to relieve the volume load on the single right ventricle, which is accommodating all of the circulating blood flow (Fig. 41.18). At this surgery, two procedures are performed:

1. Ligation of the previously placed BT or Sano shunt
2. Dissection of the SVC at its insertion to the right atrium and attachment of the SVC directly to the branch pulmonary artery. This allows deoxygenated blood

returning from the head and upper body to flow directly but passively to the lungs to get oxygenated. Normal saturations after this surgery are approximately 85%.

ASD = Atrial Septal Defect	PA = Pulmonary Artery
BDG = Bidirectional Glenn anastomosis	PV = Pulmonary Vein
IVC = Inferior Vena Cava	RA = Right Atrium
LA = Left Atrium	RV = Right Ventricle
LV = Left Ventricle	SVC = Superior Vena Cava

**Figure 41.18** Bidirectional Glenn shunt. (From Bucklin, B. A., Baysinger, C. L., & Gambling, D. [2016]. *A practical approach to obstetric anesthesia* [2nd ed.]. Philadelphia, PA: Wolters Kluwer.)

### Fontan Procedure

The final stage is performed when the child weighs approximately 15 kg or is 3 years old. At this time, the IVC is dissected from the right atrium, and flow from there is directed through an artificial conduit directly to the branch pulmonary artery. At this time, all of the patient's deoxygenated blood (except for coronary sinus return) flows directly but passively, to the lungs, and all of the blood returning to the left atrium flows across the ASD, to the right atrium, right ventricle, and out the augmented aorta to the body. Normal saturation values after this surgery range near 90% (Fig. 41.19).

**Figure 41.19** Extracardiac conduit Fontan surgery. (From Kaiser, L., Kron, I. L., & Spray, T. L. [2013]. *Mastery of cardiothoracic surgery* [3rd ed.]. Philadelphia, PA: Wolters Kluwer.)

Cardiac transplantation is an alternative form of therapy, but the availability of donor hearts, rejection problems, and the need for retransplantation make this a secondary choice for most infants.

## Cardiac Surgery

Pediatric cardiac surgery is relatively young in experience, but the advances made in the past decades have allowed for tremendous increases in survival rates. An effective method of implementing cardiopulmonary bypass allowing intracardiac repairs did not occur until the 1950s. Not only have techniques and experience advanced, so have

palliative and bridge measures such as ventricular assistive devices, balloon pumps, and ECMO, all of which have contributed to better outcomes for children with heart disease.

In pediatrics, repair of cardiac defects varies, as each defect can differ in actual anatomy and complexity. This section focuses briefly on the care of the child in the immediate postoperative period and provides more details for care of children in a later convalescent phase.

## PREOPERATIVE CARE

A child must be healthy before cardiac surgery. They must exhibit no signs of an upper respiratory tract infection or have a fever. Vital signs (blood pressure, temperature, pulse, respirations, and oxygen saturation) will be noted to establish baseline values. An accurate height and weight are also recorded. Weight must be documented in kilograms as all medication calculations in children are based on this unit of measure. Laboratory values must be checked, specifically chemistry, hematology, and coagulation values. Blood products must also be typed and cross-matched. Pregnancy testing, either urine or serum, must be performed for any girl who has begun menstruating. It is also important to ensure that consents for surgery and anesthesia have been signed by the family and the appropriate provider.

### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Deficient knowledge related to cardiac surgery and its outcome

**Outcome Evaluation:** Parents and child accurately state the reason for surgery and expected outcome.

Agreeing to cardiac surgery is a difficult choice for parents because although they want their child to feel better, they are also aware there is a definite risk from this surgery. As parents, they may have been protecting and guarding their child for months or years; they feel no less protective the morning of surgery. Parents usually appreciate a visit to the intensive care unit (ICU) before surgery and meeting the ICU staff who will care for their child later. Be certain to prepare them for the amount of equipment that will surround their child after surgery, such as a cardiac monitor, oxygen, IV equipment, chest tubes, and a ventilator, as well as all of the noises associated with an intensive care environment (Fig. 41.20).

**Figure 41.20** Orientation for cardiac surgery includes time for talking and learning more about the heart and why equipment such as chest tubes is necessary. (© Lesha Photography.)

It is important to include the child in developmentally appropriate discussions regarding the planned surgical procedure and postoperative course. By speaking with both the child and parents, the parents will be able to reinforce your teaching. This also demonstrates to children that their parents approve and feel secure with these surgery plans. Because many children scheduled for cardiac surgery have already had a cardiac catheterization, talking to them about their previous hospitalization experience can be helpful to reveal things they are worrying about. Any misconceptions they have can then be discussed and clarified. Be certain to explain that anesthesia is a “special sleep” from which they will have no difficulty waking. After the child is fully prepared, ask parents whether they need additional time to discuss the surgical procedure and ask questions they might not have wished to ask in front of their child.

Because the child will need to cough, breathe deeply, and use incentive spirometry to help the lungs expand after surgery, introduce these exercises and the idea of chest tubes and supplemental oxygen preoperatively so a child can learn that these will be expected. Including child life specialists in these discussions, especially

for younger children, can be very beneficial to the child.

When discussing postoperative care, parents and older children can be taken to the ICU where they will return after surgery and be shown the equipment that will surround them. For younger children, it may be helpful to use pictures of the equipment so it's not so overwhelming.

## POSTOPERATIVE CARE OF THE CHILD AFTER CARDIAC SURGERY

Initial management of a child after cardiac surgery occurs in an intensive care unit until the child is hemodynamically stable and invasive lines are removed. Potential complications after cardiac surgery vary given the nature of the defect and surgical repair, so it is important that you have a strong understanding of both (Fig. 41.21).

**Figure 41.21** Because children after cardiac surgery typically have a myriad of wires and tubes attached to monitors, pumps, and equipment, parents need to be prepared for how their child will look. As the child's condition improves, use of the equipment is discontinued. Here, an infant is 2 days postcardiac surgery. Note his level of alertness and the use of only a few monitoring devices and equipment. (© Caroline Brown, RNC, MS, DEd.)

Most surgical repairs for congenital heart defects require the use of cardiopulmonary bypass (CPB), which allows the surgeon to manipulate the heart in a bloodless field while maintaining perfusion and oxygenation to the body. Briefly, it accomplishes this by placing a cannula in the right atrium, where blood is removed from the body, run through a machine that oxygenates the blood, and then returned to the body via a

cannula placed in the ascending aorta. In this way, the oxygenation circuit is maintained but the actual heart is avoided. When a child undergoes surgery with CPB, he or she is cooled to decrease metabolic demand and oxygen consumption, thereby protecting the brain and other organs during the low circulatory flow that occurs with CPB. The heart itself is protected from injury during this time using hypothermia and chemical preservation.

CPB is not without secondary effects after surgery. Because of the nature of the bypass machine and the tubing the blood passes through, the body responds by releasing mediators, which cause inflammatory responses, capillary leak, and hematologic abnormalities. This can lead to acute complications such as fluid shifting out of the intravascular space into the tissues, poor urine output, edema, and poor circulating volume. Anemia and altered coagulation status can also occur. These effects will be greater if the bypass run time was long.

The surgery itself can lead to potential complications depending on length of time and the complexity of the repair. Tissue perfusion is dependent on adequate cardiac output, which can be affected by many factors in the postoperative period. Poor tissue perfusion can be a result of decreased ventricular contractility from CPB, acidosis, or electrolyte imbalance; decreased intravascular volume from excessive losses, inadequate replacement, or fluid shifts; increased resistance to ventricular ejection caused by changes in pulmonary or systemic vascular resistance from vasoconstriction or hypertension; or alterations in heart rate or rhythm. All of these potential complications must be watched for and treated immediately. They should dissipate over time but can cause significant periods of hemodynamic compromise.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for ineffective cardiopulmonary tissue perfusion related to depressed myocardial function after surgery

**Outcome Evaluation:** Vital signs remain within normal limits; physical examination demonstrates adequate cardiac output.

Taking accurate vital signs is essential in the immediate postoperative period. Continuous cardiac monitoring will occur, and assisted ventilation with endotracheal intubation is frequently necessary. Blood pressure will be monitored directly by means of an intra-arterial catheter or indirectly with an automated blood pressure recording device. Hemodynamic monitoring through a central venous catheter monitors the central venous pressure (CVP) from immediately above the right atrium as an indicator of preload. Pulse oximetry is continuous, and many children will also have near-infrared spectrometry (NIRS) monitoring.

IV fluids may be ordered at less than maintenance value to prevent fluid overload. An indwelling urinary catheter is inserted at the time of surgery so urine output can be carefully measured and recorded postoperatively. Be certain to document the amount of urine drainage present when the child first returns from surgery and hourly so that diminished urinary output will not be missed. Subtle changes in cardiac output can be noted by following urine output. Preferred urine output after surgery is approximately 0.5 to 1 ml/kg/hr for infants and will be weight based for older children. If a child is voiding well after surgery, it indicates the kidneys are receiving an adequate blood flow and the heart is working effectively.

Laboratory tests such as arterial blood gases, hemoglobin, hematocrit, clotting time, and electrolytes (particularly sodium, potassium, calcium, and magnesium) must also be monitored closely to assess postoperative hemodynamic status. IV inotropic agents such as milrinone (Primacor) or dopamine may be added to enhance cardiac output and decrease afterload.

Sternal closure can be delayed after cardiac surgery, usually in small infants with complex cardiac surgical repairs. Allowing the sternum to remain open, until tissue swelling resolves, prevents compression of the heart that would occur with closure of the chest, which would impact cardiac contractility. A sterile occlusive dressing is applied to help shield the open incision from potential infection. After swelling and edema have decreased, the sternum will be closed (usually about 24 to 72 hours after surgery) either in the ICU or the operating room. The nursing care for a child with an open chest includes the same monitoring as for all children who have had cardiac surgery, plus extreme diligence in caring for the site and monitoring for infection.

**Nursing Diagnosis:** Risk for excess or deficient fluid volume related to fluid shifts accompanying cardiac surgery

**Outcome Evaluation:** Child maintains weight; skin turgor is good; urine output is normal.

Children tend to develop relative hypovolemia after cardiac surgery because of increased production of aldosterone by the adrenal glands and an increase in antidiuretic hormone secretion by the pituitary gland in response to stress. Also, cardiopulmonary bypass causes fluids to shift from the intravascular system to the interstitial spaces because of an inflammatory response that causes leaky capillaries. After surgery, as this fluid returns by osmosis to the vessels and is excreted with the help of diuretics, balance is restored.

Monitoring central venous pressures carefully to evaluate preload will help determine which type of therapy is necessary. IV volume may be given if the circulating volume is low as indicated by a low CVP. It is usually preferred that the product given have a high oncotic pressure, as with red blood cells or albumin, in order to prevent further leakage across dilated capillaries. If the CVP is high, diuretics and restricted IV fluid intake will be necessary. Oral intake is typically not restricted in children; they will self-limit their intake.

**Nursing Diagnosis:** Impaired gas exchange related to atelectasis and/or collection of fluid in the chest cavity (pleural effusions)

**Outcome Evaluation:** Child's respiratory rate remains within age-appropriate parameters; there are no rales, crackles, or other adventitious breath sounds; chest tubes function effectively.

**Measures to Prevent Impaired Gas Exchange.** Endotracheal suctioning is necessary while a child is receiving ventilatory assistance to prevent secretion accumulation in the lungs or obstruction of the endotracheal tube. Assist with chest physiotherapy (percussion and vibration) as needed to help keep lung secretions mobile. As soon as the endotracheal tube and ventilator are removed, encourage the child to cough and breathe deeply or use an incentive spirometer at hourly intervals as a way to mobilize secretions. Although children may have practiced such procedures preoperatively, they may have difficulty carrying them out postoperatively because coughing and deep breathing after cardiac surgery can be very painful. To minimize pain, administer prescribed analgesia or alert the child to use the patient-controlled analgesia (PCA) pump 10 to 15 minutes before it is time to breathe deeply. Teach children how to use a pillow as a splint while coughing and deep breathing. Be certain parents understand that games such as blowing cotton balls or bubbles, or using the incentive spirometer, are important exercises to help achieve lung expansion. Encourage them to work with the child throughout the day to perform these exercises.

Chest tube drainage systems are used after complex cardiac surgeries to collect air from the pleural space, and fluid, typically blood, from the mediastinum, but may be used in other situations such as isolated pleural effusions, chylothorax, or pneumothorax. After surgery, typically one tube in the mediastinal space collects blood and another in the pleural space collects air.

The drainage systems are designed not only to allow the drainage and collection of fluid or air from the chest but also to prevent air or fluid from returning to the chest. This system is based on a three-chamber concept that allows for drainage into one section, application of a water seal to prevent air from reentering the pleural cavity or mediastinum, and a third chamber to allow the continuous, controlled application of suction (Fig. 41.22). Suction can be applied in two ways: either through water or “dry” suction.

**Figure 41.22** Pleur-Evac system for chest tube drainage.

Jackson-Pratt drains can also be used postoperatively if the volume of drainage is not expected to be excessive. These tubes are much smaller and more flexible so they cause less pain. They are also significantly less cumbersome.

Nursing concerns when working with a child who has a chest drainage system include:

- Keeping the system closed and below chest level
- Ensuring suction control chambers are filled or set for the ordered amount of suction. If a fluid-filled system, ensure bubbles are in the chamber.
- Making sure the water seal chamber is filled to manufacturer's recommended level
- Monitoring for bubbles in the water seal chamber, which can indicate either a leak in the drainage system or an air leak from the patient's lungs
- Assessing and documenting the amount, color, and consistency in the drainage system routinely and as ordered. Report any drainage that changes in volume, color, or bloodiness.
- NOT aggressively milking or stripping chest tubes, as this can cause very high levels of negative pressure. But it is important to keep the tubes freely draining, which can be difficult if the drainage is frank blood, which may have clots in it.
- Ensuring adequate pain control. Chest tubes can be very uncomfortable, but it is important for the child to get out of bed, ambulate, cough, or perform pulmonary toilet maneuvers. It is important to obtain a level of pain control that allows the

child to be awake and interactive.

**Nursing Diagnosis:** Risk for ineffective peripheral tissue perfusion related to dysrhythmias.

**Outcome Evaluation:** Patient will remain free of postoperative dysrhythmias; any dysrhythmias will be readily identified and treated to maintain adequate cardiac output.

When children return from the operating room after complex cardiac surgery, they are at risk for dysrhythmias due to damage to the conduction system, inflammation of or injury to the heart itself, or electrolyte imbalance. In anticipation of possible dysrhythmias, children may have two pacing wires attached to the surface of the heart and brought out through the chest wall. These are temporary pacemaker wires that can be attached to a pacemaker at the bedside in the event the child experiences a dysrhythmia or heart block. If no evidence of abnormal rhythms has been seen after several days, the pacing wires will be pulled out. If a child is dependent on the pacemaker due to heart block and normal conduction does not spontaneously return after 14 days, the child is typically taken to the operating room for placement of a permanent pacemaker. The pacemaker is placed in the abdominal cavity in infants and small children. For older children and adolescents, the pacemaker is placed in the left shoulder area, and the wires are threaded transvenously to the right heart. Currently, permanent pacemaker batteries last approximately 5 years. Having a permanent pacemaker requires monthly transmissions to document pacemaker function and will limit the child's ability to participate in contact sports.

Once a child has progressed to a less critical status and is hemodynamically stable, the child may be moved from the ICU to a routine patient care unit. This is a major step toward recovery but also may be a difficult move for both the child and the parents because they have developed confidence in the ICU staff and are reluctant to move to an area with less monitoring and entrust their child to new personnel. It helps the transition if the concept of transferring to a step-down or floor location is broached early in the postoperative phase. Visits from the floor nursing staff while the child is still in the ICU will also help. Allow parents the opportunity to voice their concern over the changes in personnel and monitoring. Understanding that their child is ready for this change and will be safe can help prepare them for the day of hospital discharge, when they will be observing and caring for their child on their own.

Once on the floor, general nursing care includes the following:

- Watching for blood loss
- Preventing infection
- Preventing/managing pain
- Maintaining lung expansion
- Encouraging mobility
- Encouraging healthy eating
- Including the family in care

**Nursing Diagnosis:** Risk for infection related to surgical incision

**Outcome Evaluation:** Child's temperature remains at or below 100.4°F (38.0°C); incision site is clean, dry, and without evidence of erythema or drainage.

Antibiotic therapy is continued for 24 to 48 hours after chest closure. To detect whether infection could be beginning, frequently monitor the temperature and assess the surgical incision site and the points of insertion of the thoracotomy tubes or central catheters for drainage and erythema.

Infants must wear shirts and bibs when feeding to prevent formula from dropping on the incision site. Older children should wear T-shirts at all times. This not only helps with food but also keeps them from scratching the site or pulling at the butterfly closures (if used).

**Nursing Diagnosis:** Parental anxiety related to lack of knowledge of postoperative routine and exercises

**Outcome Evaluation:** Family members accurately state plans for child's postoperative recovery; family members relate less anxiety after teaching and support.

Most children recover very quickly from heart surgery. Children are encouraged to be out of bed and ambulating once they are hemodynamically stable and free from cumbersome equipment. Encourage parents to participate as much as they want to in their child's care during this period. Parents can encourage their child to routinely perform breathing exercises, eat and drink throughout the day, and get out of bed.

Caution parents not to pick up an infant under the arms to move or hold the child because this pulls on the chest incision. Show them how to lift an infant by placing their hands behind the neck and scooping under the buttocks instead. Teach parents to help an older child out of bed by wrapping their arms around the child's chest. To prevent pain, they should not pull on the child's arms. Despite the sternal wound, all children should use seat belts or car seats as directed to ensure safety. Infants should not be placed prone for "tummy time" for approximately 2 to 3 weeks after surgery. If the infant rolls over independently, their own body weight will not hurt the sternal site (Box 41.5).

#### BOX 41.5

#### Nursing Care Planning Tips for Effective Communication

Megan is a 2-month-old infant who is being discharged after cardiac surgery. You stop at her hospital room to give discharge instructions to her mother.

*Tip:* Because cardiac surgery is such serious surgery, most parents assume it will take their child a long time to recover from it. Listen closely when reviewing discharge instructions and ask follow-up questions to ensure the patient fully comprehends the instructions. In the following scenario, the nurse recognizes that

Megan's mother has not heard the first instruction—to let the child return to normal activities as she is able. Older children will have more activity restrictions (sports, PE class) but should still return to normal activities of daily living within 1 to 2 weeks.

**Nurse:** Good morning, Mrs. Carver. Let me review a few instructions with you before you go home with Megan.

**Mrs. Carver:** The most important thing you can tell me is how to keep a baby on bed rest.

**Nurse:** Most infants are more tired than usual from surgery, but just let her assume her usual activities as she likes.

**Mrs. Carver:** She likes to kick a mobile in bed. It'll be hard to keep her from doing that.

**Nurse:** And that's okay for her to do that. She won't do anything if it hurts. Infants and children don't need to be confined to bed, they just need to be allowed to rest when needed, which will be more frequently for awhile. They also need adults to pick them up carefully to prevent any pain or damage to the healing breastbone.

**Mrs. Carver:** So it's okay if she sits in her car seat or if I hold her? I don't want to hurt her or cause other problems.

**Nurse:** Absolutely! We want your family to return to their normal routine, you just need to modify how she is handled, allow her to rest, and keep her in a healthy environment.

**Mrs. Carver:** We can do that. Thank you, I just couldn't imagine how to keep a baby on bed rest.

**Nurse:** I'm glad we could clarify that for you. I would like to speak with you about a few other items before you go home. Are you okay to go on?

**Mrs. Carver:** Yes, I'm ready.

*Continue with medication and infection control instructions.*

### **QSEN Checkpoint Question 41.2**

#### **EVIDENCE-BASED PRACTICE**

Surgical closure of a ventricular septal defect (VSD) is the most commonly performed procedure in cardiac surgery. Although considerably safe, complication can occur. [Schipper, Sliker, Schoof, et al. \(2017\)](#) performed a retrospective study of all VSD closures at their single center to evaluate for risk factors for a complicated postoperative course. Of 243 patients that underwent a VSD surgical repair, there were no deaths, 0.8% required a pacemaker for heart block, and 2.1% required reoperation for hemodynamically significant residual VSD. Multivariate analysis identified a genetic syndrome, long bypass time, and low weight at operation as independent risk factors for a prolonged intensive care stay and prolonged ventilation times. None of these were associated with major adverse events.

Henry is a 2-month-old with Down syndrome and a VSD. He is in CHF and has been having difficulty gaining weight so surgery has been scheduled. Based on this study, what will you include in your preoperative discussions with his family?

- a. VSDs are very difficult to repair and children can have many complications after surgery.
- b. Because Henry has Down syndrome and his weight is less than expected for his age, he may need a few extra days on the ventilator or in the ICU, but overall, he should do fine.
- c. Henry's age, being less than 12 months old, puts him at greater risk for complications after VSD surgery.
- d. A VSD repair is not done with cardiopulmonary bypass so the risk of complications is significantly less than for other defects.

*Look in [Appendix A](#) for the best answer and rationale.*

## **DISCHARGING A CHILD AFTER CARDIAC SURGERY**

There are several restrictions when a child is ready to be discharged home. Children, especially infants, are at higher risk for infection and should avoid any actively sick contacts while they are recuperating at home. Good hand washing techniques should be used by all visitors. Children are usually kept home from school for several weeks after their surgery but should return once they are cleared by the cardiologist or surgeon.

Children who have undergone a median sternotomy must be restricted from physical activity, including physical education class and any sports activities, for 6 weeks from the time of sternal closure. They should be assigned a helper in school because these restrictions include lifting heavy backpacks or other heavy items. They should also not drive a car during this time to allow for healing of the sternum. They must be cleared by the cardiologist or surgeon before they can return to these activities.

Immediately after surgery, the child will have limited range of motion of their arms. They may be provided exercises to help with movement and to decrease pain. They will need assistance with dressing and bathing for several weeks but will soon be independent again. Children may typically undergo a sponge bath or a shower when they are discharged from the hospital. However, to prevent infection, they should not submerge their wound in a tub or pool until the wound is completely healed, and it has been evaluated by a practitioner.

Studies have been done to evaluate the neurodevelopmental outcomes of the child with congenital heart disease. A significant number of children with coronary heart disease (CHD) will manifest neurodevelopmental impairments affecting cognition, motor and language development, and higher order cognitive functions ([Ringle & Wernovsky, 2016](#)). These impairments may be mild to moderate in severity but may also occur in conjunction with other developmental or behavioral problems and significantly affect school performance and academic achievement. Risk factors for worse outcomes include:

- Genetic disorders
- Single-ventricle patients
- Complicated and extensive postoperative intensive care unit (ICU) course
- Lower socioeconomic status (Forbess, Visconti, Hancock-Friesen, et al., 2002; Latal, 2016)

It is important for families to follow through with neurologic and behavioral specialists as they are referred and to seek early intervention to assure maximum success for their child. It is important for the family to understand that other than simple ASD or VSD surgical repairs, all children will need to follow-up with a cardiologist for life. Although they have undergone a corrective procedure, they are at risk for future complications related to their growth, development of scar tissue, or long-term effects of the disorder. As children with CHD continue to survive and thrive, they have progressed to adulthood. These adult survivors of congenital heart disease have long-term medical needs that healthcare providers are only now beginning to understand. Many institutions have developed *Adult Congenital Programs* to address the needs of adults who have survived congenital heart disease as a child but now have adult medical issues and yet still require cardiology follow-up for the CHD. They require specialists who understand the anatomy and physiology of congenital heart disease as well as the normal progress of these diseases after surgery and how all of this is impacted by routine aging.

### ***QSEN Checkpoint Question 41.3***

#### **SAFETY**

After cardiac surgery, infants and children have limitations to their activity and handling. When teaching parents how to help their children with daily activities, the nurse recognizes it is most important to emphasize which statement?

- Children are very resilient and recover quickly after cardiac surgery. Parents don't need to do anything different when handling their children when they go home.
- Infants and children should remain in bed or on the couch at home and not be allowed to perform any activities other than go to the bathroom to prevent pain and injury until they have at least two follow-up visits with their cardiologist.
- Infants and children should be restricted from all physical activity for 6 months from the time of their surgery. They should not lift their arms over their head or be lifted under their arms for the same time period.
- Infants and children should not be lifted under their arms for 6 weeks from the time of sternal closure. They should also not participate in physical activity or lift heavy items for this same time period.

*Look in [Appendix A](#) for the best answer and rationale.*

## Cardiac Catheterization

A **cardiac catheterization** is a diagnostic or interventional procedure where one or more small catheters are passed through a large vein and/or artery into the heart. Access for a catheterization is frequently obtained in the femoral vein and artery but radial and neck access can also be used. With catheters in the heart or major vessels, the cardiologist can obtain blood samples to evaluate oxygen content, measure direct pressures in all chambers and vessels, and inject a contrast dye to define anatomy. Cardiac output, cardiac index, and systemic and pulmonary vascular resistance can be calculated. Many interventions can be performed in the catheterization laboratory including PDA and septal defect closure, dilation of narrowed valves or vessels, stent placement in narrowed vessels, closure of collateral or abnormal vessels, placement of artificial valves, and myocardial biopsy. Although cardiac catheterizations are relatively safe, potential complications can include:

- Dysrhythmias
- Inadvertent perforation of the heart or major blood vessel
- Bleeding
- Valve or vessel damage
- Stroke
- Seizures
- Death

Children are usually deeply sedated for a catheterization procedure with an anesthesiologist providing the necessary level of sedation. Depth of sedation decisions is based on the child's age, developmental status, and the extent of the proposed catheterization procedure.

### Nursing Diagnoses and Related Interventions

Cardiac catheterization is a stress-filled procedure for parents and children.

**Nursing Diagnosis:** Anxiety related to cardiac catheterization procedure.

**Outcome Evaluation:** Parents state goal of procedure and reasons for preparation and aftercare measures; parents state they are able to manage anxiety while waiting for results.

Try to provide an explanation of the procedure to the child with the parents present so that the parents can reinforce the information as needed. After the explanation, provide parents with a more detailed explanation if desired, allowing time for questions they did not want to ask in the child's presence.

Older children enjoy a tour of the cardiac catheterization area if possible and the opportunity to meet the personnel. Because small children can become overwhelmed

by seeing the actual room, the use of developmentally appropriate play with a puppet or small doll may be helpful. Dress puppets in surgery suits and masks and have them act out what the child can expect to experience.

Do not underestimate what children know about their heart's purpose and function; even preschoolers know their heart is vital to their body. Reassure them that people are only taking pictures of their heart during this procedure, not cutting it or removing any part of it.

Let children know that after the procedure, a pressure dressing will be placed over the catheter insertion site to reduce the risk of bleeding. They will need to keep that extremity flat and straight to prevent bleeding.

## POST-CARDIAC CATHETERIZATION NURSING CARE

Once the catheterization is completed and the access catheters are removed, the child is at risk for bleeding from the insertion site. Children typically remain supine with their legs straight for 2 to 4 hours after the procedure to ensure hemostasis at the site. If the access points were in the neck or arm, the activity restrictions will be less.

It is imperative that you understand the child's underlying cardiac anatomy and physiology as well as the purpose of the catheterization before the child returns from the procedure. Recovery of a child after a catheterization must include monitoring of the respiratory status including the airway, rate, and depth of respirations as well as monitoring for the hemodynamic effects of sedative agents and the catheterization process itself. Children will have frequent vital signs initially that will include heart rate, rhythm, respiratory rate, oxygen saturation, blood pressure, and temperature. With each set of vital signs, distal perfusion to the effected extremity should be included.

Oxygen may be continued for a period of time after the procedure as the child recovers from the sedation or anesthesia. Once the child has been observed and is deemed stable, oxygen may be weaned off as long as oxygen saturations remain normal for the child.

The child will have activity restrictions upon discharge. They will typically need to miss a day or two of school while the leg site continues to heal. Depending on the procedure performed, they may be restricted from physical activities for several months after device closure of a septal defect.

### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for bleeding related to lack of hemostasis at insertion site(s)

**Outcome Evaluation:** The child's dressing will remain clean, dry, and intact, and there will be no clinical symptoms of internal bleeding.

When a child returns from the procedure, assess the pressure dressing over the catheter insertion site to be certain the dressing is snug and intact and no bleeding is present. Assess the site frequently to verify that there is no bleeding. The entire surrounding area must also be assessed for internal bleeding that has accumulated in other tissue areas such as the genitalia. The child must remain supine for several hours if the femoral site was used to prevent bleeding or hematoma formation. This is particularly important when an artery was used for catheterization because a loose dressing on an artery can cause a large blood loss in a very short time. If there is bleeding at the insertion site, apply firm, continuous pressure and notify the provider who performed the procedure immediately.

**Nursing Diagnosis:** Risk for ineffective peripheral tissue perfusion related to thrombus formation at catheter insertion site

**Outcome Evaluation:** Child's vital signs remain within established parameters; pulse is palpable distal to catheter insertion site.

Thrombus formation at the femoral site is necessary for hemostasis but can also cause compromised flow distal to that site. Vasospasm of the arterial vessels can also occur, especially in smaller children. For this reason, distal pulses (pedal and posterior tibia) are checked routinely upon arrival from the catheterization lab if the femoral artery was accessed. If a pulse cannot be palpated, a Doppler should be used in an effort to find the pulse. If no pulses are found in the foot, popliteal pulses should be obtained. A provider should be notified immediately for any loss or change in pulses. The child will need to remain flat in bed for 2 to 4 hours (although some providers may require a longer period of time supine) in an effort to prevent bleeding from the site and obstruction of flow through the femoral vessel.

