sunglass is a comfort measure. When children are seen for diagnosis and management, office staff should be aware that the child may have measles and the child should be seen after office hours. If a child is hospitalized, follow airborne precautions for the duration of the illness in addition to standard infection precautions (AAP, 2015).

### Chickenpox (Varicella)

- Causative agent: varicella-zoster virus (VZV)
- Incubation period: 10 to 21 days with the most common incidence at 14 to 16 days following exposure (Kroger, 2015)
- Period of communicability: 1 day before the rash to 5 to 6 days after its initial appearance, when all the vesicles have crusted
- Mode of transmission: highly contagious; spread by direct or indirect contact of saliva or open vesicles
- Immunity: contracting the disease offers lasting natural immunity to chickenpox; however, because VZV is latent, it causes herpes zoster (shingles) when it is reactivated at a later time
- Active artificial immunity: attenuated live virus vaccine
- Passive artificial immunity: children who are immunosuppressed, such as those with leukemia or HIV/AIDS, or those who are being treated with corticosteroids are offered varicella-zoster immune globulin (VZIG) within 72 hours of exposure to help prevent or modify disease symptoms.

### Assessment

Chickenpox is a common and highly contagious childhood infection caused by the VZV with a household attack rate approaching 90% (Alter et al., 2015). It has a decreasing incidence due to the varicella vaccine (Alter et al., 2015). In children, the rash occurs first accompanied by a low-grade fever and malaise (Kroger, 2015) (see Fig. 43.3). The lesions of varicella present as a macule, papule, and vesicle all appearing at the same time, starting on the trunk and progressing outward to the arms, face, legs, and mucosal surfaces including the genitalia. When the lesion is in the healing stage, there is a characteristic black crust. The hallmark is a 2- to 3-mm vesicle on an erythematous base. The lesions appear in crops, with each new lesion moving through progressive stages (Fig. 43.6). Usually, all four stages of lesions (macule, papule, vesicle, and crust) may be present at the same time. The fever has a wide range depending on the severity of the infection and is worse in immunocompromised patients such as patients undergoing chemotherapy or with an underlying immune deficiency. Secondary soft tissue infections can also occur with the common organisms of staphylococcus and streptococcal causing mild to severe secondary infections (Gershon, Breuer, Cohen, et al., 2015).

**Figure 43.6** An older school-age boy with varicella. (© Martin/Custom Medical Stock Photograph.)

### Therapeutic Management

The rash of varicella is very pruritic and so it is important to decrease scratching to reduce infection. Topical oatmeal-based creams along with an antihistamine such as diphenhydramine (Benadryl) can reduce the pruritus, and an antipyretic such as acetaminophen (Tylenol) can reduce the fever. The development of Reye syndrome (see [Chapter 49](#)) has been associated with aspirin use during varicella and influenza viral illnesses, so caution parents to avoid aspirin and instead use acetaminophen or ibuprofen to control fever. In high-risk patients (such as those on steroids or chemotherapy and those who are immunodeficient or older than 13 years of age), acyclovir (Zovirax), an antiviral, may be prescribed to reduce the number of lesions and shorten the course of the illness ([AAP, 2015](#)).

During hospitalization due to a complication of varicella infection, standard

infection precautions along with airborne and contact precautions are adhered to until all lesions are crusted. Children may return to school as soon as all the lesions are crusted as the crusted lesions are not infectious. Complications include secondary infections of the lesions, pneumonia, and encephalitis.

## Herpes Zoster

Herpes zoster is a reactivation of the VZV. The herpes viral family has viral latency, which means that once you develop varicella, the virus lies latent in the posterior dorsal root ganglia ([Alter et al., 2015](#)). The reactivation of the VZV occurs during aging as well as during times of immunosuppression.

The first manifestations are paresthesia and pain with subsequent groups of vesicular lesions in different stages of healing along a dermatomal distribution ([Fig. 43.7](#)). The course in the elderly and immunocompromised can be protracted, and today, there is a varicella-zoster vaccine for patients older than 50 years of age ([Keighley, Saunderson, Kok, et al., 2015](#)).

**Figure 43.7** Herpes zoster on a child's back. (© Dr. P. Marazzi/SPL/Science Source/Photo Researchers.)

Treatment for herpes zoster includes analgesia for pain and measures to reduce pruritus. Acyclovir, which inhibits viral DNA synthesis, may be effective at limiting the disease but should be started within 72 hours of the start of the rash. Administration of VZIG within 96 hours can be used for immunocompromised children and may minimize symptoms.

### **Smallpox (Variola)**

- Causative agent: smallpox virus
- Incubation period: 7 to 17 days with a mean of 12 days
- Period of communicability: The child is contagious for 24 hours before the onset of the rash and remains contagious until all lesions are dried which can take up to

4 weeks.

- Mode of transmission: airborne transmission (Kroger, 2015)

There are distinct differences between smallpox and varicella. In general, patients with smallpox develop a febrile prodrome not seen in varicella (AAP, 2015). Although the lesions of smallpox may resemble those of varicella, the lesions of smallpox are similar in the same stage of disease and all the smallpox lesions progress at the same rate. Unlike varicella, smallpox has a pustular stage. These pustular lesions are firm and deeply embedded in the skin dermal layer (AAP, 2015). In the crusting phase, the lesions of smallpox are contagious, whereas the crusted varicella lesions are not contagious.

Smallpox is a serious illness; its mortality rate is greater than 30% (AAP, 2015), and it can be spread readily by direct contact with an infected person or indirect contact with a fomite (AAP, 2015). Disease symptoms can be modified by administration of disease specific vaccinia immune globulin (VIG) with experimental drugs in development (Damon, Damaso, & McFadden, 2014). Antibiotics may be used to prevent secondary infection of lesions. Oxygen or other measures to support respiratory and cardiac function should be provided as necessary, or these systems can fail.

The last case of smallpox occurred in Somalia in 1977 (AAP, 2015), and the United States decided to stop vaccinating children in 1972. However, the chief concern in the United States is the possibility of the use of the smallpox virus as weapon of bioterrorism.

The causative agent is the smallpox virus. The lesions are similar, but the VZV has superficial vesicles as the primary lesion, whereas smallpox lesions on one part of the body do not vary and are deeper in the dermis. VIG is available through the CDC.

There is a severe prodrome phase for this disease with a high fever from 102° to 104°F (38.9° to 40.0°C) and symptoms that include headache, abdominal pain, malaise, and severe fatigue. Within 24 hours of symptoms starting, skin lesions develop on the face, spreading down the body to the forearms, trunk, and legs. The face and distal extremities are the most frequently affected (AAP, 2015). The lesions start as macules and then progress to papules, vesicles, and firm pustules by the seventh day. Eventually, the lesions become umbilicated and more confluent.

### ***QSEN Checkpoint Question 43.3***

#### **PATIENT-CENTERED CARE**

Jack's rash is causing him to scratch his skin. To maintain skin integrity and promote comfort, which action should the nurse prioritize in his plan of care?

- a. Allow him to keep his nails long.
- b. Administer an antihistamine as prescribed.
- c. Instruct Jack not to ever scratch the lesions.
- d. Cover his hands and fingernails with mittens.

*Look in Appendix A for the best answer and rationale.*

## Erythema Infectiosum (“Fifth Disease”)

- Causative agent: parvovirus B19
- Incubation period: most common between 4 to 14 days, with an outside window of 21 days (AAP, 2015)
- Period of communicability: uncertain
- Mode of transmission: respiratory tract secretion, blood transfusion, vertical transmission from mother to baby (AAP, 2015)
- Immunity: none

### Assessment

Erythema infectiosum is more common in late winter through the spring and can occur at any time during the life span. The virus has several clinical features. Because the virus causes a relative aplasia of the red cell (erythrocyte) line for 7 to 10 days, the patient with a hemolytic anemia such as sickle cell disease can develop dangerously low hemoglobin, leading to cardiac failure. In patients with an HIV infection, the child can also develop a symptomatic anemia. In the pregnant woman, infected with parvovirus B19, fetal death may occur in 2% to 6% or the child may be smaller than expected (intrauterine growth restriction); however, in the well child, the infection can be asymptomatic and may not manifest as a clinical illness. The classic presentation starts with mild systemic symptoms, which can include a fever in 15% to 30%, headache, and malaise. This is present for 7 to 10 days before the child develops a “slapped cheek” appearance with erythema of the cheeks with circumoral pallor (Fig 43.8). Following this rash, a maculopapular, lacy-appearing rash on the arms, thigh, and buttocks may appear. This can fade and become more intense depending on the child’s activity level and environmental changes, which includes sunlight and ambient room temperature.

**Figure 43.8** The “slapped face” appearance of fifth disease. (© Dr. P.

Marazzi/SPL/Science Source/Photo Researchers.)

Other presentations of this virus include a petechial, papular purpuric stocking and glove distribution or a mild respiratory illness without rash. Occasionally, the child will develop arthralgia and arthritis secondary to infection with parvovirus B19 (AAP, 2015).

### Therapeutic Management

Treatment is typically supportive, with antipyretics and analgesics and comfort measures for the rash (see Box 43.4). There are no known complications of fifth disease for a child; children with a known parvovirus B19 infection should avoid contact with pregnant women. Use droplet precautions in a hospital. Children can return to school as soon as the rash appears because they are no longer infectious after this point.

## NONPOLIO ENTEROVIRUSES

- Causative agent: member of the enteroviral family
- Incubation period: most common is between 3 to 6 days, with hemorrhagic conjunctivitis having a shorter incubation of 24 to 72 hours (AAP, 2015)
- Period of communicability: uncertain
- Mode of transmission: respiratory tract secretion, fecal–oral, vertical transmission from mother to baby at the time of birth; possibly breastfeeding (AAP, 2015)
- Immunity: none

There are over 90 serotypes (members of the same viral family) with three members of enteroviral family: numbered enteroviruses, echoviruses, and coxsackievirus (Alter et al., 2015). More recently, the virus was reclassified into enterovirus A, B, C, and D based on their genetics and their phenotypes (Lugo & Krogstad, 2016). As a group, there are several common manifestations from these viruses including:

- Nonspecific viral illness
- Respiratory illness (coryza, pharyngitis, stomatitis, pneumonia, pleurodynia, bronchitis)
- Skin infections (hand, foot, and mouth disease)
- Gastrointestinal illness (gastroenteritis, pancreatitis, and hepatitis)
- Eye infections (hemorrhagic conjunctivitis, uveitis)
- Neurologic disease (aseptic meningitis, encephalitis, acute flaccid paralysis)
- Genitourinary illness (orchiditis)
- Heart disease (myocarditis)
- Muscular manifestations (myositis) (AAP, 2015)

## Numbered Enterovirus and Echovirus Infections

These echoviruses and numbered enteroviruses are responsible for a number of

childhood diseases, including aseptic meningitis, diarrhea, acute respiratory illness, and maculopapular rashes. Although potentially serious, such infections are usually benign and self-limiting. Treatment involves supportive measures such as an antipyretic for fever and comfort measures for the rash. If a child is hospitalized, follow contact precautions for the duration of the illness in addition to standard infection precautions.

### **Coxsackievirus Infections**

The coxsackievirus groups are also responsible for a variety of diseases. Coxsackievirus A6 and A16 are associated with hand-foot-mouth disease with distinctive erythematous papules mainly on the hands and feet but occasionally on the buttocks and oral ulcers in the pharynx. It is associated with high fever and anorexia, which can lead to dehydration. Herpangina is also caused by a coxsackie virus and is associated with fever, anorexia, difficulty swallowing, sore throat, headache, abdominal pain, and vomiting. The small lesions associated with herpangina are generally discrete pinpoint grayish vesicles or ulcers appear on the tonsillar fauces, soft palate, and uvula ([Simões, 2016](#)). After a few more days, they disappear and the temperature returns to normal. There are generally no complications.

Children need a bland, soft diet or nonirritating liquids when they have the mouth lesions. Analgesia with acetaminophen (Tylenol) dosed at 10 mg/kg/dose to 15 mg/kg/dose every 4 to 6 hours but no more than five doses per day is important prior to feeding the child. If a child is hospitalized, follow contact precautions for the duration of the illness in addition to standard infection precautions.

### **Poliovirus Infections: Poliomyelitis (Infantile Paralysis)**

- Causative agent: poliovirus
- Incubation period: Nonparalytic polio—3 to 6 days. Paralytic polio is commonly 7 to 21 days with a range of 3 to 35 days.
- Period of communicability: greatest shortly before and after onset of clinical symptoms, when virus is present in the throat (1 to 2 weeks after the onset of illness and in feces (3 to 6 weeks); however, the virus is contagious as long as it is present in the feces.
- Mode of transmission: respiratory secretions and feces ([AAP, 2015](#))
- Immunity: Contracting the disease causes active immunity against the one strain of virus causing the illness.
- Active artificial immunity: inactivated polio virus (IPV) vaccine
- Passive artificial immunity: none

The last outbreak of polio caused by a wild polio virus in the United States was in 1979 ([CDC, 2016g](#)). From 1980 to 1997, the cases of polio in the United States were acquired through the use of the live attenuated trivalent (three strains) oral vaccine. In 1997, the United States changed to using the inactivated vaccine to prevent any additional cases of polio ([CDC, 2016g](#)). The illness may be caused by any of the three

strains of poliovirus.

## Assessment

It is important to recognize that 72% of infections with the polio virus do not produce a paralysis and is asymptomatic. A nonspecific fever with a sore throat occurs in approximately 24% of children infected with polio. This means that only 4% of children develop more symptoms after the poliovirus enters the child's gastrointestinal tract, where it multiplies. The symptoms of paralytic polio include fever, headache, nausea, vomiting, abdominal pain, constipation, and malaise initially followed by a period of no symptoms. Less than 1% will go on to paralysis with areflexia and bulbar symptoms such as difficulty swallowing and respiratory muscle involvement (AAP, 2015). Sensation remains intact and the disease is a motor paralysis.

In 25% to 40% of patients, a postpolio syndrome can occur 15 to 40 years after polio infection, presenting as weakness and pain affecting the muscles and joints that were most affected with the original infection.

## Therapeutic Management

Treatment for nonparalytic poliomyelitis is bed rest with antipyretics. There is no antiviral known to treat any form of polio. Supportive care is given depending on symptoms. If the respiratory muscles are involved, long-term ventilation may be necessary. Physical therapy is needed to prevent contracture and promote strength during the recovery period.

## VIRAL INFECTIONS OF THE INTEGUMENTARY SYSTEM

Viral infections of the skin include herpes infections and warts (verrucae).

### Herpesvirus Infections

Herpesviruses (HSV) infections are common, potentially life threatening, and are caused by both HSV-1 and HSV-2 (James & Kimberlin, 2015). They can be found as primary mucocutaneous infection, an acute infection of the ganglia, or in a latent form, reactivated form or a recurrent infection. They are responsible for mucocutaneous lesions in children and adolescents that can occur anywhere on the skin. HSV-1 is more commonly found acutely in the oral region as herpetic gingivostomatitis and in the chronic recurrent form as herpes labialis. HSV-2 is more commonly found in the genital region as both an acute or recurrent infection. However, both viruses can be found in either location (Stanberry, 2016).

- Causative agent: herpes simplex, type 1 or type 2 virus
- Incubation period: 2 days to 2 weeks (AAP, 2015), average of 6 days (Simos, Flynn, Peicuch, et al., 2009)
- Period of communicability: greatest early in the course of the infection
- Mode of transmission: direct contact with persons with active lesions or persons

shedding the virus asymptotically

- Immunity: Herpes viruses like VZV have viral latency, so patients can have recurrent infections. There is currently no vaccine available ([Stanberry, 2016](#)).

### Acute Herpetic Gingivostomatitis

Acute herpetic gingivostomatitis is most common in children from 6 months to 5 years but can be seen in older children. In the initial infection, there is a sudden onset of pain, drooling, anorexia, and a significant fever as high as 105°F (40.6°C) ([Stanberry, 2016](#)). Their gumline is also swollen, reddened, and bleeds easily. White, shallow ulcers with red borders appear on the gum, lips, buccal mucosa, tongue, palate, perioral skin, and, less commonly, on the tonsillar pillars. The anterior cervical lymph nodes are usually enlarged and tender. The disease runs its course in 5 to 14 days.

Children will need an antipyretic to reduce fever and soft, nonirritating, acid-free foods to reduce irritation. Popsicles, ice milk, and Jell-O are soothing against inflamed mucous membranes. Oral acyclovir can be used to shorten the course of illness. Use contact precautions with hospitalized children to avoid contact with lesions. Although usually mild, the disease can become serious, especially in infants and children where the lack of fluid intake leads to dehydration.

### Herpes Simplex (Herpes Labialis)

Herpes labialis, popularly known as a cold sore or fever blister, is the recurrent form of HSV. In the case of herpes labialis, the HSV remains dormant in the ganglia of the trigeminal or fifth cranial nerve. Herpes simplex typically appears as a cluster of painful, grouped vesicles surrounded by an erythematous base on the border of the lips (vermillion border) ([Stanberry, 2016](#)). Initially, there is tingling, burning, itching, or pain for about 6 to 48 hours prior to the eruption of erythematous papules that rapidly progress to grouped vesicles. Complete healing without scar formation occurs within 6 to 10 days ([Stanberry, 2016](#)). Although topical acyclovir (Zovirax cream/ointment) has mild effectiveness in shortening the course of herpes labialis, oral acyclovir reaches a higher plasma concentration. Children may feel conspicuous about the appearance of the lesion and need reassurance that these lesions will go away and are not as conspicuous as they think.

### Acute Herpetic Vulvovaginitis (Genital Herpes)

Genital herpes is caused primarily by HSV type 2, which remains dormant in the ganglia of the sacral nerves. Genital herpes is spread primarily by sexual contact and is discussed in [Chapter 47](#) with other sexually transmitted infections. The occurrence of HSV in children is suggestive of child sexual maltreatment and should be reported ([Frieden, Jaffe, Cono, et al., 2014](#)).

### Warts (Verrucae)

There are over 100 types of human papillomaviruses (HPV), which are members of the virus family *Papillomaviridae* (Moscicki, 2016). The papillomavirus most commonly cause skin manifestation but can cause both genital and oral malignancies (Moscicki, 2016). HPV infect the conjunctiva, oral cavity, respiratory tract, genital tract, and the skin (Gerlero & Hernández-Martín, 2016). The incubation period varies from 3 weeks to 8 months, but the average is 3 months (Gerlero & Hernández-Martín, 2016). The mode of transmission is likely direct contact as there is little evidence to suggest indirect transmission by fomites (Moscicki, 2016).

Warts appear as flesh-colored, dirty-appearing papules that generally occur on the dorsal surface of the hands. Plantar warts on the soles of the feet can be differentiated from calluses in that they obliterate skin lines as they grow and are generally painful.

Warts on the hands or the face generally are removed if they are cosmetically unattractive to children. Plantar warts may have to be removed due to pain. There are several treatment options including over-the-counter preparations with a salicylic acid solution. Carbon dioxide snow, liquid nitrogen, electrodesiccation, laser, and cryotherapy are other methods also available for removal, but these methods are painful and rarely necessary (Gerlero & Hernández-Martín, 2016).