The child will typically be monitored for several hours but if pulses do not return within a certain time frame (approximately 4 hours), an anticoagulant such as heparin may be initiated. The heparin will prevent further thrombosis formation at the site of the vasospasm or current thrombus formation.

**Nursing Diagnosis:** Risk for infection related to presence of cardiac catheterization incision site

**Outcome Evaluation:** The child's temperature remains less than 100.4°F (38.0°C) tympanic; the catheter insertion site appears free of erythema or drainage.

If the dressing for a cardiac catheterization is over the femoral artery or vein in a non-toilet-trained child, be certain to keep it clean of stool and urine. If the dressing becomes soiled, the site should be cleaned well with soap and water.

Although there is a risk for infection at the catheter site after a catheterization, it will most likely be noted by the family once the child is home. Detailed education regarding the symptoms of an infection must be provided to the family and child (age-dependent) prior to discharge. They should omit tub baths or other water

submersion such as pools or hot tubs until the site is completely healed to prevent infection. The child may receive a sponge bath or take a shower.

### *What If . . . 41.2*

**The nurse is caring for Cara, an 8-year-old otherwise healthy female who is scheduled for a cardiac catheterization to close an ASD. The nurse will also care for her after Cara's catheterization is complete. Why is it important for the nurse to assess Cara's baseline ECG and lower extremity pulses before her catheterization? What teaching points can the nurse review with Cara and her parents about her care after the catheterization is complete?**

## Cardiac Transplantation

Pediatric heart transplantation is uncommon but important and successful management technique for heart failure. Diagnoses leading to the need for a heart transplant vary with the age of the child. Congenital heart disease remains the most common indication for pediatric heart transplant in infants but as children age, cardiomyopathy becomes the more common indication. According to the registry of the International Society for Heart and Lung Transplantation, in 11- to 17-year-olds, the percentage of recipients with a diagnosis of CHD decrease to 23%, whereas the percentage of myopathy increases to 65% (Schweiger, Stiasny, Dave, et al., 2015).

The choice to pursue transplantation does not occur easily. Success is not guaranteed, and this choice requires a life-long commitment to ongoing medical evaluations, medications, and the probable need for future retransplantation. Candidates and their families will experience significant stressors in their lives that will impact the entire family structure. Given these impacts, healthcare professionals will continue to medically manage a patient with a failing heart as long as possible. If transplant is unavoidable, there are options to facilitate success as the child waits for a suitable organ. These include intensive care management with IV inotropic support, typically milrinone (Primacor). Ventricular assist devices (VADs) may be used as a bridge to transplant and offer long-term support. ECMO can offer a short-term bridge to transplant.

Outcomes after transplant vary, depending on many factors including age, donor heart, wait-list management, surgery, etc. Typically, infants survive for a longer period of time than older children. In the early stages, outcome is linked to operative mortality as well as graft (heart) function. Immediate rejection remains an important cause of mortality despite immunosuppressant agents. The use of immunosuppressants places the child at risk for infection with the greatest risk of death from an infection highest during the first year after transplant. Infection remains a significant source of mortality and morbidity in the long term.

Acute rejection continues to be a serious concern, accounting for 5% of deaths even 10 years posttransplant. Chronic graft failure is a main risk factor for death (26% more than 10 years posttransplant). There is also a risk of malignancy, specifically posttransplant lymphoproliferative disease which has a high association with Epstein-Barr virus.

Although pediatric heart transplant patients thrive and can have excellent long-term outcomes, there are many risks and challenges involved with this process that patients and families must understand.

## Dysrhythmias

The overall incidence of clinically significant dysrhythmias in children without underlying congenital heart disease is low. A 2012 review at a single center pediatric emergency department (ED) found an incidence of 11.5 of 10,000 ED presentations were for a diagnosis of “arrhythmias” and supraventricular dysrhythmias were the most frequently identified rhythm disturbance (56% of all encounters). Of all children diagnosed with a dysrhythmia, 13% of these children had an underlying CHD (Clausen, Theophilos, Jackno, et al., 2012). This data demonstrates that outside of an ICU or postoperative setting, dysrhythmia incidence is low, and rhythm disturbances that are noted do not routinely require defibrillator use and have low mortality.

There are differences in the structure and function of the pediatric heart that predispose it to nonlethal dysrhythmias such as sinus bradycardia or sinus tachycardia, including:

- Greater parasympathetic innervation
- Deficiency of mitochondria
- Decreased amounts of actin and myosin
- Increased intracellular water content
- Myofibrils in less parallel array, not allowing for adequate contractility

The structural differences are greatest in the neonatal and infancy periods. Some conduction abnormalities are inherited and have a defined genetic component as seen with long QT syndrome or atrial flutter, others such as supraventricular tachycardia can occur randomly.

Figure 41.23 shows the normal conduction cycle. All electrical impulses in the heart originate from the sinoatrial (SA) node. These impulses travel down the right atrium and across the internodal tracts to the left atrium. The impulse on the right side terminates at the atrioventricular (AV) node where it slows to allow for complete filling of the ventricles. It then continues to the Bundle of His and down the right and left bundle branches, terminating in the Purkinje fibers, which ultimately cause ventricular contraction.

**Figure 41.23** Normal conduction pathway. (From Jensen, S. [2015]. *Nursing health assessment: A best practice approach* [2nd ed.]. Philadelphia, PA: Wolters Kluwer.)

A usual ECG wave form consists of a P wave (denoting atrial contraction), a brief period of isoelectricity depicted as a flat line, and then a prominent QRS wave as the ventricles contract. This is followed by the T wave which is a result of ventricular repolarization (Fig. 41.24). Some children may have an incompletely understood additional slow wave (the U wave). A U-wave is considered normal in children.

**Figure 41.24** A normal ECG waveform. (From Shargel, L., Mutnick, A. H., Sourney, P. F., et al. [2013]. *Comprehensive pharmacy review for NAPLEX: Practice exams, cases, and test prep* [8th ed.]. Baltimore, MD: Lippincott Williams & Wilkins.)

A rhythm is considered sinus (originating from the SA node) if in Lead II there is an upright P wave before an upright QRS complex followed by a T wave immediately afterward.

## **SINUS ARRHYTHMIA**

Sinus arrhythmia is a common occurrence in children and decreases with age. This is a normal variation in the child's heart rhythm based on their respiratory pattern. As they breathe in, you will notice the heart rate slow down and as they exhale, there is a slight increase in rate. This is thought to be due to changes in autonomic tone during respirations. The ECG pattern itself is completely normal. There is no need for concern, and there is no intervention.

## **SINUS BRADYCARDIA**

Sinus bradycardia is defined as a heart rate that is less than the stated normal for a child's age. Sinus bradycardia may be physiologically normal as seen in athletes, may be secondary to medications such as beta-blockers, or may be an indicator of a pathologic state.

## **SINUS TACHYCARDIA**

Sinus tachycardia is defined as a heart rate that is greater than the stated normal for a child's age. Sinus tachycardia may be expected as with a fever, anxiety, or pain may be secondary to medications such as albuterol or may be an indicator of a pathologic state such as dehydration, anemia, or infection.

## **SUPRAVENTRICULAR TACHYCARDIA**

This is the most common symptomatic dysrhythmia in infants and children with a frequency of 1 in 250 to 1,000 patients and a peak incidence occurring in the first 2 months of life (Lewis, Arora, Tudorascu, et al., 2017). Supraventricular tachycardia (SVT) is defined as a heart rate greater than 220 beats/min in an infant and greater than 160 beats/min in a child (Fig. 41.25). The rhythm is a narrow complex with no discernible P waves and no variability in the rate with changes in the child's activity level (i.e., crying, playing, sleeping). If noted in infancy, it may regress by the time the child turns 1 year of age but then is likely to reappear later in childhood. It can be associated with a Wolff-Parkinson-White (WPW) reentry type pattern. In WPW, the patient has an extra connection in the heart called an accessory pathway that allows the electrical impulse to bypass the AV node and move from the atria to the ventricles faster than usual. WPW produces a specific pattern to the ECG and can be associated with an Ebstein's anomaly of the heart where the tricuspid valve is abnormal.

**Figure 41.25** Supraventricular tachycardia. (From Kyle, T., & Carman, S. [2016]. *Essentials of pediatric nursing* [3rd ed.]. Philadelphia, PA: Wolters Kluwer.)

### Assessment

If a child experiences an SVT event, their response will be dictated by their age. An infant may simply be irritable but, if it continues for hours without breaking, may not take oral feeds well or have changes in the level of consciousness. An older child may describe their heart as a “racing” or having a “pounding out of their chest” sensation. If the event lasts long enough (at least 20 to 30 minutes), older children may experience a light-headed sensation that may continue to a syncopal event. You will have a difficult time counting an apical or radial pulse rate as the heart rate is so high.

### Management

Treatment for an SVT event may be nonpharmacologic or pharmacologic and may include long-term treatment options.

#### Noninvasive Treatment

Vagal maneuvers are a noninvasive means of increasing intrathoracic pressure for a brief period, thus stimulating baroreceptor activity in the aortic arch and carotid bodies, resulting in increased vagal tone. The goal is to block the reentry conduction and allow the normal conduction pathway to dominate. In infants, a bag of ice water can be placed on the forehead at the nasal bridge in an effort to stimulate the diving reflex (diving reflex is a complex cardiovascular-respiratory response to immersion). Older children can be taught vagal maneuvers such as blowing through a pinched straw, bearing down as with a bowel movement, coughing, or gagging.

#### Antiarrhythmic Therapy

In a hospital setting, if none of these maneuvers is effective, management would proceed to either administration of adenosine (Adenocard) or the use of synchronized cardioversion. If the child is hemodynamically stable and they either have IV access or there is time to obtain it, adenosine is preferred. If the child is not hemodynamically stable, has lost consciousness, or IV access is not obtainable, then synchronized

cardioversion should be used.

If adenosine is administered, it must be given rapidly by IV push, closest to the central circulation with a large flush of normal saline (NS) immediately after. Once adenosine is given, it has a very short half-life (6 to 10 seconds) and will block at the AV node to reestablish a normal conduction pattern. With the effect of the medication, you will note a brief period of asystole on the monitor. This is transient; the child will return to either SVT or sinus rhythm within seconds. You should ensure that there are ECG strips of the rhythm before, during, and after medication administration.

## Long-Term Management

Long-term management of known SVT may include medications such as digoxin or a beta-blocker such as propranolol (Inderal). Of note, if the child has a WPW pattern associated with their SVT rhythm, digoxin cannot be used as it will slow AV node conduction which will accelerate conduction across the accessory pathway, placing the child at risk for atrial fibrillation. Verapamil, a calcium channel blocker, is contraindicated in children less than 1 year of age and can cause accessory pathway acceleration and is also not often used in WPW. Other medications that can be used if initial therapies fail are amiodarone, flecainide, and sotalol. Although these medications are antiarrhythmic in nature, they are also proarrhythmic and have other side effects. They should only be prescribed and managed by a pediatric cardiologist. If medications do not provide good coverage or the child is older, they may choose to pursue radiofrequency ablation in the electrophysiology laboratory as a more permanent solution.

Children with well-managed SVT, not associated with structural heart disease, do not have any activity restrictions other than to be aware of their dysrhythmia, and if they feel they are in SVT, they should stop their activity, rest, and attempt to stop the rhythm with vagal maneuvers as possible. If the dysrhythmia is associated with WPW syndrome, those children should be evaluated by a cardiologist for risk stratification before participating in competitive sporting activities. Children and families should also be advised to restrict the intake of products that may increase their heart rate such as caffeinated beverages and energy drinks. Herbal supplements should be avoided and families should contact a healthcare provider before giving their child over-the-counter cold medications as some can be contraindicated.

## **ATRIAL FLUTTER**

This rhythm disturbance is more rare in children but can be seen after ASD surgery or with inflammatory states. It can also be genetically inherited. If a child presents with palpitations and atrial flutter is diagnosed, it must be determined if the rhythm has been present for greater than 24 hours. If so, an echocardiogram (frequently transesophageal) is performed to evaluate for the presence of thrombus in the atria. If they are noted, the child is started on an anticoagulant such as a heparin infusion. If there are no thrombus

noted, or if it has been deemed safe to proceed with conversion, synchronized cardioversion will be used to break the rhythm.

Long-term therapy for this rhythm may include antiarrhythmics. Ablation or surgical correction through a Maze procedure may be pursued if the situation is severe.

## **LETHAL DYSRHYTHMIAS (VENTRICULAR TACHYCARDIA, VENTRICULAR FIBRILLATION, TORSADES DE POINTES)**

Life-threatening dysrhythmias in children are rare. They may be seen after cardiac surgery or during a life-threatening event. Torsades de pointes is the terminal rhythm associated with long QT syndrome (LQTS). LQTS is a disorder of delayed ventricular repolarization characterized by prolongation of the QT interval. This may be hereditary or acquired due to medications.

Pulseless ventricular tachycardia and ventricular fibrillation are rare in children and are usually seen late in a child suffering cardiopulmonary arrest. Both are treated with defibrillation.

### ***QSEN Checkpoint Question 41.4***

#### **INFORMATICS**

Marcus is a 12-year-old boy who presents to the emergency department complaining of chest pain and a racing heart that started suddenly about 1 hour earlier. He says he feels a little tired and dizzy, but otherwise, he is appropriate for age. The nurse notices during the assessment that his heart rate is 185 beats/min, and the ECG demonstrates a very narrow complex with P waves that are not visible. The heart rate does not change when Marcus is talking or resting. His blood pressure is 95/70 mmHg, his respiratory rate is 22 breaths/min, and his oxygen saturation is 98% on room air. Based on this assessment and data, the nurse recognizes Marcus is experiencing which of the following?

- a. Sinus tachycardia
- b. Supraventricular tachycardia
- c. Torsades de pointes
- d. Ventricular tachycardia

*Look in Appendix A for the best answer and rationale.*

## **Acquired Heart Disease**

*Acquired heart disease* is a term used to define heart disorders that develop after birth. Kawasaki disease is the leading cause of acquired heart disease in children.

### **KAWASAKI DISEASE**

Kawasaki disease (mucocutaneous lymph node syndrome) is defined as an acute febrile

syndrome associated with generalized **vasculitis** (inflammation of blood vessels) affecting all blood vessels throughout the body, including the coronary arteries. The vasculitis is a principal and life-threatening symptom because it can lead to the formation of coronary aneurysms which will predispose the child to thrombus formation and a high risk of myocardial infarction.

It has an unknown etiology. Although there does seem to be a genetic predisposition to the syndrome, there is also a strong suggestion of an infectious precursor. It occurs more commonly in winter and spring, with males affected more than females; 76% of children affected are less than 5 years old. It is more common among Americans of Asian or Pacific Island descent.

Kawasaki disease is a diagnosis of exclusion as there is no imaging or laboratory test that can diagnose it. Clinical criteria have been established to help with the diagnosis of Kawasaki disease.

## Assessment

Kawasaki disease can be divided into an acute phase (week 1) and subacute phase (weeks 2 and 3). There are certain criteria that a child must meet for this diagnosis, including:

- Prolonged fever ( $>100.4^{\circ}\text{F}$  [ $39^{\circ}\text{C}$ ]) of 5 or more days
- Four or more of the following symptoms:
  - Changes in hands and feet (erythema, edema, peeling)
  - Polymorphous exanthema (diffuse maculopapular rash of the trunk and extremities)
  - Bilateral conjunctivitis without exudates
  - Changes in lips and mouth (erythema, strawberry tongue, dry, cracked lips)
  - Cervical lymphadenopathy ( $>1.5$  cm diameter, usually unilateral) ([Box 41.6](#))

BOX 41.6

### Nursing Care Planning Using Assessment

#### ASSESSING A CHILD WITH KAWASAKI SYNDROME

Changes in laboratory data may also be noted such as thrombocytosis, leukocytosis, elevated ESR and CRP, elevated liver enzymes, and mild anemia. The changes in these infectious and inflammatory markers mandate a thorough investigation into possible causes for the child's symptoms including viral infections, scarlet fever, staphylococcal scalded skin syndrome, juvenile rheumatoid arthritis, or Rocky Mountain spotted fever to name a few. If no definitive cause is determined and the child's symptoms fit the criteria listed, the child is given the diagnosis of Kawasaki disease.

During the acute phase, children are very irritable and uncomfortable from the fever and inflammatory process that causes joint pain. After approximately 10 days, a

subacute phase begins. The skin desquamates, particularly on the palms and soles. The platelet count rises, increasing the possibility of clot formation. If an aneurysm forms in a coronary artery, accumulating thrombi can dislodge and lead to obstructed blood flow distally in the coronary artery which will lead to myocardial ischemia and infarction.

### Therapeutic Management

Treatment for Kawasaki disease is focused on addressing the immediate symptoms and preventing any long-term consequences. Primarily, supportive measures are necessary as these children are irritable and not taking adequate oral intake so antipyretics for the fever as well as IV fluids are necessary. Kawasaki disease also causes dilation of the coronary arteries and coronary artery aneurysms in 15% to 25% of untreated children, and these coronary changes can be fatal. Evidence has shown that treating these children within the first 7 to 10 days of the fever with high-dose intravenous immunoglobulin (IVIG) and high-dose aspirin therapy has demonstrated a reduction in the appearance of coronary artery ectasia and aneurysms due to their anti-inflammatory properties. Children are treated with 2 g/kg of IVIG. This dose may be repeated if the fever does not break. High-dose aspirin at 80 to 100 mg/kg divided four times a day is also continued for 48 to 72 hours after the fever breaks. The aspirin is then continued at a low dose of 3 to 5 mg/kg/day once a day for 6 to 8 weeks with no evidence of coronary artery abnormalities. If abnormalities occur, aspirin may be continued indefinitely.

### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Parental anxiety related to a lack of knowledge regarding Kawasaki disease

**Outcome Evaluation:** Parents will understand the course of this disease process and the necessary follow-up evaluations to assure their child's optimal health state.

Kawasaki disease is a frightening illness due to the danger of coronary artery aneurysm formation. Because they may never have heard of the illness before their child's diagnosis, parents need both information about and support throughout the lengthy disease process. An echocardiogram is performed at initial diagnosis to provide baseline coronary imaging, although coronary artery changes are not usually apparent at that time. Follow-up echocardiograms at 2 weeks and at 6 to 8 weeks are performed to continually evaluate for the development of any dilation or aneurysms. If there are no coronary changes at this time, it is unlikely that they will occur. It is important to explain this ongoing monitoring process to parents to help reduce parental anxiety.

Coronary images are difficult to obtain by echocardiogram, especially if the child is uncooperative. Children with Kawasaki disease are very uncomfortable and are frequently not cooperative with this test. Moderate sedation may be required to achieve accurate diagnostic imaging.

**Nursing Diagnosis:** Discomfort related to swelling of lymph nodes and inflammation of joints

**Outcome Evaluation:** Child states or demonstrates a tolerable level of discomfort, is able to participate in activities of daily living (ADLs), and maintains adequate oral intake.

A child with Kawasaki disease is uncomfortable from the joint involvement, edema, pruritic rash, and abdominal discomfort. The high fever can lead to dry, cracked lips. Antipyretics such as acetaminophen help reduce both the pain and fever. Providing additional comfort measures such as rocking and holding or distraction may help. Try to protect edematous areas from pressure; make certain clothing is not constricting and irritating areas of rash. Applying lip balm helps protect lips from drying and cracking.

Because the child's fever remains high, offer extra fluid to help maintain hydration and reduce mouth tenderness.

Children with Kawasaki disease lose their appetite and generally eat poorly because of the systemic illness, mouth soreness from cracks and fissures, and abdominal pressure from swollen lymph nodes. Carefully monitor and record the child's intake and output to be certain intake is adequate. Encourage the child to continue brushing his or her teeth (use a soft toothbrush or a commercial swab), even though the oral mucous membrane is tender, to prevent tooth decay or ulcer formation. Soft, nonirritating foods such as gelatin may be better tolerated than foods that require chewing or acidic fluids, such as orange juice, which might sting.

### *What If . . . 41.3*

**The nurse cares for Steven, a 3-year-old boy diagnosed with Kawasaki syndrome. He is irritable and continues to be febrile on day 2 of his admission. He is receiving 25 mg/kg of aspirin four times a day. His mother asks if she should be using aspirin to manage her other children when they have fevers at home. How would the nurse best respond to the mother's question?**

## **RHEUMATIC FEVER**

Although acute rheumatic fever has declined in incidence in Europe and North America over the past 50 years, it remains one of the most important causes of cardiovascular morbidity and mortality among socially and economically disadvantaged populations worldwide. Rheumatic fever is an autoimmune disease that occurs as a reaction to a

group A  $\beta$ -hemolytic streptococcal infection, specifically, a pharyngitis. Inflammation from the immune response leads to inflammatory lesions being found in the heart, blood vessels, brain, and joints.

It occurs most often in children 6 to 15 years of age, with a peak incidence at 8 years. It has not been documented in infants, even those that have had a streptococcal infection. Because children do not develop immunity to streptococcal infections, they can recur. It is thought that in genetically susceptible individuals, the sensitized child will eventually have a group A  $\beta$ -hemolytic streptococcal pharyngitis that sets off an unusually high antibody response. Approximately 10 days after recovery from the pharyngitis, the autoimmune response begins, lasts many weeks and gradually damages the left heart valves.

### Assessment

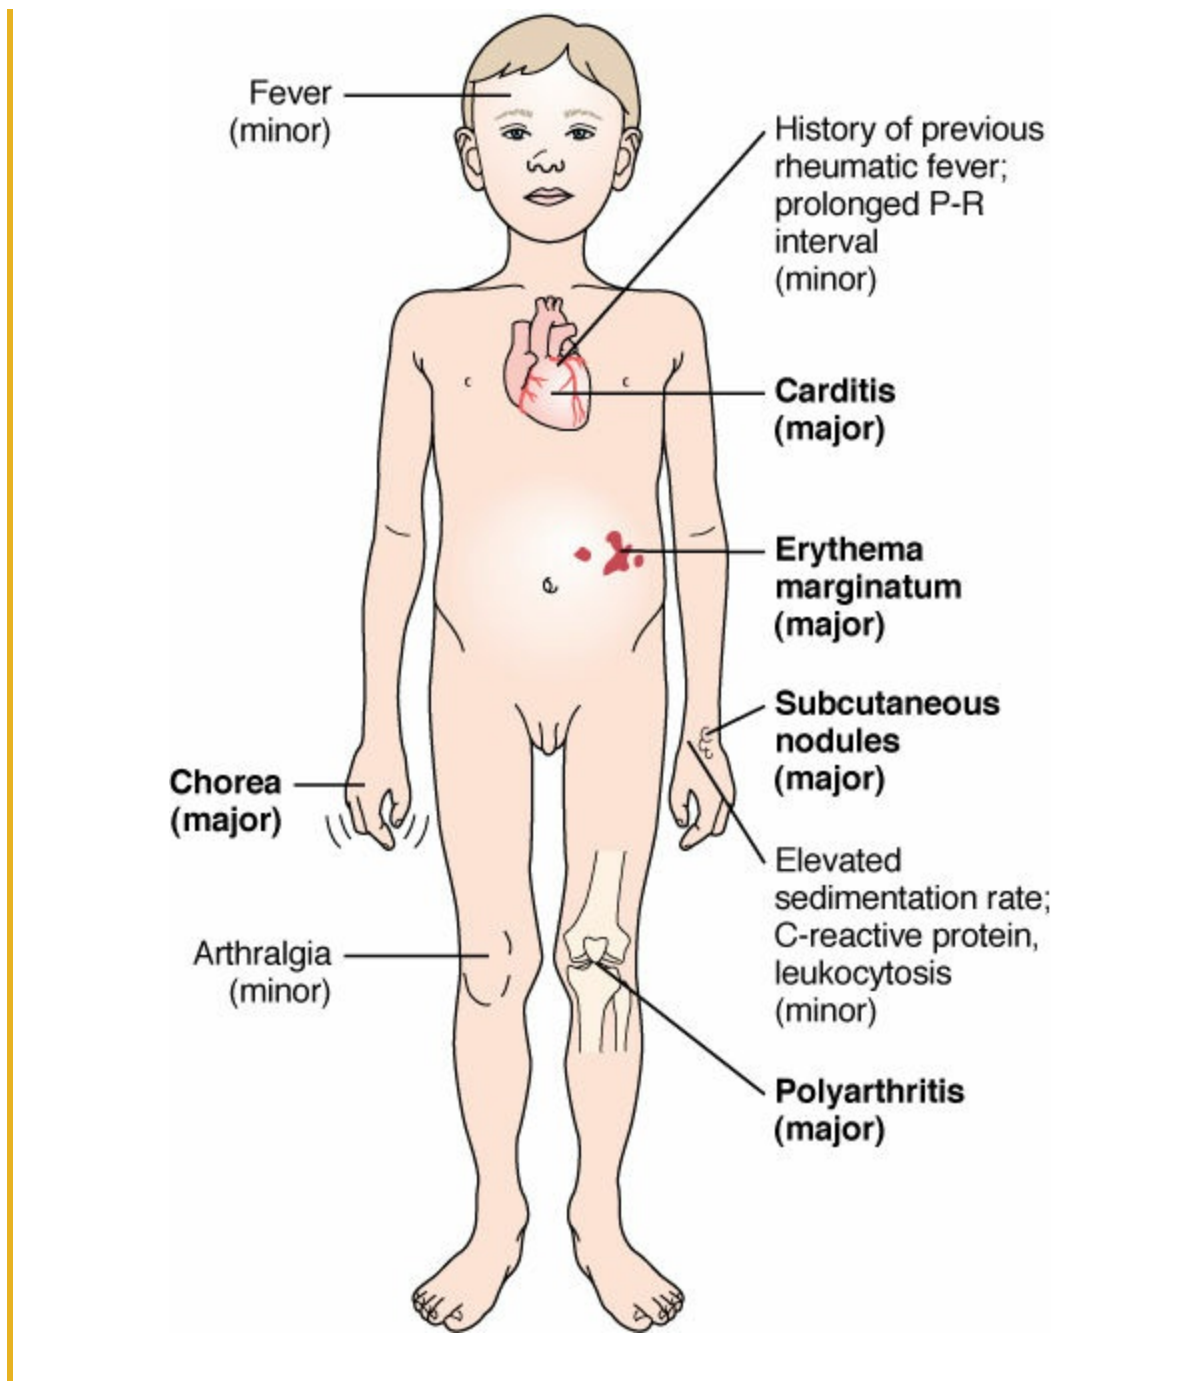

The signs and symptoms of rheumatic fever are divided into major and minor symptoms according to the Jones criteria which were recently revised in 2015 (Box 41.7). As noted, to have a diagnosis of rheumatic fever, children must have two major manifestations or one major and two minor manifestations documented. Of these, the heart involvement is the most serious.

BOX 41.7

#### Nursing Care Planning Using Assessment

##### ASSESSING A CHILD WITH RHEUMATIC FEVER

Children will present with polyarthrititis as multiple joints are inflamed and possibly have fluid accumulation. Fifty percent of the children present with carditis, usually as an apical systolic murmur from mitral insufficiency. This murmur is characteristically blowing and high frequency and transmits to the axilla. Sydenham chorea (sudden involuntary movement of the limbs) is a striking symptom that occurs in up to 10% of children and is exacerbated by stress. This loss of voluntary muscle control, which results in dysfunctional speech, facial grimacing, and poor hand control, occurs more often in younger children between 7 and 14 years of age.

*Erythema marginatum*, a macular rash found predominantly on the trunk is an infrequent symptom but if seen is a virtually definitive sign of rheumatic fever.

Subcutaneous nodules on hard bony surfaces of the joints are noted during subsequent rheumatic fever attacks with well-established heart disease.

Important laboratory findings include the presence of an elevated antistreptolysin-O (ASO) titer which is evidence that the child had a recent streptococcal infection. The child will have a fever  $>38.5^{\circ}\text{C}$ , and inflammatory markers such as ESR and CRP will also be elevated. ECG and CXR are not particularly helpful in diagnosing this disease. Echocardiogram is imperative to evaluate the extent of cardiac involvement. If a child meets the Jones diagnostic criteria and all other potential diagnoses have been ruled out, the child should be treated for rheumatic fever.

### Therapeutic Management

If rheumatic fever diagnosis is entertained, penicillin therapy is immediately begun once throat cultures and blood work have been obtained. Therapeutic doses of intramuscular (IM) or oral penicillin are prescribed for a full 10-day course. Oral nonsteroidal anti-inflammatory agents may be prescribed to reduce inflammation and joint pain. The use of steroids is controversial and thought to be utilized only in children with severe carditis and valve damage. Phenobarbital and diazepam (Valium) are both effective in reducing the purposeless movements of chorea.

The prognosis for the child with rheumatic fever depends on the extent of myocardial involvement. Valve damage may continue over time, and some children with no initial presentation of valve damage will have it occur later in life. These children will be followed for life by a cardiologist and may require surgical intervention to repair or replace the valve.

### Nursing Diagnoses and Related Interventions

Because rheumatic fever can be a severe threat to heart health, nursing diagnoses need to address both physical care and the parents' and child's reaction to the serious diagnosis.

**Nursing Diagnosis:** Risk for nonadherence to drug therapy related to knowledge deficit about importance of long-term therapy

**Outcome Evaluation:** Parents understand risk of recurrence; child takes oral penicillin daily or presents for monthly injections.