The myth that people catch warts from frogs or toads needs to be dispelled. Anogenital warts in young children, like HSV lesions, can be a mark of sexual maltreatment. Certain strains of HPV can cause vaginal, vulvar, and cervical cancer in women, penile cancer in men, as well as anal or oropharyngeal cancers in both sexes. The Gardasil 9 vaccine is protective against cancer caused by nine strains of HPV (6, 11, 16, 18, 31, 33, 45, 52, and 58). It is recommended for all children at 11 to 12 years of age as well as males from 13 to 21 years and females from 13 to 26 years who have not yet received the vaccine (Petrosky, Bocchini, Hariri, et al., 2015).

## VIRUSES CAUSING CENTRAL NERVOUS SYSTEM DISEASES

Viruses are the causative agent for central nervous system disorders such as rabies, encephalitis, and meningitis. Encephalitis and meningitis are discussed in [Chapter 49](#).

### Rabies

Rabies causes an acute encephalitis that is fatal and caused by *Lyssavirus* genus, which includes rabies virus (RABV) (Caicedo, Paez, Kuzmin, et al., 2015). RABV infections number over 59,000 people worldwide (Hampson, Coudeville, Lembo, et al., 2015) and is most common in poor countries. The domestic dog causes most rabies worldwide due to lack of vaccination (Hampson et al., 2015).

- Causative agent: RABV
- Incubation period: average is 1 to 3 months but can range from days to years
- Period of communicability: 3 to 5 days before the onset of symptoms through the course of the disease
- Mode of transmission: the bite of a rabid animal; rarely through saliva from an

infected animal being transferred to an open lesion on a child's skin

- Immunity: Contracting the disease apparently offers active immunity, but few people have ever survived the illness to verify this.
- Active artificial immunity: human diploid cell rabies vaccine
- Passive artificial immunity: rabies immune globulin (RIG) (AAP, 2015)

Any warm-blooded animal can contract rabies. Although worldwide unvaccinated dogs are the most common source of RABV infection, in the United States the most common cause is the bat (AAP, 2015). Dogs bite children more often, and therefore, more children are treated for possible rabies due to dog bites. Any mammal can be infected with the virus and unprovoked attacks are suggestive of a rabid animal (AAP, 2015). Rodents (squirrels, mice, or rats) seldom carry the RABV virus. Infection with RABV causes a rapidly progressive central nervous system infection.

## Assessment

After the long incubation period of the virus, children begin to show prodromal signs of malaise, fever, anorexia, nausea, sore throat, drowsiness, irritability, and restlessness. The clinical manifestations include anxiety, radicular pain pruritus, hydrophobia, dysautonomia, and in some patients, paralysis. The disease almost always leads to death (AAP, 2015) with a history of only four survivors of rabies (Caicedo et al., 2015). When children try to drink, they experience violent contractions of the muscles of the mouth leading to drooling of saliva. This phenomenon gives the disease its former name: hydrophobia ("water fear") (Jackson, 2016). As symptoms progress, children will become comatose. Peripheral vascular collapse and death can follow as quickly as 5 or 6 days later.

## Therapeutic Management

Once the disease process begins, rabies is almost invariably fatal, so the key is prevention of the active process. A healthcare provider, paying close attention to the circumstances and kind of animal, should evaluate the child's animal bite. In taking a history from a child, it is important to avoid naming different kinds of animals. To gain a more accurate history, ask the child what the animal looked like or show pictures of different animals asking them to point to the one that bit them. Rabid animals will bite under unprovoked circumstances so this history is key. The child needs to be assured that they will not be punished if they provoked the bite. The immunity status of the animal is key in deciding whether treatment will be necessary. The healthcare provider must know if there have been rabid animals found in the community; however, if the bite seems unprovoked, rabies vaccine and RIG should be given. The decision to immunize and use prophylaxis should be done after contact with the local department of health and/or an infectious disease specialist. In cases where a bat has been present in the room of a child, the bite or scratch may be small and not evident. Therefore, postexposure prophylaxis may be indicated if the bat is in the room (AAP, 2015).

Following any bite or close exposure to bats, prophylaxis should be initiated as soon as possible and, if the animal is unknown, or suspected to have rabies, there should be no delay in prophylaxis treatment (AAP, 2015).

Prophylaxis is twofold. The child receives human rabies vaccine immediately along with the administration of RIG (20 IU/kg) into the area of the bite with the remainder of the RIG administered in an intramuscular (IM) injection. Following this day 0 administration of rabies vaccine and RIG, the rabies vaccine is given again on days 3, 7, and 14 (AAP, 2015; Rupprecht, Briggs, Brown, et al., 2010).

The immediate administration of RIG provides antibodies against the RABV while administering the rabies vaccine allows the child to begin additional antibody formation so that by the time the RABV from the bite begins to have an effect (2 to 6 weeks after the bite), the child has developed sufficient antibodies to combat it and prevent the illness.

## OTHER INFECTIONS TRANSMITTED BY ANIMAL VECTORS

Animal vectors can transmit viruses and bacteria to human hosts. For example, mice and rats are reservoirs of the bacteria *Leptospira*. The bacteria can be transmitted to humans by the infected animal's urine, and it can pass to humans via damaged skin or mucosa (Gomes-Solecki, Santecchia, & Werts, 2017). The transmission of viruses and bacteria by animal vectors is not uncommon, and it is important to take a careful travel history as well as a history of any exposure to animals.

### Hantavirus Pulmonary Syndrome Infection

The hantavirus is a member of the arbovirus group and can cause two different diseases—hantavirus pulmonary syndrome (HPS), with a mortality rate of 60%, and hemorrhagic fever with renal syndrome (HFRS), with a mortality rate of 12% (Jonsson, Figueiredo, & Vapalahti, 2010). The virus infects rodents. There are over 22 different types of hantavirus, divided into old world and new world viruses. The “new world” viruses started infecting humans in the United States in 1993 with the initial outbreak occurring in the four corners of the Southwest. This virus was different from those that had previously been recognized in other parts of the world and became known as HPS.

HPS has an incubation period between 1 to 6 weeks. In HPS, there is prodrome of no more than 5 days, characterized by fever, chills, cough, myalgia, gastrointestinal symptoms of diarrhea, and vomiting and headache (Jonsson et al., 2010). One to 3 days after the onset of respiratory symptoms, capillary leak develops in the lung resulting in pulmonary edema and hypoxemia after cough and dyspnea. Hypotension leads to cardiac dysfunction and subsequent death (Jonsson et al., 2010).

In contrast, HFRS has an incubation of 3 weeks with a range of 10 days to 6 weeks. The clinical manifestations depend on the type of hantavirus. There are usually five phases: (a) febrile phase, (b) hypotension, (c) oliguria, (d) polyuria, and (e) convalescence (Jonsson et al., 2010).

At present, no antiviral medication immunotherapy or vaccines are approved for the treatment of hantavirus. The treatment is supportive, but prevention is key. Rodent control is the best prevention, and rodents should be kept out of the house. Campers need to avoid rodent-infested areas.

### **QSEN Checkpoint Question 43.4**

#### **QUALITY IMPROVEMENT**

Jack's sister is home with "mono," or infectious mononucleosis. In the event that she requires hospital care, assessment protocols should emphasize what action?

- a. Lymph nodes should be palpated before being percussed.
- b. The spleen should be evaluated by nontouching maneuvers using the scratch test.
- c. Lymph nodes should be assessed by Doppler.
- d. Petechiae should be lightly massaged.

*Look in Appendix A for the best answer and rationale.*

### **Zika Virus Disease**

The yellow fever mosquito is one of the world's most deadly animals, causing yellow fever, Zika virus, dengue, and chikungunya viral infections. These mosquitos lay their eggs in any containers that can hold water, including cups, tree holes, bowls, discarded tires, flower pots, cans, and clogged rain gutters. They are daytime biters with peak feeding activity 2 hours before sunrise and 2 hours after sunset (Higgs & Vanlandingham, 2016). *Aedes aegypti* is the main vector, but transmission of the virus via the *Aedes albopictus* appears possible. The Zika virus was first known to cause infection in 1947 when it was isolated in Uganda, but there have been several outbreaks recently across the globe. Nonmosquito transmission has been known to occur via sexual contact, blood products, and from mother to fetus. The relationship of microcephaly to active Zika viral infection in pregnant women has been established, and the CDC recommends testing of all pregnant women who have traveled to counties with active infection. Because Zika virus is new, the long-term sequelae is yet to be determined (Karwowski, Nelson, Staples, et al., 2016).

The incubation period is thought to be less than 1 week (Petersen, Jamieson, Powers, et al., 2016). The symptoms of Zika virus infection include fever, arthralgia, conjunctivitis, eye pain, myalgia, rash, and headache (Karwowski et al., 2016). Guillain-Barré syndrome is now a rare complication of Zika infection (Petersen et al., 2016).

To prevent infection with Zika virus, the nurse should screen potential blood donors and advise the use of condoms after travel to countries with known Zika viral infections. Stress that the use of insect repellants with a maximum of 30% *N, N*-diethyl-met-toluamide (DEET) for infants and children can help prevent mosquito bites, but to avoid over use of DEET; the use of products that combine DEET with a sunscreen should not

be used in children ([CDC, 2015b](#)).

## West Nile Virus Disease

West Nile virus is the most common arboviral disease in the United States ([Lindsey, Lehman, Staples, et al., 2015](#)). The transmission of arbovirus occurs between arthropods and their hosts, which are usually small mammals or birds. Infected mosquitoes or ticks transmit the virus to humans, with person-to-person transmission occurring from organ transplant or blood transmission.

The majority of clinical disease is asymptomatic. The symptomatic manifestations include fever, arthralgia, and myalgia. The neuroinvasive form of West Nile virus is uncommon and includes encephalitis, meningitis, and acute flaccid paralysis. The symptoms of encephalitis and meningitis include mental confusion, lethargy, photophobia, headache, muscle weakness, and coma, leading to death. Encephalitis or meningitis may not be present in cases of acute flaccid paralysis. West Nile virus disease is diagnosed when antibodies to the virus are recovered from blood serum. There is no evidence-based therapy for the disorder, except for supportive measures to maintain function; however, ribavirin and intravenous immunoglobulin (IVIG) have been used to reduce symptoms.

Commercially available West Nile virus–specific immunoglobulin M (IgM) antibodies in either serum or cerebrospinal fluid is the current way to establish the diagnosis. The antibodies can be found 3 to 8 days after illness onset and persists for 1 to 3 months at the minimum. Therefore, positive results may reflect past rather than current infection. If the testing was done before 8 days of illness, there may be an absence of West Nile virus–specific IgM antibodies and repeat testing may be needed.

There is also currently no vaccine for this condition. It is important to follow the guidelines for mosquito bite prevention previously discussed.

## OTHER VIRAL INFECTIONS

Viruses are the most common causes of infectious diseases in children. There can be isolated outbreaks of viral infections in a community even if there are vaccines for the virus available. This may be due to lack of vaccination or waning immunity.

### Mumps (Epidemic Parotitis)

- Causative agent: mumps virus
- Incubation period: usually 16 to 18 days with an outside range from 12 to 25 days ([AAP, 2015](#))
- Period of communicability: communicable for 5 days from onset of the swollen parotid gland ([CDC, 2016e](#))
- Mode of transmission: direct contact with respiratory droplets ([AAP, 2015](#); [Rubin, Kennedy, & Poland, 2016](#))
- Immunity: Contracting the disease gives lasting natural immunity.

- Active artificial immunity: attenuated live mumps vaccine in combination with measles and rubella (MMR)
- Passive artificial immunity: mumps immune globulin

## Assessment

Mumps is one of the oldest infectious diseases and is now uncommon in the United States due to the MMR vaccine (Rubin et al., 2016). Outbreaks have occurred in recent years on college campuses and in religious communities where immunizations are spotty (CDC, 2016e). If the disease occurs, it begins with fever, headache, anorexia, and malaise. About one third of infections are subclinical, and therefore, no swelling of the parotid gland is noted. Humans are the only host for the mumps virus.

Mumps cause a parotid gland enlargement without skin erythema in the majority of patients. This enlargement will obscure the angle of jaw and therefore is helpful from differentiating it from submaxillary adenitis (inflammation of lymph nodes). The best method of differentiation is to place a hand along the child's jawline. If the major amount of swelling is above the hand, it is probably mumps (Fig. 43.9). Fever typically occurs early and is accompanied by anorexia and inability to open the mouth (trismus). The swelling will resolve in 5 to 7 days (Alter et al., 2015).

**Figure 43.9** Epidemic parotitis. (A) The parotid gland is located just in front of the ear. (B) A boy with parotitis (mumps). (© Morris Huberland/Science Source/Photo Researchers.)

Boys may also develop testicular pain and swelling (orchitis) after puberty, and this complication is more likely as an adult or adolescent. Sterility is a rare complication of the orchitis.

### Concept Mastery Alert

In a patient with mumps, most of the associated swelling occurs above the jawline. If

the swelling is primarily below the jawline, the patient likely has adenitis.

## Therapeutic Management

Supportive care is key including pain control and fever control with acetaminophen or nonsteroidal anti-inflammatory and a soft bland diet. If a child is hospitalized, follow droplet precautions in addition to standard infection precautions (Alter et al., 2015).

Some parents worry that because their child had swelling only on one side, their child will develop mumps on the opposite side in the future. One attack of mumps gives lasting immunity, so the child will not contract the disease again. If a child does appear to have contracted mumps twice, the diagnosis was probably confused with cervical adenitis at one occurrence.

### *QSEN Checkpoint Question 43.5*

#### **TEAMWORK & COLLABORATION**

A nurse on the care team calls off work because she's worried she has contracted mumps (infectious parotitis). Which of the following symptoms is most associated with mumps?

- a. A productive cough and a severe runny nose
- b. Pronounced swelling behind both of her ears
- c. Swelling above the jaw line in front of the ear, obscuring the jaw line
- d. Adenoid tonsils are reddened and swollen and hurt

*Look in Appendix A for the best answer and rationale.*

## **Epstein–Barr Infectious Mononucleosis**

- Causative agent: Epstein–Barr virus (EBV)
- Incubation period: Incubation period in adults and adolescents is 30 to 50 days with a shorter incubation period in children (Pinninti et al., 2016)
- Period of communicability: occurs during direct contact with saliva by individuals who are symptomatic or asymptomatic but shedding the virus (Pinninti et al., 2016)
- Mode of transmission: direct contact and through blood transfusions
- Immunity: Most of the time, one episode gives lasting immunity; however, EBV is latent and can reactivate and cause a milder clinical presentation. No vaccination is available.

Infectious mononucleosis is the most common manifestation of Epstein–Barr infection (AAP, 2015). It is also known as glandular fever or because it was first discovered as a disease that is transferred readily from one person to another by kissing, the *kissing disease* due the presence of the virus in saliva. The highest incidence of EBV is between 15 and 24 years old, but 50% of children seroconvert before 5 years of age (Pinninti et al., 2016). Central nervous system manifestations include meningitis,

encephalitis, cranial nerve palsies, myelitis, transverse myelitis, Guillain-Barré syndrome, and Alice in Wonderland syndrome. Hematologic manifestations include agranulocytosis, hematologic complications, splenic rupture, hemolytic anemia, thrombocytosis, and hemophagocytic lymphohistiocytosis.

### Assessment

The classic symptoms of EBV infection include several days of prodromal symptoms of anorexia, chills, and malaise with fever in 90% and enlargement of the cervical nodes and tonsils. Pharyngitis with palatal petechial and periorbital edema and found with splenomegaly is present in about 5% (Pinninti et al., 2016) (Fig. 43.10). If the mesenteric lymph nodes enlarge, children may experience abdominal pain so sharp that it simulates appendicitis.

**Figure 43.10** The appearance of the tonsils in a child with infectious mononucleosis. Note the degree of erythema, enlargement, and purulent covering. (© Dr. P. Marazzi/SPL/Science Source/Photo Researchers.)

On a blood smear, atypical lymphocytosis is seen and a total elevation of the lymphocyte count peaks between 2 and 3 weeks of illness (Pinninti et al., 2016). A positive Monospot test, which can be reported in minutes, or a heterophile antibody test is positive in 80% of children older than 4 years of age and are more accurate in older adolescents. The Monospot or heterophile antibody tests in children less than 4 years tend to be negative. There are several antibodies against the EBV that will be positive at different times during the disease and a positive IgM antibody against viral capsid antigen (VCA) is diagnostic of primary infection.

### Therapeutic Management

Children with infectious mononucleosis should be treated for pain and fever with acetaminophen or nonsteroidal anti-inflammatory agents. The child should be encouraged to rest when fatigued, and all contact sports should be avoided for at least 4

weeks after the onset of infection (AAP, 2015; Pinninti et al., 2016).

It can take 3 months for the child to return to his or her baseline fitness. The nurse should stress fluid intake with cool, nonacidic fluids and soft, nonirritating foods. It can interfere with the completion of school work and normal activities. The nurse can support the child or adolescent by listening to them about talk about the effect this illness has on their lives.

## Bacterial Infections

Bacteria are independent, living organisms with a nucleus that contains both DNA and RNA. They reproduce by fission, in which one cell enlarges and duplicates itself and then divides into two equal parts. They occur in three main shapes: spheres (cocci), rods (bacilli), and spirals (spirochetes).

Types of bacteria can be distinguished after they are fixed onto a laboratory slide and then stained. Bacteria that stain violet are said to be gram-positive organisms and those that stain red are gram-negative organisms. Those that cannot be decolorized with acid after being stained are acid-fast. Different bacteria from the same family can act differently. In the case of streptococcus, they have an M protein surrounding their cell wall. Some of the M protein produce pyogenic **exotoxins**, which are toxins that act as super antigens (Silva-Costa, Carriço, Ramirez, et al., 2014). When this happens, disease symptoms arise from the bacteria and the effect of the exotoxins on the body. Tetanus, botulism, exotoxin producing staphylococcus and streptococcus, and diphtheria are examples of diseases caused by the systemic spread of toxins produced by bacteria.

## STREPTOCOCCAL DISEASES

Streptococci, which are gram-positive organisms, are found normally in the respiratory, alimentary, and female genital tracts. There are more than 120 serotypes or genotypes of group A  $\beta$ -hemolytic streptococci or *Streptococcus pyogenes*. *S. pyogenes* or Lancefield group A streptococcus are responsible for mild infections like impetigo, tonsillitis, or scarlet fever; however, they can also produce severe infections such as toxic shock syndrome or necrotizing fasciitis (Silva-Costa et al., 2014). *S. pyogenes* ( $\beta$ -hemolytic streptococci, group A) is responsible for strep throat and scarlet fever, and this is treated due to the risk of nonsuppurative complications of rheumatic fever and glomerulonephritis. A  $\beta$ -hemolytic, group B streptococcal infection can be contracted from vaginal secretions at birth (see Chapter 26); when newborns become infected with this bacteria, they can die from sepsis, pneumonia, or meningitis.

The manifestations of group A streptococcal infections include erysipelas, cellulitis, pneumonia, endocarditis, pericarditis, osteomyelitis, sepsis, bacteremia, and toxic shock syndrome (Silva-Costa et al., 2014).

Streptococcal pharyngeal infections are discussed in Chapter 40 with other throat infections. Rheumatic fever and glomerulonephritis, conditions that may result as an autoimmune response to streptococci, are discussed in Chapters 41 and 46, respectively.

## Scarlet Fever

- Causative agent:  $\beta$ -hemolytic streptococci, group A
- Incubation period: 2 to 5 days for streptococcal pharyngitis (AAP, 2015)
- Period of communicability: greatest during acute phase of respiratory illness; 1 to 7 days
- Mode of transmission: direct contact from a person with the disease and large droplets, not fomites or household pets (AAP, 2015)
- Immunity: One episode of disease gives lasting immunity to scarlet fever toxin. No vaccination is available.