Preventive maintenance doses of penicillin are started once initial treatment is completed. These doses are given either as a monthly IM injection of penicillin G benzathine or twice-daily oral tablets of penicillin V potassium. Although the IM injection is more painful and necessitates a trip to the provider's office, it is considered more effective due to the potential lack of compliance with twice-daily oral medications. Preventive therapy continues until the child is at least 21 years of

age as patients who have had acute rheumatic fever are highly susceptible to recurrent rheumatic fever. If the child incurred valve damage, preventive therapy will continue until at least 40 years of age.

## CARDIOMYOPATHY

**Cardiomyopathy** is a disorder of the heart muscle and although rare, is a common cause of heart failure in children and the most common cause of heart transplantation in children older than 1 year of age (Wilkinson, Landy, Colan, et al., 2010). Most children have either a dilated or hypertrophic form of cardiomyopathy, although there are a variety of functional types. The estimated annual incidence of pediatric cardiomyopathy is 1.13 cases per 100,000 children aged 18 years or younger.

Based on data from the Pediatric Cardiomyopathy Registry, there is a higher incidence in boys than in girls and higher in Blacks than in Whites, and the annual incidence of dilated cardiomyopathy (DCM) and hypertrophic cardiomyopathy (HCM) was 0.58 cases per 100,000 children and 0.47 per 100,000 children, respectively. The following discussion will review dilated and HCM as well as arrhythmogenic right ventricular cardiomyopathy (ARVC), a form of cardiomyopathy that is the second most common cause of sudden cardiac death in young people after HCM (Romero, Mejia-Lopez, Manrique, et al., 2013; Soni & Oade, 2011).

### Dilated Cardiomyopathy

DCM is defined as a severe disease of the heart muscle that is characterized by dilation of the left ventricle with reduced left ventricle systolic function and normal ventricular wall thickness. This is the most common cardiomyopathy noted in children, and its incidence is higher in the first year of life. Genetic causes of DCM account for 40% of cases with the remaining etiologies remaining largely unknown and considered idiopathic. Myocarditis is the most common, nongenetic, identifiable cause of DCM.

Children typically present with exercise intolerance, dyspnea on exertion, palpitations, chest pain, syncope, or possible cardiovascular collapse. Infants have more vague symptoms such as respiratory distress, poor feeding, or easy fatigability. Their physical examination may range from no significant changes except altered heart and respiratory rates to complete CHF with poor cardiac output. Cardiomegaly, pulmonary venous congestion, pulmonary edema, and pleural effusions may be noted on CXR. An ECG typically shows sinus tachycardia and other nonspecific changes. Echocardiogram will define the actual presence of a dilated ventricle with poor systolic function.

If no identifiable, treatable cause is found for the cardiomyopathy, treatment is supportive and nonspecific, aimed at controlling symptoms of CHF and ventricular dysfunction. This will include ACE inhibitors, beta-blockers, and inhibition of the renin–angiotensin system. If a child does not respond to supportive therapies and progressively declines, heart transplantation is an option with ECMO or VADs as a bridge if necessary.

In general, outcomes for a child diagnosed with DCM are quite varied. Recovery of function, if it will occur, will be within the first year. This will be approximately 50% of those that survive the initial presentation. In the remaining 50%, 25% will have improved but abnormal function, and 25% will have persistently severely depressed function. One- and 5-year rates of death or transplantation are 31% and 46%, respectively (Wilkinson et al., 2010).

### **Hypertrophic Cardiomyopathy**

HCM is characterized by hypertrophy of the left ventricle, a nondilated left ventricle cavity, systolic hypercontractility, diastolic dysfunction, and, in approximately 20% of the cases, obstruction of left ventricle outflow secondary to mitral–septal contact during systole (hypertrophic obstructive cardiomyopathy). This is the most common cardiovascular disorder with an autosomal dominant genetic etiology and is the most common cause of sudden cardiac death in otherwise healthy children.

Patients typically present with limited exercise capacity as their primary symptom due to either dyspnea or chest pain. Infants will present with the typical congestive CHF clinical symptoms. Chest pain is also very common with HCM, occurring at rest or with activity. The coronary arteries have been reported to be abnormal with increased size of arteries, thickened walls, and narrowed lumens in a high percentage of children with familial HCM. Both atrial and ventricular arrhythmias are less frequent in children than in adults, and although thought to be the mechanism of sudden death in adults, this theory is not supported in children. Adolescents have the highest incidence of sudden death but are rarely found to have arrhythmias. Echocardiogram will confirm this diagnosis.

Management is aimed at reducing symptoms and prolonging survival. Beta-blocker therapy (i.e., metoprolol) is the primary pharmacologic agent used. Beta-blockers decrease the contractile force, the left ventricular outflow tract (LVOT) gradient, and the overall myocardial workload and oxygen demand. They also increase diastolic filling by slowing the heart rate and allowing for more passive filling of the left ventricle. This therapy relieves chest pain and dyspnea, but it does not improve exercise capacity. Calcium channel blockers, specifically verapamil, have a negative chronotropic effect which increases the diastolic relaxation time which increases preload and allows for symptomatic improvement. More definitive therapy such as pacemakers and surgical removal of any LVOT obstruction are patient dependent. The use of antiarrhythmics has not been effective in reducing arrhythmias associated with HCM.

## **Nursing Diagnoses and Related Interventions**

**Nursing Diagnosis:** Risk for disturbed personal identity due to inability to participate

in physical exercise

**Outcome Measures:** Child and family understand the importance of the exercise restrictions; child finds other activities that allow him or her to interact with peers.

Exercise restriction is necessary for children diagnosed with HCM. The incidence of sudden death is high in patients with HCM with one third of those deaths occurring during activity. Therefore, patients diagnosed with HCM through genetic testing or who have presented with clinical symptoms of HCM must abide by activity restrictions. They may not participate in highly aerobic activities or high school–level competitive sports. If the child does not manifest arrhythmias or exercise-induced arrhythmias, he or she may participate in mild to moderate types of exercise. Isometric activities such as weight lifting and rope climbing are prohibited because they are associated with high levels of circulating catecholamines that can predispose them to arrhythmias.

### **Restrictive Cardiomyopathy**

Restrictive cardiomyopathy is characterized by restrictive filling and reduced diastolic volume of either or both ventricles with normal or near-normal systolic function and wall thickness. It may be idiopathic or associated with another disease process. This type of cardiomyopathy is fairly rare and accounts for only 2.5% to 5% of all diagnosed cardiomyopathies. The restrictive physiology results from increased myocardial stiffness with decreased compliance, causing a marked ventricular pressure increase with small changes in volume. This leads to poor cardiac output and ultimately symptoms of heart failure. Prognosis is poor with half of the children dying within 2 years of diagnosis.

### **Arrhythmogenic Right Ventricular Cardiomyopathy**

ARVC is a rare inherited disease of the heart that causes ventricular tachyarrhythmias and sudden death in young people and athletes. It results in fibro-fatty replacement of the right ventricle and the subepicardial region of the left ventricle. Ultimately, certain cardiac proteins are defective and cannot keep the myocytes together when under stress such as with exercise. As the damaged and dead cells get replaced with fatty and fibrous tissue, the electrical system is impaired and ventricular dysrhythmias result.

ARVC presentation can be variable from palpitations and syncope to sudden cardiac arrest occurring during exercise. Any clinical symptom such as chest pain, palpitations, or syncope that occurs during exercise should always be noted as a red flag and further evaluated. Diagnosis of ARVC is made through patient and family history, 12-lead ECG evaluation, and an echocardiogram. Unfortunately, there is no treatment for this disorder, only management through restriction of physical exercise, antiarrhythmic drugs, beta-blocker therapy, and an implantable cardioverter defibrillator (ICD).

## INFLAMMATORY PROCESSES

Inflammatory processes that impact the heart can be secondary to an infectious process (viral or bacterial) but can also be due to toxins, hypersensitivity reactions, systemic disorders, trauma, or be idiopathic. This inflammation can affect any layer of the heart, and presentation, management and outcomes vary with each form.

### Myocarditis

Myocarditis is an acute or chronic inflammatory process affecting the myocardium. Specifically, there is an inflammation of the myocardium with necrosis or degeneration of adjacent myocytes. This disease can be caused by a wide variety of toxins, drugs, or infectious agents, most commonly viral agents such as coxsackievirus, adenovirus, or parvovirus. It is rare for a child to be diagnosed with myocarditis during the initial infectious event. The next phase is an acute phase where there is extensive interstitial inflammation and injury with direct myocardial damage. This appears to be initiated by an autoimmunity triggered by the initial injury. At this time, the patient presents with overt symptoms of CHF, but the presence of an actual infection is rare. Although the acute inflammatory phase may resolve, there is a third, chronic phase that is mediated by T cells. During this phase, fibroblasts replace normal myofibers with resultant scar tissue formation. This creates an electrically unstable myocardium, predisposed to the development of ventricular tachydysrhythmias.

Diagnosis of myocarditis is difficult with only clinical data. Patient presentation such as chest pain, exertional dyspnea, fatigue, syncope, or palpitations in association with acute CHF associated with left ventricle dilation and/or segmental wall abnormalities may indicate a possible myocarditis diagnosis. If suspected, an endomyocardial biopsy may be performed in an effort to provide a definitive diagnosis, but this is not completely accurate either. More recently, cardiovascular MRI has emerged as an important noninvasive tool for the diagnosis and monitoring of myocarditis. In addition to providing reliable measurements of ventricular size and function, MRI myocardial tissue characterization techniques can assess for inflammatory changes such as edema, hyperemia, capillary leak, and myocyte necrosis (Banka, Robinson, Uppu, et al., 2015).

Management of myocarditis is symptomatic, typically following heart failure management protocols. The use of steroids or immunosuppressants is not well established in the literature for global treatment of myocarditis but has been shown to be beneficial with certain types of myocarditis. For fulminant myocarditis that does not improve with pharmacologic therapy, the use of mechanical circulatory support devices (i.e., VAD or ECMO) may be necessary as a bridge to transplant or recovery.

### Pericarditis

Acute pericarditis is an inflammation of the pericardial membrane with or without accumulation of excess pericardial fluid. There are a multitude of potential causes, but

most are idiopathic and thought to be viral or postviral in origin. Idiopathic pericarditis accounts for 37% to 68% of inpatient admissions for pericardial effusions or acute pericarditis in children. Presentation frequently includes chest pain which can be sharp, precordial, radiating, and worse with inspiration or cough. It is characteristically positional, and patients feel better when sitting up and leaning forward. Fever is also common. Physical examination reveals an uncomfortable child, typically with a pericardial friction rub. A pericardial friction rub is a superficial scratchy or squeaking sound that is best heard with the diaphragm of the stethoscope. The rub may be localized or widespread but is usually loudest over the left sternal border.

Diagnosis of pericarditis may begin with a 12-lead ECG and CXR. The CXR may be normal if there is not an appreciable effusion. An echocardiogram may be normal but typically shows at least a small collection of pericardial fluid. Laboratory analysis will only note an infectious process and not be specific to pericarditis. If the effusion is large or there appears to be restricted myocardial contractility, a pericardiocentesis must be performed. This fluid may be sent for cultures to further investigate for causative organism or malignancy.

Treatment of pericarditis involves anti-inflammatory agents such as ibuprofen to relieve symptoms and accelerate resolution. Corticosteroids may be used if nonsteroidal anti-inflammatory drugs (NSAIDs) are not successful. Colchicine use has been reported in children to treat refractory pericarditis. Pericarditis can recur. Recurrences develop in up to 36% of children after the first episode of idiopathic acute pericarditis and in 50% of children after pericardial injury that would occur with certain cardiac surgeries such as repair of an ASD. Relapses may occur up to 2 months after the injury. Treatment remains the same and should follow a stepwise approach.

### ***QSEN Checkpoint Question 41.5***

#### **TEAMWORK & COLLABORATION**

The nurse is caring for James, a 2-year-old boy who has been admitted to the pediatric floor after his parents noted a fever of 103°F (39.4°C) for 2 days. He had an ASD repaired approximately 4 weeks earlier and has since developed a pericardial effusion. The effusion was drained, and the fluid was purulent. He is now being treated with IV antibiotics. The nurse enters the room and notes that James is only breathing about 5 breaths/min and his heart rate on the monitor is 40 beats/min. What is the nurse's first action?

- a. Call for help and wait for direction when the arrest team arrives.
- b. Run from the room and get the defibrillator, calling for help as you go.
- c. Call the pediatric cardiologist to perform an echocardiogram and evaluate for reaccumulation of the pericardial fluid.
- d. Call for help and begin providing compressions per basic life support (BLS) protocol (CPR).

*Look in Appendix A for the best answer and rationale.*

## Infective Endocarditis

Infective endocarditis is inflammation and infection of the endocardium or valves of the heart. It is noted in children with and without heart disease. The incidence of infective endocarditis in children is rare but may be increasing due to the increased survival of children with congenital heart disease. The high-velocity blood stream of some defects creates forces thought to damage the endothelium. Indwelling catheters such as peripherally inserted central catheters (PICCs) similarly may injure the endocardial or endothelial layer allowing for the deposition of red blood cells, platelets, and fibrin. Bacteria then can adhere to the damaged endothelial layer, with further fibrin and platelet deposition trapping the bacteria in the evolving vegetation. This results in localized endocardial injury and valvulitis.

The infection is generally caused by *Streptococcus viridans* and *Staphylococcus aureus*, although fungal organisms have also been noted.

### Assessment

Presentation can be acute or subacute. Acute presentation includes a systemic response to the infection and can be rapidly progressive. Children have high-spiking fevers and are severely ill and toxic in appearance. Symptoms of CHF may be present. Murmurs are frequently noted due to destruction of the cardiac valve tissue.

Subacute presentation is associated with persistent low-grade fever, malaise, weight loss, arthralgias, fatigue, rigors, and diaphoresis.

Diagnostic testing will include laboratory analysis and imaging studies. Positive blood cultures are necessary for a diagnosis of infective endocarditis. Echocardiogram is extremely helpful in allowing for visualization of the vegetations as well as the damage to the heart itself such as valve destruction and perforation, rupture of chordae, and development of valvar leaks. Other laboratory studies will reveal proteinuria or hematuria, a normochromic, leukocytosis, and an increased ESR.

### Treatment

Treatment is aimed at the underlying bacterial infection but an extended course of antibiotics is necessary as the organisms are imbedded in a fibrin platelet matrix in high concentrations. Once sensitivity is determined, treatment is typically for 4 to 6 weeks of IV therapy. This will necessitate the insertion of a PICC in children so they may go home and receive home nursing services to administer their antibiotic therapy. Lesions will heal, but children may be left with long-term sequelae such as renal dysfunction from thrombi or leaky cardiac valves from primary damage.

All children diagnosed with endocarditis must receive prophylactic antibiotics prior to some invasive procedures including dental work. The 2007 recommendations from the AHA state prophylaxis prior to dental work for children with underlying cardiac disease is appropriate only if the child has:

- Prosthetic cardiac valve or prosthetic material used for cardiac valve repair

- Previous infective endocarditis
- Congenital heart disease, specifically:
  - Unrepaired cyanotic CHD, including palliative shunts and conduits
  - Completely repaired CHD with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure
  - Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplantation recipients who develop cardiac valvulopathy

## Preventive Heart Disease

Although much of the heart disease previously discussed cannot be prevented, there is a great deal that can be done to help children avert the development of cardiovascular heart disease in adulthood, typically related to hypertension or atherosclerosis.

Hypertension in children is rising and is thought to be connected to the increasing numbers of children who are overweight or obese. Healthcare professionals must take on the responsibility of providing heart-healthy guidance at all encounters with children and their families to ensure these children lead long, healthy lives.

## HYPERTENSION

High blood pressure in children is a growing health problem in the United States. If a child presents with hypertension, it is important to differentiate primary from secondary. Evaluating for an underlying etiology includes a thorough medical and family history and a physical examination. Diagnostic testing may be ordered based on the results of the history and physical exam. Common causes of hypertension in children can be renal (renal artery stenosis, renovascular disease, neurofibromatosis), hormonal (primary aldosteronism, adrenal insufficiency, pheochromocytoma, neuroblastoma) or cardiac (CoAo).

Management of secondary hypertension will be focused on the underlying disorder.

### Assessment

Hypertension can begin in childhood and contributes to the early development of cardiovascular disease. When evaluating children for or with hypertension, it is important to follow published guidelines. Blood pressure percentile tables in the United States have been developed and are based on gender, age, and height and distributed by the National Heart, Lung, and Blood Institute (NHLBI). It is important to evaluate both the systolic and diastolic values. There are three categories ([Table 41.3](#)):

- Normal
- Prehypertension
- Hypertension (including Stage 1 and Stage 2).

**TABLE 41.3 NATIONAL HIGH BLOOD PRESSURE EDUCATION PROGRAM CLASSIFICATION OF PREHYPERTENSION AND HYPERTENSION IN CHILDREN AND ADOLESCENTS**

<b>Classification</b>	<b>Systolic or Diastolic Blood Pressure*</b>
Normal	<90th percentile for both values
Prehypertension	≥90th percentile or if BP>120/80**
Hypertension	≥95th percentile
Hypertension—Stage 1	Between 95th percentile and 5 mmHg above 99th
Stage 2	≥99th percentile plus 5 mmHg

BP, blood pressure.

\*Based on age, gender, and height. Must be measured with correct size cuff on three separate occasions.

\*\*If the blood pressure reads greater than 120/80 mmHg, a diagnosis of prehypertension is given, regardless of whether it is less than 90th percentile for age/gender/height.

When measuring blood pressure in children, it is important to use the correct size blood pressure cuff. The cuff should cover approximately 40% of the child’s upper arm and the length of the cuff must completely cover the circumference of the arm. If a cuff is too small, it may result in a falsely elevated reading. Although a too large cuff may provide a reading that is lower, a larger cuff should be chosen if the child is in-between sizes. Blood pressure should be measured in the right arm with the child’s arm supported at heart level. If an automatic blood pressure device is used and the reading is elevated, the measurement should be repeated with a manual cuff and auscultation. A diagnosis of hypertension cannot be given to a child unless the blood pressure reading is elevated on three separate readings at three different visits. Providers ask the school systems to help with blood pressure measurements to avoid the stress of going to a provider’s office, which can cause a false increase in blood pressure readings.

### **Therapeutic Management**

If there is no indication of a secondary etiology to the hypertension, the child must be managed for primary hypertension. Primary hypertension is associated with overweight or a positive family history of hypertension. Recent data also suggests an association between sleep disordered breathing and hypertension. Management of children with prehypertension or hypertension includes therapeutic lifestyle changes. These include weight reduction if necessary, regular physical activity, a healthy diet, and healthy habits including no smoking or alcohol. Family-based interventions have been shown to improve success rates. High blood pressure in childhood commonly leads to hypertension in adulthood, and adult hypertension is the leading cause of premature death around the world (Riley & Bluhm, 2012).

In adolescents, increasing the amount of sleep may also be helpful in reducing stress and development of hypertension. Adolescent girls are advised to use another reproductive life planning choice than estrogen-based oral contraceptives because these

can elevate blood pressure (Narang, Manlhiot, Davies-Shaw, et al., 2012).

Unfortunately, because mild hypertension produces few symptoms, often children and their family members do not adhere to nutritional suggestions or recommended exercise programs so their hypertension does not decrease.

If hypertension persists despite these interventions, antihypertensive medications may be warranted. There are multiple medications that can be used including ACE inhibitors, ARBs, beta-blockers, calcium channel blockers, diuretics, and vasodilators. It is imperative for the nurse to understand the side effects of the chosen medications when evaluating and managing these patients.

### ***QSEN Checkpoint Question 41.6***

#### **PATIENT-CENTERED CARE**

Charlene is a 15-year-old female with a family history of hypertension. She is overweight and is being evaluated because she has had four separate blood pressure readings that are higher than 95% for her gender, age, and height. Her mother is with her and wants to know what she can do to get her daughter's blood pressure down.

Which response by the nurse is best?

- a. Explain to Charlene's mother that the high blood pressure is genetic and her daughter can only take medications to treat the problem.
- b. Tell her mother that Charlene should decrease her salt intake.
- c. Discuss with Charlene and her mother heart-healthy changes such as increasing her activity level, increasing her vegetable intake, and decreasing her sodium intake.
- d. Develop an exercise plan and review it with Charlene's mother to implement with her daughter in the coming months.

*Look in Appendix A for the best answer and rationale.*

## **DYSLIPIDEMIA**

Atherosclerotic cardiovascular disease remains the leading cause of death in North Americans, but it is rare to see this disease in children or adolescents. Risk factors and risk behaviors that accelerate the development of atherosclerosis begin in childhood and evidence suggests that decreasing risk factors will delay progression toward clinical disease ([Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents, 2011](#)). It is important that all pediatric healthcare providers understand the risks that predispose to early atherosclerotic heart disease and the recommendations for monitoring and treating children of all ages.

The NHLBI published guidelines on reducing cardiovascular disease in children and adolescents in 2011 ([Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents, 2011](#)). These guidelines have been endorsed by the American Academy of Pediatrics. They recommend universal lipid

screening once between the ages of 9 and 11 years and again between 17 and 21 years. For children with a family history of dyslipidemia or atherosclerotic disease less than 55 years of age (male) or less than 65 years of age (female), it is recommended that children be screened twice between 2 and 8 years of age with the results averaged. This testing is also recommended if the child has diabetes, hypertension, or a BMI greater than 95th percentile.

Management for children with elevated lipid or cholesterol levels initially focuses on dietary and lifestyle changes. There are recommendations for an initial specific diet that focuses on a low-fat/low-saturated fat/low-cholesterol diet. This is termed the *Cardiovascular Health Integrated Lifestyle Diet* (CHILD-1); details on this diet can be found in the NHLBI guidelines and its implementation should be guided by a registered dietitian if possible. Increased activity for obese children is also among the initial recommendations. Younger children are not placed on low-fat diets because they need calories for growth. Infants younger than 2 years of age need fat for myelination of nerve tissue so they must continue with whole fat milk.

If no change is noted on a fasting lipid profile after a 3-month trial, then a more restrictive diet (CHILD-2) may be used. If after another 3 months, no changes are noted and if the child is 10 years of age or older, a statin medication may be prescribed.

Children taking a statin should have routine clinical monitoring for symptoms of muscle toxicity and assessment of hepatic transaminases and CK.

Because hypercholesterolemia has no symptoms, it is difficult to motivate children to continue a special diet and take medication unless the entire family changes to a lower fat diet and exercises more. Children need continued counseling at healthcare visits so they understand the damage that excess lipids can cause to coronary arteries (Lipshultz, Schaechter, Carillo, et al., 2012).

## OVERWEIGHT CHILDREN AND OBESITY

One in three children in the United States is overweight or obese, which results in physical and psychological comorbidities that often persist into adulthood (National Association of Pediatric Nurse Practitioners [NAPNAP], 2015). It is a multifactorial condition with lifelong physical, emotional, social, and economic implications. Obesity is defined as a BMI at or above the 95th percentile, being overweight is  $\geq 85$ th percentile BMI. Over the past 30 years, the prevalence of obesity has nearly tripled for children 2 to 5 years of age and 12 to 19 years of age and quadrupled for children 6 to 11 years old. The increasing prevalence and severity rates have resulted in a higher prevalence of hypertension, type 2 diabetes mellitus, and the development of atherosclerosis (Daniels, Jacobson, McCrindle, et al., 2009). Nurses must use every opportunity to provide education for children and their families by encouraging them to choose healthy lifestyle behaviors such as:

- Consuming low-fat diets
- Eliminating sweetened beverages and other sugary foods
- Increasing physical activity

- Decreasing screen time

It is important for these behaviors to be implemented by the entire family. It is also important to note that restricting calories is not a first-line management choice for children because they have significant metabolic needs as they grow. Childhood obesity and its risk factors must be addressed early to prevent premature cardiovascular disease in adulthood.

#### *What If . . . 41.4*

**The nurse is particularly interested in exploring one of the 2020 National Health Goals related to achieving cardiovascular health in childhood (see [Box 41.1](#)). The nurse identifies which possible research topic to explore pertinent to this goal that would be applicable to Megan’s family and also advance evidence-based practice? (Megan is the newborn with Down syndrome and an atrioventricular septal defect that will be surgically repaired.)**

### **KEY POINTS FOR REVIEW**

- Cardiovascular disorders in children may be either structural, such as congenital heart disease, or acquired, such as Kawasaki syndrome, rheumatic fever, or cardiomyopathy. Assessment of children with heart disease includes history and physical examination. Echocardiogram, MRI, and cardiac catheterization are procedures used frequently to aid with diagnosis and management.
- Congenital heart disorders are classified as those associated with increased pulmonary blood flow, decreased pulmonary blood flow, and obstruction to blood flow. Single-ventricle defects are classified separately due to their complex anatomy and physiology.
- Common signs of CHF seen in children include tachycardia, tachypnea, enlarged liver, dyspnea, and poor weight gain. Signs tend to be subtle in infants and may be manifested chiefly by difficulties with feeding and gaining weight due to increased caloric consumption due to tachypnea and increased work of breathing.
- Cardiac catheterization and surgery both offer palliative and corrective options for children born with congenital heart disease. Catheterization also can provide diagnostic information to ensure optimal management of heart disease.
- The families of children undergoing cardiac surgery need a great deal of support from healthcare personnel so they can cope with this major event and provide effective support to their child and other family members.
- SVT is the most common dysrhythmia in children, can be well tolerated, and does not typically cause any activity restrictions. If the SVT is associated with WPW, a cardiologist should perform risk stratification before the child participates in competitive sports. Many dysrhythmias can be addressed with an electrophysiologic study and ablation later in childhood if necessary.

- Kawasaki syndrome is a diagnosis of exclusion. If diagnosed, it is imperative that the child receive IV immunoglobulin and high-dose aspirin therapy within 10 days of fever in an effort to prevent coronary artery aneurysms.
- Hypertension in children usually occurs as a result of a secondary disorder. Helping families limit saturated fat intake and follow a consistent exercise program to help children avoid obesity and heart disease in later life is a strategy that not only meets QSEN competencies but also best meets the family's total needs.

### CRITICAL THINKING CARE STUDY

Dwight is a full-term, first-born child and is 2 hours old. His respiratory rate is 68 breaths/min, and his oxygen saturation is 82%. He has a heart rate of 160 beats/min with mild cyanosis around his mouth. An echocardiogram indicates that Dwight has been born with transposition of the great arteries. Dwight's parents did not have consistent prenatal care due to transportation problems.

1. Dwight's father is concerned because he realizes a prenatal sonogram might have revealed his son's heart disorder during the pregnancy. He asks you whether he and his wife are at fault for their child being born with this heart disorder. Could they have prevented this with more routine prenatal care? How should you respond?
2. You are preparing to start a prostaglandin E1 infusion for Dwight. How would you explain to the father the purpose of this infusion?
3. Dwight's father tells you he is worried his health insurance will not cover the two surgeries described by the cardiac surgeon. "Is he trying to make money off of us?" he asks you. "Are two procedures really necessary?" How should you respond?

## Nursing Care of a Family When a Child Has an Immune Disorder

*Dexter Goodenough is a 6-year-old boy you meet in an ambulatory clinic. He had atopic dermatitis (infantile eczema) as an infant. Today, his eyes look red and are watering; his nose is draining a clear discharge. His mother tells you he is constantly listless, and other children have started to bully him because of his appearance and the fact he has a peanut allergy. His grades are “terrible” because his rhinitis symptoms begin the minute he gets to school. Dexter is diagnosed as having allergic rhinitis. His mother responds, “Are you sure it’s just another allergy? He has a cold all of the time. I think there is something wrong with his immune system.”*

*Previous chapters described normal growth and development of children. This chapter adds information about the dramatic changes, both physical and psychosocial, that can occur when a child is born with or develops a disorder of the immune system.*

**In light of the effect this condition is having on Dexter’s life, is this “just” an allergy? What additional information would you want his mother to know about his condition? Knowing his problem is worse at school, what environmental control measures would you want to suggest for Dexter?**

### KEY TERMS

**allergen**  
**anaphylaxis**  
**antigen**  
**atopic dermatitis**  
**autoimmunity**  
**cell-mediated immunity**  
**chemotaxis**  
**complement**  
**cytotoxic response**  
**delayed hypersensitivity**

**environmental control**  
**humoral immunity**  
**hypersensitivity response**  
**hyposensitization**  
**immune response**  
**immunity**  
**immunogen**  
**immunoglobulins**  
**lymphokines**  
**lysis**  
**macrophages**  
**phagocytosis**  
**tolerance**

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe the effects of an underactive or overactive immune response as it relates to childhood illnesses.
2. Identify the 2020 National Health Goals that nurses can help the nation achieve as related to immune disorders.
3. Assess a child with a disorder of the immune system.
4. Formulate nursing diagnoses for a child with a disorder of the immune system.
5. Establish outcomes for a child with a disorder of the immune system that can help the family manage seamless transitions across different healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care for a child with an immune disorder.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of immune disorders with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

The immune system is made up of a variety of proteins and cell types, which work together to protect the body against invasion by foreign substances. The study of the immune system is a growing field as more diseases and genetic mutations are identified, making it important to have an understanding of how the immune system works in health and disease in order to provide safe nursing care ([Hellmann & Imboden, 2013](#)).

Disorders of the immune system can be the result of an underactive or nonfunctional system (immunodeficiency), an overactive or poorly regulated system (allergy or hypersensitivity), or an abnormal or excessive response against one's own cells (autoimmune disease). Immunodeficiencies and allergic disorders are described in this chapter. Autoimmune disorders include a wide range of diseases and often affect a particular body system. These are described in the chapter that discusses the affected system (e.g., juvenile arthritis, which affects the joints, is discussed in [Chapter 51](#)). The 2020 National Health Goals related to immune disorders and children are shown in [Box 42.1](#).