### Assessment

Scarlet fever occurs most commonly in school-age children, peaking in the 7- to 8-year-old age group (AAP, 2015). The incidence is highest in temperate climates, and the disease occurs usually in late autumn, winter, and early spring (AAP, 2015).

Symptoms of streptococcal pharyngitis begin abruptly and include fever, sore throat, headache, chills, a rapid pulse, and malaise. As the disease progresses, the production of exotoxins SpeA, SpeC, and SSA causes a rash that appears 12 to 48 hours after the onset of the pharyngeal symptoms (Silva-Costa et al., 2014).

The skin rash typically is red with pinpoint lesions that blanch on pressure and feel as rough as sandpaper (see Fig. 43.3). They tend to be densest on the trunk and very prominent in skin folds (Pastia's sign). The rash persists for approximately 1 week. It desquamates or peels off in fine flakes (AAP, 2015).

In addition to the rash, the tonsils appear inflamed and enlarged and are usually covered with white exudate. The palate may be covered with reddened punctiform (pinpoint) lesions and perhaps scattered petechiae. The tongue, during the first 2 days of the illness, is white and appears furry. By day 3, papillae enlarge and protrude through the white coat, giving the tongue a "white strawberry" appearance. By day 4 or 5, the white coat disappears and the prominent papillae of the tongue give it a "red strawberry" appearance. A "strawberry tongue" is a hallmark symptom of scarlet fever and helps to differentiate the disease from other rashes or pharyngeal infections. A positive rapid strep test or positive throat culture is the diagnostic test of choice.

### Therapeutic Management

Children with scarlet fever usually recover without sequela once penicillin is administered. Penicillin V is the drug of choice, but the American Heart Association guidelines and the Pediatric Infectious Disease Society guidelines all endorse orally administered once a day amoxicillin at 50 mg/kg up to 1,200 mg as a daily dose for 10 days (Lennon, Stewart, & Anderson, 2016; Shulman, Bisno, Clegg, et al., 2012; Wilson, Taubert, Gewitz, et al., 2007). IM penicillin G benzathine is an alternative therapy if there is a history of noncompliance. Children may need an analgesic and antipyretic, such as acetaminophen (Tylenol) or children's ibuprofen (Motrin) for pain and fever.

They need a soft or liquid diet until the pain from the pharyngitis improves. Comfort measures are important for the rash. Because the underlying cause of the illness is a streptococcal infection, a course of antibiotics is prescribed (AAP, 2015). Caution parents to give the full amount prescribed for the full course to prevent the complications of  $\beta$ -hemolytic, group A streptococcal infections (acute glomerulonephritis or rheumatic fever); however, poststreptococcal reactive arthritis can also occur (AAP, 2015). Box 43.5 describes a one of the disorders previously discussed (varicella) that presents with a rash.

## BOX 43.5

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR A CHILD WITH VARICELLA

Jack, a 10-year-old boy, was admitted to the hospital yesterday for appendicitis. This morning after surgery, he breaks out in varicella. “His sister is home with mono,” his mother tells you. “How could our family get two infections plus appendicitis all in 1 week?”

**Family Assessment:** Child has three siblings: a 16-year-old sister and two brothers, 6 years and 10 days old. Parents are migrant crop workers. Family moves yearly from Florida to Connecticut to follow crops. Mother rates finances as “We have no money.”

**Patient Assessment:** Multiple papular and vesicular lesions over the body centered on the trunk. Temperature: 103°F (39.5°C). There are several papular lesions on the palate and oral mucosa. Other physical examination findings within normal limits for postoperative course. Child upset and crying, saying, “I wish my mom was here to stay with me. I can’t even go to the playroom.” Mother usually visits once a day in the late afternoon.

**Nursing Diagnosis:** Social isolation related to required restrictions associated with infection control precautions

**Outcome Evaluation:** Child states reason for restrictions, identifies time when restrictions will be lifted, and expresses interest in activities proposed.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
-------------------------	------------	--------------	-----------	------------------

#### *Activities of Daily Living, Including Safety*

Nurse	Assess what child understands about how	Review the reason for restrictions and infection	Child may associate precautions and restrictions with	Child states he understands reason for
-------	---	--	---	--

	communicable diseases are spread.	control precautions. Institute droplet precautions.	feelings of being punished. Droplet precautions help reduce the spread of the disease.	isolation; cooperates to maintain infection precautions.
Nurse	Assess what play activity would provide stimulation.	Visit the child frequently and provide him with opportunities for therapeutic play.	Frequent visits help to decrease feelings of being alone. Therapeutic play helps the child deal with resentment about condition.	Child states that although he wants to go to playroom, he has found an enjoyable activity to occupy his time in his hospital room.

*Teamwork & Collaboration*

Nurse/primary healthcare provider	Determine whether hospital infection control committee is aware of contagious illness in a postoperative patient.	Consult with infection control members on the possibility that surgical personnel may have been exposed to varicella.	Varicella is contagious for 1 to 2 days prior to the outbreak of a rash (AAP, 2015).	Infection control officer states she is aware of possible spread of illness and the need for varicella vaccine for exposed unimmunized healthcare personnel and family members.
-----------------------------------	---	---	--	---

*Procedures/Medications for Quality Improvement*

Nurse	Determine whether child has ever had a reaction to	Begin acyclovir (Zovirax) therapy as prescribed.	Acyclovir is effective for varicella-zoster, the causative	Child's parents are contacted and report child
-------	--	--	--	--

	acyclovir.		organism of varicella.	has not had a previous reaction to acyclovir. Child should take oral acyclovir as prescribed.
Nurse	Ask child to rate pain of postoperative site and itchiness of rash on scale of 1 to 10.	Administer analgesia and antihistamine prescribed. Caution child that antihistamine may make him feel sleepy.	An antihistamine such as diphenhydramine (Benadryl) can greatly reduce the pruritus of a rash.	Child states the itchiness of rash and pain of operative site have decreased to tolerable levels.

*Nutrition*

Nurse/nutritionist	Assess what fluid child would find most appealing to drink.	Provide frequent oral fluids. When soft diet is begun (child is post-op appendicitis), provide soft foods.	Adequate fluid intake is important to prevent skin dryness, which increases discomfort. A soft or liquid diet is less irritating to the child's mouth.	Child identifies favorite fluid to drink; states he is able to eat soft foods even with mouth lesions
--------------------	---	--	--	---

*Patient-Centered Care*

Nurse/primary care provider	Determine whether other members of family will need a varicella vaccine.	Explain the purpose of varicella immunization for susceptible family members.	Because family members were near the child during the prodromal period, they are susceptible to also contracting the disease.	Parent identifies susceptible family members; she will get them immunized today.
-----------------------------	--	---	---	--

*Psychosocial/Spiritual/Emotional Needs*

Nurse	Assess whether child and parent understand the cause of scarlet fever.	Discuss that the spread of infectious diseases is not related to “good or bad” values.	Mother voiced she was concerned because two diseases happened to her child at the same time.	Mother and child state they understand diseases are caused by infectious organisms, not moral status.
-------	--	--	--	---

*Informatics for Seamless Healthcare Planning*

Nurse	Assess if parent is aware the child’s rash will be itchy for about 1 week.	Discuss possible measures the parent can take to reduce pruritus (e.g., loose clothing, cool compresses) and measures to reduce pain of sore throat (e.g., analgesic).	If children scratch pruritic lesions, they can cause a secondary infection. Mouth lesions interfere with comfort and an ability to eat well.	Parent states she understands common measures to reduce pruritus and will begin them.
-------	--	--	--	---

***QSEN Checkpoint Question 43.6***

**INFORMATICS**

Jack, who has varicella, is missing his school friends so is eager to return to school. When should the nurse inform the school nurse that it would be safe for Jack to return to school?

- a. Whenever he feels that he is strong enough
- b. When all the lesions have dried and there are no new lesions
- c. As soon as his fever is within normal range
- d. One week after he began the antibiotic

*Look in Appendix A for the best answer and rationale.*

**Impetigo**

- Causative agent:  $\beta$ -hemolytic streptococcus, group A or *S. aureus* including MRSA
- Incubation period: 7 to 10 days for impetigo (AAP, 2015)
- Period of communicability: from outbreak of lesions until lesions are healed
- Mode of transmission: direct contact with lesions
- Immunity: none

It is common to see several children in a family with identical impetigo lesions because it is spread by direct contact. An underlying scabies infection can cause impetigo due to infection from scratching with nails (Tasani, Tong, Andrews, et al., 2016).

### Assessment

Impetigo involves the top layer or epidermal layer of the skin and is generally characterized by honey-colored crusts with local erythema (Fig. 43.11). It is usually caused by either *S. aureus* or by group A hemolytic streptococci. The lesions are found most commonly on the face and extremities. They are often seen as secondary infections of insect bites or in children who have body piercings. If the impetigo is extensive, children may have local lymph node enlargement.

**Figure 43.11** Impetigo in a toddler. Note the honey-colored crust appearance of some of the lesions. (© Dr. P. Marazzi/SPL/Science Source/Photo Researchers.)

### Therapeutic Management

Localized disease is treated with mupirocin (Bactroban) ointment for 7 to 10 days (Box 43.6) or with retapamulin (Altabax) for children over 9 months twice a day (bid) for 5 days. The use of oral antibiotic that cover both staphylococcus and streptococcus is reserved for extensive impetigo.

#### BOX 43.6

### Nursing Care Planning Based on Responsibility for Pharmacology

#### MUPIROCIN (BACTROBAN)

**Classification:** Mupirocin is a topical antibiotic.

**Action:** Mupirocin is used to treat impetigo caused by *Staphylococcus aureus* and *Streptococcus pyogenes*.

**Pregnancy Risk Category: B**

**Dosage:** small amount applied three times a day to the affected areas for 10 days duration

**Possible Adverse Effects:** local irritation including erythema, dry skin, pruritus, burning, stinging (Taketomo, 2015)

**RETAPAMULIN OINTMENT 1% (ALTABAX)**

**Classification:** Retapamulin ointment 1% is a topical antibiotic.

**Action:** Retapamulin ointment 1% is used to treat impetigo caused by *S. aureus* and *S. pyogenes*.

**Pregnancy Risk Category: B**

**Dosage:** small amount applied twice times a day to the affected areas for 5 days duration

**Possible Adverse Effects:** local irritation including erythema, pruritus, burning, stinging (Taketomo, 2015)

**Nursing Implications**

- Advise parents to wash the lesions with soap and water and pat dry before applying ointment to soften crusts for better absorption.
- Caution parents that causative organisms are infectious by direct contact. Instruct them to wash their own hands before and after applying the ointment.
- Although the lesions may begin to improve before 10 days have elapsed, urge parents to continue to use the ointment to ensure eradication of the causative bacteria.
- Instruct parents to use caution if applying the ointment around the eyes because the ointment is irritating to the eyes.

Although rare, complications of rheumatic fever or acute glomerulonephritis may occur as a sequelae to impetigo.

**Cat-Scratch Disease**

- Causative agent: *Bartonella henselae* bacteria which is slow growing
- Incubation period: usually 1 to 2 weeks with a range of 7 to 60 days
- Period of communicability: unknown
- Mode of transmission: bite or scratch from more commonly a kitten rather than a cat
- Immunity: one episode of disease gives lasting immunity; no passive artificial immunity

Cat-scratch disease occurs most commonly in preschool children because children at that age play roughly with cats or pick them up and so receive scratches. At the time, the child contracts the disease, the cat does not appear ill.

The first symptom is a single skin papule or pustule at the site of inoculation which precedes the lymphadenopathy by 1 to 2 weeks (range of 5 to 50 days). A Bartonella-infected lymph node will usually resolve over a period of 4 to 6 weeks without treatment, and 10% to 25% will eventually drain spontaneously. Other forms of this disease includes Parinaud oculoglandular syndrome, which presents clinically with preauricular lymphadenitis and a follicular conjunctivitis as well as 1 to 2 weeks of fever with nonspecific symptoms. Less common presentations include neuroretinitis, endocarditis, osteolytic lesions, pneumonia, thrombocytopenia purpura, and encephalopathy (AAP, 2015).

The diagnostic test is an indirect immunofluorescent antibody (IFA) for antibody detection to serum antigens of the Bartonella species. Culture is difficult because it is such a slow-growing organism. Although enzyme immunoassays (EIAs) for antibody detection have been developed, more research is needed about their specificity and sensitivity.

Treatment is symptomatic, although azithromycin may be prescribed to decrease the lymph node size. With more severe disease, treatment with antimicrobials for several weeks will be initiated (AAP, 2015). Children may need an analgesic to relieve pain from the swollen lymph node.

Parents may ask if the cat should be destroyed. Because an attack of cat-scratch disease gives lifetime immunity and fewer than 10% of children scratched by the same cat contract cat-scratch disease, there is no need to destroy the cat for an act it may have seen as defending its safety.

## STAPHYLOCOCCAL INFECTIONS

Gram-positive *S. aureus* is the most common infecting organism for pyogenic infections of the skin as well as soft tissue (Gaensbauer & Todd, 2016). Staphylococci are normally found on the skin surface; therefore, they are commonly the organisms involved in skin infections (pyodermas). Because the organisms grow rapidly in cream foods that are not well refrigerated, such as potato salad or cream pies, they are also often the organisms involved in summer food poisoning episodes. Because food poisoning produces gastrointestinal symptoms, these infections are discussed in Chapter 45.

### Furunculosis/Carbunculosis (Abscesses or Boils)

A furuncle is a staphylococcal infection of a single hair follicle, and a carbuncle has multiple hair follicles with openings. A single or multiple yellow pustule forms at the site. There is localized redness, pain, and edema of the surrounding skin. As these enlarge, they may need an incision and drainage to drain the pus. The nurse should educate the family and child to never press an abscess to rupture the lesions. The use of antibiotics after an incision and drainage is controversial and depends on the size of carbuncle.

## Cellulitis

Cellulitis is staphylococcal inflammation of the dermal and subcutaneous layers of skin. It can occur anywhere on the body and there will be warmth, tenderness, and erythema at the area of cellulitis. The treatment is a systemic antibiotic that will cover both staphylococci and streptococci.

## Methicillin-Resistant *Staphylococcus aureus*

MRSA is a strain of staphylococcus that causes skin infections and has become resistant to common broad-spectrum antibiotics. When an infection occurs in a healthcare setting, it is referred to as health care–associated MRSA or HA-MRSA. If it occurs in a community setting, it is termed community-associated MRSA (CA-MRSA). Children with weakened immune systems are at greatest risk for contracting the infection. A recent retrospective research review found the rates of MRSA are falling in the pediatric population (Sutter, Milburn, Chukwuma, et al., 2016).

Vancomycin is the drug of choice for treatment of hospital-based lesions because the bacteria are still susceptible to its design. Clindamycin or trimethoprim-sulfamethoxazole is commonly used with community infections. Use strict standard infection precaution measures when caring for a child with an MRSA infection.

Prevention centered on nasal, skin, and household decolonization is important because most children with a *S. aureus* skin or soft tissue infection will have a recurrence within 1 year (Creech, Al-Zubeidi, & Fritz, 2015).

Good hand washing and reporting skin wounds to a healthcare provider before an open wound can become infected can help prevent these infections.

## Scalded Skin Disease

Staphylococcal scalded skin syndrome (Ritter disease) is a staphylococcal infection seen in infants. Newborns develop rough-textured skin and general erythema, especially on areas that encounter friction. Large bullae (vesicles) filled with clear fluid form. The epidermis separates in large sheets and desquamates, leaving a raw, red, glistening, and scalded-looking surface. This is called Nikolsky sign.

## OTHER BACTERIAL INFECTIONS

*S. aureus* and streptococcal infections are the most common bacterial infections in children, but other bacteria are also responsible for infections in pediatric patients. Although vaccines are available to protect against *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Clostridium tetani*, and diphtheria, children can still get infections with other serotypes due to lack of vaccination, waning immunity, or be infected with a serotype that vaccines do not protect against.

## Diphtheria

- Causative agent: *Corynebacterium diphtheriae* (Klebs–Löffler bacillus)
- Incubation period: 2 to 5 days with a range of 1 to 10 days (AAP, 2015)
- Period of communicability: In untreated persons, the organism is contagious from nares, throat, skin, and eyes for 2 to 6 weeks following infection; 48 hours after initiation of antibiotics in treated children and adults.
- Mode of transmission: direct contact or indirect contact droplets
- Immunity: Contracting the disease gives lasting natural immunity.
- Active artificial immunity: diphtheria toxin given as part of diphtheria, tetanus, and pertussis (DTaP) vaccine
- Passive artificial immunity: diphtheria antitoxin

### Assessment

Diphtheria is a rare illness due to available immunizations with only 2 cases in the United States since 2004 and under 8,000 cases reported to WHO worldwide (CDC, 2016a). Diphtheria bacilli invade and grow in the nasopharynx of children and produce an exotoxin that causes massive cell necrosis and inflammation. The endotoxin promotes bacilli growth and causes the infected cells form a characteristic gray membrane on the nasopharynx. This may extend up into the nose and down into the major bronchi, causing a purulent nasal discharge and a brassy cough. The toxin is absorbed from the membrane surface and spreads systemically by the bloodstream to affect major organs, such as the heart and nervous system. If untreated, myocarditis with heart failure and conduction disturbances may occur. Central nervous system involvement can include severe neuritis with paralysis of the diaphragm and pharyngeal and laryngeal muscles. Diphtheria can also form skin lesions aside from the usual presentation of respiratory infections. As a result, the diagnosis of diphtheria is made based on clinical appearance and culture from the nose, throat, or any mucosal or cutaneous lesion, and it must be placed on special media so the lab must be notified that there is a suspicion of diphtheria bacilli (AAP, 2015).

### Therapeutic Management

Treatment involves a single dose of equine antitoxin based on clinical suspicion, and this can be obtained through the CDC (AAP, 2015). In addition, children are given penicillin or erythromycin intravenously. Complete bed rest is crucial during the acute stage of the illness. Droplet precautions must be followed until cultures are negative. Children need careful observation at all times to prevent airway obstruction. If obstruction occurs, endotracheal intubation may be necessary.

Due to the vaccine, the disease is almost extinct, but in cases of travel, this disease should be considered in a sick child with a classic gray membrane on the tonsils. Prompt recognition and treatment are necessary to avoid death.

### Whooping Cough (Pertussis)

- Causative agent: *Bordetella pertussis*
- Incubation period: 5 to 21 days
- Mode of transmission: highly contagious by direct or indirect contact
- Period of communicability: greatest in catarrhal (respiratory illness) stage; eliminates contagiousness within 5 to 7 days of treatment, but it continues for weeks in the untreated patient (Gabutti, Azzari, Bonanni, et al., 2015)
- Immunity: contracting the disease offers lasting natural immunity
- Active artificial immunity: pertussis vaccine given as part of DTaP vaccine
- Passive artificial immunity: pertussis immune serum globulin

Pertussis has been increasing in the United States despite an active vaccine program (Faulkner, Skoff, Tondella, et al., 2016). This is due to healthcare providers' awareness, improved diagnostic lab tests, waning immunity from the acellular vaccine, and decreases in immunization rates in certain parts of the United States (Faulkner et al., 2016).

## Assessment

The disease can primarily manifest as a mild rhinitis with a mild cough to persistent cough illness or to the classic pertussis disease. Classic pertussis manifests itself in three steps: the catarrhal stage, the paroxysmal stage, and the convalescent stage. The **catarrhal stage** begins with upper respiratory symptoms such as coryza, sneezing, lacrimation, cough, and a low-grade fever, symptoms subtle enough they may at first be mistaken for those of a common cold. This first period lasts 1 to 2 weeks.

The paroxysmal stage lasts from 2 to 6 weeks (Long, 2016). During this time, the cough changes from a mild one to paroxysmal, involving 5 to 10 short, rapid coughs, followed by a rapid inspiration, which causes the hallmark “whoop” or high-pitched crowing sound of whooping cough. Children are in obvious distress while coughing. They may become cyanotic or red faced, and their nose may drain thick, tenacious mucus. They often vomit after a paroxysm of coughing, and they feel exhausted afterward from the effort. Immunized children and adolescents have shortened phases in the classic presentation.

During the convalescent stage, there is a gradual cessation of the coughing and vomiting.

Pertussis is diagnosed by its striking symptoms, although in children younger than 6 months of age, the “whoop” of the cough may be absent, making it more difficult to diagnose. Current diagnostics available include culture, direct fluorescent antibody (DFA) testing, polymerase chain reactions (PCR), and serology; however, PCR is the primary method of diagnosis early in the disease with serology more commonly used later in the disease and in adults (Faulkner et al., 2016; Heininger, 2012). The serology tests are poorly standardized from lab to lab (Heininger, 2012). The WBC count, particularly the lymphocyte count, is markedly increased to as high as 20,000 to 30,000/mm<sup>3</sup> (normal levels are 5,000 to 10,000/mm<sup>3</sup>).

## Therapeutic Management

Infants younger than 3 months with pertussis are generally admitted to the hospital for at least 48 hours to see how the disease course is progressing and to monitor for complications from paroxysms, particularly nutritional intake and oxygen levels (Long, 2016). The child may need oxygen if the pertussis is severe. The family must keep children with pertussis secluded from environmental factors, such as cigarette smoke and dust, and to avoid strenuous activities because these initiate coughing episodes. Nutrition may become a problem if the child is constantly coughing and vomiting. As a rule, frequent small meals are vomited less than larger meals and so should be encouraged.

A full 10-day course of erythromycin or azithromycin may be prescribed because these drugs have the potential to shorten the period of communicability and may shorten the duration of symptoms. Droplet precautions are used until 5 days after a child starts antibiotic therapy. Complications of pertussis include alkalosis and dehydration caused by vomiting and pneumonia, atelectasis, or emphysema from plugged bronchioles. Epistaxis, subconjunctival and subarachnoid bleeding, or seizures from asphyxia as a result of severe paroxysms of coughing may also occur. Infants with pertussis may be admitted to a healthcare facility for observation because they become dehydrated or may have such tenacious secretions that they need airway suction. For safety, place an intercom in the infant's room so you can identify severe coughing even when not in the room.

## Prevention

The current recommendation is to immunize the pregnant woman from 27 weeks to 36 weeks of gestation to maximize maternal antibody transfer to the fetus and reduce the risk of pertussis to the newborn (Kroger, 2015). Cohorting of young infants and making sure that all caretakers are immunized is another method of risk reduction to the young infant. All children should be immunized in infancy with DTaP and a booster dose given at 11 to 12 years of age (Kroger, 2015).

### *What If... 43.2*

**An adolescent who has pertussis vomits after an episode of coughing. Should the nurse urge him to try to eat again immediately, or would he be too nauseated to do so?**

## Anthrax

- Causative agent: *Bacillus anthracis*, a bacteria
- Incubation period: 1 to 7 days (inhalational), 1 to 12 days (cutaneous), 1 to 7 days (gastrointestinal)

- Mode of transmission: originally contracted from contact with the feces of infected cows or sheep; not transmissible from person to person
- Types of immunity: unstudied
  - Active artificial immunity: At present, the anthrax vaccine is not used in children but is available for adults 18 to 65 years of age who work with anthrax in the lab, certain vets who handle animals or animal products contaminated with anthrax, and only some members of the military (CDC, 2016i).
  - Passive artificial immunity: not available

Anthrax is an acute infectious disease that is contracted from exposure to the anthrax bacteria or its spores. As the organism grows inside the human body, a toxin is produced that causes the bulk of the symptoms. Children may present with any of the three clinical forms: cutaneous, inhalational, or gastrointestinal.

Inhalational anthrax has a mortality rate of over 90%. It begins with a brief prodromal period of flulike symptoms, followed shortly by dyspnea, severe systemic shock, and marked evidence of mediastinal widening and pleural effusion on X-ray. Because it can be fatal and spreads through coughing, anthrax has been proposed as bacteria that could be used in bioterrorism (AAP, 2015).

Cutaneous anthrax is characterized by a skin lesion that begins as a papule and then passes through a vesicle stage, to a painless depressed black eschar. Fever, malaise, headache, and regional swollen lymph nodes may accompany the skin lesion. The mortality of cutaneous anthrax is as low as 1% with antibiotic therapy.

Gastrointestinal anthrax is contracted by eating undercooked meat infected with the organism. The child develops severe abdominal pain, fever, bloody diarrhea, and **septicemia** (blood infection). The mortality rate for this form is about 25%.

If exposed to anthrax, prophylaxis with ciprofloxacin (Cipro) for those older than 18 years of age and doxycycline for younger patients are the drugs of choice. Drug therapy is continued for 60 days because of the potential persistence of and difficulty in killing spores.

## Tetanus (Lockjaw)

- Causative agent: *C. tetani*
- Incubation period: 3 days to 3 weeks
- Period of communicability: none
- Mode of transmission: direct or indirect contamination of a closed wound
- Immunity: development of the disease gives lasting natural immunity
- Active artificial immunity: tetanus toxoid contained in DTaP vaccine
- Passive artificial immunity: TIG

Tetanus occurs worldwide causing an acute, spastic paralytic illness caused by neurotoxin produced by *Clostridium* (Arnon, 2016). It is a highly fatal disease if untreated and is caused by an anaerobic, spore-forming bacillus found in soil and the excretions of animals. It enters the body through an open wound. If the wound is deep,

such as a stab wound, where the distal end of the wound is shut off from an oxygen source, tetanus bacilli begin to reproduce. The organism may also enter through a burn site, which crusts, thus creating an anaerobic environment. As the bacilli grow, they produce exotoxins that cause the disease symptoms by affecting the motor nuclei of the central nervous system (Arnon, 2016). The onset of the disease occurs gradually over 1 to 7 days with severe muscle spasm stimulated by external stimuli and autonomic dysfunction causing arrhythmias, tachycardia, and diaphoresis (AAP, 2015).

The entrance site of the bacillus does not appear infected (no pus or reddened area is present unless a secondary infection also exists). After the incubation period, the exotoxins have developed to such an extent, however, that they are capable of disrupting the nervous system. In the United States, most children are vaccinated against tetanus. In developing countries, it continues to have a high incidence, caused by infection of an entry point such as the umbilical cord at birth (AAP, 2015).

### Assessment

The first symptoms that are noticeable are stiffness of the neck and jaw (lockjaw). Within 24 to 48 hours, muscular rigidity of the trunk and extremities develops. The back becomes arched (opisthotonos), the abdominal muscles are stiff and board-like, and the face assumes an unusual appearance, with wrinkling of the forehead and distortion of the corners of the mouth (a “sardonic grin” sign). Any stimulation, such as a sudden noise, a bright light, or a touch, causes painful, paroxysmal spasms. The sensorium is clear throughout the course of the disease, so the child is aware of the pain associated with the muscle spasms. As these spasms begin to include the larynx, respiratory obstruction and death by asphyxiation can occur.

### Therapeutic Management

A child needs to be cared for in a quiet, stimulation-free room with total parenteral nutrition, sedation, and a muscle relaxant to prevent aspiration from muscle spasms. If the wound is filled with necrotic tissue, it may be debrided to ensure no secondary infections arise. The first line of treatment is human tetanus immune globulin (TIG) with parenteral penicillin G or oral or intravenous metronidazole (Flagyl) administration to decrease the vegetative forms of *C. tetani*. A child may need to be intubated and mechanical ventilation begun to maintain respiratory function.

### Prevention

Tetanus is a serious disease, but it can be prevented through active immunization and suitable booster immunizations. Children routinely receive tetanus immunization as part of routine DTaP immunization with a booster dose at school age; thereafter, they should receive a booster dose every 10 years. At the time of a wound, the wound site should be cleaned well with soap and water and a suitable antiseptic. It should not be sutured but should be left open to heal by secondary intention to reduce the possibility of an

anaerobic pocket forming in the wound. If the child received basic immunization against tetanus and it has been fewer than 10 years since the last injection, no booster or antitoxin management is needed at the time of the wound.

If a child's immunization record cannot be obtained or is fewer than three doses, a child will be treated with a booster injection and TIG. The booster injection provides tetanus antigen to the child. If the child has received three or more DTaP, Td, or Tdap vaccines, and the wound is clean and it has been less than 10 years since the child received a vaccine, no immunization is needed; however, if the wound is dirty and it has been more than 5 years, then a Td is needed.

## Lyme Disease

- Causative agent: *Borrelia burgdorferi*, a spirochete
- Incubation period: 3 to 30 days
- Period of communicability: not communicable from one person to another
- Mode of transmission: deer tick
- Active artificial immunity: none available; Lyme vaccine discontinued
- Passive artificial immunity: immune globulin

Lyme disease is caused by a spirochete, *B. burgdorferi*, which is transmitted by a tick frequently carried on deer (Choi, Pyzocha, & Maurer, 2016). The disease is the most frequently reported vector-borne infection in the United States, occurring most often in the summer and early fall and on the east coast (it is named after the city in Connecticut where it was first identified). A vaccine for the disease is not currently available because the manufacturer ceased production in 2002 due to low demand (CDC, 2015c).

Almost immediately after a tick bite, an erythematous papule is noticeable at the site, which spreads over the next 3 to 30 days (the incubation period) to become a large, round ring with a raised swollen border (erythema chronicum migrans) (Fig. 43.12). This is followed by systemic involvement that can lead to cardiac, musculoskeletal, and neurologic symptoms. Cardiac involvement may be so severe that it includes heart block from atrioventricular conduction abnormalities. Neurologic symptoms commonly include stiff neck, headache, and cranial nerve palsy. Musculoskeletal symptoms include painful swollen arthritic joints, particularly in the knee.

**Figure 43.12** The rash of Lyme disease. (© Larry Mulvehill/Science Source/Photo Researchers.)

Amoxicillin is administered to symptomatic children less than 8 years old, whereas doxycycline is given to those older than 8 years of age. Encourage parents to inspect the skin of children who have been playing in wooded areas for tick bites to help identify the disorder before debilitating symptoms occur (CDC, 2016h). Other suggestions for avoiding Lyme disease are shown in [Box 43.7](#).

#### BOX 43.7

#### Nursing Care Planning to Empower a Family

##### TIPS FOR AVOIDING EXPOSURE TO LYME DISEASE

**Q.** Jack's father tells you, "My children love to play in the woods, but I'm so afraid they'll get Lyme disease. What can I do to protect them?"

**A.** Here are some suggestions to help reduce the risk of exposure:

- Wear protective clothing when hiking or playing in wooded areas, such as long sleeves, high necklines, and long slacks. Tuck bottom of slacks into socks or boots.
- Wear light-colored clothing so any tick present on clothing can be readily observed.
- Inspect the skin daily and thoroughly for ticks after hiking or playing in wooded areas.
- Remove any ticks found with tweezers placed at the head of the tick, pulling gently and steadily for several seconds. The tick mouth takes a while to release their hold.
- Report any area of inflammation that might be a tick bite to a healthcare provider for early diagnosis.

## Other Infectious Pathogens

### RICKETTSIAL DISEASES

Rickettsiae are organisms that resemble viruses both in size and in their inability to reproduce except inside the cells of a host organism. They reproduce by fission, however, as bacteria do; like bacteria, they are complete organisms containing both RNA and DNA. They multiply inside ticks, lice, mites, or fleas (arthropods) without causing disease. They are transmitted to humans through the bite or feces of the infected arthropod. An exception is Q fever, which is spread by droplet infection. All rickettsial diseases include fever, trigger an immune response, and almost all include a rash caused by rickettsial multiplication in the endothelial cells of small blood vessels.

#### *What If... 43.3*

**Jack's mother tells the nurse that she's always been afraid her children would contact Lyme disease because, in the winter, the family picks both limes and lemons in Florida. Can the nurse assure her Jack will never contract Lyme disease while in an orchard picking fruit?**

### Rocky Mountain Spotted Fever

- Causative agent: *Rickettsia rickettsii*
- Incubation period: 3 to 12 days
- Period of communicability: not communicable from one person to another
- Mode of transmission: wood, dog, or rabbit tick
- Active artificial immunity: Rocky Mountain spotted fever (RMSF) vaccine is not available.

RMSF is transmitted by ticks and is a common rickettsial disease seen in the United States (Biggs, Behravesh, Bradley, et al., 2016).

Most tick infections occur between April and October; however, ticks can bite in the winter with 9% of infections in New York, New Jersey, and Pennsylvania reported in the winter (Mukkada & Buckingham, 2015). The initial presentation is nonspecific and includes malaise, nausea, vomiting, and myalgia. The reported clinical presentation of RMSF is a triad rash, fever, and tick bite history; however, this occurs in fewer than 60% of children (Mukkada & Buckingham, 2015). The others reported a prominent reddened area at the site of the tick bite. In 2 to 8 days, a blanching pink macular rash on the ankles, wrists, or forearms develops, eventually spreading to the palms, soles, arms, legs, and trunk but tending to spare the face (Biggs et al., 2016). The classic petechial rash will develop by 5 to 6 days and is a sign of advanced disease (Fig. 43.13).

**Figure 43.13** The typical rash of Rocky Mountain spotted fever. (Courtesy of Stuart Starr, MD, The Children's Hospital of Philadelphia.)

Approximately 50% of patients have no rash in the first 3 days of illness (Biggs et al., 2016). The child will also have abdominal pain that mimics appendicitis, diarrhea, gastroenteritis, conjunctiva redness, and periorbital and peripheral edema (Biggs et al., 2016). A persistent headache and fever (as high as 104°F [40°C]) with mental confusion can also occur.

In late-stage disease, untreated children will develop central nervous system involvement including a meningoencephalitis (stiff neck and seizures) and renal failure, with signs of cardiac and pulmonary failure including pneumonia.

RMSF is the most common fatal rickettsial disease in the United States (Kellen & Berlin, 2016) and was a serious childhood illness before antibiotic therapy was available. First-line therapy is with doxycycline for 7 to 10 days and should be initiated within the first 5 days of the appearance of symptoms. Children are generally admitted for initiation of treatment and as they improve are discharged home. Caution parents to finish the full course of therapy to ensure disease eradication and to prevent the risk of complications.

## PSITTACOSIS

Psittacosis, caused by *Chlamydophila psittaci*, is a respiratory disease transmitted to children through the inhalation of aerosolized excrement or respiratory sections from the eyes or beaks of birds that are infected with the bacteria (AAP, 2015). Although the bird does not appear ill, children develop symptoms of a respiratory infection with

cough, fever, pharyngitis, headache, malaise, or diarrhea. An extensive interstitial pneumonia can develop. More serious complications include myocarditis, endocarditis, nephritis, hepatitis, or encephalitis. The course of the disease is as long as 3 to 4 weeks. The treatment of choice is either tetracycline or doxycycline for children older than 8 years or erythromycin or azithromycin for younger children or pregnant teens (AAP, 2015).

## PARASITIC INFECTIONS

Parasites are organisms that live on and obtain their food supply from other organisms. Although many of these can cause illness, ones frequently associated with children include head lice and scabies (Table 43.3). Parents are often embarrassed when they learn their child has one of these illnesses. You can reassure them that these infestations could happen to any child (Box 43.8).

**TABLE 43.3 COMMON PARASITIC INFECTIONS**

Infection	Organism	Symptoms	Treatment
Pediculosis capitis	Head lice	Small, white flecks on hair shaft (nits or eggs of lice); extreme pruritus	Wash hair with one of several approved products, starting with an over-the-counter permethrin-based or pyrethrin-based shampoo (AAP, 2015) and comb nits from hair with fine-toothed comb. Wash bed sheets and recently worn clothes; vacuum pillows, mattresses, or other items unable to be washed. Teach children not to exchange combs, hair barrettes, or other personal items.
Pediculosis	Pubic lice	Same as for head lice except on pubic hair	Same as head lice
Scabies	Female mite ( <i>Acarus scabiei</i> )	Black burrow filled with mite feces 1–2 in. long, usually between fingers and toes, on palms,	Caution that adolescent groin infestations might be spread by physical intimacy. Topical permethrin 5% cream is the drug of choice with two doses of oral ivermectin (off-label use) 1 week apart, also being an effective drug (AAP, 2015).

or in  
axilla or  
groin

BOX 43.8

### Nursing Care Planning Tips for Effective Communication

When Jack's 6-year-old brother Joshua visits him, you notice Joshua has scratch marks on his neck and forehead. His hair shafts are covered by sand-like particles. You suspect he has pediculosis capitis or head lice.

*Tip:* Ask follow-up questions and provide appropriate patient education. The following scenario is an example of what can happen if people believe the myth that communicable diseases are always associated with poor hygiene or poverty. Head lice can spread easily in locker rooms or classrooms, so any child can contract them.

**Nurse:** I am noticing sand-like particles in your son's hair.

**Mrs. Noma:** Well, you know boys. They don't always wash well.

**Nurse:** They resemble the eggs of head lice.

**Mrs. Noma:** We're not that poor. Don't insult us.

**Nurse:** I apologize if you think I am insulting you. People from all walks of life get head lice. Let's talk about head lice and how easy it is for anyone to get them.

## HELMINTHIC INFECTIONS

*Helminths* are pathogenic or parasitic worms. They include roundworms (nematodes), flukes (trematodes), or tapeworms (cestodes). Most helminths begin life when the eggs or larvae are eliminated in the feces or urine of humans. They are then transmitted to the oral cavity by contaminated foods or hands. Because children tend to be careless about washing their hands before eating or tend to suck their thumbs, it makes them prone to these infections.

### Roundworms (Ascariasis)

*Ascaris lumbricoides* are generally asymptomatic infections but when there is an extensive parasite load, malnutrition and gastrointestinal symptoms result (AAP, 2015). With an incubation period of 8 weeks, the nurse must obtain a history of travel to underdeveloped countries. The roundworm parasite lives in the intestinal tract. Larvae, which hatch from the ingested eggs, penetrate the intestinal wall and enter the circulation. From there, they may migrate to any body tissue. Children develop a loss of appetite and nausea and vomiting. Intestinal obstruction may occur from a mass of roundworms in the intestine. Ascariasis can be prevented by the sanitary disposal of feces to prevent contamination of the soil. There are several treatment options: (a) a single dose of albendazole with food, (b) nitazoxanide twice a day for 3 days, or (c) a

single dose of ivermectin (off-label use and not to be used in children less than 15 kg) (AAP, 2015).

### Hookworms

Hookworm infections tend to be asymptomatic and are more common in children living in tropical climates with poor sanitation. Hookworm eggs, like roundworm eggs, are found in human feces. They enter children's bodies through the skin and then migrate to the intestinal tract, where they attach themselves onto the intestinal villi and suck blood from the intestinal wall to sustain themselves. Abdominal pain which is colicky in nature, nausea, and diarrhea with marked eosinophilia can be a presenting sign 4 to 6 weeks after exposure. If a great number of hookworms are present, severe anemia may result. Treatment is with albendazole (Albenza), mebendazole (Vermox), and pyrantel pamoate (Pin X) are effective (AAP, 2015). Children may also need therapy for the anemia.