### BOX 42.1

#### Nursing Care Planning Based on 2020 National Health Goals

Allergies affect at least 25% of the population; therefore, efforts to reduce them are reflected in several 2020 National Health Goals:

- Reduce indoor allergen levels such as cockroach allergens in settled dust from a baseline of 0.51 units to 0.46 units.
- Increase the proportion of the nation's elementary, middle, and high schools that have an indoor air quality management program to promote a healthy and safe physical school environment from a baseline of 51.4% to a target level of 56.5%.
- Reduce new cases of perinatally acquired AIDS from a baseline of 28 cases yearly to 25 new cases yearly.
- Reduce new AIDS cases among adolescents and adults from a baseline of 14.4 new cases per 100,000 to a target level of 13.0 new cases per 100,000.
- Increase the proportion of sexually active unmarried females aged 15 to 44 years who use condoms from a baseline of 34.5% to a target level of 38% ([U.S. Department of Health and Human Services, 2010](#); see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by advocating for improved air quality in schools and initiating educational programs for children and adolescents that includes teaching about the way HIV is transmitted (sexual relations and unclean intravenous needles) and protective measures they can take to avoid contracting the disease (using safer sex practices and not using intravenous drugs).

### *Nursing Process Overview*

#### FOR A CHILD WITH AN IMMUNE DISORDER

##### **ASSESSMENT**

The purpose of the immune system is to provide protection to the body from invading organisms or antigens. A deficiency in any of the components of the immune system or alteration in function can limit this protection. An assessment focuses on the types of illnesses or problems the child is having in order to target the part of the immune

system which is mal- or nonfunctioning. A thorough history and analysis of presenting symptoms is the best way to identify the problem and to develop appropriate interventions.

## **NURSING DIAGNOSES**

Examples of nursing diagnoses associated with immune disorders include:

- Risk for infection related to altered immune response
- Impaired skin integrity and risk for infection related to atopy
- Activity intolerance related to chronic illness
- Risk for delayed or altered growth and development related to chronicity of immune disorder

Nursing diagnoses specific to the child with allergies focus on the specific symptom. Examples include:

- Situational low self-esteem related to symptoms of contact dermatitis or atopy
- Ineffective breathing pattern related to bronchospasm of allergic response or anaphylaxis
- Anxiety related to continuing or uncontrolled allergic response
- Powerlessness related to difficulty determining cause of allergy

## **OUTCOME IDENTIFICATION AND PLANNING**

Outcome identification and planning for a child with an immune disorder should focus both on present and future concerns. Relief of immediate symptoms is the first priority followed by planning for long-term care and infection prevention. Examples of organizations helpful for supplying information to parents or children are the National Eczema Association ([www.nationaleczema.org](http://www.nationaleczema.org)), the Asthma and Allergy Foundation of America ([www.aafa.org](http://www.aafa.org)), American Academy of Allergy Asthma and Immunology ([www.AAAAI.org](http://www.AAAAI.org)), the Jeffrey Modell Foundation ([www.info4pi.org](http://www.info4pi.org)), and the Immune Deficiency Foundation ([www.primaryimmune.org](http://www.primaryimmune.org)). Other allergy-specific resources include the PRACTALL program, which is a common initiative of the European Academy of Allergy and Clinical Immunology and the American Academy of Allergy Asthma and Immunology. It focuses on practical aspects of allergy to deliver updated and evidence-based recommendations for clinicians. Several PRACTALL publications are referenced in the chapter.

## **IMPLEMENTATION**

A major nursing intervention in the care of children with immune disorders is child and family teaching. The family of a child with an immunodeficiency may need help in identifying ways to keep the child from contracting life-threatening infections while at the same time providing enough stimulation and social contact to promote normal growth and development. The family of a child with a chronic allergic disorder needs to learn ways to help their child avoid triggers or situations that provoke the allergic response but at the same time not keep the child so isolated or fearful that the child misses out on important socialization and life experiences.

## OUTCOME EVALUATION

Outcome evaluation with immune disorders must be ongoing because these diseases are not static. Children with allergies can develop new allergic triggers at any time. Children with immunodeficiencies can similarly develop infections or related comorbidities at any time. New therapies for disease processes are constantly being investigated. Because the field of immunology is continually evolving, theories about immune diseases and associated treatments change year to year. This means that healthcare providers need to keep abreast of the latest developments. Emphasize to parents that they need to know the latest technologic information as well, especially as it relates to providing a safe environment for their child. Examples of outcomes suggesting the achievement of goals include:

- The child voices high self-esteem despite altered skin integrity related to atopy.
- The child and parents are able to adhere to the plan of care.
- The child lists three actions he takes daily to help feel a greater sense of control and well-being.
- The child demonstrates achievement of developmental milestones within age-acceptable parameters despite chronic illness.

## The Immune System

The immune system is composed of a variety of cell types and proteins. The cells either recognize or react against foreign substances (**antigens**); some cells both recognize and react against antigens. Antigens include pathogens (bacteria, fungi, or viruses), food proteins, and pollens. There is significant redundancy in the immune system so that if one part does not function properly, another component may serve as a backup to take over some or all of the role of the malfunctioning part. The immune system response includes host defenses, nonspecific responses, and specific responses.

Host defenses include physical protective barriers including the skin, mucous membranes, cilia, and normal flora. Nonspecific responses include complement, phagocytes, and natural killer cells. Specific responses include antibody production and cellular immunity. All these components work together to protect the system from foreign invasion. If an invading pathogen does get through the physical, protective barrier, **phagocytosis**, or the destruction of the invaders, begins. **Macrophages** (mature white blood cells) engulf, ingest, and neutralize the pathogen. At the same time, an inflammatory response creates vascular and cellular changes that help to rid the body of dead tissue and the inactivated antigens. The immune system maintains cells ready to attack this way whenever necessary, directing the efforts of macrophages and supplementing the inflammatory response as necessary. It also singles out specific antigens for interactions (*antibody–antigen reactions*). This immune response not only furnishes immediate protection but also creates a template for how to destroy that particular antigen again in the future.

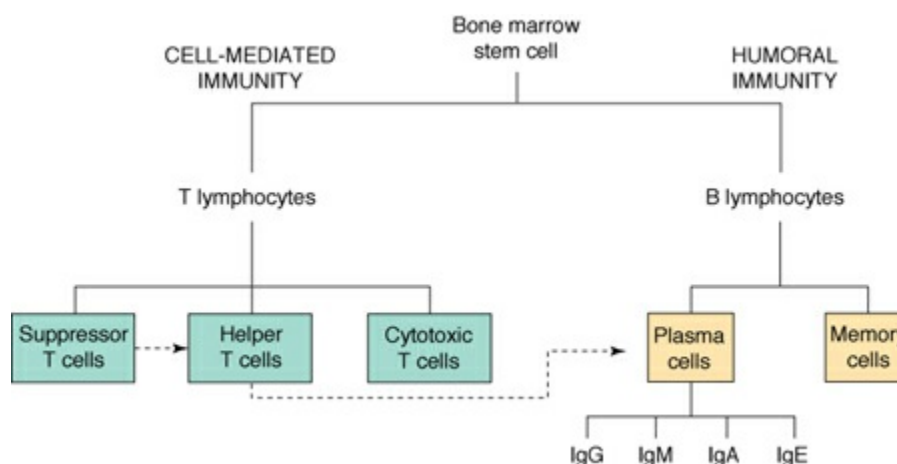

## IMMUNE RESPONSE

The **immune response** is the body's action plan devised to combat invading organisms or substances by leukocyte and antibody activity. An antigen is any foreign substance capable of stimulating an immune response. Most antigens are proteins, but other large molecules such as polysaccharides may also function the same way. Penicillin, although not antigenic by itself, can become antigenic when it combines with a higher weight molecule, usually a protein (a process called *haptens formation*). If an antigen is one that can be readily destroyed by an immune response, and **immunity** (the ability to destroy like antigens) results, the antigen may be referred to as an **immunogen**.

If, during the immune response, mediating substances are released that cause tissue injury and allergic symptoms, the antigen is termed an **allergen**. Allergens can enter the body through a variety of routes. They may be ingested (foods such as milk, egg, or peanut), inhaled (pollen, dust, or mold spores), injected (drugs), or absorbed across the skin or mucous membranes (poison ivy).

## IMMUNE SYSTEM ORGANS AND CELLS

The major organs of the immune system are the thymus, liver, bone marrow, spleen, tonsils, lymph nodes, and blood. All of the cells of the immune system originate in the bone marrow where they develop from stem cells. Lymphocytes, produced in the bone marrow travel to different parts of the body, where they function. In the thymus, lymphocytes mature into T cells (Fig. 42.1). In other organs, such as the tonsils and spleen, lymphocytes collect and communicate with each other. The liver synthesizes the proteins of the complement system and contains large numbers of phagocytes to ingest and destroy bacteria.

**Figure 42.1** Lymphocyte production. From the bone marrow stem cell, T and B lymphocytes are formed. T-Lymphocyte action leads to cell-mediated immunity. B-Lymphocyte action results in humoral immunity. Ig, immunoglobulin.

### B Lymphocytes

B Cells originate in the bone marrow where they develop from plasma or memory cells. Their major function is to produce antibodies or **immunoglobulins**. These immunoglobulins bind to and destroy specific antigens. When an antibody is formed in response to a particular antigen, it is specific to that antigen. For example, an antibody against the pertussis antigen, for instance, will not have any effect on the tetanus antigen. *Memory cells* are responsible for retaining the formula or ability to produce specific immunoglobulins. Immunoglobulins are classified as IgG, IgA, IgM, IgD, and IgE. Those involved in immunity include IgG, IgA, and IgM.

IgE is primarily responsible for allergic or hypersensitivity responses and is present at proportions capable of extreme response early in infancy. The functions of immunoglobulins are summarized in [Table 42.1](#).

**TABLE 42.1 LOCATIONS AND FUNCTIONS OF IMMUNOGLOBULINS**

Immunoglobulin	Description
IgM	Effective in agglutinating antigens as well as lysing cell walls; discovered early in the course of an infection in the bloodstream as it is the first response to pathogenic antigens.
IgG	Most frequently occurring antibody in plasma; during secondary response, it is the major immunoglobulin to be synthesized. It freely diffuses into extravascular spaces to contact antigens. In prenatal life, it diffuses across the placenta to supply passive immune protection to the fetus until the infant can effectively produce immunoglobulins. It has the major responsibility for neutralizing bacterial toxins and in activating phagocytosis (destruction of bacteria).
IgA	Found in external body secretions such as saliva, sweat, tears, mucus, bile, and colostrum. It provides defense against pathogens on exposed mucosal surfaces, especially those of the gastrointestinal tract and respiratory tract, and works, apparently, by preventing adherence of pathogens to mucosal cells.
IgD	Found in plasma. It may be the receptor that binds antigens to lymphocyte surfaces but its true function is unclear.
IgE	Involved in immediate hypersensitivity reactions. It exists bound to mast cells on tissue surfaces. When contacted by an antigen, cellular granules are released. It is associated with allergy and parasitic infections.

## T Lymphocytes

T Lymphocytes account for 70% to 80% of blood lymphocytes and are responsible for *cell-mediated immunity*. They are produced by the bone marrow but mature under the

influence of the thymus gland (hence their name). When mature, T lymphocytes leave the thymus to enter specific body regions (thymus-dependent zones), mostly in the lymph nodes and spleen; there, they react specifically to viruses, fungi, and parasites but have an effect on all antigens. T cells can be differentiated into three subtypes.

The first type, *cytotoxic (killer) T cells*, are T lymphocytes that have a specific ability to bind to the surface of antigens and directly destroy the cell membrane and, therefore, the cell. As a part of this process, cytotoxic cells secrete **lymphokines**, the purpose of which is to contain or prevent the migration of antigens as well as to call other lymphocytes into the area (the property of chemotaxis). *Interferon* is an example of a lymphokine widely discussed because it is important in preventing viral infections.

The second type, *helper T cells* (CD4 cells), serve the purpose of stimulating B lymphocytes to divide and mature into plasma cells so the B cells can begin secreting immunoglobulins. The IgA antibody response, especially, depends on stimulation by helper T cells. Helper T cells can be identified in blood because of specific markers on their surfaces. In patients with HIV/AIDS, analysis of these (CD4 counts) is an important assessment criteria used to determine if antiretroviral therapy is beginning to be effective (Boyd, 2011).

The third type, *suppressor T cells*, are specific cells that reduce the production of immunoglobulins against a specific antigen and prevent their overproduction.

## TYPES OF IMMUNITY

The action of B and T lymphocytes leads to two different types of immunity: humoral and cell mediated.

### Humoral Immunity

**Humoral immunity** refers to immunity created by antibody production or B-lymphocyte involvement. The process begins when helper T cells recognize an antigen and cause activation of B lymphocytes (possibly by an intermediary macrophage). B lymphocytes differentiate into plasma cells and begin the creation of specific immunoglobulins that mark the antigen for destruction (Fig. 42.2). A few antigens (e.g., *Escherichia coli*) are capable of activating a B-lymphocyte response without recognition by T lymphocytes.

A

B

**Figure 42.2** Mechanism of immunity response. (A) Humoral immunity. (B) Cell-mediated immunity.

The first time a specific antigen enters the body and is identified by T lymphocytes, B-cells differentiate and growth begins rapidly. Within 6 days, IgM antibodies specific to the antigen can be measured in the bloodstream. This level peaks at 14 days and then declines until, within a few weeks, little IgM can be measured. At approximately day

10, antigen-specific IgG production begins and remains high for several weeks (Fig. 42.3). When a specific antigen enters the body an additional time, antibody production is able to begin again immediately because of the presence of memory cells which develop after the first exposure. The main type of immunoglobulin produced in a secondary response is IgG (see Fig. 42.3). This secondary response is why immunocompetent people do not get the same disease twice.

**Figure 42.3** Primary and secondary humoral responses. Immunoglobulin (Ig)M is the first to appear in the serum.

### Complement Activation

**Complement** is composed of 20 different proteins that are normally nonfunctional molecules; however, when activated by antigen–antibody contact, these molecules begin a cascade response that leads to increased vascular permeability, smooth muscle contraction, **chemotaxis** (“calling” leukocytes into the area), phagocytosis, and **lysis** (killing) of the foreign antigen. The accompanying inflammatory reaction causes the area to feel warm and look red and swollen. Although an inflammatory reaction causes some local injury to tissue around the antigen, it is helpful overall because it produces an environment that is harmful to the antigen. Complement reactions that persist beyond the usual time for resolution (2 to 3 days) may be responsible for autoimmune disorders such as lupus. Children who have complement deficiencies are prone to repeated systemic infections (sepsis) from encapsulated bacteria

### Cell-Mediated Immunity

**Cell-mediated immunity** is the type of immune response caused by T-lymphocyte activity. Cytotoxic T cells attack and directly destroy invading antigens through the release of chemical compounds onto the antigen membrane, through the injection of a toxin directly into the antigen, or through the secretion of lymphokines. A wheal-and-

flare response occurs because of the accumulation of lymphocytes around small blood vessels, which results in minor destruction of blood vessels (see [Fig. 42.2](#)). This response is termed **delayed hypersensitivity** if the T-lymphocyte activity occurs solely without an accompanying humoral response. It is this response that causes transplant rejection.

## Autoimmunity

**Autoimmunity** is the result of the immune system being unable to distinguish self from nonself, causing the immune system to trigger immune responses against normal cells and tissue rather than invading antigens. Autoimmune responses may be limited to one organ, as happens with Hashimoto disease where the thyroid gland is involved (see [Chapter 48](#)), or may be generalized and systemic (i.e., not organ specific), as in systemic lupus erythematosus (see [Chapter 20](#)). There is currently much research oriented toward the study of autoimmune responses and their possible implications in a wide variety of disorders, such as multiple sclerosis ([Spiro, 2012](#)). Autoimmune disorders occur at a greater rate in some families than in others and in girls and women more than boys and men.

### *QSEN Checkpoint Question 42.1*

#### **SAFETY**

Dexter is at his primary care provider's office and the nurse had been asked to assist with his physical examination. What safety intervention should the nurse use with Dexter because he's known to have many allergies?

- Assess his blood pressure using a new blood pressure cuff.
- Distract him by showing him a tropical fish tank.
- Spot-check his oxygen saturation using pulse oximetry.
- Use nonlatex gloves to conduct the examination.

*Look in [Appendix A](#) for the best answer and rationale.*

## Immunodeficiency Disorders

When any portion of the immune system is missing or not functioning properly, an immunodeficiency can result. An immunodeficiency can be primary (congenital) or acquired (secondary to a viral infection, exposure to a toxic substance or some drugs). If a child is suspected to have a humoral immunodeficiency, live viral vaccines are contraindicated, and all blood products should be irradiated.

### **PRIMARY IMMUNODEFICIENCY**

Primary immunodeficiencies comprise over 150 inherited disorders. They can present and be diagnosed at various ages and affect all parts of the immune system, including

humoral defects, cell-mediated defects, complement deficiencies, and phagocyte disorders (Younger, Epland, Zampelli, et al., 2015).

### **Humoral Deficiencies**

Children with humoral defects are generally well until 4 to 6 months of age because of the presence of maternal antibody which crosses the placenta. As this antibody wanes and the child fails to produce his or her own antibody, infections can begin to present. Selective IgA deficiency, agammaglobulinemia (either X-linked or autosomal recessive), and common variable immunodeficiency (CVID) are the most common humoral defects. In X-linked agammaglobulinemia, male children lack the enzyme necessary for B cells to mature; the B cells are incapable of maturing into antibody, and patients are susceptible to infection from a wide variety of pathogens. In patients with CVID, the levels of immunoglobulins are low but usually not absent, and antibody development is impaired. The cellular or T-lymphocyte response remains adequate in CVID, protecting the child from some pathogens.

Agammaglobulinemia and CVID are treated with the regular infusion of pooled human immunoglobulin, synthesized from human plasma. Immunoglobulin can be delivered intravenously every 3 to 4 weeks or subcutaneously every 1 to 2 weeks. The importance of early recognition of signs and symptoms of infection needs to be emphasized to both children and parents. Children with these immunodeficiencies may need longer courses of antibiotic treatment than immunocompetent children with the same infection. There is also an association with a higher prevalence of autoimmune diseases and lymphoreticular cancers in children with CVID. Healthcare providers and families must be taught to be aware of the signs of these illnesses.

Selective IgA deficiency is the most common of the humoral immunodeficiencies. The clinical definition for this disorder is an undetectable level of IgA, not merely a low level. The disorder can occur in as frequently as 1:500 people. Most people who lack IgA are completely asymptomatic, and the deficiency is noted when the person is being evaluated for another illness, such as celiac disease. IgA deficiency may result from an increase in IgA suppressor cells or defect in helper T-cells necessary for IgA production. IgA is normally found on mucosal surfaces, so in patients who are symptomatic, it is possible to see upper respiratory infections or inflammatory bowel disease. IgA deficiency is also associated with atopic diseases (allergies) because without IgA on the surface mucosa, many more antigens than usual can enter the body, thus permitting more antigens to interact with IgE and produce allergic symptoms. There is no treatment specific for IgA deficiency because there is no way to provide IgA to the body.

### **T-Lymphocyte Deficiencies**

T-Lymphocyte immunodeficiencies involve inadequate numbers or inadequate functioning of one or more types of T lymphocytes; this affects cell-mediated immunity

and, because of helper T-lymphocyte function, possibly humoral immunity as well. An example of one of these types of illnesses is DiGeorge syndrome. DiGeorge syndrome is a chromosomal deletion syndrome with tremendous phenotypic variability. Manifestations include congenital heart disease, abnormal facies, aplastic or hypoplastic thymus, hypocalcemia, and cleft lip and/or palate (Woo & Bahna, 2011).

### **Combined T- and B-Lymphocyte Deficiency**

Severe combined immunodeficiencies (SCID) are a group of inherited rare disorders associated with large defects in T- and B-cell immunity (Hellmann & Imboden, 2013). SCID is caused by a developmental abnormality (sometimes but not always related to the absence of a particular enzyme), which prevents the formation of T lymphocytes (a stem cell abnormality). This, in turn, prevents the maturation of both T and B lymphocytes. Children cannot respond directly to antigen invasion, and no antibodies are produced. The definitive treatment for children with SCID is correction of the immunologic defect by hematopoietic stem cell transplantation, possibly from cord blood (Accetta Pedersen, Verbsky, & Routes, 2011).

In many states, newborns with SCID can be identified via a T-cell receptor excision circle (TREC) assay done at the same time as other routine newborn screening via dried blood spots. Low TREC numbers indicates a low number of lymphocytes and indicates further testing. This is critically important because SCID is 100% fatal if untreated, and early recognition is key to early treatment and survival (Kwan & Puck, 2015).

### **SECONDARY (ACQUIRED) IMMUNODEFICIENCY**

Secondary immunodeficiency, or loss of immune system response, can occur from factors such as severe systemic infection, cancer, radiation therapy, severe stress, malnutrition, monoclonal antibody therapy targeted at B cells, other immunosuppressive therapy, and aging. Anything that causes the body to lose protein such as renal disease or protein-losing enteropathies may also cause a secondary immunodeficiency. There can be complete or partial loss of both B- and T-lymphocyte response.

Stress appears to alter the immune response by stimulating the release of corticosteroids from the adrenal gland. This suppresses the inflammatory response by inhibiting macrophage action. Immunosuppressive drugs, such as prednisone, also act to suppress the inflammatory response. The action of radiation or chemotherapy limits the function of or destroys rapidly growing cells and so destroys both T and B lymphocytes as these are rapidly growing and dividing cells. Extreme infection is yet another cause for a decreased immune response because the body's continued ability to combat infection becomes exhausted over time.

### **HIV Infection and AIDS**

HIV is a slowly replicating retrovirus and has at least two main divisions, HIV-1 and HIV-2, followed by a variety of further subtypes. The virus acts by attacking the

lymphoreticular system, in particular CD4-bearing helper T lymphocytes. The virus enters the cell, substitutes its own RNA and DNA for the cell's DNA, and begins to replicate, destroying the lymphocytes in the process as well as their ability to initiate an effective B-lymphocyte response.

There is no effective way to destroy the HIV, so it remains in the body for life and can activate if the immune system becomes depressed. When monocytes and macrophages become affected, the person with HIV infection cannot resist usual infections such as the common cold. When the CD4 count falls below 500 cells/mm<sup>3</sup> or the viral load rises above 5,000 copies/ml, it is difficult for infected individuals to resist opportunistic infections such as fungal infections. The final result is that both the immune response and the ability to screen and remove malignant cells from the body are lost (Smith, 2011).

## Transmission

HIV infection is spread by exposure to blood and/or other body secretions through sexual contact, the sharing of contaminated needles for injection, the transfusion of contaminated blood or blood products, perinatally from mother to fetus, and possibly through breastfeeding. Children can also acquire the infection because of sexual maltreatment. Healthcare providers must maintain vigilance to guard against needle punctures, as these injuries can be a direct source of blood transfer and, potentially, infection.

Although it is decreasing in incidence, the transmission of HIV from mother to child by placental spread is still the most common reason for childhood HIV infection in the United States. Transmission of HIV through sexual activity is a growing concern for adolescents and an important area where health education is needed (Sawyer, Afifi, Bearinger, et al., 2012). HIV is not transmitted by animals or through usual, casual contact, such as shaking hands or kissing.

## Assessment

HIV has a long incubation period of about 10 years in adults. The disorder appears to progress more rapidly in children and infants, however, who receive the virus via placental transmission (if mothers do not receive treatment). These children are usually HIV positive by 6 months and develop clinical signs of the disease by 1 to 3 years of age. Children who receive the virus from another source usually convert to HIV positivity by 2 to 6 weeks or at least by 6 months after exposure. During this preconversion time, a child may display preliminary symptoms such as poor resistance to infection, fever, swollen lymph nodes, respiratory tract infections, and oral candidiasis.

All infants born to infected mothers test positive for antibodies to the virus at birth because of passive antibody transmission (which persists for about 18 months). The disease is diagnosed, therefore, by recovery of the HIV antigen in children under this

age and antibodies to the virus in children over this age. Tests to detect the antigen are termed *polymerase chain reaction* (PCR) tests; those for the antibody are termed *enzyme-linked immunosorbent assay* (ELISA) or Western blot confirmation. CD4 counts are used to document the disease status and predict disease progression. Normal counts vary somewhat according to age because the lymphocyte count normally varies by age, but generally, a CD4 count of 500 cells/mm<sup>3</sup> to 1,500 cells/mm<sup>3</sup> is a healthy count.

The Centers for Disease Control and Prevention (CDC, 1994) classification of HIV infection in children has three categories:

- Category A, *mildly symptomatic*: Two or more symptoms such as enlarged lymph nodes, hepatomegaly and/or splenomegaly, or recurrent or persistent upper respiratory infections, sinusitis, or otitis media are present.
- Category B, *moderately symptomatic*: More serious illnesses such as oropharyngeal candidiasis, bacterial meningitis, pneumonia, sepsis, cardiomyopathy, cytomegalovirus (CMV) infection, hepatitis, herpes simplex virus (HSV), bronchitis, pneumonitis, esophagitis, herpes zoster (shingles), lymphoid interstitial pneumonia (LIP), pulmonary lymphoid hyperplasia complex, or toxoplasmosis are present.
- Category C, *severely symptomatic (AIDS)*: Serious bacterial infections such as septicemia, mycobacterial pneumonia, meningitis, bone or joint infection, abscess of an internal organ or body cavity, candidiasis (esophageal or pulmonary), encephalopathy, herpes simplex lasting over 1 month, histoplasmosis, lymphoma, tuberculosis, *Pneumocystis jiroveci* pneumonia (PCP; a form of pneumonia caused by a yeast-like fungus), and Kaposi sarcoma (a malignancy that causes large purple/blue tumors to grow from the lining of capillaries) have occurred.

## Therapeutic Management

Because of advances in general health care, increased birth control education focused on the needs of women who are HIV positive as well as the availability of antiretroviral medications, the number of infants born with HIV infection is decreasing (Gay, Hardee, & Croce-Galis, 2011). Those infants who are born with HIV, once thought to have a short life expectancy, now have an opportunity for long-term survival.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for infection related to decreased immune function

**Outcome Evaluation:** Child's temperature is within normal parameters; no signs of infection are present.

Combating HIV infection and maintaining an effective CD4 count requires continuous specific antiretroviral medications to prevent progressive deterioration of the immune system and to provide prophylactic measures against opportunistic infections. The introduction of highly active antiretroviral therapy (HAART) in pediatric HIV/AIDS treatment has made the difference between an acute disease where 60% of children died by age 6 years to a life expectancy of 40 to 50 years (Shulman, Yogev, & Murphy, 2011). Four classes of drugs are the mainstay of therapy: nucleoside reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), and integrase strand transfer inhibitors (ISTIs). NRTIs are designed to block the production of viral DNA, limiting the ability of the virus to infect cells; zidovudine is an example (Box 42.2). NNRTIs also inhibit the DNA synthesis of viruses but act at different sites on the viral enzyme; nevirapine and efavirenz are examples. Children are prescribed a regimen involving multiple drugs, such as one PI plus two NRTIs.

## BOX 42.2

### Nursing Care Planning Based on Responsibility for Pharmacology

#### ZIDOVUDINE

**Classification:** a nucleoside analog reverse-transcriptase inhibitor (NRTI)

**Action:** Zidovudine (ZDV) inhibits the replication of some retroviruses, including HIV. It reduces the possibility of maternal–fetal transmission of HIV (Commins, 2017).

**Pregnancy Risk Category:** C

**Dosage:** Individually determined based on the infant’s or child’s weight and whether it is administered twice or three times a day. Making certain the infant takes the full dose is an important nursing responsibility.

**Possible Adverse Effects:** nausea, loss of appetite, change in taste, paresthesia (tingling or numbness), headache, fever, agranulocytopenia, and rash

#### Nursing Implications

- When administering the drug intravenously, infuse the drug over 60 minutes to avoid too rapid infusion.
- Administer the drug around the clock for maximum effectiveness.
- Monitor blood studies frequently for change.
- Advise child to eat or feed child frequent, small meals to counteract change in taste and loss of appetite.
- If the child experiences paresthesias, institute safety precautions and instruct child and parents in measures to prevent injury related to loss of feeling.
- Caution child and parents that ZDV does not reduce the risk of HIV transmission

except placentally. Reinforce the importance of hygiene and infection control measures.

In addition, many children are given prophylactic therapy for PCP (such as trimethoprim-sulfamethoxazole [TMP-SMZ]) beginning at 6 months of age. Children with HIV infection are more susceptible to tuberculosis than other children, so they also must be safeguarded against contracting this (Getahun, Raviglione, Varma, et al., 2012). If a child develops tuberculosis, a combination of antituberculosis drugs, such as isoniazid or rifampin, is used.

Children with HIV should receive routine immunizations according to the usual schedule including pneumococcal and human papillomavirus (HPV) vaccines. Attenuated live vaccines such as varicella and measles, mumps, and rubella (MMR) should be used with caution in children who are symptomatic or who have low CD4 counts. If a child is exposed to varicella, intravenous varicella zoster immune globulin (VZIG) can be prescribed in an attempt to prevent disease.

In addition to these measures, children with HIV infection and their families must maintain strict personal hygiene by measures such as frequent hand washing and avoiding close contact between the child and anyone who is ill to try to prevent the child from contracting dangerous opportunistic infections such as yeast and herpes infections. If a viral or fungal infection does occur, antiviral and antifungal treatment should be prompt and aggressive. The same is true of bacterial infections.

**Nursing Diagnosis:** Risk for compromised family coping related to the diagnosis of HIV infection in child

**Outcome Evaluation:** Parents state an ability to continue providing child's physical and emotional care; identify outside resources for help with care and decision making as needed.

The diagnosis of HIV infection in an infant or child can prove devastating for a family. When the infection is transmitted maternally, this diagnosis may be the first indication of the existence of HIV infection in the mother; as such, this signals tremendous stress for the whole family. When it occurs in an adolescent, parents may blame themselves for not supervising the child's activities more closely or providing better safe sex information. In any instance, the family's coping skills are certain to be stressed. Siblings may feel left out of the family circle because of the many healthcare appointments needed for the ill child. The siblings may fear contracting the infection themselves. One of the first nursing priorities in the care of such a family should be to help the family establish an appropriate level of functioning so they can focus on their child's emotional and physical care needs and to total family needs as well.

Physical care requirements for the child with HIV infection can be extensive depending on the child's symptoms and disease progression. No matter what the

child's physical needs, love and emotional support continue to be essential to the child's well-being and psychological health. To continue to offer this support for such a long-term illness, parents need extensive support, education, and anticipatory guidance from healthcare providers. Telehealthcare (information received by electronic means such as laptops or smartphones) is an emerging phenomenon whereby healthcare personnel can provide support to families and patients; a caution is that this should always be supplemental support and should not take the place of "hands-on" care (McLean, Chandler, Nurmatov, et al., 2011).

## A Pregnant Woman With HIV Infection

One fourth of the nearly 1 million people in the United States infected with this virus are female; a number of them become pregnant each year through intended or unintended conception (Hoyt, Storm, Aaron, et al., 2012). If the disorder is first discovered during pregnancy, pregnancy does not appear to accelerate the progression of the disease. It occurs more often in women who have bisexual or multiple sexual partners or when women or their partners use intravenous drugs.

### Assessment

Unlike other sexually transmitted infections (STIs), HIV infection rarely begins with reproductive tract lesions. Instead, early symptoms are more subtle and often difficult to differentiate from those of other diseases or even from the symptoms of early pregnancy such as fatigue, anemia, diarrhea, and weight loss.

Without therapy, HIV infection progresses more slowly in adults than it does in children, and so the pregnant woman can be seen passing through a number of stages:

- The initial invasion of the virus, which may be accompanied by mild, flu-like symptoms
- Seroconversion, in which a woman converts from having no HIV antibodies in her blood serum (HIV serum negative) to having antibodies against HIV (HIV serum positive). Seroconversion happens 6 weeks to 1 year after exposure.
- An asymptomatic period during which the woman appears to be disease free except for symptoms such as weight loss and fatigue. She is not free of the disease, however, because the virus continues to replicate during this time. The length of this period varies but averages 3 to 11 years.
- A symptomatic period during which a woman develops opportunistic infections and possibly malignancies including oral and vaginal candidiasis, gastrointestinal illness, herpes simplex, PCP, *Candida* esophagitis, Kaposi sarcoma, and HIV-associated dementia. At this point, the CD4 count is usually below 200 cells/mm<sup>3</sup>.

Although women are not as yet routinely screened for HIV during pregnancy, women who practice high-risk sexual behaviors should be asked if they want to be screened. A woman with HIV infection may also have contracted other diseases and

STIs such as syphilis, gonorrhea, chlamydia, and hepatitis B and so should be screened for these diseases as well as tuberculosis. Because they are also at higher risk for developing toxoplasmosis and CMV infections, a health history should include questions about cat ownership, ingestion of raw meat, and recent mild, flu-like symptoms (see [Chapter 12](#)).

If a woman is found to be HIV positive during pregnancy (i.e., has developed antibodies from having been exposed to the virus) through an ELISA antibody reaction or a Western blot analysis, the issues of safer sex practices, testing of sexual contacts, and treatment during pregnancy need to be addressed. If a woman is not treated, as many as 20% to 50% of infants contract the virus and develop AIDS in the first year of their life. HIV infection is associated with both preterm births and low-birth-weight infants. The use of rapid HIV testing for all women in labor who did not receive prenatal care is being encouraged throughout the United States in order to identify women in need of specialized care and to help identify those infants in need of immediate antiviral therapy ([Levison, Williams, Moore, et al., 2011](#)).

### Therapeutic Management

Women who are identified as HIV positive need education about reproductive life planning so they can effectively prevent pregnancy if they so desire. Often, however, the existence of HIV is discovered only after the affected woman is already pregnant. Progression of the disease is assessed by frequent CD4 cell counts and viral load levels during the pregnancy.

A goal of therapy during pregnancy is to maintain the CD4 cell count at greater than 500 cells/mm<sup>3</sup> by administering oral zidovudine, which helps to dramatically halt maternal-fetal transmission (see [Box 42.2](#)) along with one or more PIs, such as ritonavir (Norvir) or indinavir (Crixivan), in conjunction with an NRTI.

If PCP develops, a woman is treated with TMP-SMZ (Bactrim, Septra), a combination drug not without consequences, because trimethoprim may be teratogenic in early pregnancy and sulfamethoxazole may lead to increased bilirubin levels in the newborn if administered late in pregnancy. Although not well studied, pentamidine (Pentam), the drug of choice for PCP in nonpregnant women, is yet another option.

Kaposi sarcoma is normally treated with chemotherapy. Chemotherapy is contraindicated during early pregnancy, however, because of the potential for fetal injury. It can be used later in pregnancy to halt these malignant growths.

Thrombocytopenia (low platelet counts) may be present as a part of HIV disease pathology or as a response to zidovudine therapy. Women may need a platelet transfusion close to birth. This may make a woman a poor candidate for an epidural injection for anesthesia during labor or for an episiotomy. To reduce the risk of mother-to-newborn transmission, affected women should be offered the option of a cesarean birth.

Follow-up testing of newborns being treated with zidovudine for the first 6 weeks of

life is important because if the child has two negative HIV tests by 4 months of age, HIV infection can be reasonably excluded.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for infection (opportunistic) related to dysfunction of the immune system secondary to invasion of HIV

**Outcome Evaluation:** CD4 counts remain above 500 cells/mm<sup>3</sup>; viral load less than 5,000 copies/ml; no symptoms of lung, vaginal, esophageal, or central nervous system infections are present.

Pregnant women who have CD4 counts below 200 cells/mm<sup>3</sup> may be prescribed drugs to help prevent opportunistic infections. Such drugs include acyclovir (Zovirax) for herpes simplex, clotrimazole troches (Mycelex) for oral candidiasis, pyrimethamine (Daraprim) and sulfadiazine for toxoplasmosis, and trimethoprim and sulfamethoxazole (Bactrim) for PCP. They may be immunized against pneumonia, influenza, and hepatitis B.

During pregnancy and at birth, active interventions are necessary to reduce the possibility of fetal exposure to maternal blood, often the mode of transmission to the fetus. Amniocentesis, for example, presents a risk of exposure to maternal blood and therefore is avoided if at all possible. During labor, internal fetal monitors, scalp blood sampling, forceps, and vacuum extraction are avoided to prevent the creation of a source of bleeding (i.e., an open lesion on the fetal scalp). Episiotomy also is avoided to limit this as a possible blood source. Although the risk may be lower than previously believed, breast milk can transmit HIV and breastfeeding can be exhausting for a debilitated woman; in nations where safe infant formula is not available, however, the advantages of breastfeeding may outweigh the risk of HIV transmission (Natchu, Liu, Duggan, et al., 2012).

Women who are HIV positive need to be aware that they can spread their illness to others through unprotected sexual relations or unintentional contamination by blood, even though they are being treated with zidovudine or other antiviral drugs. Nurses can help reduce this risk by providing patient education about the mode of HIV transmission and safer sex practices.

In addition, healthcare providers must be conscientious in their use of standard infection precautions (see [Chapter 43](#)) to protect against the spread of all infections, including HIV. This includes the use of gloves when there is a possibility of contact with body secretions, cover gowns if clothing will be exposed to secretions, and goggles worn at birth when there may be splashing of amniotic fluid. Gloves should be worn when handling the newborn until all maternal blood has been removed by a first bath. Also, no blood sampling or injections should be completed on the neonate

until after a first bath and the removal of maternal blood.

Caring for a woman who is HIV positive during pregnancy and childbirth calls for great sensitivity in order to respect the woman as a patient with a possibly fatal disease while at the same time encouraging her to continue with prenatal care and bond with her newborn. Research into the cause and treatment of this disease is ongoing, and as a result, recommendations constantly change. Because of this, nurses need to remain current on recommendations for therapy or prevention.

### *QSEN Checkpoint Question 42.2*

#### **INFORMATICS**

When Dexter’s mother heard he had another allergic diagnosis, she wanted Dexter worked up for an immune system disorder “because he has colds all of the time.” When reviewing the blood work of a child with allergic rhinitis, what results are most helpful? Select all that apply.

- a. Specific IgE levels to cat, dog, tree, grass, and weed mix
- b. Serum immunoglobulins (IgG, IgA, and IgM)
- c. Complete blood count with differential
- d. Basic metabolic panel

*Look in [Appendix A](#) for the best answer and rationale.*

## **Allergy**

Allergic diseases occur as a result of abnormal antigen–antibody responses. Symptoms can be chronic and minor, such as those that occur with seasonal rhinitis, or acute and severe, as in an anaphylactic reaction. Because they can be constant, they can disrupt a child’s life and development and the life of the family. When the cause of an allergic response is difficult to pinpoint, it is easy for the child and parents to become frustrated. Even when the child has a known allergy, symptoms can vary from minor to acute without warning, ultimately disrupting family functioning ([Box 42.3](#)).

**BOX 42.3**

### **Nursing Care Planning Using Assessment**

#### **ASSESSING A CHILD WITH AN ALLERGIC DISORDER**

*What If . . . 42.1*

**Dexter tells the nurse that his symptoms always increase at school or that school “is making him sick.” He’s being bullied at school and acting out both in school and at home. How could the nurse explain Dexter’s disease process to him in language he can understand?**

**HYPERSENSITIVITY**

The underlying cause of all allergic disorders appears to be an excessive antigen–antibody response when the invading organism is an allergen rather than an immunogen. This is termed a type I response, or a **hypersensitivity response**, when it happens immediately. It can also occur as a type II, III, or IV response (Table 42.2). Types I, II, and III are mediated by antibodies (humoral response), whereas type IV is mediated by the T lymphocytes (cell-mediated response).

**TABLE 42.2 CLASSIFICATIONS OF HYPERSENSITIVITY REACTIONS**

Type	Involved Cell	Mechanism	Effect
I: Immediate	IgE	IgE attached to surface of mast cell triggers release of intracellular	Allergies, asthma, atopic

		granules from mast cells on contact with antigens.	dermatitis, anaphylaxis
II: Cytotoxic	IgG or IgM	Antigen–antibody reaction leading to antigen destruction; complement is activated.	Hemolytic anemia, transfusion reaction, erythroblastosis fetalis
III: Immune complex disease	IgG or IgE	Antigen–antibody complexes precipitate; complement is activated, leading to inflammatory response.	Rheumatoid arthritis, systemic lupus erythematosus
IV: Delayed	T lymphocyte	T cells combine with antigen to induce inflammatory reactions by direct cell involvement or the release of lymphokines.	Contact dermatitis, transplant graft reaction

### Type I: Immediate

With an immediate or type I allergic response, IgE receptor sites attached to the surface of mast cells bind to IgE antibodies responding to the presence of an antigen. Mast cells are specialized cells found lining blood vessels, in the lungs and in connective tissue, the mucous membranes, and the skin. IgE triggers mast cells to release intracellular granules. These contain histamine, leukotrienes, a slow-reacting substance of anaphylaxis (SRS-A), and chemotactic substances (substances to draw leukocytes into the area). Histamine and leukotrienes cause peripheral vasodilation and permeability of blood vessels. This leads to lowered blood pressure and edema. SRS-A causes extreme bronchial constriction. If not treated immediately by an injection of epinephrine to dilate the airway and initiate vessel vasoconstriction, this “anaphylactic reaction” can lead to shock and death. Anaphylactic reactions can be caused by stinging insect bites, exposure to certain drugs, or latex; however, food allergy is the most common cause of anaphylaxis seen in hospital emergency rooms in both children and adults ([Robison & Pongracic, 2012](#)).

### Type II: Cytotoxic Response

In a **cytotoxic response**, cells are detected as foreign and immunoglobulins directly attack and destroy them without harming surrounding tissue. Foreign red blood cells that are introduced to an Rh-negative woman by an Rh-positive fetus are destroyed by this process (see [Chapter 26](#)). Tumor cells may be destroyed by this process. Why this immune response fails when malignant cells begin to proliferate is not understood. Current research is attempting to devise ways to activate this natural immune response

as a method of destroying malignant cells. Care of the child with a malignancy (neoplasm) and immunotherapy is discussed in [Chapter 53](#).

### **Type III: Immune Complex**

A type III response is an IgG- or IgE-mediated antigen–antibody complex reaction that involves complement and initiates the inflammatory response. Complement reactions that persist beyond the usual inhibition may serve as the basis for many autoimmune illnesses and serum sickness.

### **Type IV: Cell-Mediated Hypersensitivity**

In a delayed hypersensitivity response, T lymphocytes react with antigens and release lymphokines to call macrophages into the area. An inflammatory response occurs that helps to destroy the foreign tissue. A Mantoux or purified protein derivative (PPD) tuberculin test is an example of this. Redness and induration of the site do not begin initially but only approximately 12 hours after the injection. The reaction peaks in 24 to 72 hours (a delayed response).

Contact dermatitis is another example of a delayed hypersensitivity response. Certain substances, such as cosmetics, household products, or cured leather, alter the protein of skin cells so that the skin cells become an antigen or the foreign substance combines with the protein (hapten formation) to become an antigenic protein. Lymphocytes and macrophages infiltrate the area and attempt to destroy the offending protein. Redness and vesicles develop, and pruritus may be intense.

## **ASSESSMENT OF ALLERGIES IN CHILDREN**

### **History**

Taking a health history of a child with an allergy can be time-consuming because many factors have to be considered. A family history is important because there seem to be familial tendencies with allergic diseases. Obtaining the exact symptoms of the allergy is important to help identify the allergen: Rhinitis, for example, can be related to an airborne antigen; urticaria (swelling and itching) is often caused by ingested antigens; and contact dermatitis (often a rash) is usually related to something that contacts the skin in that area of the rash. The time of the year the allergy occurs also may give a clue to its cause. If the child’s allergy exists all year, the antigen is likely one that is present all year (e.g., house dust mites or pet dander). If it occurs in the spring, it may be due to a tree pollen; in the early summer, a grass pollen; and if it occurs just in the fall, ragweed is a prime suspect.

Children with allergic rhinitis develop common symptoms such as a horizontal crease across the nose (called a Dennie line) from their habit of constantly wiping away nasal secretions. They also may develop dark patches (“allergic shiners”) under their eyes secondary to back pressure from nasal congestion (see [Box 42.3](#)).

Many symptoms of allergy are vague, described as “colds all winter,” “itching,” or

“runny nose.” Listen carefully: Even though no one symptom is acute, together, such symptoms can interfere with a child’s comfort, school experience, and long-term health. Children are often poor reporters of when they have symptoms. Sometimes, they cannot remember clearly whether they had the same rhinitis and watery eye symptoms last summer as they do this summer. Having the parents and the child keep a chart or diary of when symptoms are worse and better often helps identify a specific allergen. Children with allergic rhinitis, for example, may have more symptoms on a windy day when pollens are being blown around and fewer after a rainstorm when the pollen is washed out of the air. A record that details when symptoms start—on arising, or only after the child reaches school, as another example—also can help identify an allergen.

### **Laboratory Testing**

Clinical laboratory testing is important in the diagnosis and management of allergic disorders. The presence of IgE antibodies detected either in serum or via skin testing are useful biomarkers. It is important to note that although the presence of allergen-specific IgE is necessary to diagnose type I sensitivity, the mere presence of allergen-specific IgE is not sufficient to diagnose type I sensitivity. Lab-based serologic analysis for IgE antibodies such as ImmunoCAP, Immulite, and HYTEC 288 are only useful in the context of a thorough clinical history. Because allergies tend to raise an eosinophil count, most children with allergies have 5% or more eosinophils on a differential white blood cell count and a total eosinophil count of  $\geq 250$  cells/mm<sup>3</sup>. Another cause of an increased eosinophil count, however, is invasion by ova or parasites, which is why a stool specimen for ova and parasites may be collected to rule out these problems as the cause of the increased eosinophil count in the absence of any atopic symptoms.

### **Skin Testing**

Skin testing is done to determine potential triggers for atopic symptoms by detecting the presence of IgE to specific allergens. When an allergen is introduced into the child’s skin and the child is sensitive to that allergen, a wheal (a small, raised bump that looks like a mosquito bite) and flare (erythema that surrounds the wheal) response will appear at the site of the test from the release of histamine by the local mast cells. Because this reaction appears quickly, the test should be read within 15 to 20 minutes. Systemic administration of an antihistamine will suppress the response, so the child must be off of antihistamines for five half-lives of the antihistamine (usually 5 to 7 days before testing). Corticosteroid therapy does not affect immediate skin reactivity and so may be continued during skin testing.

Scratch, prick, or puncture skin testing is done to detect sensitivity to aeroallergens, foods, stinging insects, and some drugs. Skin testing is done by placing a drop of allergen solution on the skin of the upper back or volar aspect of the arm and then scratching/pricking or puncturing through the drop of liquid with a sharp device (needle, lancet, or multihead device). In order to be valid, both a positive (histamine) and

negative (saline) control must be included in the panel tested. The average diameter of the negative control should be less than 3 mm, and the positive control must be at least 3 mm larger than the negative control for the testing to be interpreted.

Skin testing interpretation has limitations. The sensitivity and specificity for aeroallergens are acceptable, but there is a high false-positive rate for skin testing to foods. All skin testing results should be interpreted in terms of clinical history.

Intracutaneous testing to allergens is done when a sensitivity to aeroallergens, some drugs (primarily penicillin), or stinging insects is suspected but not confirmed by prick/puncture/scratch skin tests. Intracutaneous testing is done by injecting a small amount of a solution of allergen below the epidermis of the skin of the forearm or back. The forearm is usually preferred to allow for the application of a tourniquet if a systemic reaction occurs. Solutions used for intracutaneous injections are 100 to 1,000 times more dilute than those used for scratch testing. The extracts are not interchangeable from a group prepared for scratch testing to a group prepared for intracutaneous injections or vice versa. Intracutaneous testing is never done with food allergens because of the potential for the intracutaneous testing to cause an anaphylactic reaction. With all forms of skin testing, if the child is sensitive to the test solution, a wheal and flare will occur at the test site (Fig. 42.4). The size of the reaction is then measured and graded as 1+ to 4+ or as slight, moderate, or marked response in comparison to the wheal and flare response to the positive control.

**Figure 42.4** Allergy skin testing. Note the positive reactions. (© SPL/Custom Medical Stock Photograph.)

Always have a syringe filled with 0.3 ml epinephrine (Adrenalin) 1:1,000 on hand to counteract an unexpected anaphylactic reaction from skin testing (Box 42.4).

Epinephrine is given intramuscularly in doses of 0.01 mg/kg, up to 0.3 mg. Children should be observed in the healthcare setting for at least 30 minutes after skin testing to ensure anaphylaxis management is available in the event of a reaction.

BOX 42.4

## EPINEPHRINE HYDROCHLORIDE (ADRENALIN)

**Classification:** Epinephrine is a sympathomimetic drug.

**Action:** Acts on both  $\alpha$ - and  $\beta$ -receptor sites of sympathetic receptor cells to cause increased blood pressure and heart rate. It also relaxes the smooth muscles of the bronchi. It is used to counteract the symptoms of anaphylaxis (Commins, 2017).

**Pregnancy Risk Category:** C

**Dosage:** 0.01 mg/kg, up to 0.3 mg of a 1:1,000 solution intramuscularly into the vastus lateralis of the thigh every 20 minutes for up to four doses. This may be followed by an individualized intravenous bolus if symptoms still persist.

**Possible Adverse Effects:** Anxiety, restlessness, headache, nausea, arrhythmias, hypertension, palpitations, pallor

### Nursing Implications

- Be sure to calculate the drug dosage and check the solution strength carefully; solution is available in different concentrations, and epinephrine is a very potent drug.
- Obtain blood pressure, pulse, and respirations and auscultate breath sounds before and immediately after administration. Assess the child for signs indicating the resolution of anaphylaxis.
- Rotate injection sites to prevent necrosis at the site.
- Have a rapidly acting  $\alpha$ -adrenergic blocking agent or vasodilator readily available in case of a hypertensive reaction or have a  $\beta$ -adrenergic blocking agent readily available in case of arrhythmias.
- Protect the drug from light and heat. Use only solutions that are clear and colorless.

The allergens chosen for any IgE testing (serum IgE, prick/puncture/scratch skin testing or intracutaneous testing) is always done in context of the clinical history. Determining the seasonality or timing of the symptoms may eliminate or identify potential triggers. Clinical history is especially critical when dealing with suspected food allergies.

## THERAPEUTIC MANAGEMENT

No matter what the symptoms of a child's allergy are, the goals for therapy are to reduce the child's exposure to the allergen and modify the child's response to the allergen with a pharmacologic agent. If symptoms persist, immunotherapy to produce a state of increased clinical **tolerance** or "sustained unresponsiveness" should be considered.

Reducing the child's exposure to the allergen is possible when the offending

allergen is a drug, food, or irritant. Reducing exposure can be much more difficult when the allergic trigger is ubiquitous in the environment.

## Environmental Control

**Environmental control** involves limiting exposure to allergens in a child’s environment. Common measures of environmental control are shown in [Table 42.3](#) and [Box 42.5](#). Some control measures such as dust mite covers on mattresses and pillows are inexpensive and very effective. Others measures, such as replacing carpeting with hardwood in the bedroom or removing the family pet from the house are expensive or just not feasible for every family. Help parents understand that goal of environmental controls measures are to decrease exposure to allergic triggers and reduce their child’s symptoms and decrease the need for medications or immunotherapy ([Krouse, 2014](#)).

**TABLE 42.3 COMMON MEASURES FOR ENVIRONMENTAL CONTROL OF ALLERGENS**

Area of Concern	Measures	Rationale
Child’s bedroom	Encase mattress and pillow in allergy encasements that are impervious to house mites.	Reduces dust and dust mites
	Cover the zipper of plastic pillow and mattress case with adhesive tape.	Keeps dust confined
	Use blankets or quilts made of or stuffed with smooth, synthetic material; avoid wool.	Minimizes dust; wool is a good dust collector or may be an allergen itself.
	Wash bed linens including mattress pads, sheets, blankets, and comforters in hot water every 2 weeks. Dry thoroughly in a hot dryer.	The heat from the hot water and hot dryer kills dust mites.
	Take down any ornamental items, such as a bed canopy.	Prevents dust collection
	Remove stuffed chairs and replace with wooden ones.	Removes dust collectors
	Remove venetian blinds and curtains that need to be dry cleaned; replace with easily laundered types.	Removes dust collectors
	Remove stuffed toys unless filled with synthetic material.	Removes dust collectors and possible sources of

	Remove aquariums and plants.	allergens Removes mold spores
	Clean closet, so it contains only currently used items.	Eliminates dust collectors
	Remove any fur or woolen items from the child's wardrobe.	Removes possible allergens
Living or television room	Remove all carpets. If a rug is necessary, vacuum at least weekly; replace an animal hair pad with a foam rubber one.	Avoids containers for dust collection
	Provide a wooden chair, not a stuffed one, for sitting.	Provides space free from allergens
	Vacuum floor surfaces frequently.	Minimizes dust collection
	Use a piece of linoleum or plastic laminate surface on top of carpet if the child sits on the floor.	Provides space free from allergens
Bathroom	Use nonscented toilet paper, soaps, and cleaners.	Minimizes exposure to potential irritants
School room	Have child sit away from blackboard, caged animals, or fish tanks.	Minimizes exposure to chalk, mold spores, and animal dander, which are allergens
	Keep locker free of collectibles.	Reduces dust collection
General	Purchase a dehumidifier; add compounds to paint to decrease mold spores.	Reduces mold spores
	Use high-efficiency particulate air (HEPA) filters on furnaces and vacuums.	Filters air of possible allergens
	Keep a favorite pet but do not purchase a new pet.	Reduces exposure to animal dander
	Dust daily with a moist cloth.	Controls dust better than dry dusting

### BOX 42.5

#### Nursing Care Planning Tips for Effective Communication

The Goodenough family has been instructed on environmental control measures because Dexter has severe allergic rhinitis. Despite this, Dexter's symptoms have not improved. You meet with his parents to confirm they are carrying out recommended measures.

*Tip:* Be careful not to make assumptions by taking patient or caregiver responses to questions at face value. Ask follow-up questions and review patient education when needed.

**Nurse:** Have you been able to make any of the needed changes around your house to reduce dust?

**Mrs. Goodenough:** As many as we can.

**Nurse:** What about Dexter's bedroom? Do you have the mattress covered? Any frilly curtains taken down? His stuffed animals taken out?

**Mrs. Goodenough:** I've done everything I can.

**Nurse:** Let's discuss what changes you've been able to make.

**Mrs. Goodenough:** I covered the mattress. I had to leave the curtains up, though, because they match the rug. I took out a lot of the toys but had to leave the stuffed bears because they were gifts from his grandmother.

**Nurse:** Getting the mattress covered is a good start. Our goal is to decrease Dexter's exposure as much as possible to improve his symptoms. Let's discuss any other possible measures we could take.

### *Concept Mastery Alert*

Environmental control of allergens works to remove as many allergens and reservoirs for allergens as possible from the child's environment. For items that cannot be removed, it is best to encase them in a hypoallergenic covering.

## **Pharmacologic Therapy**

A number of pharmacologic preparations can be used to reduce the symptoms of childhood allergies. Intranasal steroids can be used prophylactically to prevent inflammation (de Souza Campos Fernandes, Ribeiro de Andrade, & da Cunha Ibiapina, 2014). Second- and third-generation antihistamines, such as cetirizine (Zyrtec) and loratadine (Claritin), cause little drowsiness yet effectively block histamine release and, as a result, control itching, sneezing, and rhinorrhea (Nayak, Berger, LaForce, et al., 2017). Decongestants, such as pseudoephedrine (Sudafed), decrease nasal edema and can help enlarge breathing space and so may also be recommended.

## **Immunotherapy**

Immunotherapy, or **hyposensitization**, is done when the child's allergy symptoms cannot be controlled by avoidance of an allergen or conventional drug therapy. It can be accomplished by subcutaneous immunotherapy (SCIT) or by tablets that are given sublingually.

Immunotherapy works by increasing the plasma concentration of IgG antibodies, which then act to prevent or block IgE antibodies from coming in contact with an

allergen. For the injection method, after specific environmental allergens have been determined with skin testing, small amounts of allergy extracts, which are dilute enough to be clinically subreactive, are injected subcutaneously at weekly intervals. The dose of antigen is increased in strength each time until the peak concentration, called “maintenance,” is reached. Following immunotherapy, the child’s allergy symptoms should be greatly reduced. Unfortunately, the child then needs periodic injections every 3 to 4 weeks to maintain maintenance to the allergen. This approach is not currently approved by the U.S. Food and Drug Administration (FDA) for treatment of food allergy because of the real threat of significant anaphylaxis.

Sublingual immunotherapy (SLIT) administration of chosen allergen solutions is growing in use because it has the advantage of being painless, can be self- or parent-administered, and produces results equal to that of other therapies. The liquid form of SLIT is widely used in Europe, but, currently, the only FDA-approved SLIT are tablets directed at two types of grass and short ragweed.

If children are going to have an anaphylactic reaction to an injected or sublingual allergen, it generally occurs within 30 to 60 minutes after the injection. Therefore, children must be observed for a minimum of 30 minutes after an allergy shot. Caution parents to observe their child for anaphylaxis after sublingual administration.

Immunotherapy is generally continued for 3 to 5 years because the longer it is used, the longer the period of relief from symptoms occurs after it is stopped. Be certain parents know from the beginning of treatment that this therapy will not “cure” their child. However, it can reduce allergy symptoms for a length of time. It may also prevent a mild atopic disorder such as allergic rhinitis from turning into a severe atopic disorder such as asthma (Tsabouri, Mavroudi, Feketea, et al., 2017) (see Chapter 40). Be certain children have adequate education and preparation if injection procedures are used. Help them understand the importance of returning for additional injections and remaining under observation after the administration of immunotherapy.

### ***QSEN Checkpoint Question 42.3***

#### **PATIENT-CENTERED CARE**

Dexter’s mother asks the nurse about the potential risks and benefits of immunotherapy, stating that some websites she has consulted convey dire warnings against the practice. What potential benefit could the nurse describe to Dexter’s mother to alleviate her anxiety?

- a. Dexter will recover more quickly from infections.
- b. Dexter will be protected against secondary infections.
- c. Dexter’s level of helpful immunoglobulins will be increased.
- d. The overall health of Dexter’s immune system will be increased.