### Enterobiasis (Pinworms)

Pinworms are small, white, threadlike worms that live in the cecum. After ingestion of the egg either by ingestion or breathing, the mature worms develop over a period of 2 months in the cecum. The mature female pinworm then migrates out of the anus to deposit eggs on the skin in the anal and perianal region (CDC, 2016f). The movement of the worms causes the anal area to itch, and the child will awaken at night crying and scratching. Some of the eggs are then carried from the child's fingernails to the mouth. After being ingested, they hatch in the child's intestinal tract, and the cycle is repeated (CDC, 2016f).

The worms are large enough that they can be seen if the child's buttocks are separated. Pressing a piece of cellophane tape against the anus and then inspecting it under a microscope will generally reveal pinworm eggs.

Treatment is with a single dose of mebendazole (Vermox) or pyrantel pamoate (antihelminthic) (CDC, 2016f). Underclothing, bedding, towels, and nightclothes should be washed before reuse. In addition, all family members need to be treated for pinworm infestation because the worms are easily transmitted from person to person. Teach children to avoid nail biting and to wash their hands before food preparation or eating to avoid transfer of pinworm eggs and to prevent this type of infection.

## PROTOZOAN INFECTIONS

Protozoa are unicellular organisms. They absorb fluid through their cell membrane and can move from place to place by pseudopod, flagella, or cilia action. They are most pathogenic in the gastrointestinal, genitourinary, and circulatory systems. Some protozoa reproduce by simple binary fission, whereas other forms have complex life cycles. They have the ability to form cysts or surround themselves with a membrane, which makes them resistant to destruction.

## Giardiasis

*Giardia lamblia*, a flagellated protozoa, is the most common intestinal parasitic infection in the United States with transmission occurring from ground water contamination and untreated surfaces that are contaminated (Painter, Gargano, Collier, et al., 2015). The peak of the disease occurs in the early summer through the fall (AAP, 2015).

Transmission occurs through the fecal–oral route and occurs from fecal contaminated water and stool. Transmission can occur from person to person or from person to animal. The child ingests the cysts of the organism, and the cysts develop in the intestine into the mature form of the organism. Ingestion of as little as 10 cysts has been associated with illness (Painter et al., 2015). It is contagious as long as the infected person still has excreted cysts (AAP, 2015).

The disease can be asymptomatic or, in symptomatic people, associated with diarrhea, weight loss, abdominal cramps, bloating, and weight loss. The diagnosis is made through DFA assays as well as specific EIA (AAP, 2015, Painter et al., 2015) with DFA being the recommended test by the CDC (Painter et al., 2015). According to the 2015 *Red Book*, metronidazole (Flagyl), nitazoxanide (Alinia, Nizonide), and tinidazole (Tindamax) are the drugs of choice in pediatric patients, with metronidazole being the least expensive (AAP, 2015). Nitazoxanide is approved over 1 year of age, whereas tinidazole is approved over 3 years of age. Treatment of asymptomatic carriers is not recommended for well children living in a household with well people (AAP, 2015).

Prevention measures include hand washing for more than 20 seconds (CDC, 2017), improved sanitation at day care, adequate chlorination of pool and drinking water, and camping water decontamination.

## FUNGAL INFECTIONS

Fungi are larger than bacteria; some are unicellular (yeasts), but generally, they are multicellular (molds). Deep mycoses invade internal organs. Respiratory transmission is by the inhalation of spores. Subcutaneous mycoses invade the skin, subcutaneous tissue, and bone. Infections usually occur from introduction of the fungi into a wound. Superficial mycoses invade only the hair, skin, or nails.

### Superficial Fungal Infections

Four superficial fungal infections seen frequently in children are tinea cruris, pedis, capitis, and corporis.

#### Tinea Cruris

Tinea cruris (jock itch) is a brownish to erythematous, well-demarcated patch on the groin, inner thighs, and scrotum. The patch can sometimes have central clearing and may have a papular or vesiculopapular border. The area is pruritic and may result from

moisture, close-fitting garments, and obesity. The incubation period is from 1 to 3 weeks (AAP, 2015). Local application of an antifungal agent for 4 to 6 weeks is needed, and the use of corticosteroids in the area should be avoided.

### Tinea Pedis

Tinea pedis (athlete's foot) produces pruritic, pinpoint vesicles with fissuring between the toes and on the plantar surface of the foot. It is treated with antifungal agent such as clotrimazole (Lotrimin).

### Tinea Capitis

Tinea capitis is a dermatophytic fungal infection of the scalp which can present one of four ways: (a) a patchy alopecia with short 2 to 4 mm broken-off hair shafts, (b) a well demarcated scaling erythematous patch in circular area, (c) a yellow crusting, perifollicular erythema of scalp which has heavy hair loss, or (d) a kerion or boggy circular area of hair loss which is the result of an inflammatory response to the fungus. The child must be treated with oral antifungal such as griseofulvin (Gris-PEG) or terbinafine (Lamisil) and topical shampoo such as selenium sulfide (Selsun Shampoo), ketoconazole (Nizoral shampoo), and ciclopirox (Loprox Shampoo) applied two to three times a week (AAP, 2015).

Adolescents should be cautioned not to consume alcohol while taking any oral antifungal medications as they are metabolized by the liver and can cause nausea and vomiting. Safety of the drug during pregnancy is not established. Caution children to avoid strong sunlight during griseofulvin therapy because photosensitivity may occur (AAP, 2015).

### Tinea Corporis

Tinea corporis is a superficial, well-demarcated, mildly erythematous, ring-like infection of the epidermal layer of the skin characterized by slightly scaly central clearing and raised papular borders. It starts as a papular lesion and spreads over several days. It is called ringworm due to its circular shape (Fig. 43.14). The incubation period is 1 to 3 weeks. The lesions are confused with granuloma annulare and nummular eczema. Topical antifungal treatment should be applied to the affected area for 1 week following complete clearing of the lesion.

**Figure 43.14** Ringworm (*tinea corporis*). The fungus spreads rapidly, producing a circular, ringlike lesion. (© SPL/Science Source/Photo Researchers.)

### Candidiasis

*Candida albicans* is a yeast that reproduces by budding and, in well infants, causes oral and skin monilial or candida infections (AAP, 2015). *Candida* is common normal flora of the vagina and infants acquire this during the birth process (see Chapter 47).

The common clinical presentation in well infants is mild and easily treated, with person to person transmission being rare. Oral candidiasis, or thrush, is characterized by white plaques on an erythematous base on the buccal membrane and the surface of the tongue. It resembles a milk curd left from a recent milk feeding; however, unlike milk curds, the thrush plaques do not scrape away. The underlying surface is erythematous and therefore may be painful. On the skin *C. albicans* can also cause a severe, bright red, sharply circumscribed rash, most commonly in the diaper area (Fig. 43.15). The diaper rash is marked by intense erythema with a well-demarcated border surrounded by satellite lesions and goes into the folds. It fails to improve with usual diaper rash measures, such as application of a protective ointment, frequent changing of diapers, or exposure to air.

**Figure 43.15** Monilial (candidiasis) diaper rash. Note the intense red color of the rash and the satellite lesions. (© Custom Medical Stock Photograph.)

Skin infections are treated with antifungal drugs like nystatin (Mycostatin), clotrimazole (Lotrimin), naftifine (Naftin), ketoconazole (Nizoral), econazole (Spectazole), ciclopirox (Ciclodan), or miconazole (Zeasorb); however, nystatin (Mycostatin) is the cheapest agent (AAP, 2015). For oral candidiasis, nystatin is generally administered by mouth approximately four times a day. The lesions need to be cleaned prior to the application of the nystatin and it should be administered after feeding. Oral candidiasis or thrush is common.

#### *What If . . . 43.4*

**A nurse is particularly interested in exploring one of the 2020 National Health Goals related to infectious diseases in children (see Box 43.1). What would be a possible research topic pertinent to this goal that would be applicable to Jack and his family and that would also advance evidence-based practice?**

## **KEY POINTS FOR REVIEW**

- The incubation period of an infectious disease is the time between the invasion of an organism and the onset of symptoms. The prodromal period is the time between the beginning of nonspecific symptoms and specific ones and the time when children are most infectious. Illness is the stage during which specific symptoms are evident. The convalescent period is the period from when the symptoms fade and the child returns to baseline.
- The chain of infection depends on the presence of a reservoir, a portal of exit, a mode of transmission, a portal of entry, and a susceptible host. To reduce the spread of infection, use standard infection precautions to break the chain of infection. Transmission-based precautions—airborne, droplet, and contact—also may be necessary.
- Common viral infections of childhood include exanthem subitum (roseola), rubella (German measles), measles (rubeola), chickenpox (varicella), herpes zoster, erythema infectiosum (fifth disease), mumps (epidemic parotitis), infectious mononucleosis, and cat-scratch disease. Other important viral infections include poliomyelitis (now almost extinct), herpesvirus infections, verrucae (warts), rabies, West Nile virus disease, and Zika virus.
- Common streptococcal diseases include streptococcal pharyngitis, scarlet fever, and impetigo. Staphylococcal infections include impetigo, furunculosis (boils), cellulitis, and staphylococcal scalded skin syndrome. There has been a resurgence of pertussis in the United States due to immunization refusal and waning of efficacy. Outbreaks of diphtheria and tetanus (lockjaw) are rare.
- Common examples of tick-borne diseases are Rocky Mountain spotted fever and Lyme disease. Parasitic infections are pediculosis capitis (head lice), pediculosis pubis, and scabies. Helminthic infections include roundworms, hookworms, and pinworms. Fungal infections are tinea capitis and tinea corporis, both of which are forms of ringworm.
- Teaching parents and children about infection control measures and the need for keeping immunizations up to date is essential not only for reducing the risk of infectious disorders in children but also for meeting QSEN competencies and best meeting the family’s total needs.

### CRITICAL THINKING CARE STUDY

While working as a nurse at a residential summer camp, you meet Madison, a 10-year-old. Both her forearms and lower legs have several crusted erythematous superficial lesions with some. Four days ago was “sleep out” day, so she spent the night in a tent with three friends but didn’t sleep well because “mosquitoes bit me all night.” Madison’s parents return from their vacation, and when they learn of the lesions comment, “Look at her; she’ll probably end up with scars from this.”

1. What do you suspect is the cause of the scattered lesions?
2. Given how impetigo is transmitted to others, what implications does its presence

have for infection control practices in the camp setting?

3. What if you learn Madison has never had more immunizations than those she received as an infant because her mother believes the danger of vaccines is higher than contracting “simple childhood infections”? Would immunization have prevented Madison from contracting impetigo? Would you recommend she receive routine immunizations now or, at 10 years of age, is she no longer in much danger from common contagious illnesses?

## Nursing Care of a Family When a Child Has a Hematologic Disorder

*Lana is a 4-year-old girl diagnosed with thalassemia major whom you meet at a pediatric clinic. She has a prominent mandible and wide-spaced upper front teeth from overgrowth of bone marrow centers. Joey is a 7-year-old with sickle-cell anemia who attends the same clinic. His growth is only in the fifth percentile, and he's had two vaso-occlusive crises in the past year. "Why did this happen to our families?" Lana's mother asks you. "What can we do to help our children have better lives?"*

*Previous chapters described the growth and development of well children. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur when children have a hematologic disorder.*

**What additional health teaching does Lana's mother need so she can better understand hematologic diseases?**

### KEY TERMS

**allogeneic transplantation**  
**aplastic crisis**  
**autologous transplantation**  
**blood dyscrasias**  
**erythroblasts**  
**erythrocytes**  
**erythropoietin**  
**granulocytes**  
**hemochromatosis**  
**hemolysis**  
**hemosiderosis**  
**ischemia**  
**leukocytes**  
**megakaryocytes**  
**pancytopenia**

petechiae  
plethora  
poikilocytic  
priapism  
purpura  
reticulocyte  
syngeneic transplantation  
thrombocytes  
thrombocytopenia

## OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the major hematologic disorders of childhood.
2. Identify 2020 National Health Goals related to children with hematologic disorders that nurses could help the nation achieve.
3. Assess a child with a hematologic disorder such as sickle-cell anemia.
4. Formulate nursing diagnoses related to a child with a hematologic disorder.
5. Identify expected outcomes for a child with a hematologic disorder to help parents manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care related to a child with a hematologic disorder, such as reducing the possibility of infection.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of childhood disorders of the blood with the interplay of nursing process and Family Nursing to promote quality maternal and child health nursing care.

The blood and blood-forming tissues that make up the hematologic system play a vital role in body metabolism because they transport oxygen and nutrients to body cells, remove carbon dioxide from cells, and initiate blood coagulation when vessels are injured. As a result of all of these functions, any alteration in the substance or function of blood can have immediate and life-threatening effects on the functioning of all body systems (Zempsky, Palermo, Corsi, et al., 2013).

Hematologic disorders, often called **blood dyscrasias**, occur when components of the blood are formed incorrectly or either increase or decrease in amount beyond normal ranges. Most blood dyscrasias in children originate in the bone marrow, where blood

cells are formed. They do not occur at equal rates in all countries because many of these disorders are inherited. Sickle-cell anemia, for example, occurs mainly in Blacks; thalassemia occurs in children of Mediterranean heritage. Being aware of the differences in the incidence of blood dyscrasias this way can be helpful in planning care and providing healthcare services for children and communities. Treatment for blood disorders vary as well based on cultural influences. Families who are Jehovah's Witnesses, for example, may refuse blood transfusions, a common therapy for blood disorders, on religious grounds (Campbell, Machan, & Fisher, 2016). Box 44.1 shows 2020 National Health Goals related to blood disorders.

#### BOX 44.1

### Nursing Care Planning Based on 2020 National Health Goals

2020 National Health Goals speak to ways to improve children's health. Because both iron-deficiency and sickle-cell anemia are seen worldwide, improving care in these areas could have a dramatic effect on both national and world health.

- Reduce the incidence of iron deficiency among children aged 1 to 2 years from a baseline of 15.9% to a target level of 14.3%; in children aged 3 to 4 years, from 5.3% to 4.3%.
- Reduce the incidence of iron deficiency among adolescents 12 to 18 years of age from 10.4% to 9.4%.
- Reduce the proportion of persons with hemophilia who develop reduced joint mobility due to bleeding into joints from 82.9% to 74.6%.
- (Developmental) Reduce hospitalization due to preventable complications of sickle-cell disease yearly among children aged 9 years and younger.
- Increase the proportion of children with special healthcare needs who have access to a medical home from 47.1% to 51.8% (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by educating parents about the importance of women taking an iron supplement during pregnancy, encouraging iron-rich food sources for young children, and educating adolescents about healthy diets. Being certain that parents are well informed about preventive measures for children with all types of hematologic disorders could help reduce hospital admissions.

#### *Nursing Process Overview*

### FOR A CHILD WITH A HEMATOLOGIC DISORDER

#### **ASSESSMENT**

Many of the symptoms of hematologic disorders begin insidiously, with symptoms such as pallor, lethargy, and bruising. These are such minor symptoms that parents may not bring their children to a healthcare facility for some time. When they do,

they are surprised to learn such subtle symptoms signify the presence of a serious illness.

Children with iron deficiency, for example, aside from appearing pale and irritable, look plump and “healthy.” It takes careful history taking to reveal the possibility of an iron deficiency.

### **NURSING DIAGNOSIS**

When a child is diagnosed with an inherited disorder, parents may feel guilty or blame themselves or their partner for their child’s disease. This can make it difficult for a family to act together to support a child during an illness when members need intensive support themselves. Examples of nursing diagnoses that address the entire family include:

- Deficient knowledge related to the cause of the child’s illness
- Imbalanced nutrition, less than body requirements, related to family pattern of not eating iron-rich foods
- Anxiety related to frequent blood-sampling procedures
- Pain related to tissue **ischemia** (inadequate blood supply to a local area due to blockage)
- Compromised family coping related to long-term care needs of child with a chronic hematologic disorder

### **OUTCOME IDENTIFICATION AND PLANNING**

When helping parents plan outcomes, be certain that the outcomes planned are realistic for both the child and family. It may not be possible to reduce the number of blood-sampling procedures, for example, but fear, pain, and anxiety related to the procedures can be addressed with distraction techniques.

Children with hematologic disorders often are prescribed a long-term medication such as a corticosteroid. When a child appears very ill, parents are usually very conscientious about giving such medicine. When a child has a disorder with few symptoms, however, like a blood dyscrasia, it is easy for parents to forget to give the medication. In addition, a child may refuse to take the medication for a long time because it tastes bad or upsets the stomach. Planning, therefore, includes helping parents devise ways to disguise the taste and to remember to give medication over the long term. If a child will be restricted in activity for long periods because the immune system is compromised as a part of the illness, planning must include ways to keep the child engaged with friends to promote development. Parents may need help investigating possible resources for education and support to do this.

Some organizations helpful for referral are the Aplastic Anemia and MDS International Foundation (<http://www.aamds.org>), the Sickle Cell Disease Association of America ([www.sicklecelldisease.org](http://www.sicklecelldisease.org)), the American Society of Pediatric Hematology/Oncology ([www.aspho.org](http://www.aspho.org)), and the National Hemophilia Foundation ([www.hemophilia.org](http://www.hemophilia.org)).

### **IMPLEMENTATION**

Nursing interventions for children with hematologic disorders range from obtaining blood specimens for testing to assisting with blood or hematopoietic stem (bone marrow) cell transfusions. Remember that a fingertip puncture for blood is often as painful as a venipuncture. Suggesting that blood be drawn by means of an intermittent device and applying an anesthetic cream (mixtures of lidocaine and prilocaine) before finger punctures or venipunctures are effective measures to help reduce pain and improve cooperation with these procedures. Even so, children may need some therapeutic playtime with a syringe and a doll to express their anger about constant invasion by needles.

### OUTCOME EVALUATION

An evaluation focuses on whether short-term outcomes such as moderation of pain or elimination of anxiety in a child undergoing diagnosis or treatment were achieved. The focus also includes assessing the achievement of long-term outcomes such as improving the ability of the family to manage the stress of raising a child with a chronic illness or dealing with frequently occurring health crises.

Examples of expected outcomes that suggest goals were achieved include:

- Parents correctly state the most frequent causes of iron-deficiency anemia.
- Child states she feels better able to cope with blood-sampling procedures through the use of imagery.
- Parents describe realistic plans to ensure adherence to long-term medication administration.
- Parents voice that they understand the importance of preventing dehydration in their school-age child with sickle-cell anemia.

## Anatomy and Physiology of the Hematopoietic System

Blood components originate in the bone marrow, circulate through blood vessels, and ultimately are destroyed by the spleen.

### BLOOD FORMATION AND COMPONENTS

The total volume of blood in the human body is roughly proportional to body weight: 85 ml/kg at birth, 75 ml/kg at 6 months of age, and 70 ml/kg after the first year. Although the *blood plasma* is important in diseases that cause vomiting and diarrhea (when this fluid may become depleted, leading to dehydration), plasma is not a major site of hematologic disease. The formed elements—the erythrocytes (red blood cells [RBCs]), leukocytes (white blood cells [WBCs]), and thrombocytes (platelets)—are the portions most affected by hematologic disorders in children.