*Look in Appendix A for the best answer and rationale.*

# Common Allergic Reactions

## ANAPHYLACTIC SHOCK

Anaphylactic shock is an immediate, life-threatening, type I hypersensitivity reaction that occurs after exposure to an allergen in a previously sensitized child. **Anaphylaxis** can be caused by exposure to foods such as milk, egg, peanut, and tree nuts; stinging insects including yellow jackets, honeybees, paper wasps, hornets, and fire ants; certain drugs, primarily antibiotics, nonsteroidal anti-inflammatory drugs (NSAIDs), and neuromuscular blocking agents; and latex. Anaphylactic shock must be recognized and treated immediately because it can be fatal (Simons, Arduoso, Bilò, et al., 2014).

### Assessment of Anaphylaxis

Symptoms of anaphylaxis may include:

- Breathing: wheezing, shortness of breath, throat tightness, cough, hoarse voice, chest pain/tightness, trouble swallowing, itchy mouth/throat, nasal stuffiness/congestion
- Circulation: pale/blue color, low pulse, dizziness, light-headedness/passing out, low blood pressure, shock, loss of consciousness
- Skin: hives, swelling, itch, warmth, redness, rash
- Stomach: nausea, pain/cramps, vomiting, diarrhea
- Other: anxiety, feeling of impending doom, itchy/red/watery eyes, headache, cramping of the uterus

### Therapeutic Management of Anaphylaxis

Preventing and recognizing anaphylaxis are as important as knowing how to respond when it occurs. Exposure to certain food, stinging insects, medications, and latex are the most common triggers of anaphylaxis. Avoiding offending foods is extremely difficult because of the presence of unexpected food proteins in prepared foods and significant issues with cross-contamination during food preparation and packaging. Avoiding stinging insects is easier given the seasonality of insect exposure, but insect stings are unpredictable. Exposure to offending drugs and latex is manageable if a thorough history has been obtained.

Epinephrine, injected intramuscularly, is the standard of care for the treatment of anaphylaxis regardless of the cause (Muraro, Lemanske, Castells, et al., 2017).

Epinephrine is the only treatment for anaphylaxis that reduces the risk of prolonged hospitalization and death. For maximum effectiveness, if anaphylaxis follows an injection or an insect sting, inject the epinephrine into the vastus lateralis muscle of the thigh or the unaffected arm. Additional emergency interventions to take in a healthcare setting are summarized in [Box 42.6](#).

#### BOX 42.6

## Emergency Measures for Anaphylactic Shock

Anaphylaxis is a true emergency, so fast interventions are necessary.

- Administer aqueous epinephrine (Adrenalin) 1:1,000 intramuscularly at a dosage of 0.01 mg/kg of body weight up to 0.3 mg. This relieves laryngeal edema and severe bronchospasm by widening the airway.
- Initiate 911 emergency or notify the cardiac arrest team because both respiratory and cardiac arrest may occur.
- If hypoxia is present, administer oxygen by mask or nasal cannula.
- Anticipate the need for an intravenous (IV) fluid line as a route for a vasopressor such as dopamine and fluid to help restore blood pressure.
- If an insect sting was the cause of the condition, a tourniquet, applied above the site of the bite, may be prescribed to limit absorption of the insect venom into the bloodstream.
- Anticipate use of a nebulized bronchodilator such as albuterol to halt wheezing or diphenhydramine (Benadryl) intramuscularly or IV if urticaria (itching and swelling) is present.
- If the child is experiencing seizures, turn the child onto his or her side and prepare to administer an antiseizure medication such as phenobarbital or diazepam.
- A corticosteroid may be administered as a second-line drug. This does not act immediately but does reduce inflammation. IV methylprednisolone is a typical drug given.
- Keep the child and family members calm; anxiety adds to bronchospasm and decreases breathing ability.

Administering antihistamines, steroids, and/or albuterol to treat the symptoms of anaphylaxis does nothing to address the immediate cause of the symptoms, thus allowing the anaphylactic event to progress. The vasoconstrictor effects of epinephrine prevent/relieve airway edema, hypotension, and shock and the beta-agonist effects increase the effectiveness of cardiac contractions and lead to bronchodilation ([Simons, Ebisawa, Sanchez-Borges, et al., 2015](#)).

Every child with a history of anaphylaxis needs a written anaphylaxis treatment plan such as the one in [Figure 42.5](#). When a sensitized child reacts, parents, teachers, coaches, day-care providers, and family members all must know the proper procedure to follow for anaphylactic shock so they can give the child immediate help. All children with a history of anaphylaxis need to carry an epinephrine auto-injector ([Box 42.7](#)). Anyone who has responsibility for a child with history of anaphylaxis needs to know how to recognize the symptoms of anaphylaxis and how to administer epinephrine using the auto-injector device. Responsible adults and children need practice using the epinephrine auto-injector correctly. There are reports of people using the auto-injectors incorrectly and accidentally puncturing their thumb, thus creating circulation problems in their own hand ([Sheikh, Simons, Barbour, et al., 2012](#)).

## Anaphylaxis Emergency Action Plan

Patient Name: \_\_\_\_\_ Age: \_\_\_\_\_

Allergies: \_\_\_\_\_

Asthma  Yes (*high risk for severe reaction*)  No

Additional health problems besides anaphylaxis: \_\_\_\_\_

Concurrent medications: \_\_\_\_\_

	Symptoms of Anaphylaxis
MOUTH	itching, swelling of lips and/or tongue

### BOX 42.7

## Nursing Care Planning Based on Family Teaching

### **GUIDELINES FOR USING AN EPINEPHRINE AUTO-INJECTOR**

**Q.** Dexter's father says to you, "If my child is stung by a bee, I'm supposed to inject epinephrine. How do I do that?"

**A.** It is important you think about this in advance because from the moment your

child is stung, it will be an emergency situation.

- Obtain a prescription for an epinephrine auto-injector, which is a preloaded syringe with a designated dose of epinephrine for use in emergencies.
- Epinephrine auto-injectors need to be available at home and at your child's school/day care. You or your child needs to carry an epinephrine auto-injector with you at all times.
- Store epinephrine auto-injectors at room temperature; don't refrigerate or allow epinephrine to be exposed to heat.
- Inspect the color of the epinephrine solution and replace it if it is cloudy or discolored.
- If your child exhibits symptoms of a severe allergic reaction, see your anaphylaxis plan for a description of symptoms that constitute a severe allergic reaction. Administer the epinephrine by removing the safety cap, grasping the auto-injector by the barrel (avoid placing your thumb over the end), and, using firm pressure, applying the auto-injector to the outer aspect of the thigh until the auto-injector "clicks."
- If necessary, the device can inject through clothing. The needle is long enough to pass through clothing and into your child's skin.
- Be careful before injecting that you are holding the auto-injector by the barrel with the needle toward your child. If not, you will accidentally inject your own thumb (a serious circumstance because the dose of epinephrine could seriously injure your thumb).
- Keep in mind that not all the solution in the auto-injector will be ejected. Do not try to give the remainder of the solution.
- Call 911 for transportation assistance or transport your child to an emergency facility for further care.

Once epinephrine has been administered, the emergency response system (911) must be activated. An anaphylactic event can be stopped with a single dose of epinephrine, but in some cases, the epinephrine only stops the reaction temporarily, and once the dose of epinephrine has been metabolized, the reaction come roaring back. In addition, some anaphylactic reactions are biphasic and involve a second wave of symptoms several hours later. Children who have had an anaphylactic reaction need to be observed for a minimum of 4 hours to ensure that a reaction has subsided. An evaluation of the child after an anaphylactic reaction involves not only a physical examination but also an evaluation of the exposure and the implementation of the anaphylaxis treatment plan to determine appropriate avoidance measures as well as potential improvements in the response to anaphylaxis.

#### *QSEN Checkpoint Question 42.4*

### **TEAMWORK & COLLABORATION**

Any child can have an anaphylactic reaction to a food, drug, or insect sting, and Dexter is at risk because of his allergy history. If Dexter, who weighs 48 kg, had an anaphylactic reaction after a bee sting, what is the correct dose of epinephrine for a school nurse or staff member to give him?

- a. 0.03 mg
- b. 0.15 mg
- c. 0.3 mg
- d. 3.0 mg

---

Look in [Appendix A](#) for the best answer and rationale.

---

## URTICARIA AND ANGIOEDEMA

*Urticaria*, or hives, refers to macular wheals surrounded by erythema arising from the chorion layer of skin; they are intensely pruritic (often described as having a burning sensation). Hives may occur so closely together that they tend to coalesce (blend together); dilatation of capillaries and venules with increased permeability occurs around the lesions. The cause of urticaria is a type I or immediate hypersensitivity reaction created by the release of histamine from an antibody–antigen reaction, similar to but of lesser intensity than anaphylaxis. In chronic urticaria, it is possible that no causative allergen can be found.

*Angioedema* is edema of the skin and subcutaneous tissue. This occurs most frequently on the eyelids, hands, feet, genitalia, and lips—areas where skin is loosely bound by subcutaneous tissue. Angioedema can be distinguished from other edemas because it is not dependent, is generally asymmetrically distributed, and usually occurs in conjunction with urticaria. With severe angioedema, the larynx may be involved. This is a serious problem because laryngeal edema could be so extreme that it leads to airway obstruction and, subsequently, asphyxiation and death.

The allergens that most frequently cause urticaria and angioedema include drugs, foods, and insect stings. In some children, exposure to hot or cold can also cause these reactions. All children need the causative agent be identified so it can be avoided. Although a rare event, children who have a reaction to hot or cold especially must be identified because, if they swim in cold water, the sudden release of histamine could cause dizziness so severe that they could drown. Immediate therapy for urticaria or angioedema is an intramuscular epinephrine injection or the administration of an oral antihistamine. For long-term therapy, corticosteroids may be prescribed; cyclosporine (an immunosuppressant) and omalizumab (Xolair), a monoclonal antibody, are usually reserved for older adolescents or adults (Kaplan, 2012).

## Atopic Disorders

Individuals with atopic disease are prone to all types of allergic responses. Three disorders occur most frequently: allergic rhinitis, eczema (**atopic dermatitis**), and

asthma (discussed with other respiratory diseases in [Chapter 40](#)). The gene responsible for an immune response is located near the human leukocyte antigen that is responsible for graft rejections. In certain children, a tendency for sensitivity to antigens or abnormality of this gene is apparently inherited. These children have a higher-than-normal production of IgE antibodies, which makes them more responsive to allergens than other people. There are familial tendencies with these diseases, but not all family members manifest the symptoms in the same way. In one family, for example, the father may have allergic rhinitis, one child may have asthma, and another may have atopic dermatitis.

## ALLERGIC RHINITIS

Allergic rhinitis is associated with an IgE-mediated inflammatory response to allergen exposure. It is a risk factor for the development of asthma. Rhinitis can have a major impact on quality of life, including sleep impairment and decreased work and school performance. It is also one of the most common chronic conditions affecting people in the United States with estimates of 35 to 50 million people affected; incidences are increasing, especially among the pediatric population ([Muraro, Lemanske, Hellings, et al., 2016](#)).

### Assessment

Common symptoms of allergic rhinitis include congestion, sneezing, nasal engorgement, and profuse watery nasal discharge. The mucous membrane of the nose is generally paler than normal. It may be edematous, adding to nasal congestion. The eyes tend to water. The conjunctivae may be pruritic, often with a distinctive pebbly appearance, called cobblestoning. Children constantly rub their noses in an upward motion, termed an “allergic salute.” Over a long period, rubbing the nose this way leads to a horizontal crease across the tip of the nose, called an allergic crease or Dennie line. Because of congestion in the nose, there tends to be back pressure to the blood circulation around the eye orbit, which leads to blackened areas under the eyes, termed “allergic shiners” ([Fig. 42.6](#)).

**Figure 42.6** Back pressure to the blood circulation around the eye orbit from allergic rhinitis may lead to dark areas under the eyes (allergic shiners). The frequent rubbing of the nose in an upward direction can lead to a peculiar horizontal crease (Dennie line).

Children older than 6 years of age (when frontal sinuses develop) may report full frontal headaches that become even more marked with adolescence. Some children have many symptoms—they feel exhausted and lethargic and do not function well in school. Recurrent otitis media may occur because of swollen pharyngeal tissue causing eustachian tube blockage. A smear of the nasal discharge will reveal an increased eosinophil count (more than 10% of the white cell count). Children with allergic rhinitis are also prone to allergic conjunctivitis.

The triggers that usually cause allergic rhinitis are pollens, molds, or irritants rather than foods or drugs. Many children are brought to a healthcare setting during peak pollen months because parents think they have a constant “summer cold.” However, with an upper respiratory infection, the mucous membrane of the nose is more apt to be reddened than pale and the secretions draining from the nose are apt to be thick white or yellow rather than the thin, watery secretions of allergic rhinitis. With an upper respiratory infection, a sore throat and cervical adenopathy may also be present, whereas these rarely accompany allergic rhinitis.

### **Therapeutic Management**

Allergic rhinitis is managed by a three-pronged program: avoidance of offending allergens, use of pharmacologic agents (antihistamines, leukotriene inhibitors, or corticosteroids), and/or immunotherapy. It may be impossible for some children to avoid all the allergens that cause symptoms because the child has sensitivity to so many

allergens. If children always show symptoms at one particular time of the year, parents may be able to carry out environmental control for that period of the year to limit symptoms.

Parents usually ask how sick children should be before they need to see an allergist about skin testing and definitive treatment. As a rule, if the child's symptoms are increasing in intensity, if there is associated lower respiratory tract involvement, or if the condition interferes with activities in which the child wants to participate, the child needs testing and treatment. Those children with minor symptoms can be managed by environmental control and medications such as antihistamines and/or intranasal steroids to reduce symptoms.

It is helpful if children and parents choose an antihistamine that causes the least amount of drowsiness so the medication does not interfere with schoolwork or, if an adolescent, with safe driving. Review with parents that if nasal antihistamine sprays are given for more than 3 days, a rebound effect can occur (the nasal mucosa becomes more edematous rather than less edematous) and symptoms will appear to worsen rather than improve.

Allergic rhinitis is often considered a minor illness by parents, something children will outgrow. However, although the condition exists, it may not be a minor illness for the child if it keeps the child from interacting with peers because going outside intensifies symptoms. [Box 42.8](#) shows an interprofessional care map illustrating both nursing and team planning for a child with allergic rhinitis.

## BOX 42.8

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR A CHILD WITH ALLERGIC RHINITIS

Dexter Goodenough is a 6-year-old boy you meet in an ambulatory setting. His mother has just been told he has allergic rhinitis (hay fever). “Thank heavens,” his mother exclaims. “I thought when I heard he had an immune system disease he had AIDS. What a relief it’s only an allergy.”

**Family Assessment:** Child lives with his mother and stepfather in a beachfront cottage. Also in the family is a brother, 8 years old; a stepbrother, 16 years old; and a paternal grandmother. His stepfather owns a jewelry store. His mother is a stay-at-home mom. Finances are rated as “not a problem.”

**Patient Assessment:** Child has documented peanut allergy. Child’s eyes are reddened and watery; nose drains a clear discharge. His mother tells you he frequently has a headache and is constantly listless. Other children at school have started to bully him because of his appearance. His grades are “terrible” because the minute he gets to school, his symptoms begin. Dexter is prescribed an antihistamine and environmental control.

**Nursing Diagnosis:** Situational low self-esteem related to feelings of inadequacy and embarrassment

**Outcome Criteria:** Patient states he is able to function in school despite allergy symptoms and discomfort; is taking active measures to avoid allergens; will report bullying to school official.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess if Dexter has an epinephrine auto-injector to manage his peanut allergy at home, at school, and during day-care or after-school events.	Obtain a prescription for epinephrine auto-injectors and ensure that the family has the resources to obtain the devices. Demonstrate the proper use of the auto-injector and provide the family and school with a written anaphylaxis management plan.	Epinephrine is necessary to maintain a safe environment for food-allergic children.	Dexter has access to epinephrine at home, at school, and during his home activities. The adult responsible for Dexter's safety throughout the day will be notified when an epinephrine auto-injector is used in the case of an allergic reaction.
Nurse	Assess what Dexter's classroom is like to identify potential allergens because child's symptoms are most intense when he is at school.	Discuss potential source of allergens with mother; ask her to meet with teacher to see if modifications could be made.	Environmental control can reduce the number of allergens that cause symptoms.	Mother will be notified of classroom allergens and necessary actions suggested such as removing Dexter's allergen from the classroom.
<i>Teamwork and Collaboration</i>				
Nurse/primary healthcare	Assess if child's symptoms could	Arrange a consultation with	Hyposensitization can greatly	Parent and

provider	be reduced with hyposensitization.	allergist about the possibility of hyposensitization.	reduce allergy symptoms if specific allergens can be identified.	allergist discuss the possibility of sublingual hyposensitization if antihistamine is not effective.
----------	------------------------------------	---	--	--

*Procedures/Medications for Quality Improvement*

Nurse	Assess if child has had experience with taking medicine.	Help mother set up a medicine chart that will help with antihistamine adherence.	Allergy medicine is most effective when it is taken conscientiously.	Parent should be conscientious about antihistamine administration.
-------	--	--	--	--

*Nutrition*

Nurse/nutritionist	Ask the child how he manages the peanut allergy.	Review with the mother how to read labels to detect the presence of peanut in foods. Review potential hidden sources of peanut allergen in baked goods, restaurant, and prepared foods.	Most food reactions are the result of accidental exposure to offending allergens.	Mother should describe how to read a food label for the presence of peanut allergen as ways to avoid accidental exposure to peanut in foods.
--------------------	--	---	---	--

*Patient-Centered Care*

Nurse	Assess environmental aspects at home that could be causing the child's symptoms.	Discuss environmental control with parents.	Reducing allergens in the home can also aid in reducing the child's symptoms.	Parents should consider any modifications necessary at home.
Nurse	Assess if the child is exposed to secondary smoke in the home.	Educate family on the damage that secondary smoke can cause.	Secondary smoke is a potent allergen that also contributes to asthma symptoms.	Parents should consider ways to reduce exposure to secondary smoke in the home.

	home.		lung and heart disease.

**QSEN Checkpoint Question 42.5**

**QUALITY IMPROVEMENT**

Dexter is prone to allergies. When planning his care, what desired outcome should the nurse prioritize?

- a. Dexter states that his symptoms do not interfere with being able to play with his friends.
- b. Dexter is able to describe the cause of his allergic response.
- c. Dexter states that he no longer has allergies.
- d. Dexter states he enjoys taking medicine to prevent his allergy symptoms.

Look in *Appendix A* for the best answer and rationale.

**PERENNIAL ALLERGIC RHINITIS**

Allergic rhinitis becomes perennial (year round) when the allergen is one that is present in the environment year round, such as house dust mites or pet hair. Although the child's symptoms may not result in the obvious distress associated with seasonal allergic rhinitis, the child needs treatment just as much because the symptoms otherwise may never go away. In addition, serous otitis media can accompany the disorder as a

long-term consequence (see [Chapter 50](#)). Because the agent that causes perennial allergic rhinitis is often something in the house, environmental control as well as SLIT can play a big role in the control of the allergic symptoms ([Papadopoulos, Bernstein, Demoly, et al., 2015](#)).

## **ATOPIC DERMATITIS (INFANTILE ECZEMA)**

Atopic dermatitis is a highly pruritic, chronic inflammatory skin disease that is often the first manifestation of allergic disease. Many children with atopic dermatitis will go on to develop allergic rhinitis and asthma. Food allergy is a major trigger of atopic dermatitis in infants. Any infant who presents with atopic dermatitis needs to have a thorough food allergy evaluation. Atopic dermatitis can have a significant impact on quality of life for children and their families. This disorder involves intense pruritus and associated scratching that disturbs sleep. Sweating, heat, tight clothing, and contact irritants such as soap tend to increase the pruritus associated with eczema. Symptoms may be more annoying in the winter when the skin dries out and heavier clothing is worn. Other children have eczema triggered by sweating and find the humid, summer months more difficult ([Muraro et al., 2016](#)).

### **Assessment**

Atopic dermatitis is a complex inflammatory process that involves an epidermal barrier defect. Children develop papular and vesicular skin eruptions with surrounding erythema. The vesicles rupture and exude yellow, sticky secretions that form crusts on the skin as they dry. Because the lesions are extremely pruritic, the child scratches and further irritates the lesions, causing linear excoriations. Secondary infections of open lesions may then occur. As the infected lesions heal, the skin becomes depigmented and lichenified (shiny), and dry, flaky scales form. If a secondary infection occurs, the infant may have a low-grade fever and pus-filled lesions, and local lymph nodes may be enlarged.

The common sites for lesions change as the child grows and develops dexterity. Infants usually present with rash on the face, neck, and extensor surfaces ([Fig. 42.7](#)). Infants with atopic dermatitis will rub their face, arms, and legs to relieve the intense itching. As children develop dexterity, they focus on flexural folds of the extremities and neck. Because the lesions feel so uncomfortable, children with infantile atopic dermatitis become fussy and irritable. They may not eat well because of this generalized discomfort. The combination of poor sleep patterns, poor intake, and an increase need of energy to repair damaged skin can result in a decrease in nutritional status.

**Figure 42.7** An infant with atopic dermatitis. (From Goodheart, H. P. [2003]. *Goodheart's photoguide of common skin disorders* [2nd ed.]. Philadelphia, PA: Lippincott Williams & Wilkins.)

Although infantile atopic dermatitis is generally diagnosed based on a family history (by considering other allergic individuals in the family) and noticing the characteristic lesions and their patterns, it is sometimes difficult to distinguish from seborrheic dermatitis (cradle cap; see [Chapter 29](#)). The findings in seborrheic dermatitis and infantile atopic dermatitis are contrasted in [Table 42.4](#). A child with seborrheic dermatitis needs little therapy than soaking the scales in mineral oil and then lifting them away; infants with infantile atopic dermatitis must be referred for long-term therapy.

**TABLE 42.4 COMPARISON OF SEBORRHEIC DERMATITIS AND ATOPIC DERMATITIS**

Finding	Seborrheic Dermatitis	Atopic Dermatitis
Age at onset	0–6 months	2–6 months
Length of disease	Rarely 1 year	2–3 years
Mood of child	Happy; parents happy	Irritable; parents tired
Location of lesions	Scalp, behind ears, near umbilicus	Cheeks, extensor surfaces, some flexor surfaces
Types of lesions	Salmon-colored erythematous lesions with greasy scales	Papulovesicular erythematous lesions with weeping and

		crusting
Itching	No	Severe
Depigmentation	No	Yes
Lichenification	No	Yes
White dermographism	No	Yes
Eosinophilia	No nasal mucus or blood eosinophilia	Nasal mucus or blood eosinophilia
IgE serum levels	Low	High

## Therapeutic Management

The treatment of atopic dermatitis is aimed at reducing the amount of allergen exposure, if such allergens can be identified. The most likely foods to which infants are allergic are milk, eggs, and peanuts. The use of elimination diets to identify food allergens is discussed later in this chapter. A second major consideration in treatment is aimed at reducing pruritus so children do not irritate lesions and cause secondary infections by scratching. Microbial colonization and superinfection increase pruritus contributing to the scratch-itch-scratch cycle and can justify additional antimicrobial treatment. Hydrating the skin by bathing or applying wet dressings (moistened with tap water or Burow's solution) for 15 to 20 minutes, followed by the application of a barrier to seal in the moisture is helpful. In children who develop frequent secondary infections, weekly use of dilute bleach baths can be very effective ([Schneider, Tilles, Lio, et al., 2013](#)).

Regardless of the mode of hydration, the skin should still be wet or moist when applying lubricants. While infants are having wet dressings applied, be conscientious that they don't become chilled, especially if a large portion of the body is to be covered with the dressings. Use a stockinette dressing with holes cut out for the eyes, nose, and mouth pulled over the head to hold wet dressings in place so you don't have to use any form of tape. To prevent corneal irritation, be careful that dressings don't come in contact with the eyes. Antihistamine can be useful to reduce itching. Low potency steroids can be used for maintenance with intermittent and high-dose topical steroids for exacerbations. Intermittent and high-dose topical steroids should not be applied to face, eyelids, or genitalia, and they need to be used sparingly in young infants. Although absorption with topical application is limited, some absorption does occur with the intermittent and high-dose topical steroids and can suppress adrenal gland functioning. Topical calcineurin inhibitors tacrolimus and pimecrolimus are also useful in atopic dermatitis management. Relapsing atopic dermatitis and severe refractory cases of atopic dermatitis may require long-term, anti-inflammatory therapy with intermittent use of systemic anti-inflammatory or immunosuppressive treatment ([Wollenberg, Oranje, Deleuran, et al., 2016](#)).

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for impaired parenting related to feelings of inadequacy secondary to infant's chronic atopic dermatitis

**Outcome Evaluation:** Parents express confidence in their ability to follow recommended therapy; express positive aspects of infant; hold and interact with infant warmly.

Parents of children with infantile atopic dermatitis need a great deal of support through the course of the disease because infants can become extremely irritable from the constant pruritus. No matter how hard parents try, they do not seem to be able to make their child happy. Parents need a listening ear so they can vent these concerns and maintain their self-esteem as parents. Attending support groups with other parents also can help meet this need.

**Nursing Diagnosis:** Impaired skin integrity related to infantile atopic dermatitis

**Outcome Evaluation:** Infant does not scratch lesions; parents state infant is less irritable and easier to care for; lesions show signs of healing.

Skin hydration with liberal use of moisturizers is essential to prevent excessive skin dryness. Be certain that parents know that the infant should soak in the bath for approximately 15 to 30 minutes and then be patted dry, not rubbed, so lesions are not aggravated. The moisture must immediately be applied to seal in the moisture to help prevent dryness and avoid evaporation which contributes to pruritus. Caution them not to use soap for bathing because it can be drying.

Suggest that parents trim the infant's fingernails short or cover the hands with cotton socks to prevent scratching. Let them know that exposure to the herpes virus can cause a generalized reaction. This means that they should screen babysitters and/or alert childcare personnel with active herpes lesions not to care for the infant while atopic dermatitis is active.

In most infants, the lesions of infantile atopic dermatitis clear by the time they are 3 years old. Unless secondary infection with scarring has occurred, the skin surface will not be marked. Many of these children go on to develop other allergies, however. In the preschool years, parents may report that the child has "one cold after another" (allergic rhinitis). By early school years, the child may show signs of asthma.

### ATOPIC DERMATITIS IN THE OLDER CHILD

Atopic dermatitis that occurs at later ages is prominent on the flexor surface of the extremities and on the dorsal surfaces of the wrists and ankles. It often occurs in the

eyebrows; if the child scratches the lesions, hair loss and scant eyebrows can result. Depigmentation or hyperpigmentation is usually noticed as lesions fade; lichenification can be marked. Often, the child's fingernails have a glossy sheen caused by the buffing action of constant rubbing and scratching. In some children, an "itch-scratch cycle" occurs as a response to stress and leads to an exacerbation of symptoms. For example, children, who feel pressured in school to achieve or who are upset because their parents are about to be divorced, rub their skin, a nervous, comforting mannerism; the rubbing or scratching leads to irritation of lesions. The lesions itch intensely, and the child scratches even more vigorously because of the increased discomfort. The accelerated scratching leads to an increased number of lesions, the increased number of lesions leads to more scratching, and so on.

### Therapeutic Management

Atopic dermatitis is a difficult disease for older children because they realize the scratching leads to depigmentation or lichenification, but they are unable to stop scratching because the itching is so intense. Adolescents, especially, are acutely aware of their appearance, so this can be an especially difficult illness for them. Suggest that adolescents use only a prescription soap (or none at all) to prevent skin drying. Swimming in chlorinated pools may also help for those who experience chronic secondary infections. When children swim in chlorinated pools, encourage them to shower well afterward to remove chlorine from the skin as well as to apply a skin emollient and moisturizer after the shower. After a period of activity in which sweating occurs, such as gymnastics, suggest the child take a shower to remove perspiration so this doesn't irritate the skin. Avoiding tight clothing at the flexor portions of the extremities is also important.

Medical treatment for older children is basically the same as for the infant with atopic dermatitis: keeping the skin hydrated and identifying allergens and any psychological problems that are initiating an itch-scratch cycle. The application of hydrocortisones or phototherapy with ultraviolet light both can make a big difference in helping lesions improve.

An evaluation for the older child with atopic dermatitis should include an assessment of not only how well the lesions are healing but also how well the child is adjusting to school and family in light of having this irritating disorder.

#### *What If . . . 42.2*

**When Dexter had atopic dermatitis (infantile eczema) as an infant, almost his entire face was covered with weeping, crusting lesions and his forehead was lined with scratch marks. His mother was exhausted because Dexter never slept because of the constant itching. What suggestions could the nurse have made to Dexter's mother for making him more comfortable? What could the nurse suggest his mother do for herself?**

---

## Drug and Food Allergies

### DRUG ALLERGIES

One of the hazards of giving any medication is the risk that a child may experience a reaction to it or exhibit allergic symptoms (Muraro et al., 2017). Because reactions to drugs differ, it is important to be familiar with the differences between an allergic reaction, a toxic reaction, or a known side effect to a drug.

A *toxic reaction* is one that occurs when a child has received too much of a drug. *Side effects* of drugs are those that are known to occur in addition to a therapeutic effect. When an *allergic effect* occurs, a range of unpredictable symptoms occurs. With the exception of antibiotics, acetylsalicylic acid (aspirin), and NSAIDs, allergies rarely occur to orally administered drugs. Children with atopic diseases appear to be most prone to allergic drug reactions, although anyone can have such a reaction.

A drug itself may not be an allergen, but when the drug combines with body protein, it becomes an allergen, which is why allergic responses occur not with the initial administration of a drug but only after the protein interaction (hapten formation or sensitivity) has occurred.