#### Erythrocytes (Red Blood Cells)

**Erythrocytes** (RBCs) function chiefly to transport oxygen to and carry carbon dioxide away from body cells. They are formed in the bone marrow under the stimulation of

**erythropoietin**, a hormone formed by the kidneys that is produced whenever a child has tissue hypoxia. Children with kidney disease often have a low number of RBCs because erythropoietin secretion is inadequate in diseased kidneys. *Polycythemia*, which is displayed as an elevated hematocrit, often occurs when a child has impaired tissue oxygenation and increased erythropoietin (Jeevasankar, Agarwal, Chawla, et al., 2008).

At birth, an infant has approximately 5 million RBCs per cubic millimeter of blood. This concentration diminishes rapidly in the first months, reaching a low of approximately 4.1 million/mm<sup>3</sup> at 3 to 4 months of age. The number then slowly increases until adolescence, when the adult value of approximately 4.9 million/mm<sup>3</sup> is reached.

RBCs form first as **erythroblasts** (large, nucleated cells), then mature through normoblast and reticulocyte stages, to mature, nonnucleated erythrocytes. An elevated **reticulocyte** (immature red blood cell) count (more than 1% of the total count) indicates that rapid production of new RBCs is occurring. At the end of their life span (about 120 days), erythrocytes are destroyed through phagocytosis by reticuloendothelial cells, found in the highest proportion in the spleen.

## Hemoglobin

The component of RBCs that allows them to carry out the transport of oxygen is *hemoglobin*, composed of globin, a protein, and heme, an iron-containing pigment. It is the heme portion that combines with oxygen and carbon dioxide for transport.

The hemoglobin in erythrocytes during fetal life differs from that formed after birth. Fetal hemoglobin is composed of two  $\alpha$  and two  $\gamma$  polypeptide chains. At birth, 40% to 70% of the infant's hemoglobin is this type (hemoglobin F). During the first 6 months of life, this is gradually replaced by adult hemoglobin (hemoglobin A), which is composed of two  $\alpha$  and two  $\beta$  chains. For this reason, diseases such as sickle-cell anemia or the thalassemias, which are disorders of the  $\beta$  chains, do not become apparent clinically until this hemoglobin change has occurred (at approximately 6 months of age). Because some hemoglobin A is present, however, even in early intrauterine life, they can be diagnosed prenatally by hemoglobin analysis or electrophoresis in fetal or newborn life (Hartung, Olson, & Bessler, 2013).

Hemoglobin levels are highest at birth (13.7 to 20.1 g/100 ml); they reach a low at approximately 3 months of age (9.5 to 14.5 g/100 ml) and then gradually rise again until adult values are reached at puberty (11 to 16 g/100 ml).

## Bilirubin

After an RBC reaches its life span of approximately 120 days, it disintegrates and its protein component is preserved by the reticuloendothelial cells of the liver and spleen for further use. Iron is reused by the bone marrow to construct new RBCs. As the heme portion is degraded, it is converted into protoporphyrin; protoporphyrin is then further broken down into indirect bilirubin. Indirect bilirubin is fat-soluble and so cannot be

excreted by the kidneys. It is therefore converted by the liver enzyme glucuronyl transferase into *direct bilirubin*, which is water-soluble and excreted in bile.

In the newborn, generally, liver function is so immature that the conversion from indirect to direct bilirubin is difficult, allowing a portion of bilirubin to remain in the indirect form. When the level of indirect bilirubin in the blood rises to more than 7 mg/100 ml, it permeates outside the circulatory system, and the infant begins to show signs of yellowing or jaundice from the color of bilirubin. At any point in life, if excessive **hemolysis** (destruction) of RBCs occurs from other than usual causes, a child will also show signs of jaundice.

### Leukocytes (White Blood Cells)

**Leukocytes** (WBCs) are nucleated cells and few in number compared with RBCs (there is approximately only 1 WBC to every 500 RBCs). Their primary function is defense against antigen invasion; their life span varies from approximately 6 hours to unknown intervals. With the exception of neutropenia (a reduced number of WBCs), leukocytes are not major hematologic concerns; because they are important in immune disorders and malignancies, they are further discussed in [Chapters 42](#) and [53](#).

### Thrombocytes (Platelets)

**Thrombocytes** are round, nonnucleated bodies formed by the bone marrow; their function is capillary hemostasis and primary coagulation. The usual number is 150,000 to 300,000/mm<sup>3</sup> after the first year. Immature thrombocytes are termed **megakaryocytes**. If large numbers of these are present in serum, it indicates that a rapid production of platelets is occurring.

## BLOOD COAGULATION

Effective blood coagulation depends on a complex series of four events, including a combination of blood and tissue factors released from the plasma (the intrinsic pathway) and from injured tissue (the extrinsic pathway) ([Overbey, Jones, & Robinson, 2014](#)). The numbers of coagulation factors refer to the order in which factors were discovered, not to the order of action in coagulation. The plasma-released factors include factors VIII, IX, and XII. Factors released from injured tissues are a tissue factor (an incomplete thromboplastin or factor III), plus factors VII and X. Together, these pathways unite to form factor V.

When a vessel is injured, vasoconstriction occurs in the area proximal to the injury, thus narrowing the vessel lumen and reducing the amount of blood that can flow to the injured area. Platelets begin to adhere to the damaged vessel site and to one another, forming a platelet plug and initiating the first stage of clotting ([Fig. 44.1](#)).

**Figure 44.1** The steps in blood coagulation.

In the second stage, factors from either the intrinsic or the extrinsic system combine with platelet phospholipids to form complete thromboplastin. In the third stage, thromboplastin converts prothrombin (factor II) to thrombin if ionized calcium is present. The production of prothrombin and factors VII, IX, and X all depend on the presence of vitamin K. This stage will be incomplete, therefore, if levels of any of factors VIII through XII, vitamin K, or calcium are deficient.

In the fourth stage, thrombin converts fibrinogen (factor I) to fibrin. Fibrin strands form a mesh incorporating RBCs, WBCs, and platelets to form a permanent protective seal at the site of injury. Factor XIII (fibrin stabilizing factor) then acts to make the fibrin clot insoluble and permanent.

To prevent too much coagulation after the seal is complete, plasminogen is then converted to plasmin (a fibrinolysin) near the injury to halt the clotting sequence. Common tests for blood coagulation are described in [Table 44.1](#).

**TABLE 44.1 COMMON TESTS FOR BLOOD COAGULATION**

Test	Definition	Normal Value
Prothrombin time (PT)	Measures the action of prothrombin; reveals deficiencies in prothrombin, factors V, VII, and X	11–13 s (PT) or 2.0–3.0 international normalized ratio (INR)
Partial thromboplastin time (PTT)	Measures activity of thromboplastin; reveals deficiencies in thromboplastin, factors VIII to XII	30–45 s
Bleeding time	Measures the time required for bleeding at a stab wound on the earlobe to stop; reveals deficiencies in platelet formation and vasoconstrictive ability	3–10 min

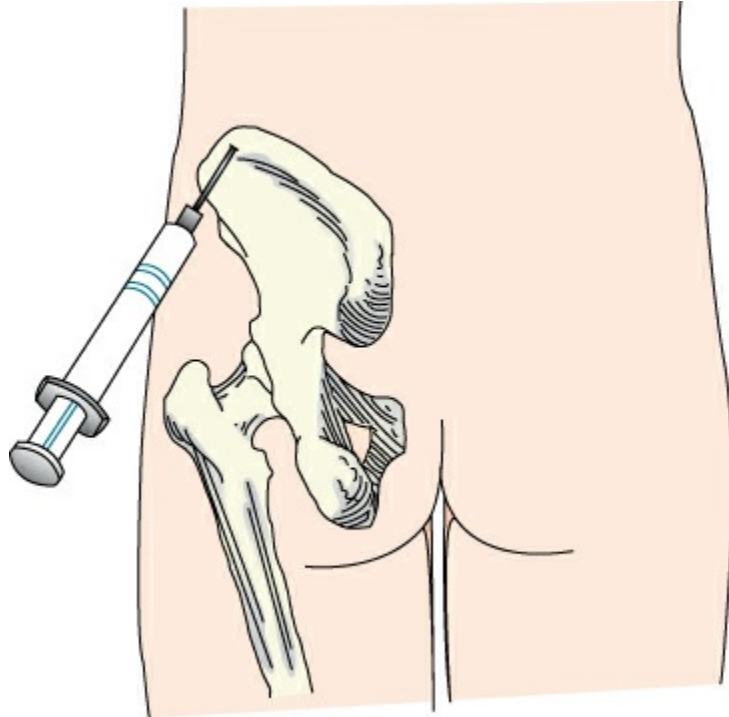

Clot retraction	Measures platelet function; interval from placement of blood in a tube to the point clot shrinks and expels serum	Retraction at side of test tube should be present by 1 hr; complete in 24 hr
Tourniquet	Measures capillary fragility and platelet function; response of tissue to application of tourniquet to forearm for 5–10 min	0–2 petechiae per 2-cm area
Prothrombin consumption time	Evaluates thromboplastin function; if clot formation used a great deal of prothrombin (as it should), serum prothrombin time will be brief; prolongation denotes defects in thromboplastin function	Approximately 20 s
Thromboplastin generation time	Tests basic ability to form thromboplastin; distinguishes factor VIII from factor IX disorders	12 s or less
Plasma fibrinogen	Measures stage 4 clotting process or level of fibrinogen in blood	200–400 mg/100 ml plasma
Venous clotting time (Lee-White clotting time)	Measures factor deficits in stages 2 and 4	9–12 min

## Assessment and Therapeutic Techniques for Hematologic Disorders

An assessment of children with hematologic disorders begins with a complete history, including family history, to identify inherited disorders. For a specific diagnosis, children generally require several diagnostic procedures such as blood cell or bone marrow analysis.

### BONE MARROW ASPIRATION AND BIOPSY

Bone marrow aspiration provides samples of bone marrow so the type and quantity of cells being produced can be determined (Ambruso, Nuss, & Wang, 2016). In children, the aspiration sites used are the iliac crests or spines (rather than the sternum, which is commonly used in adults) because performing the test at these sites is usually less frightening for children (Fig. 44.2). These sites also have the largest marrow compartments during childhood. In neonates, the anterior tibia can be used as an additional site.

**Figure 44.2** A common site used for bone marrow aspiration in children is the iliac crest. In neonates, the anterior tibia may be used.

For a bone marrow aspiration, following conscious sedation, a child lies prone on a hard surface such as a treatment table because pressure is needed to insert the needle through the surface of the bone into the marrow compartment. Topical anesthesia may be applied to help reduce pain (Kato, Maeda, Aoki, et al., 2014).

The area of the aspiration is cleaned with an antiseptic solution and draped. The overlying skin is infiltrated with a local anesthetic and then a large-bore needle and stylus is introduced through the overlying tissue into the bone. When the marrow cavity is reached, the stylus is removed, a syringe is attached to the needle, and bone marrow is aspirated (which appears as thick blood in the syringe). The syringe is then removed, and the marrow obtained is expelled onto a slide, sprayed with a preservative, and taken to a laboratory for analysis. Pressure must be applied to the puncture site for 5 to 10 minutes immediately afterward to prevent bleeding. A pressure dressing is then applied to maintain pressure and to continue to halt bleeding.

A child will feel pain from the local anesthetic injection and uncomfortable pressure while the needle is inserted. Some report a sharp pain when the marrow is actually aspirated. If conscious sedation is used, monitor vital signs until the child is fully awake. Monitor pulse and blood pressure and observe the dressing every 15 minutes for the first hour after the procedure to be certain no bleeding is occurring. Keep the child fairly quiet for the first hour by playing a quiet game or other activity. Because bone marrow aspiration is a painful and invasive procedure, allow young children an opportunity for therapeutic play with a doll and syringe to help them express their feelings about the procedure. If the procedure was done as an ambulatory one, instruct

parents to take the child’s temperature 12 and 24 hours after the procedure to detect infection.

## BLOOD TRANSFUSION

Transfusions of blood or its products are commonly used in the treatment of blood disorders, and may include whole blood, packed RBCs, washed RBCs (as much “foreign” matter is removed as possible to reduce the possibility of an antagonistic reaction), plasma, plasma factors, platelets, WBCs, and albumin. No matter what type of blood product is used, it is important that it has been carefully matched with the child’s blood type and is infused with a solution as nearly isotonic as possible (normal saline). If blood should be given with a hypertonic solution, this will cause fluid to be drawn out of the transfused RBCs, causing them to shrink and be useless; if blood is infused with a hypotonic solution, fluid will be drawn into the cells, causing them to burst, and again, be destroyed.

Packed RBCs are the most common form of transfusion used with children because they help minimize the risk of fluid overload. The usual amount of blood transfused is typically 15 ml/kg of body weight. The commonly accepted rate for transfusions in a child is 10 ml/kg/hr unless the child has hypovolemic shock and volume equilibrium needs to be established quickly. An infusion of packed RBCs at a proportion of 10 ml/kg will raise the hematocrit level 5 points. A transfusion of platelets will elevate the platelet count by approximately 10,000 cells. Because platelet life span may be shortened after transfusion as a result of increased platelet destruction, frequent transfusions may be necessary (Ambruso et al., 2016).

Even if given slowly, a blood transfusion is always a strain on a child’s circulation beyond that of a regular intravenous infusion because the circulatory system must accommodate such a thick, difficult-to-mobilize fluid.

Before any transfusion, ensure a signed consent form is obtained that respects sociocultural or religious beliefs. Obtain vital signs to establish a baseline and monitor these about every 15 minutes during the first hour and about every half hour for the remainder of the transfusion. Keep the infusion rate slow for the first 15 minutes; then, if no reaction occurs, increase the rate to about 10 ml/kg/hr or as otherwise prescribed. Common symptoms of blood transfusion reactions that may occur are shown in [Table 44.2](#).

**TABLE 44.2 COMMON SYMPTOMS OF BLOOD TRANSFUSION REACTIONS**

Symptoms	Cause	Time of Occurrence	Nursing Interventions
Headache, chills, back pain, dyspnea,	Anaphylactic reaction to incompatible blood; agglutination of red	Immediately after start of transfusion	Discontinue transfusion. Maintain normal

hypotension, hemoglobinuria (blood in urine)	blood cells occurs; kidney tubules may become blocked, resulting in kidney failure		saline infusion for accessible intravenous (IV) line. Administer oxygen as necessary. Anticipate administration of a diuretic to increase renal tubule flow and reduce tubule plugging and/or heparin to reduce IV coagulation.
Pruritus, urticaria (hives), wheezing	Allergy to protein components of transfusion	Within first hour after start of transfusion	Discontinue transfusion temporarily. Give oxygen as needed. Anticipate administration for antihistamine to reduce symptoms.
Increased temperature	Possible contaminant in transfused blood	Approximately 1 hr after start of transfusion	Discontinue transfusion. Obtain blood culture to rule out or identify bacterial invasion.
Increased pulse, dyspnea	Circulatory overload	During course of transfusion	Discontinue transfusion; give oxygen as needed. Provide supportive care for pulmonary edema or congestive heart failure, which may develop. Anticipate administration of

			diuretic to increase excretion of excess fluid.
Muscle cramping, twitching of extremities, seizure	Acid-citrate-dextrose anticoagulant in transfusion combines with serum calcium and causes hypocalcemia	During course of transfusion	Discontinue transfusion. Anticipate administration of calcium gluconate intravenously to restore calcium level.
Fever, jaundice, lethargy, tenderness over liver	Hepatitis from contaminated transfusion	Weeks or months after transfusion	Obtain transfusion history of any child with hepatitis symptoms. Refer for care of hepatitis.
Bronze-colored skin	Hemosiderosis or deposition of iron in skin from transfusion	After repeated transfusions	Support self-esteem with altered body image. Administer iron-chelating agent (deferoxamine) as prescribed to help reduce level of accumulating iron.

To prevent children from becoming bored or attempting to increase the infusion rate to speed up the process, think of and provide an enjoyable activity for children during transfusions.

## HEMATOPOIETIC STEM CELL TRANSPLANTATION

Stem cell transplantation is the intravenous infusion of hematopoietic stem cells from bone marrow obtained by marrow aspiration or from peripheral or umbilical cord blood drawn from a compatible donor to reestablish marrow function in a child with deficient or nonfunctioning bone marrow.

Stem cell transplantation has become a relatively common procedure for children with blood disorders such as acquired aplastic anemia, sickle-cell disease, thalassemia, leukemia, and some forms of immune dysfunction diseases. Although a stressful procedure to undertake, it offers children the opportunity for a complete reversal of

symptoms. However, there is no guarantee that the grafted cells will be accepted by the recipient or that improvement will occur, but with good tissue compatibility in the absence of infection, it can be effective in most children.

Stem cell transplantation can be allogeneic, syngeneic, or autologous. **Allogeneic transplantation** is the transfer of stem cells from an immune-compatible (histocompatible) donor, usually a sibling, or from a national cord blood bank or national volunteer donor registry (Petrini, 2013). **Syngeneic transplantation** (which is rare) involves a donor and recipient who are genetically identical (i.e., identical twins). **Autologous transplantation** involves use of the child's own stem cells removed from cord blood banked at the time of the child's birth. If this is not available, in some instances, stem cells can be aspirated from the child's bone marrow or obtained from circulating blood, treated to remove abnormal cells and then reinfused.

Hematopoietic stem cells are recovered from a donor's circulating peripheral blood after the stimulation of stem cell production by a cytokine or stem cell colony-stimulating factor. Success is most likely if the recipient has not already received multiple blood transfusions that have sensitized the child to blood products and the donated stem cells are a close human leukocyte antigen (HLA) match to the child's blood. Siblings have about a 25% chance of being HLA compatible with the ill child.

To prevent a child's T lymphocytes from rejecting the newly transplanted donor stem cells, total body irradiation to destroy the child's marrow or an immunosuppressive drug such as cyclophosphamide (Cytosan) is administered intravenously to the child before the procedure. This is a difficult time for the child because even with antiemetic therapy, both total body irradiation and the immunosuppressive drug cause extreme nausea, vomiting, and diarrhea.

If the marrow will be taken directly from a donor rather than from peripheral blood, on the day of the procedure, the donor is admitted to the hospital for a 1-day stay and receives epidural anesthesia or conscious sedation because multiple bone marrow aspirations from the posterior iliac crests are necessary for retrieval. The marrow is strained to remove fat and bone particles and any other unwanted cells. An anticoagulant is added to prevent clotting, and it is then infused intravenously into the recipient's bloodstream.

Because an infused hematopoietic stem cell solution is fairly thick, the infusion takes 60 to 90 minutes. The filter normally used with the infusion of blood products should not be used because it would filter out the marrow tissue. Monitor the child's cardiac rate and rhythm during the infusion to detect circulatory overload or pulmonary emboli from unfiltered particles.

Fever and chills are common reactions to a hematopoietic stem cell transplant infusion. Acetaminophen (Tylenol) or diphenhydramine hydrochloride (Benadryl) may be prescribed to reduce this reaction. After the infusion, take the child's temperature at 1 hour and then about every 4 hours to detect an infection that could occur because the child's WBCs are nonfunctional from radiation or immunosuppression. Reinforce strict hand washing and limit the child's diet to cooked foods to reduce exposure to bacteria.

Almost immediately after the infusion, stem cells begin to migrate from the child's bloodstream into the marrow. If *engraftment* occurs (the transplant is accepted), new RBCs can be detected in the peripheral blood in approximately 3 weeks. The WBC count will be measured daily to be certain WBCs are regenerating, although WBCs and platelet cells may not return to normal for up to 1 year after the transplant. Bone marrow aspirations or venous blood samples are then scheduled at regular intervals over the next year to assess the growth of the new marrow.

### *What If . . . 44.1*

**Lana's 12-year-old sister donates hematopoietic stem cells to Lana, but the transplant is not successful. The sister tells the nurse she knew it wouldn't be successful because she and Lana are more rivals than compatible sisters. How would the nurse best provide patient education for Lana's sister?**

## **Nursing Diagnoses and Related Interventions**

Because it takes a long time for the success or failure of stem cell transplantation to be documented, the procedure almost always produces anxiety not just in the child but also in the donor and the entire family.

**Nursing Diagnosis:** Anxiety related to long period of waiting to receive results of hematopoietic stem cell transplant and necessary extended restrictions and infection control precautions in hospital or at home.

**Outcome Evaluation:** Parents state they are managing their level of anxiety, are carrying out infection restrictions as prescribed, and are expressing satisfaction with child's ongoing development.

Be certain when discussing the risks of a stem cell transplant that both the child who received the transplant and the donor understand they are not responsible for the outcome of the procedure because its success does not depend on their behavior or what kind of person they are but on immunologic factors over which they have no control.

Because not all hematopoietic stem cell transplants are successful, some children will die of the original disease that necessitated the transplant. And, even if the transplant was successful, another risk is that a child will develop an infection despite all precautions and die of sepsis in the weeks immediately after the transplant.

To prevent the child from contracting an infection until the WBC count returns to a safe range, children are restricted from interacting with other children either by

remaining in the hospital or by employing visiting restrictions at home. Be certain to visit the room of an isolated child frequently and provide sterilized play materials the child can enjoy as appropriate. Because raw vegetables and fruits have the potential to carry germs, thick-skinned fruits such as bananas and oranges can be given soon after the procedure, but unwashed foods are typically avoided because these are foods most likely to carry bacteria.

Be certain children are well prepared for all procedures. Allow them to make as many choices as they can about their care to help them preserve a sense of control over their lives. Encourage periods of therapeutic play into their care so they can begin to express their anger and frustration at the number of intravenous therapies or follow-up bone marrow aspirations they require. Frequent visits by their parents and measures to help the child cope with pain, such as imagery, can help them accept one more painful procedure.

Ask the parents if they have made provisions for schoolwork as soon as the child has a return of RBCs in the peripheral blood (about 3 weeks). This can be accomplished by assisting parents with setting up a meeting with the child's teachers and school principal to devise an individualized education plan. Help them locate a support group in their community if they feel this will be helpful. Be certain they feel free to call the transplant center after discharge to discuss any problems. Once the danger of infection has passed and the restrictions can be discontinued, some parents may still be reluctant to allow their child outside or to interact with other children. This makes frequent follow-ups by e-mail or texting for the next year necessary to not only ensure that the child is free of infection but also assess whether the parents allow their child to pursue age-appropriate activities to encourage growth and development.

### **Graft-Versus-Host Disease**

Graft-versus-host disease (GVHD) is a potentially lethal immunologic response of donor T cells to the tissue of the bone marrow recipient (Alousi, Bolaños-Meade, & Lee, 2013). The symptoms range from mild to severe and generally include a rash and general malaise beginning 7 to 14 days after the transplant. Severe symptoms include high fever, diarrhea, and liver and spleen enlargement.

Because there is no known cure for GVHD, prevention is essential. Careful tissue typing, intravenous administration of a corticosteroid and an immunosuppressant before transplant, and irradiation of blood products (which helps to inactivate mature T lymphocytes) before the infusion all can help reduce the incidence of this complication. Immunosuppressant drugs such as methotrexate or cyclosporine work by killing all rapidly growing cells, including WBCs and T lymphocytes, so administration of these drugs after transplantation cannot be continued or they would also interfere with the growth of the host's new stem cells. Prophylactic antibiotics and intravenous immune globulin are prescribed to decrease the risk of infection, and should be given consistently (Graham, Craddock, Quinones, et al., 2016).

### **PATIENT-CENTERED CARE**

Lana, who has thalassemia major, is scheduled for a bone marrow transplant, and her mother is highly anxious about this upcoming procedure. The nurse recognizes which statement is most accurate and best exemplifies patient-centered care?

- a. “If you can hold her still during the procedure, the pain will pass more quickly for her.”
- b. “We will go to great lengths to make sure Lana doesn’t develop an infection.”
- c. “Lana will need to lie still while the new bone marrow infuses into her bones.”
- d. “She will not need any further bone marrow aspirations after this.”

*Look in [Appendix A](#) for the best answer and rationale.*

### **SPLENECTOMY**

One of the purposes of the spleen is to remove damaged or aged blood cells. This poses a problem with diseases such as sickle-cell anemia and the thalassemias because the spleen interprets the typical cells of these diseases as damaged and destroys them. This causes children with these disorders to have a continuous anemia, with hemoglobin levels as low as 5 to 9 g/ml. In some children, therefore, removal of the spleen (splenectomy) will not cure the basic defect of the blood cells but will limit the degree of anemia. Splenectomy formerly required a large abdominal incision, but today, it can be performed by laparoscopy so, although still a procedure with risks, it does not require as long a recovery period.

A second function of the spleen is to strain blood particles that might lead to blood clots, as well as invading microorganisms, from the blood plasma so phagocytes and lymphocytes can destroy them. Children who have their spleen removed are more susceptible to pneumococcal infections and other bacterial infections because the spleen is no longer present to remove invading microorganisms from the body ([Ambruso et al., 2016](#)). After surgery, oral penicillin is typically given as a prophylactic antibiotic for a year or two to guard against infection. Assess to be certain the child also receives *Haemophilus influenzae* type b (Hib) and pneumococcal and meningococcal vaccines for further protection. Review with parents the signs of infection (e.g., cough, fever, general malaise) and encourage them to report any such signs immediately to their primary care provider.

### **Health Promotion and Risk Management**

Hematologic disorders cover a wide range of diseases, both inherited and as an immunosuppressive response to infection, so they produce multiple symptoms in children ([Box 44.2](#)). Health promotion and disease prevention, therefore, begins with

ensuring families have access to genetic counseling so they can be aware of the incidence of a disorder in their family and the potential for the disease to develop in their child.

BOX 44.2

## Nursing Care Planning Using Assessment

### ASSESSING A CHILD WITH A HEMATOLOGIC DISORDER

#### History

*Chief concern:* Fatigue, easy bruising, epistaxis.

*Past medical history:* Low birthweight; blood loss at birth; lack of vitamin K administration at birth.

*Nutrition:* "Picky eater" or presence of pica. Increased milk intake.

*Past illnesses:* History of recent illness; history of recent medicine ingestion.

*Family history:* Inherited blood disorder; parents known to have sickle-cell trait, thalassemia minor, or hemophilia in family.

#### Physical examination

##### General appearance

Obese infant

Fatigue

##### Eyes

Retinal hemorrhage

##### Face

Bossing of maxillary bone

##### Mouth

Pale mucous membrane

Ecchymotic or bleeding gumline

##### Heart

Increased rate,

possible murmur

##### Skin

Petechiae, ecchymosis

Blood oozing from wound or injection point

Jaundice

Pallor

Bronze color

##### Abdomen

Pain on palpation

Increased liver or spleen size

##### Genitourinary

Delayed secondary sex characteristics

##### Extremities

Spoon-shaped nails

Joint swelling, pain

##### Neurologic

Weak muscle tone

##### Possible significance

Iron-deficiency anemia

Anemia

Sickle-cell anemia

Thalassemia

Iron-deficiency anemia

Decreased coagulation ability

Anemia

Decreased coagulation ability

Hemolytic anemia

Frequent blood transfusion

Sickle-cell anemia

Hemolytic anemia

Sickle-cell anemia

Sickle-cell anemia

Sickle-cell anemia

Iron-deficiency anemia

Hemophilia, sickle-cell crisis

Iron-deficiency anemia

The most frequently occurring anemia in children, iron-deficiency anemia, could be virtually eliminated if all infants were breastfed and those infants who are formula fed were fed iron-fortified formula for the full first year. The disorder occurs again with a high incidence in adolescents because adolescent diets tend to be low in meat and green

vegetables, the chief dietary sources of iron. Adolescents who begin pseudovegetarian diets are another group especially prone to developing the disorder. Counseling parents of young children to maintain well-child healthcare visits and urging adolescents to ingest iron-rich foods could have a major impact on decreasing the incidence of the disorder.

*Aplastic anemia*, or the inability to form blood elements, can be acquired if a child is exposed to a toxic drug or chemical. Educating parents about the importance of keeping poisons out of the reach of children and being aware of toxic substances in their community could help decrease the incidence of this disorder. Because children with hematologic disorders may have a changed physical appearance and also need to avoid contact sports to prevent bleeding episodes, they may be the victims of bullying or stigmas; be certain parents talk with their children about this so children know to report bullying rather than continue to be a victim (Bhatt-Poulose, James, Reid, et al., 2016).

## Disorders of the Red Blood Cells

Most RBC disorders fall into the category of the anemias, or a reduction in the number or function of erythrocytes. Polycythemia, or an increase in the number of RBCs, can also occur and, because it can lead to blood clots, may be as dangerous to a child as a reduction in RBC production.

Anemia occurs when the rate of RBC production falls below that of cell destruction, or when there is a loss of RBCs, causing their number and the hemoglobin level to fall below that of production. Anemias are classified according to the changes seen in RBC numbers or configuration, or according to the source of the problem. Although any reduction in the amount of circulating hemoglobin lessens the oxygen-carrying capacity, clinical symptoms are not usually apparent until the hemoglobin level reaches 7 to 8 g/100 ml. Average values for hemoglobin and RBC number are available at <http://thePoint.lww.com/Flagg8e>.

### NORMOCHROMIC, NORMOCYTIC ANEMIAS

Normochromic (normal color), normocytic (normal cell size) anemias occur because of impaired production of erythrocytes by the bone marrow or by abnormal or uncompensated loss of circulating RBCs, as with acute hemorrhage. The RBCs appear normal in both color and size; however, there simply are too few of them for effective oxygen transport.

#### Acute Blood-Loss Anemia

Blood loss that is sufficient to cause anemia can occur from trauma such as an automobile accident with internal bleeding; from acute nephritis in which blood is lost in the urine; or in the newborn from disorders such as placenta previa, premature separation of the placenta, maternal–fetal or twin-to-twin transfusion, or trauma to the

cord or placenta. In childhood, it can occur from the action of long-term intestinal parasites such as a tapeworm or hookworm or, in small infants, bedbug bites.

With sudden blood loss, children immediately appear pale. Because their heart must push the reduced amount of blood through their body more rapidly than usual, tachycardia will occur. Children will also begin to breathe rapidly because body cells are still not able to receive adequate oxygen. Newborns may have gasping respirations, intercostal retractions, and cyanosis. Children with rapid heart and respiratory rates due to this do not respond well to oxygen therapy because they lack RBCs to transport and use the oxygen. They become listless and inactive, dizzy, and, possibly, comatose.

This type of acute blood-loss anemia generally is transitory because the sudden reduction in available oxygen stimulates the release of erythropoietin from the kidney and a regeneration response in the bone marrow. The reticulocyte count rises, which is evidence that the bone marrow is trying to increase production of erythrocytes to meet the sudden shortage.

Treatment involves control of bleeding by addressing its underlying cause and transfusing additional RBCs. Lay the child flat to provide as much circulation as possible to brain cells. Keep the child warm with blankets; place the infant in an incubator or under a radiant heat warmer. Until blood is available for transfusion, a blood expander such as plasma or intravenous fluid such as normal saline or lactated Ringer's may be given to expand blood volume and improve blood pressure. With such emergency steps, the situation should be transitory with no long-term consequences.

### **Anemia of Acute Infection**

Acute infection or inflammation, especially in infants, can cause increased destruction or decreased production of erythrocytes. Common conditions that do this include osteomyelitis and ulcerative colitis. Management involves treatment of the underlying condition. When the condition is reversed, blood values will return to normal.

### **Anemia of Renal Disease**

Either acute or chronic renal disease can cause loss of function in kidney cells, which causes an accompanying decrease in erythropoietin production, resulting in a normocytic, normochromic anemia. Administration of recombinant human erythropoietin can increase RBC production and correct the anemia, but not the renal disease.

### **Anemia of Neoplastic Disease**

Malignant growths such as leukemia or lymphoma (common neoplasms of childhood) result in normochromic, normocytic anemias because the invasion of bone marrow by proliferating neoplastic cells impairs RBC production. There may be accompanying blood loss if platelet formation also is decreased. The treatment of such an anemia involves measures designed to achieve remission of the neoplastic process and

transfusion to increase the erythrocyte count.

## Hypersplenism

Under usual conditions, blood filters rapidly through the spleen. If the spleen becomes enlarged, however, blood cells pass through more slowly, with more cells being destroyed in the process. The overactive spleen then leads to increased destruction of RBCs which can cause anemia and may lead to **pancytopenia** (deficiency of all cell elements of blood). Virtually any underlying splenic condition can cause this syndrome.

Therapeutic management consists of treating the underlying splenic disorder and includes a possible splenectomy.

## Aplastic Anemias

Aplastic anemias result from depression of hematopoietic activity in the bone marrow. The formation and development of WBCs, platelets, and RBCs can all be affected (Ambruso et al., 2016).

*Congenital* aplastic anemia (Fanconi syndrome) is inherited as an autosomal recessive trait. A child is born with several congenital anomalies, such as skeletal and renal abnormalities, hypogenitalism, and short stature. Within 10 years, most of these children develop bone marrow failure as well as thrombocytopenia and neutropenia (Ambruso et al., 2016).

*Acquired* aplastic anemia is a decrease in bone marrow production, which occurs if a child is excessively exposed to radiation, drugs, or chemicals known to cause bone marrow damage. Exposure to insecticides and chemotherapeutic drugs temporarily causes this. Other examples of drugs that cause acquired aplastic anemia include chloramphenicol, sulfonamides, arsenic (contained in rat poison, sometimes eaten by children), hydantoin, benzene, or quinine. A serious infection such as meningococcal pneumonia might cause autoimmune suppression of the bone marrow, which then also results in this condition.

## Assessment

When symptoms begin, a child appears pale, fatigues easily, and has anorexia from the lowered RBC count and tissue hypoxia. Because of reduced platelet formation (**thrombocytopenia**), the child bruises easily or develops **petechiae** (pinpoint, macular, purplish-red spots caused by an intradermal or submucous hemorrhage). A child may have excessive nosebleeds or gastrointestinal bleeding. As a result of a decrease in WBCs (neutropenia), a child may contract an increased number of infections and respond poorly to antibiotic therapy. Observe closely for signs of cardiac decompensation such as tachycardia, tachypnea, shortness of breath, or cyanosis from the long-term increased workload of all these effects on the heart. Bone marrow samples will show a reduced number of blood elements, and blood-forming spaces will be infiltrated by fatty tissue (Ambruso et al., 2016).

The child is apt to be irritable because of the fatigue and recurring symptoms. Parents may feel distressed if the illness originated from exposure to a chemical they should have kept away from their child, such as an insecticide. This can cause parents to have less confidence in healthcare personnel if the illness followed treatment with a drug such as chloramphenicol. They may wonder how they can trust in a drug to cure the illness if they believe a prescribed drug caused the illness.

## Therapeutic Management

The first step in therapy is to immediately discontinue any drug or chemical suspected of causing the bone marrow dysfunction and removing the substance from the child's environment to avoid exposure. The ultimate therapy for both congenital and acquired aplastic anemia is hematopoietic stem cell transplantation (Korthof, Békássy, & Hussein, 2013). If a donor cannot be located, the disease is managed by a variety of procedures to supplement blood or to suppress T lymphocyte-dependent autoimmune responses while waiting for a histocompatible donor. Packed RBCs, platelet transfusions, cyclosporine, antithymocyte globulin (ATG), and an RBC-stimulating factor such as erythropoietin are generally necessary to maintain adequate blood elements. Some children show improvement with a course of an oral corticosteroid (prednisone) to further decrease the immune response or a course of testosterone to stimulate RBC growth. Be certain to observe a child well when administering ATG intravenously because of the high risk for anaphylaxis.

For children who receive a hematopoietic stem cell transplant, chances of complete recovery are good. For others, the course will be uncertain. A decreased WBC count leaves the child open to infection. The decreased platelet count may persist for years after other blood elements have returned to normal, producing long-term problems of bleeding, especially petechiae or purpura (Box 44.3).

### BOX 44.3

#### Nursing Care Planning to Empower a Family

#### TECHNIQUES FOR REDUCING BLEEDING WITH THROMBOCYTOPENIA

**Q.** Lana's mother asks you, "What precautions do you take to limit black and blue spots on Lana when her platelet count is low?"

**A.** "We try, as a team, to do the following."

- Limit the number of blood-drawing procedures; combine samples whenever possible.
- Use a blood pressure cuff instead of a tourniquet to reduce the number of petechiae.
- Apply pressure to any puncture site for a full 5 minutes before applying a bandage.

- Minimize the use of adhesive tape to the skin (pulling for removal may tear the skin and cause petechiae).
- Pad side and crib rails to prevent bruising. Assess the need for routine blood pressure determinations because tight cuffs can lead to petechiae.
- Protect intravenous sites to avoid numerous reinsertions.
- Administer medication orally or by intravenous infusion when appropriate to minimize the number of subcutaneous or intramuscular injection sites.
- Assess that the child is using a soft toothbrush and is offered foods that can be chewed without irritation (e.g., avoid toast crusts).
- Check toys for sharp corners, which may cause scratches. Urge the child to be careful with paper because paper cuts can bleed out of proportion to their size.
- Distract the child from rough play; suggest stimulating but quiet activities to minimize risk of injury.

## Nursing Diagnoses and Related Interventions

Nursing diagnoses need to speak to not only the physical symptoms of aplastic anemia but also the continual stress the parents feel if laboratory reports do not reveal a dramatic change in their child's blood cell production. It may be helpful to urge them to deal with this problem by facing only one day or one blood test at a time rather than trying to dwell on the outcomes of all the blood tests to come.

**Nursing Diagnosis:** Risk for disturbed body image related to changed appearance occurring as medication side effects

**Outcome Evaluation** Child views self as a worthwhile person; does not appear to be excessively shy or reluctant to interact with peers.

Children who receive corticosteroids such as prednisone to suppress the immune response almost always experience some of the drug's side effects, such as a cushingoid appearance, hirsutism, hypertension, and marked weight gain. Long-term therapy with testosterone can result in masculinizing effects, such as growth of facial and body hair, the development of acne, and deepening of the voice. Be certain both children and their parents know these effects are related to the medication and will fade when the medication is withdrawn.

Adolescents may have an especially difficult time accepting weight gain and increased acne and so need a chance to express their feelings about their changed appearance. Reinforce and emphasize things they are doing well such as how well they are managing this unexpected turn in their life.

## Hypoplastic Anemias

Hypoplastic anemias also result from depression of hematopoietic activity in bone marrow and can also be either congenital or acquired. Unlike aplastic anemias, however, in which WBCs, RBCs, and platelets are all affected, with hypoplastic anemias, only RBCs are affected.

Congenital hypoplastic anemia (Blackfan–Diamond syndrome) is a rare disorder apparently caused by an inherent defect in RBC formation that affects both sexes and shows symptoms as early as the first 6 to 8 months of life (Sakaguchi, Nakanishi, & Kojima, 2013). An acquired form of this can be caused by infection with parvovirus B19, the infectious agent that causes fifth disease.