Skin manifestations seen frequently include urticaria, angioedema, allergic contact dermatitis, flushing, pruritus, and/or purpura. Respiratory symptoms include wheezing or rhinitis. Thrombocytopenia and hemolytic anemia may develop. Anaphylactic shock may occur. Children with a known drug allergy should wear a medical identification bracelet stating the drug to which they are sensitive.

Injectable drugs that are most frequently involved in allergic reactions are cephalosporins and penicillin. In most instances, discontinuing the drug or never again administering the drug or vaccine is the only therapy needed. If urticaria, an antihistamine such as diphenhydramine hydrochloride (Benadryl) may be helpful in relieving the symptoms. If anaphylaxis results, the treatment would be the administration of epinephrine.

### FOOD ALLERGIES

Food allergies are an abnormal immune response caused by exposure to a particular food protein. They can be IgE-mediated, cell-mediated, or mixed reactions, although IgE-mediated (type I hypersensitivity) reactions account for most food reactions (Robison & Pongracic, 2012). Symptoms of food allergies vary greatly among children, but cutaneous reactions to foods including urticaria, angioedema, flushing, and pruritus are some of the most common presentations of food allergy (Sampson, Aceves, Bock, et al., 2014).

Type I hypersensitivity reactions can manifest themselves only seconds after an offending food is eaten. Additional symptoms may develop over a period of 2 hours, often making the offending food difficult to recognize. Symptoms can begin gradually

and crescendo to a full blown anaphylactic event. Although not every food allergic reaction develops into anaphylaxis, food is the number 1 cause of anaphylaxis, and prior reaction severity does not predict future reactions. Every child with a history of significant symptoms with a food trigger needs an epinephrine auto-injector and an anaphylaxis action plan. The most common foods that cause immediate allergy symptoms include peanut, egg whites, milk, wheat, soy, seafood, and tree nuts. If children are allergic to milk, caution them that they are allergic to milk products such as ice cream, yogurt, and cheese as well. Children who are allergic to eggs often cannot eat any foods that contain eggs, such as egg noodles or mayonnaise.

Children with milk and egg allergy may be able to tolerate baked good that contain milk and/or egg. Because the exposure to high heat destroys the conformational epitopes, about 70% of children with a diagnosed milk or egg allergy tolerate those proteins after they have been baked in foods such as muffins and cakes (Bloom, Huang, Bencharitiwong, et al., 2014). Because milk and egg avoidance present a major challenge to families and eliminates important dietary proteins, children who are avoiding milk or egg should be evaluated for tolerance to baked milk and baked egg.

## Assessment

For some children, the food allergy diagnosis is clear. Sensitization can occur as food protein cross the placenta or via breast milk. For some children, the first “known” exposure to milk, egg, or peanut causes an immediate type I response such hives, swelling, and vomiting. These reactions can be anaphylactic. Other reactions are less intense and may involve things such as an increase in atopic dermatitis. Young children may not be able to describe why they do not enjoy eating a particular food, but they do tend to avoid foods that affect them, which often earns them the reputation of being “fussy eaters.” This is not diagnostic of food allergies, however, because children may refuse to eat foods as a form of toddler rebellion or may be reported as fussy eaters because parents are expecting them to eat more than their small size requires.

Encouraging a child or the parents to keep a food diary or a record of everything a child eats each day and then documenting if any symptoms occur is often the best way to spot offending foods that don't present with immediate reactions. A food that is found on lists when symptoms were few but not on days when the child is in distress is not an offending food. A food that appears only on “bad days,” however, can be strongly suspected as being an allergen.

An elimination diet can be an effective tool to detect mild food allergies. The suspect food is eliminated from the child's diet to see if symptoms resolve. If the symptoms reoccur when the suspect food is added back to the diet, the food is the likely culprit. Because most of the foods that are implicated in food allergy are major food proteins such as milk or egg, eliminating foods has significant implications to the child's nutrition. For example, milk is a major source of vitamin D and calcium. Children who are forced to avoid all milk and milk products need a vitamin D and calcium supplement. To establish whether the problem is truly a milk allergy, milk can

be reintroduced under medical observation every 6 to 12 months. If the problem is a true milk allergy, symptoms will recur.

## **Therapeutic Management**

The easiest treatment for a food allergy is to eliminate offending foods from the child's diet. This is difficult when the foods are great in number or if, like milk, wheat, or eggs, are found in many products. If many foods are involved, the child's nutrition status (whether the child is growing adequately and increasing in weight) needs to be assessed at healthcare visits.

Urge parents to become conscientious shoppers and read labels carefully to be certain the foods they are buying do not contain products to which their child is sensitive. Help school-age children learn to choose foods they can safely eat at the school cafeteria or at summer camp to avoid reactions. The National Institutes of Health expert panel has created guidelines for the diagnosis and management of food allergy. The guidelines are available at <https://www.niaid.nih.gov/diseases-conditions/guidelines-clinicians-and-patients-food-allergy>.

## **VACCINES**

Mild local reactions and fever after vaccinations are common and do not contraindicate future doses. Anaphylactic reactions to vaccines are rare. Children who are egg allergic can and should receive injectable influenza vaccine (Kelso, Greenhawt, & Li, 2013) as well as the MMR vaccine. The yellow fever vaccine requires special precautions for children with egg allergy.

## **MILK INTOLERANCE**

Milk is one of the leading causes of type I reactions to foods. However, not all milk reactions are IgE-mediated reactions. Milk intolerance usually presents in infancy and is typified by failure to gain weight, diarrhea, perhaps vomiting, and abdominal pain. Because these symptoms also occur in gastrointestinal disorders, infants with colic (characterized by abdominal pain, no change in stools, and no failure to gain weight), those with lactase deficiency, or those with a gastroenteritis infection (have nausea and vomiting) may be incorrectly diagnosed as having a milk allergy. Most infants can tolerate breast milk, even if the mother consumes milk in her diet. Supplementing with a hydrolyzed protein-based formula usually decreases symptoms dramatically.

## **PEANUT HYPERSENSITIVITY**

Peanut and tree nut ingestions are the cause of more than 85% of fatalities caused by food anaphylaxis in the United States (Robison & Pongratic, 2012). Adults who care for children who are food allergic including day-care providers, coaches, grandparents, and school personnel need to be very aware of this danger and need anaphylaxis action plans and epinephrine auto-injectors available at all times (Pistiner & Lee, 2012).

Because peanut allergy affects 1% to 3% of children, and peanut is a major contributor to food allergic reactions and anaphylaxis, there is significant interest in preventing peanut allergy rather than dealing with the consequences once the allergy has developed. In the past, recommendations to prevent peanut allergy included avoiding peanut allergen through the first 3 years of life. There is emerging evidence to contradict this and support early rather than delayed introduction of peanut, especially in “high-risk” infants. Children at “high risk” for developing peanut allergy include those 4 to 11 months old diagnosed with egg allergy and/or those with severe eczema. High-risk infants require skin testing and possible observed ingestion of peanut prior to home introduction (Du Toit, Roberts, Sayre, et al., 2015; Togias, Cooper, Acebal, et al., 2017).

### ***QSEN Checkpoint Question 42.6***

#### **EVIDENCE-BASED PRACTICE**

Food allergies are an important concern for nurses working in childcare or preschool settings because such sites may be where a child eats allergenic food and experiences a possibly fatal reaction. Early, appropriate administration of epinephrine for the treatment of the symptoms of anaphylaxis can significantly reduce the likelihood of anaphylaxis-related hospital admission. Delayed administration of epinephrine contributes to anaphylaxis-related fatalities. Epinephrine is significantly less likely to be injected in food-induced anaphylaxis than in venom-induced anaphylaxis. Reasons for failure to administer epinephrine include poor perception of the severity of symptoms or patient refusal (Simons et al., 2015). Based on the previous study and the fact that Dexter is allergic to peanuts, which statement by Dexter’s mother should cause a nurse the most concern?

- a. “I pack his lunch every day so I’ll know what he eats.”
- b. “He doesn’t need one of those EpiPen things. They are too expensive, and it’s not like he has a bee sting allergy. If he goes to a party, I’ll ask if peanuts will be served.”
- c. “I know how to read food labels to limit Dexter’s food to things I know are safe.”

*Look in Appendix A for the best answer and rationale.*

## **Stinging Insect Hypersensitivity**

Children may have severe hypersensitivity reactions to stings from bees, wasps, hornets, or yellow jackets (Yavuz, Sahiner, Buyuktiryaki, et al., 2013). Although a serum sickness reaction may occur, the usual reaction to these stings is an immediate type I hypersensitivity reaction (anaphylaxis).

## **THERAPEUTIC MANAGEMENT**

The best way to protect children with allergies to stinging insects is to begin hyposensitization by immunotherapy against insect stings after the first reaction. An extract of wasp, yellow jacket, hornet, and honeybee venom accomplishes this.

The child who has not been hyposensitized must be treated immediately after a sting by an injection of epinephrine. If children are going on a hiking or camping expedition away from parents, caution parents that their child needs to learn to self-administer epinephrine or be certain that a responsible adult accompanying them will be able to do it. Someone at school should be given the responsibility of administering epinephrine if a child is stung during recess or an outside gym period. If a school nurse is in attendance, this certainly is the nurse's responsibility. In schools where there is no full-time nurse, however, another person must be designated and taught how to give the injection. If the child has an antihistamine medication in addition to epinephrine, antihistamine should never be taken in place of epinephrine. Ice applied to the site minimizes the amount of venom absorbed. After the initial epinephrine administration, the child should be transported to a healthcare setting in case additional epinephrine is needed (the initial injection will be effective for only approximately 20 minutes).

Teach children who are allergic to stinging insects ways to avoid them such as not using scented preparations such as hair spray, deodorants, lotions, or perfume because these attract insects. They also should not go outside barefoot because bees are often found in ground clover. They should not be assigned household chores such as mowing the lawn or weeding the garden, actions that might stir up bees. Because insects tend to cluster around garbage containers, taking out the trash is also an inappropriate chore for these children. Whenever they are out of doors, they should have a fast-acting insecticide handy to use on flying insects. Encourage them to refrain from drinking out of open soda cans at outside activities because bees and wasps are drawn to the sugar in the soda, but the child may be unaware that an insect has entered the open can.

### *What If . . . 42.3*

**Dexter's school does not have a plan for managing students with immune disorders. After obtaining a parent's permission to discuss his care with the school nurse, how could the nurse involve the school nurse more in Dexter's plan of care?**

## Contact Dermatitis

*Contact dermatitis* is an example of a delayed or type IV hypersensitivity response; it is a reaction to skin contact with an allergen (a substance irritating to the child only with prior sensitization). The first reaction is generally erythema, followed by the development of intensely pruritic papules and then vesicles. The allergen causing the irritation is often suggested by the part of the child's body that is affected. For example,

dermatitis from a diaper-washing compound appears in the diaper area. Allergy to cosmetics appears on the face. Oozing at the site of pierced ears suggests an allergy to the nickel used in earring posts. Poison ivy appears on the hands and arms where the child brushed against the plant (Fig. 42.8). Children who have had repeated surgeries such as those with spina bifida are at high risk of developing allergies to latex and will have lesions where the latex touches them (Martin, 2015).

**Figure 42.8** Poison ivy on a child's hand. (© Beckman/Custom Medical Stock Photograph.)

## ASSESSMENT

Patch testing may be used to identify contact dermatitis allergens. A child should not be taking a corticosteroid at the time of patch testing because these drugs reduce delayed hypersensitivity reactions. However, a child may continue to take antihistamines or sympathomimetic drugs because these do not interfere with this testing. After 48 hours, the patches used for testing are removed and the reactions are graded 1+ to 4+, the same as in regular skin testing.

## THERAPEUTIC MANAGEMENT

Treatment for contact dermatitis consists of removing the identified allergen from the child's environment. In children, this is generally not difficult to do. In adults, because allergens may be work related, this is much more difficult.

Dressings moistened with water, saline, or Burow's solution relieve itching. Calamine and Caladryl lotions are also generally effective. Hydrocortisone lotions or creams reduce itching and also promote healing. Baths with baking soda or oatmeal in the water may be helpful if a large area of the body is involved. Some children may need a sedative to relieve their discomfort during the period of intense pruritus. As with all allergies, nurses need to document contact allergies on health records so all

healthcare providers can be aware of them and guard against a reaction.

#### *What If . . . 42.4*

**A nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to immune disorders and children (see Box 42.1). What would be a possible research topic pertinent to this goal that would be applicable to Dexter and his family and that would also advance evidence-based practice?**

### Unfolding Patient Stories: Charlie Snow • Part 1

**Charlie Snow**, a 6-year-old with a known hypersensitivity to perfumes and dyes and an allergy to peanuts, comes for a routine clinic visit accompanied by his aunt. He is living with his aunt and uncle while his parents are serving in the military. The nurse discovers a rash in multiple areas underneath his clothing. What questions should the nurse ask to determine the cause of the rash? What education should the nurse provide for the aunt, who has limited knowledge of allergies and childcare experience? (Charlie Snow's story continues in Chapter 55.)

Care for Charlie and other patients in a realistic virtual environment: *vSim for Nursing* ([thepoint.lww.com/vSimMaternityPed](http://thepoint.lww.com/vSimMaternityPed)). Practice documenting these patients' care in DocuCare ([thepoint.lww.com/DocuCareEHR](http://thepoint.lww.com/DocuCareEHR)).

### KEY POINTS FOR REVIEW

- An antigen is a foreign substance capable of stimulating an immune response. The immune system protects the body from invasion by such substances.
- Humoral immunity refers to immunity created by antibody production originated by B lymphocytes. Cell-mediated immunity refers to T-lymphocyte involvement.
- Autoimmunity results from an inability to distinguish self from nonself, causing the immune system to carry out immune responses against normal cells.
- HIV/AIDS is spread by the retrovirus HIV through blood and body secretions. Conscientious use of standard infection precautions is essential to prevent transmission.
- Allergic disorders occur as a result of an abnormal antigen–antibody response. These generally are long-term disorders, and children must participate in their own care to remain well, such as avoiding allergens or conscientiously taking a medication to suppress reactions. Involving children from the start both helps them play an active role in their own care and helps to plan nursing care that not only meets Quality & Safety Education for Nurses (QSEN) competencies but that also best meets a family's total needs.

- Anaphylactic shock is an acute type I hypersensitivity reaction characterized by extreme vasodilation and bronchoconstriction. If action is not taken immediately, the reaction can be fatal. Epinephrine is the standard of care for treatment.
- Atopic disorders include allergic rhinitis, atopic dermatitis, and asthma.
- Environmental control refers to ways to reduce the number of allergens to which children are exposed.
- Hyposensitization by subcutaneous or sublingual immunotherapy is a method to increase the plasma concentration of IgG antibodies to prevent or block IgE antibody formation and allergic symptoms.

### CRITICAL THINKING CARE STUDY

Kayla is a 14-year-old girl with a diagnosis of multiple allergies, among them eggs, shellfish, and cats. Although she admits she doesn't take her prescribed antihistamine on a regular basis (it wouldn't be "cool" for her friends to see it in her purse), she's concerned because her runny nose and frequent cough have been growing worse over the last 6 months. Because she finds her family "old fashioned," she spends a lot of time at her new best friend's house. The community where she lives is a coastal one where shellfish is a popular food; her best friend's mother is a waitress at a seafood restaurant. Kayla had an episode last month when she was taken to the local emergency room with sudden shortness of breath because she was eating at the restaurant with a group of friends and "forgot" about her allergy.

1. What may be a reason that Kayla's allergy symptoms are worsening?
2. How can you work with Kayla to create a plan of care that minimizes the impact of her allergies on her social life and development and that creates a safe environment for her as well?
3. Kayla has been advised to carry an epinephrine auto-injector with her at all times. She usually "forgets," however, and leaves it at home. How would you approach Kayla to teach her the importance of having the epinephrine auto-injector with her at all times? What facts or safety concerns would you want to discuss with Kayla?

## Nursing Care of a Family When a Child Has an Infectious Disorder

*Jack Noma, a 10-year-old boy, was admitted to the hospital yesterday for appendicitis. The morning after surgery, he broke out in a papular rash with some vesicles. He was diagnosed with varicella. His family works as migrant farm workers. His mother is not sure whether he received all of his vaccines because she did not feel comfortable giving some of them to him. “His sister is home with mono,” his mother tells you. “How could our family get two infections plus appendicitis all in 1 week?”*

*Previous chapters described the growth and development of well children. This chapter will address the physical and psychosocial changes that can occur when children contract an infectious disorder. The clinical presentation of childhood infection varies from an asymptomatic viral infection confirmed through diagnostic testing to a critical life-threatening illness (Alter, Bennett, Koranyi, et al., 2015). It’s important to know about the spread and care of these diseases to limit spread to other people.*

**How would you respond to Jack’s mother? Is it most likely that Jack contracted this new disease while he was in the hospital or before he was admitted? What is a measure you would recommend to help reduce the household transmission of infection?**

### KEY TERMS

**catarrhal stage**

**chain of infection**

**convalescent period**

**enanthem**

**exanthem**

**exotoxin**

**fomites**

**health care–associated infections**

**incubation period**

**Koplik spots**  
**mode of transmission**  
**nosocomial infections**  
**portal of entry**  
**portal of exit**  
**prodromal period**  
**reservoir**  
**septicemia**  
**susceptible host**  
**vectors**

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe the causes and course of common infectious disorders of childhood.
2. Identify 2020 National Health Goals related to infectious disorders in children that nurses could help the nation achieve.
3. Assess a child with an infectious disorder.
4. Formulate nursing diagnoses for a child with an infectious disorder.
5. Establish outcomes to help a family manage an infectious disorder as well as manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Plan nursing care for a child with an infectious disorder, such as helping them understand infectious precautions.
8. Evaluate expected outcomes for the achievement and effectiveness of care.
9. Integrate knowledge of infectious diseases with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to achieve quality maternal and child health nursing care.

---

Although immunizations have protected an increasing number of children against infections, infectious diseases remain a leading cause of morbidity in children ([Alter et al., 2015](#)). Nurses can play a key role in reducing the incidence of these disorders by educating parents about the importance of household infection control measures and how infectious diseases are spread. Prevention measures can be successful in controlling the spread of infectious diseases, but vaccination programs have been the most effective in reducing infectious diseases in children. Nurses should understand the signs and symptoms of a variety of infections to properly triage children to reduce transmission to

others. Several 2020 National Health Goals, shown in [Box 43.1](#), relate to the prevention of infectious disorders in children.

### BOX 43.1

#### Nursing Care Planning Based on 2020 National Health Goals

Several 2020 National Health Goals address ways to prevent and reduce the incidence of infectious disease in children.

- Reduce, eliminate, or maintain elimination of vaccine-preventable diseases such as measles from 115 infected children per year to a target of 30 children per year.
- Achieve and maintain effective vaccination coverage levels for universally recommended vaccines such as the diphtheria, tetanus, and acellular pertussis (DTaP) vaccine among young children from 84% to 90%.
- Increase the number of states that use electronic data from rabies surveillance to inform public health prevention programs from 8 states to 29 states.
- Reduce central-line–associated bloodstream infections (developmental).
- Reduce invasive health care–associated methicillin-resistant *Staphylococcus aureus* (HA-MRSA) infections from 26 per 100,000 people to 6.5 per 100,000 people ([U.S. Department of Health and Human Services, 2010](#); see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by educating parents about the importance of immunizations and ways to avoid infections. They can also help prevent the spread of infection in hospital units by scrupulously adhering to infection control precautions.

#### *Nursing Process Overview*

### FOR A CHILD WITH AN INFECTIOUS DISORDER

#### **ASSESSMENT**

Many infectious diseases have an insidious onset, whereas others present acutely with high fever and rapid deterioration. With the insidious onset of an infection, parents note behavioral, sleep, elimination, or appetite changes. They may comment, “He doesn’t act like himself” or “She’s not eating as well.” Fever, malaise, myalgia, and arthralgia are common associations with infectious diseases due to an increase in cytokines—leukotrienes and interleukins. The child can be contagious only before the onset of the infection, as with parvovirus B19, or may be contagious until the lesions start to dry, as with varicella. In other cases of infectious diseases, such as sepsis of the newborn or toxic shock syndrome, there is an acute onset of high fever with rapid deterioration of vital signs and organ failure. These patients are not contagious.

#### **NURSING DIAGNOSIS**

Common nursing diagnoses used with children directly related to the infectious

process include:

- Pain related to pruritus from skin lesions
- Impaired skin integrity related to rash, pruritus, and scratching
- Risk for infection related to presence of infective organism in sibling or family member
- Altered body temperature (fever) related to systemic infection
- Fluid volume deficit related to insensible fluid loss from increased body temperature
- Knowledge deficit (learning) related to disease prognosis, prevention, and treatment

Additional diagnoses when children must be separated from others to prevent infection transmission might include:

- Social isolation related to precautions required to prevent infection transmission
- Deficient diversional activity related to activity restriction and precautions to prevent disease transmission

## **OUTCOME IDENTIFICATION AND PLANNING**

Nursing outcomes for care of children with infectious disorders center around preventing disease through immunization, treating the current infection, and preventing further spread by practicing good infection control measures in the household or the medical setting. Educating parents about infection control measures and teaching them about how the particular infectious agent is spread remains critical to preventing the spread of disease in the community. There are several websites to educate families about the reduction of infectious disease including the National Foundation for Infectious Diseases ([www.nfid.org](http://www.nfid.org)), Immunization Action Coalition (<http://www.immunize.org>), World Health Organization (WHO) (<http://www.WHO.org>), and the Centers for Disease Control and Prevention (CDC) ([www.cdc.gov](http://www.cdc.gov)).

## **IMPLEMENTATION**

Nursing responsibilities when caring for a child with an infectious disorder always includes patient education regarding the disease, its management, possible complications, when to seek health care, and modes of disease transmission. Patients can use a variety of new technologies (including secure text messages, e-mail, and Skype) to transmit pictures of rashes for evaluation and management. Counseling parents about techniques to relieve the irritation of rashes and managing mild symptoms can be done over the telephone, through secure text messages, or by secure e-mail programs. The use of these technologies can allow for children with mild self-limiting illnesses to be cared for at home; however, children who are sicker and/or who appear toxic need to be brought in for a more complete evaluation. The nurse doing telephone triage must use standardized protocols to avoid missing key points in the history. Nursing responsibilities include getting a complete history including

immunization status, evaluating vital signs, obtaining a history, and doing a physical assessment in order to appropriately triage patients as they arrive in the medical setting. In addition, the nurse must monitor for changes in the patient's condition, relieve symptoms such as fever, promote rest, and administer medications including antipyretics and anti-infectious agents. In the inpatient setting, planning care for a child who requires restrictions to prevent disease transmission requires thoughtful consideration to prevent boredom and promote development.

### OUTCOME EVALUATION

An evaluation of outcomes for a child with an infectious disease promote a return to the child's previous state of wellness, prevent complications, prevent transmission to the family and community members, and promote the importance of hand washing in disease prevention. If one member of the family has a decreased immune response due to chemotherapy or steroid therapy, prevention of transmission takes on even greater importance.

Examples of expected outcomes that would indicate achievement of goals include:

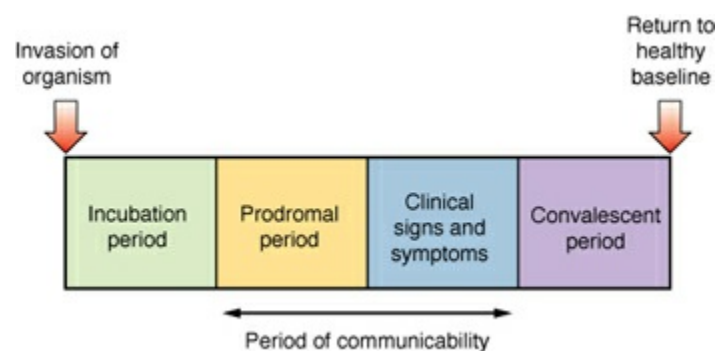

- Child indicates relief from pruritus and pain.
- All family members remain free of signs and symptoms of the infectious disorder.
- Parent identifies appropriate diversional activities for distracting the child.
- Parent verbalizes how to prevent transmission of infectious disease to other family members and understands the importance of proper hand washing.

## The Infectious Process

*Pathogens* are any organism that causes disease and can be classified into five types of microorganisms: viruses, bacteria, rickettsia, helminths, and fungi. The properties of these organisms are discussed in conjunction with the common diseases that they cause.

### STAGES OF INFECTIOUS DISEASE

Infectious diseases follow certain stages, during which the communicability (i.e., ability to be spread to others) or severity of the illness can be predicted (Fig. 43.1).

**Figure 43.1** The time frame for infectious diseases. Period of communicability is the time during which the disease can be transmitted to other people.

- The **incubation period** is the time between the invasion of an organism and the onset of symptoms of infection. During this time, microorganisms grow and multiply. Incubation periods vary widely depending on the virulence of the organism, the mechanism of spread, and the host. The incubation period for tetanus, for example, is 2 to 21 days.
- A **prodromal period** is the time between the beginning of nonspecific symptoms such as malaise, low-grade fever, fatigue, and arthralgia to the onset of disease-specific symptoms such as a rash, diarrhea, and vomiting. Depending on the organism, children may be infectious (capable of spreading the microorganisms to others) during the prodromal period. During the prodromal period, therefore, infectious diseases spread readily through communities from a person with the disease to any susceptible individual. Fortunately, prodromal stages are generally short, ranging from hours to a few days.
- *Illness* is the stage during which specific symptoms occur. It is important to keep in mind that the body's response to infectious agents causes a variety of symptoms including fever, myalgia (muscle aches), arthralgia (joint pain without swelling), malaise, increased need for sleep, and headache, which is usually secondary to fever. There is also a site-specific reaction such as coughing, runny nose, and sore throat when a respiratory virus like rhinovirus or respiratory syncytial virus infects the respiratory tract (Mauskopf, Margulis, Samuel, et al., 2016) or diarrhea and/or vomiting when rotavirus infects the gastrointestinal tract.
- Some childhood infections will manifest with a specific rash on the skin (**exanthem**) or mucous membrane (**enanthem**) (Box 43.2).
- The **convalescent period** is the interval between when symptoms first begin to fade and when the child returns to a healthy baseline. The return to baseline will vary from child to child depending on the host, other underlying illnesses, and the type and severity of infection.

#### BOX 43.2

### Nursing Care Planning Using Assessment

#### ASSESSING A CHILD FOR COMMON SIGNS AND SYMPTOMS OF INFECTIOUS DISORDERS

### History

**Chief concern:** Does child have a fever, general malaise, vomiting, or diarrhea? Was child recently exposed to someone with an infection?

**Past medical history:** Are child's immunizations current?

### Physical examination

## CHAIN OF INFECTION

The **chain of infection** is the method by which organisms are spread and enter a new individual to cause disease. Breaking the chain at one of its susceptible points is the most efficient way to prevent infection from spreading (Chusid & Rotar, 2016). Nurses are instrumental in doing this by teaching parents the importance of infection control measures such as good hand washing and asking them to monitor that every person that touches their child also washes their hands. In practicing hand washing and teaching parents to act as advocates for their child, nurses can prevent **nosocomial infections** (infections transmitted in healthcare facilities).

### Reservoir

The **reservoir** is the container or place in which an organism grows and reproduces. The reservoir would be another person with the disease, a contaminated object such as a kitchen counter, or an animal or insect. Not all infectious agents can live on fomites.

**Fomites** are inanimate objects that can also transmit infections from one person to

another without direct contact with a human vector.

## Portal of Exit

The **portal of exit** is the route by which an organism leaves an infected child's body to be spread to others. Organisms can be carried out of the body by upper respiratory excretions, feces, vomitus, saliva, urine, vaginal secretions, blood, or lesion secretions (Table 43.1). Depending on the way an organism is spread, it may be necessary to wear gowns, gloves, or mask and/or face shield to care for the child. In some cases, nothing more than standard precautions are needed even though the child has an infectious disease. Washing after contact with any body secretions and covering a cough and/or sneeze with tissue can limit droplet or airborne spread. Hand washing is the most effective way to prevent the spread of infection (Chusid & Rotar, 2016).

**TABLE 43.1 METHODS BY WHICH INFECTIONS SPREAD**

Portal of Exit	Means of Transmission	Portal of Entry	Prevention Measures
Blood	Arthropod vectors	Injection into the bloodstream	Decreasing exposure to vectors
	Blood sampling		Careful handling of blood sampling equipment
	Transfusion		Prescreening of blood for organisms such as HIV or hepatitis B
Respiratory secretions	Airborne droplets	Respiratory tract	Wearing a mask
	Fomites		Droplet and airborne precautions Hand washing
Feces	Water, food	Gastrointestinal tract	Hand washing before eating, after using bathroom, or after handling diapers
	Fomites		
	Vectors such as flies		
Exudate from lesions	Direct contact	Skin, mucous membranes	Contact precautions
	Contact with soiled dressings		Self-screening for sexual contacts

**QSEN Checkpoint Question 43.1****EVIDENCE-BASED PRACTICE**

Multiple studies reported the effectiveness of hand hygiene in the reduction of infection. As a result, the WHO and the CDC have endorsed the importance of hand hygiene to reduce infection (WHO, 2016a). A study Chittleborough, Nicholson, Basker, et al. (2012) conducted in the primary school setting found that proper hand hygiene correlated positively with student observations of teaching practicing hand hygiene. Based on this study, the nurse determines which action is most effective to ensure Jack, a 10-year-old, consistently washes his hands before meals?

- a. Continue to remind him to wash his hands as often as possible.
- b. Talk to Jack's mother about the importance of modeling good hand hygiene practices.
- c. Explain to Jack the role that bacteria play in the transmission of illness.
- d. Stress that washing his hands makes him look grown-up and responsible.

Look in [Appendix A](#) for the best answer and rationale.

**Means of Transmission**

The **mode of transmission** refers to whether the infection is spread by *direct* or *indirect* contact. Sexually transmitted infections, for example, are spread by mucous membrane to mucous membrane or direct contact. Other infections are spread indirectly by fomites—inanimate objects such as soil, food, water, bedding, towels, combs, nonrefrigerated food, or drinking glasses. Infections can also be spread by **vectors** such as insects, rats, or other vermin—who may not be ill but are carriers of a human disease.

The most common means of indirect contact is the spread of mouth and nose secretions (droplet infection) through talking, sneezing, coughing, breathing, kissing, and sharing drinking glasses or straws. Some droplets containing pathogenic organisms are spread immediately to another individual in this way. Some droplets fall to the ground, where the organisms dry and then are spread by dust. If small, the organisms become suspended in the air (airborne transmission) and can move with the wind to infect people at a distance. A common respiratory tract infection is an example of an illness spread by indirect contact.

To break a chain of infection at this point, use transmission-based precautions as appropriate and wash hands before, between, and after patient care. Household measures such as using paper bathroom cups, separating toothbrushes, and using different towels for different people can help prevent house reinfection.

**Portal of Entry**

The **portal of entry** refers to the opening through which a pathogen can enter a child's

body such as by inhalation, ingestion, or breaks in the skin from bites, abrasions, or burns. To break a chain of infection at this point, teach children to wash their hands after sneezing or coughing, before eating, and after using the bathroom. It is important to teach girls to wipe their perineum from front to back after defecating or voiding to prevent organisms from spreading from the rectum to the urethra. Parents need to wash dirt from cuts with soap and water and avoid hydrogen peroxide as a cleaning agent as this interferes with fibroblast production, delaying wound healing (Totoraitis, Cohen, & Friedman, 2017; Wilkins & Unverdorben, 2012).

### Susceptible Host

For infection to occur, one more step must be present: The child must be susceptible to the infection (**susceptible host**). Certain characteristics make some individuals more prone to infection than others, including:

- Age: Infection occurs most readily in the very young and the very old.
- Gender: Girls, for example, have more urinary tract infections than boys.
- Virulence: Some organisms are stronger than others or cause disease more readily.
- Body defenses: Physical, chemical, and immune responses all protect against foreign invaders. Children with immunosuppression are more susceptible than others. Infants who are breastfed are less susceptible to infection than formula-fed infants.

## THE BODY'S IMMUNE RESPONSE TO ORGANISMS

The immune system has two lines of defense—innate immunity, which is a nonspecific response, and adaptive immunity, which is more specific to the infective organism. Because of the innate response, when a foreign organism (antigen like a bacteria, virus, or fungi) enters the body, it is first met by neutrophils, phagocytic (cell-engulfing) white blood cells (WBCs). Neutrophils are the first line of defense and will activate another WBC, a monocyte, to become a macrophage. Macrophages have two roles—to clean cellular debris and kill the infecting organism. These cells do not need to have a previous exposure to the infecting antigen. The neutrophils, macrophages, complements, and cytokines (such as leukotrienes, interferons, and tumor necrosis factor alpha) provide a host defense to help ward off infection. The different actions of all the WBCs are summarized in [Table 43.2](#).

**TABLE 43.2 TYPES AND FUNCTIONS OF WHITE BLOOD CELLS (LEUKOCYTES)**

Type	Percentage of Total Count	Origin	Function
<i>Granular Forms</i>			
Neutrophils	60% at birth;	Bone	Active in acute bacterial infections

	33% at 2 years of age; 60% thereafter	marrow	
Eosinophils	1%–4%	Bone marrow	Increased in parasitic infection
Basophils	0.0%–0.5%	Bone marrow	Increased with inflammation
<i>Nongranular Forms</i>			
Lymphocytes	30% at birth; 50% at 2 years of age; 30% thereafter	Bone marrow	T lymphocytes (stored in the thymus gland) directly react with invading antigens; B lymphocytes from bone marrow produce antibodies that inactivate antigens
Monocytes	5%–10%	Bone marrow	Serve as a backup for neutrophils in acute infection; macrophages are mature form

Complement and cytokines signal specific cellular and humeral immunity to add in host defenses. Complement amplifies the innate immune response by enhancing phagocytosis via opsonin and attracting white cells to the site of inflammation (chemoattractive quality). The vascular response to antigens or breaks in the skin brings the plasma protein (clotting factors), WBCs, and platelets to the area.

The initial adaptive response is linked to adaptive immunity. In terms of adaptive immunity, the T lymphocyte has a twofold role. The T lymphocyte differentiates into TH1 cell. The TH1 promotes cellular immunity by activating microphages, enhancing cytotoxic T cell function, producing cytokines, and recognizing the infecting agent. TH2 cells release cytokines, which enhance antibody formation (immunoglobulins) by B cells and mediating eosinophil recruitment and activation (Nayak & Sant, 2011). The immunoglobulins can be specific to the particular infecting organism. (See [Chapter 42](#) for a more detailed discussion of the immune response and [Chapter 34](#) for a discussion of immunizations.)

The action of phagocytes on organisms produces a small amount of pus (remnants of the organisms, phagocytes, and destroyed tissue) and indicates phagocytosis is occurring and the infection is resolving. A large amount of pus may indicate that the infecting organism is overwhelming the immune response. When an infecting organism is overwhelming the immune response, the bacteria can enter the blood and lymphatic system and infect other organ systems such as the bone causing a bone infection (osteomyelitis), or an infection of the blood stream.

Pathogenic organisms in the bloodstream can cause a nonspecific bacteremia without any signs of organ failure in which the person can clear the bacteria. This is

called a blood infection. When the organism leads to a more serious systemic inflammatory response syndrome, it can present in three ways: (1) sepsis syndrome or infection with some alteration of body temperature, respiratory rate, heart rate, or WBC; (2) septic shock with organ dysfunction, hypotension, and hypoperfusion; or (3) severe sepsis with hypotension despite vigorous treatment (Randolph & McCulloh, 2014). A systemic inflammatory response is always serious as it can progress, leading to organ failure and death.

## Health Promotion and Risk Management

Preventing infectious diseases is important due to the risk of death (mortality) and complications (morbidity) secondary to the infection. An assessment of overall health status includes that the child has basic needs met as defined by Maslow (1943). A second important step is to be certain all parents are aware of the need for their children to be immunized. Nurses need to ensure immunizations are offered to children at healthcare visits to avoid missed opportunities and maintain the immunization schedule (Restrepo-Méndez, Barros, Wong, et al., 2016). A recent review showed a relationship between vaccine refusal and reoccurrence of vaccine-preventable disease (Phadke, Bednarczyk, Salmon, et al., 2016). Continual education about the effectiveness of vaccines to prevent serious diseases need to be done at every visit whether the family is refusing to vaccinate or regularly vaccinating. The nurse should educate guardians that common childhood illness such as scarlet fever, chickenpox (varicella), and mumps (infectious parotitis) have the potential to be serious and can be complicated by secondary infections such as pneumonia and toxic shock syndrome. Prompt evaluation and treatment for any changes in the expected course of an illness can prevent mortality.

Prevention of transmission of infectious disease is a public health issue with advice for prevention and treatment coming from the CDC in the United States and the WHO internationally. Federal, state, and local departments of health play an active role in case finding as well as making sure that immunizations are available for all children in the United States. Parents are expected to obtain such immunizations for children by school age. Schools and school nurses, as well as the school system's frontline health officers, take an active role in enforcing these regulations. Community health nurses serve an important role in educating families about immunizations and administering immunizations. Nurses also should educate families about vaccine resources that provide accurate information about the possible side effects of vaccines. In 2007, Andrew Wakefield authored an article published in *Lancet* that linked the measles, mumps, and rubella (MMR) vaccine to autism (Chittleborough et al., 2012). Despite the fact that the research was proven to be false, resulting in both the loss of Andrew Wakefield's license and withdrawal of the article, the information continues to be spread via the Internet by members of the anti-vaccine movement (Haberman, 2015). A recent meta-analysis showed no association between autism spectrum disorder and vaccines (Taylor, Swerdfeger, & Eslick, 2014.)

Developing countries use the immunization schedule recommended by WHO. This schedule is different from the United States, and therefore, vaccines for diseases such as varicella, meningococcal, and hepatitis A may not be recommended for the child's country of origin (WHO, 2016b). When caring for children from families of newly arrived immigrants, the child may need the missing immunizations. The family may question this need for further immunizations.

## PREVENTING THE SPREAD OF INFECTIONS

*Nosocomial* or **health care–associated infections** (HAIs) are infections that are contracted while in a hospital or other healthcare setting. At present, there is a three-pronged approach to prevent HAIs that center around prevention of infection with surgery or catheter placement, prevent spread of infection between patients, and appropriate antibiotic use (CDC, 2016c). These kinds of infections are a major threat to hospitalized children. Antibiotic misuse is the chief reason for the emergence of resistant bacteria (Goldman & Newland, 2015). At the present time, HAIs include six antibiotic-resistant bacteria that are identified by the CDC as either urgent or serious infections. They include carbapenem-resistant Enterobacteriaceae (CRE), methicillin-resistant *Staphylococcus aureus* (MRSA), extended-spectrum  $\beta$ -lactamases (ESBL)-producing Enterobacteriaceae, vancomycin-resistant enterococci (VRE), multidrug-resistant pseudomonas, and multidrug-resistant *Acinetobacter* (CDC, 2016c). It is important for nurses to know about antibiotic-resistant infections in their workplace and use dedicated equipment for a patient who has resistant bacteria (CDC, 2016c).

The children at highest risk for contracting an HAI include children younger than 2 years of age, children with a nutritional deficit, those who are immunosuppressed, those who have indwelling vascular lines or catheters, are receiving multiple antibiotic therapy, or who remain in the hospital for longer than 72 hours. Nurses should follow hand hygiene protocols, use appropriate isolation required for the patient's infection, and make sure that device and cleaning practices follow protocols (CDC, 2016c). Summaries of standard infection precautions and transmission-based infection control precautions are available at <http://thePoint.lww.com/Flagg8e> and in Box 43.3.

### BOX 43.3

#### Standard and Transmission-Based Precautions for Infection Control

To decrease the transmission of infectious agents in the healthcare setting:

1. Wash hands for at least 20 seconds immediately with a non-antimicrobial soap and water or alcohol-based hand sanitizers before and after examining patients and after any contact with blood, body fluids, excretions, secretions, and contaminated items despite the use of gloves (AAP, 2015). Soap and water is always used if the hands are visibly dirty or contaminated.
2. Wear clean, nonsterile gloves anytime contact with blood, body fluids, mucous membranes, or broken skin is likely. Hand hygiene should be done before and

after glove use. Change gloves between tasks or procedures on the same patient. Before going to another patient, remove gloves, wash hands, and then put on new gloves.

3. Wear a mask, protective eyewear, gowns, and face shields during any patient care activity when splashes or sprays of body fluids, excretions, secretions, or blood are likely. Remove the soiled gown and wash hands as soon as possible. Remove the gown and gloves in the room of the patient before moving to the next patient (CDC, 2016b).
4. Make sure contaminated nondisposable equipment is not reused with another patient until it has been cleaned, disinfected, and sterilized properly. Do not recap needles. Dispose of nonreusable needles, syringes, and other sharp patient care instruments in puncture-resistant containers.
5. Ensure housekeeping routinely clean and disinfect frequently touched surfaces including beds, bed rails, examination tables, and bedside tables.
6. Do not touch linens soiled with blood or body fluids with bare hands. Use plastic bags to transport soiled linen.
7. Place a patient whose blood or body fluids are likely to contaminate surfaces or other patients in an isolation room or area.
8. Minimize the use of invasive procedures to avoid the potential for injury and accidental exposure. Use oral rather than injectable medications whenever possible.
9. When a specific diagnosis is made, find out how the disease is transmitted. Use precautions according to the transmission risk (AAP, 2015)

#### AIRBORNE PRECAUTIONS

Airborne precautions reduce the risk of small-particle organisms being transmitted through the air as microorganisms carried by this route can be carried widely. If airborne transmission is possible:

1. Place the patient in a single-patient isolation room that is not air-conditioned or where air is not circulated to the rest of the healthcare facility. Make sure the room has a door that can be closed.
2. Wear a high-efficiency particulate air (HEPA) or other biosafety mask when in the patient's room.
3. Limit movement of the patient from the room to other areas. Place a surgical mask on a patient who must be moved.

#### DROPLET PRECAUTIONS

Droplet precautions reduce the risk of pathogens being spread through large-particle droplet contact by acts such as coughing, sneezing, and talking or through procedures such as suctioning or bronchoscopy. Large droplets do not remain suspended in the air for long periods and generally travel only short distances, so close proximity is required for the spread of disease. Respiratory viruses, *Bordetella pertussis*, and patients within the first 24 hours of meningococcal infections or group A streptococcal infections can be transmitted by droplets. If droplet transmission is

possible:

1. Place the patient in a single-patient isolation room.
2. Wear a HEPA or other biosafety mask when caring for the patient.
3. Limit movement of the patient from the room to other areas. If the patient must be moved, place a surgical mask on the patient.

#### CONTACT PRECAUTIONS

Contact precautions reduce the risk of transmission of pathogens by direct contact such as skin-to-skin contact (shaking hands) or indirect contact through an intermediate object such as a comb or soiled dressing. If contact transmission is possible:

1. Place the patient in an isolation room and limit access.
2. Wear gloves during contact with the patient and with infectious body fluids or contaminated items.
3. Wear a disposable gown when in the patient's room.
4. Limit movement of the patient from the isolation room to other areas.
5. Avoid sharing equipment between patients. Designate equipment for each patient if supplies allow. If sharing equipment is unavoidable, clean and disinfect it before use with the next patient.

#### What If . . . 43.1

**The nurse realizes that Jack, who was diagnosed as having scarlet fever a day after surgery for appendicitis, must have been infectious while he was in surgery because that was his prodromal period. What can the nurse do to make sure other people do not contract the infection?**

## Caring for the Child With an Infectious Disease

Most all childhood infectious diseases include one of the following symptoms: fever, malaise, arthralgia, or myalgia. Nursing care must address identification and relief of these symptoms.

### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Pain related to infection

**Outcome Evaluation:** Child states he is more comfortable; several simple remedies are available for reducing discomfort ([Box 43.4](#)).

#### BOX 43.4

### Nursing Care Planning Based on Family Teaching

#### RELIEVING THE ITCHINESS OF A RASH

**Q.** Jack's mother says to you, "Our son is miserable because his rash is so itchy. What can we do to help him?"

**A.** Itching is a very uncomfortable sensation. Use the following to help relieve the itch of a rash:

- Dress your child in light cotton clothing so overheating and perspiration do not occur. Perspiration can make itching worse.
- Avoid wool clothing because it can irritate the skin and increase itching.
- Offer adequate fluid to maintain good hydration because dry skin increases discomfort.
- Keep your child's fingernails short to avoid injury to the skin from scratching.
- Teach your child to press on an itchy area rather than scratching to relieve discomfort; cold cloths or compresses applied to an area can also be helpful.
- Administer an analgesic, such as acetaminophen, as needed for comfort.
- Adding a few teaspoons of baking soda to bath water can be soothing. Use lukewarm rather than hot water.
- Keep in mind that some children need an antihistamine such as diphenhydramine (Benadryl) to reduce itching. Ask your primary care provider about using this medication.

**Nursing Diagnosis:** Fever related to infection

Some infectious diseases also involve fever. Measures to combat fever in children are discussed in [Chapter 37](#).

**Nursing Diagnosis:** Social isolation related to required activity restriction associated with precautions to prevent disease transmission

**Outcome Evaluation:** Child states reasons for restrictions; expresses interest in activities proposed by nurses or parents.

A child who is restricted from others because of infection control precautions can begin to feel lonely and depressed unless stimulation and social needs are met. The nurse should try to have a child life specialist therapist visit the child on a daily basis and encourage families to play games with the children during the day. It is important to plan nursing care appropriately to avoid excessive exposure to infection by coming in and out of the room.

Parents must be educated on the type of precautions that their child needs to avoid infecting themselves and other patients on the unit. Helping the family feel comfortable with these procedures so they continue to visit is a nursing responsibility. Remember that when children are admitted to a hospital, parents may not hear everything said to them during admission because of their anxiety. Reeducation and reinforcement of infection control measures is key to prevent the spread of disease.

Parents may be reluctant to give children who require transmission-based precautions their favorite toy, thinking it will have to be destroyed after contagious precautions are discontinued. There are few toys, however, that cannot be cleaned with soap and water, so there is no reason to restrict such items. A child should always have an activity or toy to play with to promote development and keep them occupied for the length of time they will be alone. See [Chapter 36](#) for a discussion of interventions that can be used to promote adequate stimulation for a child requiring transmission-based precautions as well as the role of a child life specialist to help locate and provide stimulating activities for children.

## Viral Infections

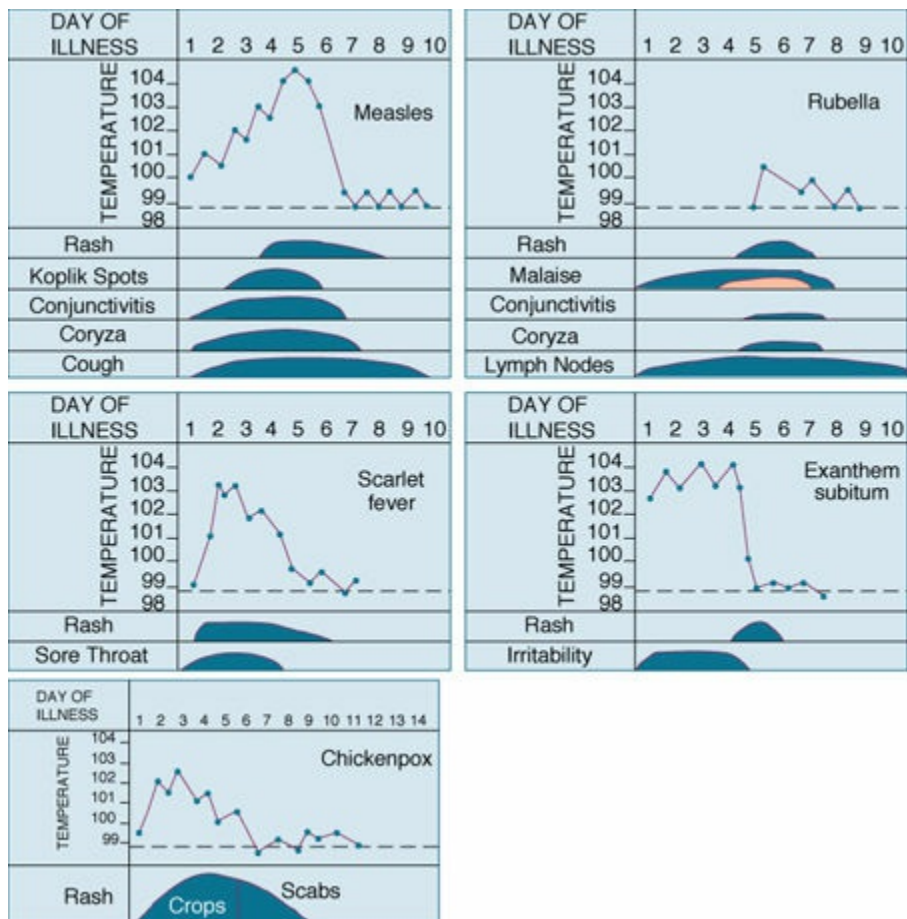

In children, infections by viral agents are the majority of recognized infectious diseases ([Alter et al., 2015](#)). Most viral infections are treated based on symptoms with only a small number of viral infections treated with antiviral agents. Viruses are the smallest infectious agents known and are so small that they cannot be seen through an ordinary microscope. They actually are not true cells because they contain either RNA or DNA but not both. As a result, viruses cannot replicate on their own but only by invading bacteria, plant, animal, or human cells and using the biochemical products of those cells to function. Although body cells may not look to be outwardly altered by a viral invasion, they can fail to function or die because of lysis of internal components or rupture. Symptoms usually do not become apparent until many cells have been invaded in this way, creating a long incubation period. Some viruses are capable of invading only specific cells. The Epstein–Barr virus, for example, resides in the B lymphocytes ([Pinninti, Hough-Telford, Pati, et al., 2016](#)), HIV viruses invade CD4 T lymphocytes, and influenza viruses affect specific receptor sites in tracheal cells. Most viral agents have a site-specific organ or cell that they infect, but the systemic manifestations are due to cytokines release as discussed above.

### VIRAL EXANTHEMS

Viruses cause childhood exanthems (skin rashes). Each of these diseases has specific symptoms, characteristic lesions, and a specific distribution or pattern to the rash that allows it to be identified ([Figs. 43.2](#) and [43.3](#)). There are several vaccine-preventable viral infections: rubeola (regular measles), rubella (German measles), mumps, varicella, rotavirus, hepatitis A, hepatitis B, polio, influenza, and human papillomavirus.

**Figure 43.2** Primary and secondary skin lesions and their characteristics.

**Figure 43.3** The differences between five acute exanths characterized by rash.

### Exanthem Subitum (Roseola Infantum)

- Causative agent: human herpesvirus 6 (HHV-6)

- Incubation period: 9 to 10 days
- Period of communicability: during febrile period
- Mode of transmission: unknown
- Immunity: Contracting the disease offers lasting natural immunity; no vaccine is available ([American Academy of Pediatrics \[AAP\], 2015](#)).

## Assessment

Roseola is a disease with fever followed by a defervescence. HHV-6 is the causative viral agent, and nearly all humans develop this infection with 77% of children acquiring roseola by age 2 years ([Alter et al., 2015](#)). The first symptom is fever (101° to 105°F [38.3° to 40.6°C]). Infants may be cranky due to the fever, but they will be playful and alert when the fever is done. There may be associated cervical adenopathy with mild injection of the pharynx. The fever will fall abruptly after 3 to 5 days ([Alter et al., 2015](#)), and a distinctive rash of discrete, rose-pink macules approximately 2 to 3 mm in size appears (see [Fig. 43.3](#)). The lesions occur most prominently on the trunk, fade on pressure, and last 1 to 2 days. The children have no accompanying coryza (upper respiratory symptoms), conjunctivitis, or cough. Not all children who seroconvert from infection with the virus will develop clinical symptoms. The condition is diagnosed based on the history with the hallmark appearance of a rash appearing immediately after the sharp decline in fever ([AAP, 2015](#)).

Roseola is a cause of febrile seizure in up to 10% to 15% of children. Other rare complications of roseola include encephalitis, encephalopathy, and bulging fontanelles ([AAP, 2015](#)).

## Therapeutic Management

Treatment focuses on measures to reduce the fever with acetaminophen (Tylenol) or ibuprofen (Motrin) if the child is over 6 months. Management of this type of seizure is discussed in [Chapter 49](#).

There are no long-term effects of roseola. If an infant should develop this exanthem in the hospital, follow standard infection precautions.

## Rubella (German Measles)

- Causative agent: rubella virus
- Incubation period: generally 14 days within a range of 12 to 23 days ([CDC, 2015a](#); [CDC, 2016j](#))
- Period of communicability: 7 days before to approximately 7 days after the rash appears
- Mode of transmission: direct and indirect contact with droplets
- Immunity: Contracting the disease offers lasting natural immunity; a high rubella antibody titer reveals infection has occurred.
- Active artificial immunity: attenuated live virus vaccine (e.g., MMR vaccine)

- Passive artificial immunity: Immune serum globulin is considered for pregnant women exposed to the virus.

## Assessment

Rubella (often called German or 3-day measles) is rarely seen today, but when it does occur, it is seen most commonly during the spring and mostly affects older school-age and adolescent children. In younger children, the rash is the first manifestation of the disease with no prodrome. The rash is characterized by a discrete pink-red maculopapular rash (see [Fig. 43.3](#)) that begins on the face and then spreads downward to the trunk and extremities. In older children and adolescents, the disease has a 1- to 5-day prodromal period, during which children have a low-grade fever, headache, malaise, anorexia, mild conjunctivitis, upper respiratory symptoms, and lymphadenopathy such as those in the suboccipital, postauricular, and cervical chains ([AAP, 2015](#)). This prodrome is followed by a rash, which disappears by the third day. The fever with rubella is not marked, although arthritis (joint pain) with effusion into the joints occurs in some children on the second or third day and lasting as long as 5 to 10 days. Complications from rubella include congenital rubella syndrome from the transmission from mother to baby, arthralgia and arthritis in adult females to encephalitis, orchitis, neuritis, and hemorrhagic manifestation due to thrombocytopenia ([AAP, 2015](#)).

## Therapeutic Management

Children need comfort measures for the rash and an antipyretic such as acetaminophen (Tylenol) or ibuprofen (Motrin) for fever or joint pain. If a child develops rubella while in the hospital, follow droplet precautions for 7 days after the onset of the rash in addition to standard infection precautions.

If a woman contracts rubella while pregnant, it can cause extensive congenital malformation in the fetus (see [Chapter 12](#)). Due to the risk of fetal malformations as a result of exposure to rubella virus in utero, this disease is not considered a simple disease. It is important that girls are immunized against rubella before they reach childbearing age. Therefore, the MMR vaccine is administered at age 1 year and again at age 4 years to expand protection. MMR vaccine is not recommended in pregnancy because it is a live viral vaccine ([CDC, 2016j](#)).

### *QSEN Checkpoint Question 43.2*

#### **SAFETY**

A nurse is preparing to enter Jack's room. Because his infection involves potential airborne transmission, what isolation precautions should the nurse use?

- a. Goggles and nonsterile gloves
- b. Gown and nonsterile gloves
- c. Mask, gown, and nonsterile gloves

d. No precautions provided Jack wears a mask

Look in *Appendix A* for the best answer and rationale.

## Measles (Rubeola)

- Causative agent: measles virus
- Incubation period: 8 to 12 days from time of exposure to onset of any symptoms (AAP, 2015) with a range from 7 to 21 days (Goodson & Seward, 2015)
- Period of communicability: 4 days before the rash to 4 days after the rash appears (AAP, 2015)
- Mode of transmission: direct contact with droplets or airborne spread (AAP, 2015)
- Immunity: Contracting the disease offers lasting natural immunity.
- Active artificial immunity: attenuated live measles vaccine (e.g., MMR)
- Passive artificial immunity: immune serum globulin

## Assessment

Measles is an acute febrile viral illness associated with cough, coryza (clear nasal discharge), and conjunctivitis (the “three Cs”) with a confluent maculopapular, erythematous rash, which starts behind the ear and spreads to the feet over a course of 3 to 6 days. **Koplik spots**, or small white spots with a bluish white center on an erythematous background, are seen in the oral mucosa opposite the buccal mucosa before symptoms appear (AAP, 2015; Goodson & Seward, 2015).

Globally, measles is still seen because funding shortfalls have affected immunization programs (Shibeshi, Masresha, Smith, et al., 2014). Recent outbreaks of measles in the United States have occurred with a peak of 667 cases in 2014 (CDC, 2016d) due to declining rates of immunizations. When it does occur, it can be a devastating illness because of the serious complications that can occur.

During the prodromal period, postauricular, cervical, and occipital lymph nodes become enlarged, and the child develops a low-grade fever along with malaise, photophobia, cough, coryza, and mild gastrointestinal symptoms. The child may look like they are developing an upper respiratory infection (Drutz, 2016). Koplik spots then develop on the buccal mucosa and are a hallmark symptom because they are unique to measles (Fig. 43.4). Koplik spots look like raised papules on an erythematous base (Drutz, 2016). Any rash on mucosa surfaces is called an enanthem.

**Figure 43.4** Koplik spots on the oral mucous membrane. (© SPL/Custom Medical Stock Photograph.)

As this enanthem fades, the fever rises to as high as 104°F (40°C) and a viral exanthem develops on the skin, gradually spreading down over the body as described earlier (AAP, 2015; Drutz, 2016). This maculopapular coalescing rash develops over the entire body and eventually turns from red to brown desquamation over a few days (Fig. 43.5). While the rash is red, it fades on pressure; when it is brown, it does not fade. This differentiates it from the rash of scarlet fever, which always fades on pressure. After 5 to 6 days, the rash fades, leaving a fine desquamation of skin cells behind.

**Figure 43.5** The typical rash of measles on a child's upper body. (© NMSB/Custom Medical Stock Photograph.)

The complications of measles can involve multiple systems ([Goodson & Seward, 2015](#)) and includes otitis media, pneumonia, croup, and diarrhea. Pneumonia is the most common complication and can be from the measles virus or a secondary bacterial infection ([Goodson & Seward, 2015](#)). A rare subacute sclerosing panencephalitis leading to central nervous system degeneration, behavioral changes, and seizures can occur 7 to 11 years after the initial measles infection ([Goodson & Seward, 2015](#)). Fever that lasts beyond the third or fourth day of a rash or coughing that continues generally suggests one of the complications of measles, such as pneumonia, has occurred.

### Therapeutic Management

Children with measles need comfort measures for the rash and an antipyretic for the fever. Applying a lubricating jelly or an emollient (e.g., A&D ointment) to the area below the nose may help prevent excoriation. The use of buckwheat honey in children older than 1 year of age may be helpful with the cough ([Paul, Beiler, McMonagle, et al., 2007](#)). Photophobia is an accompanying symptom, so drawing the curtains or wearing