The onset of a hypoplastic anemia is insidious, and at first, it may be difficult to differentiate from iron-deficiency anemia. With iron-deficiency anemia, blood cells appear hypochromic and microcytic and are few in number; however, in hypoplastic anemia, they are not only few in number but also their structure is normochromic and normocytic.

With the acquired type, the reduction of RBCs is transient, so no therapy other than monitoring is necessary. Children with the congenital form receive corticosteroid therapy along with transfusions of packed RBCs to raise erythrocyte levels. As a result of the necessary number of transfusions, **hemosiderosis** (a deposition of iron in body tissue) can occur. An iron chelation program such as subcutaneous infusion of deferoxamine (Desferal) may be started concurrently with transfusions to bind with iron and aid its excretion from the body in urine. Although an oral form is available for children over 10 years of age, this is usually given by a subcutaneous infusion pump over an 8-hour period for 5 or 6 nights a week. Remind the parent to assess that the child is voiding as usual and that his or her specific gravity is normal (1.003 to 1.030) before beginning an infusion so iron removed from tissues can be excreted (Karch, 2013).

To begin such an infusion, an area beside the scapula or on the thigh is cleaned with alcohol and a short 25-gauge needle is inserted at a low angle into the subcutaneous tissue and attached to an infusion pump by intravenous tubing. In addition to the assessments of voiding and specific gravity, periodic slit-lamp eye examinations should be scheduled to check for cataract formation, a possible adverse effect of deferoxamine.

Although congenital hypoplastic anemia has to be thought of as a chronic condition, about one fourth of affected children will undergo spontaneous permanent remission before the age of 13 years. If not, they are candidates for hematopoietic stem cell transplantation. As with aplastic anemia, both the child and the parents need support from healthcare personnel to help them accept the many procedures and tests required before full remission is finally achieved.

### *QSEN Checkpoint Question 44.2*

## INFORMATICS

Lana has received iron chelation therapy by deferoxamine in the past. Which statement by her mother would best assure the nurse she understands the use and action of iron chelation therapy?

- a. “I know the drug acts to remove excess iron from my child.”
- b. “I have to check Lana’s pulse before I turn on the pump.”
- c. “The drug is used to increase the level of iron in bone cells.”
- d. “The drug has minimal side effects, so I can’t really give it wrong.”

---

*Look in Appendix A for the best answer and rationale.*

---

## **HYPOCHROMIC ANEMIAS**

When hemoglobin production is inadequate, erythrocytes appear pale (hypochromia) and are also usually reduced in diameter (microcytic).

### **Iron-Deficiency Anemia**

Although the incidence of iron-deficiency anemia is decreasing in the United States due to improved infant nutrition, it is still the most common anemia of infancy and childhood, occurring whenever the intake of dietary iron is inadequate. Without adequate iron, hemoglobin cannot be incorporated into RBCs.

Children are at a higher risk for iron-deficiency anemia than adults because they need more daily iron in proportion to their body weight to maintain an adequate iron level than do adults—a daily intake of 11 to 15 mg of iron. This type of anemia occurs most often between the ages of 9 months and 3 years from infants drinking more milk than they are eating iron-rich foods. Its frequency rises again in adolescence, when iron requirements increase, especially for girls who are menstruating. It is also found at a high incidence in overweight teenagers if they ingest most of their calories from high-carbohydrate, not iron-rich, foods.

#### **The Infant**

A newborn usually has enough iron in reserve to last for the first 6 months of life. After that, the infant needs iron incorporated into the diet. Because iron stores are laid down near the end of gestation, infants born preterm will have fewer iron stores than those born at term and so tend to develop iron-deficiency anemia before 5 to 6 months. Women with iron deficiency during pregnancy tend to give birth to iron-deficient babies because the babies do not receive iron stores. As a preventive measure, preterm infants and those whose mother was iron deficient during pregnancy may be given an iron supplement beginning at about 2 months of age.

Infants born with structural defects of the gastrointestinal system, such as gastroesophageal reflux or achalasia (where an immature valve exists between the esophagus and stomach resulting in regurgitation) or pyloric stenosis (narrowing between the stomach and duodenum, resulting in vomiting), are particularly prone to iron-deficiency anemia because iron is not adequately digested. Infants with chronic

diarrhea may not be able to make use of iron due to inadequate absorption. If infants are fed cow's milk rather than breast milk, so much minimal gastrointestinal bleeding may occur that iron deficiency anemia may develop.

Urging parents to breastfeed or use iron-fortified formula as well as introduce iron-fortified cereal as a "first food" are important health teaching measures to prevent this form of anemia. Occasionally, infants can become constipated while ingesting iron-rich formula, but this is the exception rather than the rule.

### Older Children

In children older than 2 years of age, chronic blood loss is the most frequent cause of iron-deficiency anemia caused by gastrointestinal tract lesions such as polyps, ulcerative colitis, Crohn disease, protein-induced enteropathies, parasitic infestation, or frequent epistaxis. Adolescent girls with heavy menstrual periods can become iron deficient when this is combined with frequent attempts to diet or with overconsumption of snack foods that are low in iron.

### *Assessment*

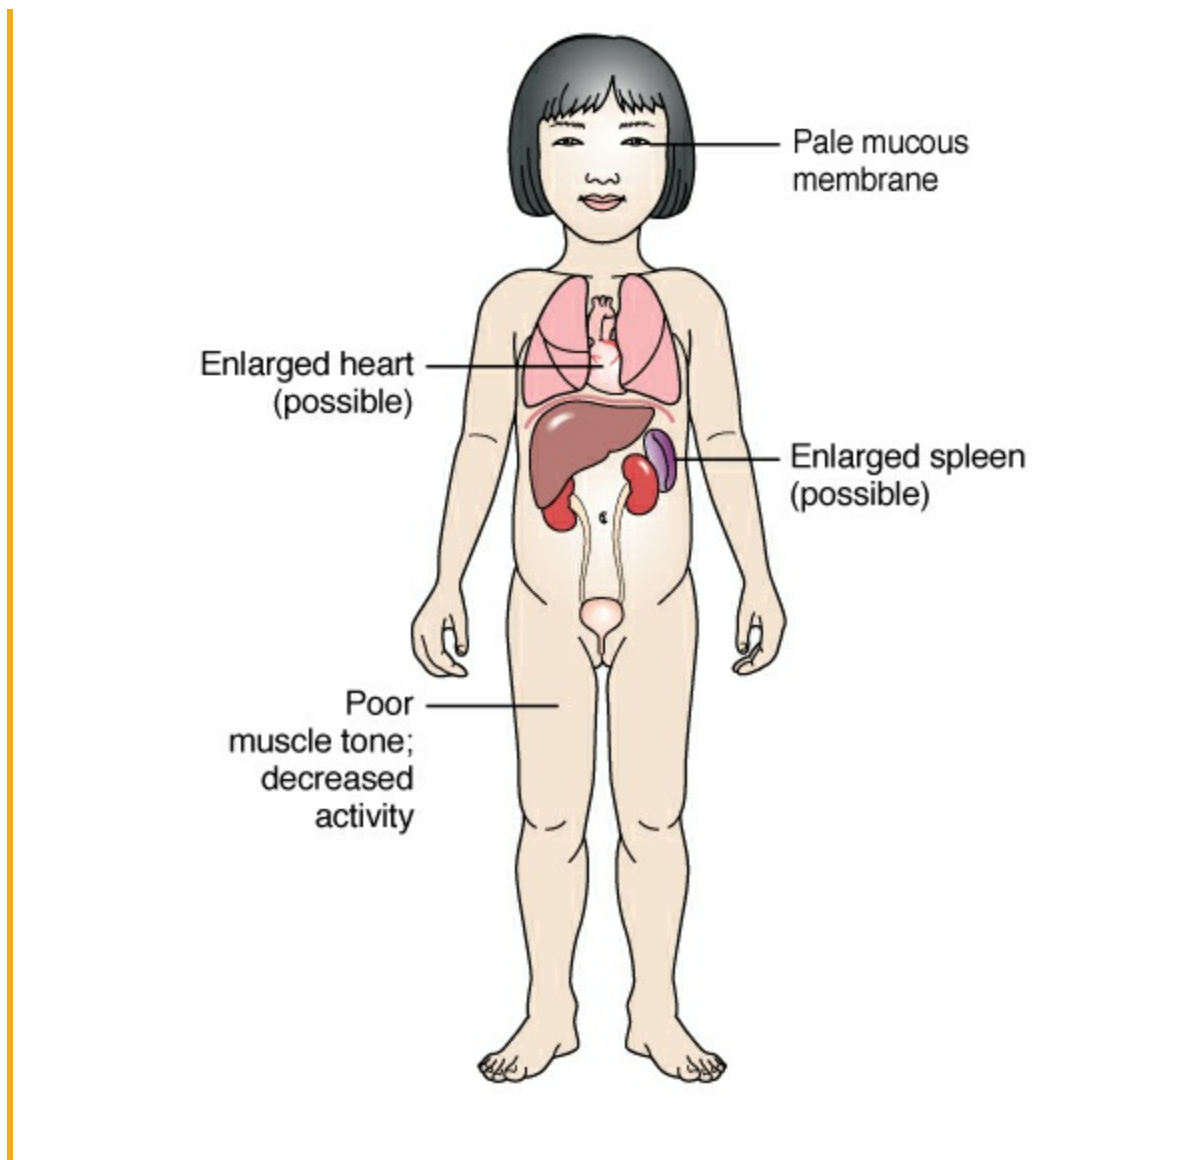

Common symptoms of iron-deficiency anemia are shown in [Box 44.4](#). The mark of iron-deficiency anemia is pale conjunctiva. Because this pallor develops slowly, however, parents may describe their child as "fair skinned" especially when their face develops the same pale appearance.

#### BOX 44.4

#### Nursing Care Planning Using Assessment

#### ASSESSING A CHILD WITH IRON-DEFICIENCY ANEMIA

With extended iron deficiency, infants develop poor muscle tone and reduced activity. Their heart may enlarge and, on auscultation, demonstrate a soft systolic precordial murmur as the heart beats faster in an attempt to supply body cells with more oxygen. The spleen may be slightly enlarged. Fingernails typically become spoon-shaped or depressed in contour.

As a rule, infants should not ingest more than 32 oz of milk a day. A 24-hour dietary history of an iron-deficient infant generally reveals a much higher milk intake than this, perhaps as high as 50 oz a day. Parents also report the child resists or parents do not offer iron-fortified cereal (1 quart of milk provides only about 0.5 mg of iron; in contrast, 1 tablespoon of iron-fortified baby cereal supplies 2.5 to 5.0 mg of iron).

Laboratory studies will reveal a decreased hemoglobin level (a level less than 11 g/100 ml of blood) and reduced hematocrit level (below 33%). The RBCs are not only microcytic and hypochromic but possibly also **poikilocytic** (irregular in shape). The mean corpuscular volume, the mean corpuscular hemoglobin, and serum iron levels are all low. Monoamine oxidase (MAO) is an enzyme important for central nervous system

maturation. Because iron is a basic component of MAO, without available iron, this necessary enzyme will be absent, possibly affecting central nervous system maturation.

In school-age children, there is an association between iron-deficiency anemia and poor school achievement, probably related to the chronic fatigue children experience. It is also associated with pica (the craving for ice cubes or the eating of inedible substances such as dirt and paper). Until the anemia is corrected, parents need to supervise their child's environment to keep inedible materials out of his or her reach (Rabel, Leitman, & Miller, 2016).

### *Therapeutic Management*

Therapy for iron-deficiency anemia focuses on treatment of the underlying cause: the lack of iron. An iron compound such as ferrous sulfate for 4 to 6 weeks is the drug of choice to improve RBC formation and replace iron stores (Box 44.5) (Ambruso et al., 2016). In addition, the diet of the child must be changed to one rich in iron and vitamin C, which enhances iron absorption.

#### BOX 44.5

#### Nursing Care Planning Based on Responsibility for Pharmacology

### **FERROUS SULFATE (FEOSOL)**

**Classification:** Ferrous sulfate is an iron salt.

**Action:** Supplies iron for red cell production. It elevates the serum iron concentration and then is converted to hemoglobin or trapped in the reticuloendothelial cells for storage and eventual conversion to a usable form of iron (Karch, 2013).

**Pregnancy Risk Category:** A

**Dosage:** For severe iron-deficiency anemia: 4 to 6 mg/kg/d in three divided doses. For mild iron-deficiency anemia: 3 mg/kg/d in two divided doses.

**Possible Adverse Effects:** Gastrointestinal upset, anorexia, nausea, vomiting, constipation, dark stools, stained teeth (liquid preparations)

### **Nursing Implications**

- Instruct parents to administer the drug on an empty stomach with water to enhance absorption. If this causes gastrointestinal irritation, administer it after meals. Avoid giving it with milk or tea because these interfere with absorption.
- If the liquid preparation is ordered, advise parents to mix it with water or juice to mask the taste. Have the child drink the medication through a straw to avoid staining the teeth.
- Remember that iron is absorbed best in the presence of an acid. Suggest parents give the iron with a citrus juice such as orange juice to help absorption. Some children may be prescribed vitamin C to take concurrently to increase absorption.
- Inform the child and parents that iron may turn stools black.

- Encourage parents to include high-fiber foods in the child's diet to minimize the risk of constipation.
- Reinforce the need for thorough brushing of teeth to prevent staining.
- Remind parents about the need for follow-up blood studies to evaluate the effectiveness of the drug.

### *Concept Mastery Alert*

Ferrous sulfate will stain the teeth, and a simple rinse with water will not remove drug left in the mouth after swallowing. The patient should be reminded to brush teeth thoroughly after administration.

## **Nursing Diagnoses and Related Interventions**

**Nursing Diagnosis:** Imbalanced nutrition, less than body requirements, related to inadequate ingestion of iron

**Outcome Evaluation** Parents report child's dietary intake includes iron-rich foods; parents administer ferrous sulfate as prescribed; serum iron levels increase to normal by 6 months.

When planning care for an infant with iron-deficiency anemia, it is helpful to minimize the child's activities to prevent fatigue, particularly at mealtime because a fatigued child is more reluctant to eat any food, let alone iron-rich foods.

Counsel parents on measures to improve their infant's nutrition, such as adding iron-rich foods while decreasing formula or breast milk intake. If the child is not fond of meat, suggest parents substitute cheese, eggs, green vegetables, or fortified cereal. Because iron-rich foods are often expensive, remind parents that these items are important and they should not substitute less expensive, high-carbohydrate foods for them. Help them also devise a reminder system so they can manage to give the iron supplement over a long period of time. Alert parents to possible side effects, such as stomach irritation, constipation, and that liquid iron preparations can stain teeth if not taken through a straw. Iron is absorbed best with an accompanying acid medium, so ascorbic acid may also be prescribed (or the parent should be advised to give the iron medication with orange juice) to increase absorption. To avoid constipation, the child may need additional fiber like that supplied by green leafy vegetables. If oral iron is not tolerated or if there is a doubt the child will take it, an iron-dextran injection (Imferon) can be given intramuscularly, although this is extremely irritating and stains the skin unless it is given by deep Z-track intramuscular injection.

Of all age groups, adolescents tend to do the least well with taking medicine

consistently. Help them plan a daily time for taking their iron supplement with a medication reminder chart. At first, they may reject this as childish, but assure them that everyone needs some sort of aid to remember such things. Review with them the iron-rich foods they will need to eat daily and that an iron supplement is only a supplement if taken with iron-rich foods.

After 7 days of iron therapy, a reticulocyte count is usually obtained. If elevated, this means the child is now receiving enough iron that erythrocytes are now proliferating and correcting the anemia. Iron medication is taken for at least 4 to 6 weeks after the RBC count has returned to normal so iron stores are rebuilt as well. In some children, maintenance therapy may continue for as long as a year.

### **Chronic Infection Anemia**

Acute infection interferes with RBC production, producing a normochromic, normocytic anemia. When infections are chronic, however, anemia of a hypochromic, microcytic type occurs, which is probably caused by impaired iron metabolism. The degree of anemia is directly related to the severity of the underlying disease; treatment of the underlying cause will usually result in increased hemoglobin levels ([Ambruso et al., 2016](#)).

### **MACROCYTIC (MEGALOBLASTIC) ANEMIAS**

A macrocytic anemia is one in which the RBCs appear abnormally large ([Wang, 2016](#)). Such cells are actually immature erythrocytes or megaloblasts (nucleated immature red cells), so these anemias are often also referred to as megaloblastic anemias. Because these anemias are caused by nutritional deficiencies, they occur most often in developing countries.

#### **Anemia of Folic Acid Deficiency**

A deficiency of folic acid combined with vitamin C deficiency produces an anemia in which the erythrocytes grow abnormally large. There is often accompanying neutropenia and thrombocytopenia. Although the mean corpuscular hemoglobin concentration will be normal, the mean corpuscular volume and mean corpuscular hemoglobin will both be increased. Bone marrow contains megaloblasts, indicating inhibition of the production of erythrocytes at an early stage. Megaloblastic arrest, or inability of RBCs to mature past this early stage, may occur in the first year of life from the continued use of infant food containing too little folic acid or from an infant drinking goat's milk, which tends to be deficient in folic acid. Treatment is daily oral administration of folic acid. With this treatment, the response is dramatic.

#### **Pernicious Anemia (Vitamin B<sub>12</sub> Deficiency)**

Vitamin B<sub>12</sub> is necessary for the maturation of RBCs. Pernicious anemia results from a

deficiency in vitamin B<sub>12</sub>, either from inadequate intake or malabsorption (Sun, Chang, Wang, et al., 2016).

In children, the cause is more often a lack of ingestion of vitamin B<sub>12</sub> rather than poor absorption. Adolescents may be deficient in vitamin B<sub>12</sub> if they are ingesting a long-term, poorly formulated vegetarian diet because the vitamin is found primarily in foods of animal origin (Stredny, Frosch, Singhi, et al., 2016).

For vitamin B<sub>12</sub> to be absorbed from the intestine, an intrinsic factor must be present in the gastric mucosa. If a child is born with an intrinsic factor deficiency, symptoms occur as early as the first 2 years of life. The child appears pale, anorexic, and irritable, with chronic diarrhea. The tongue appears smooth and beefy red due to papillary atrophy. If not identified and treated at that point, neuropathologic findings such as ataxia, hyporeflexia, paresthesia, and a positive Babinski reflex will develop.

The rate and efficiency of absorption of vitamin B<sub>12</sub> can be tested by the ingestion of the radioactively tagged vitamin when a dose of intrinsic factor is also measured. If the anemia is identified as being caused by a vitamin B<sub>12</sub>-deficient diet, temporary injections of vitamin B<sub>12</sub> will reverse the symptoms. If the anemia is caused by lack of the intrinsic factor, lifelong monthly intramuscular injections of vitamin B<sub>12</sub> may be necessary.

## HEMOLYTIC ANEMIAS

Hemolytic anemias are those in which the number of erythrocytes is low because there is increased erythrocyte destruction. The destruction may be caused by fundamental abnormalities in erythrocyte structure or by extracellular destruction forces.

### Congenital Spherocytosis

Congenital spherocytosis is a hemolytic anemia that occurs most frequently in the White Northern European population and is inherited as an autosomal dominant trait. RBCs are small and have a short life span apparently due to abnormalities of the protein of the cell membrane (Ambruso et al., 2016).

The anemia can be noticeable shortly after birth, although symptoms may not be recognized until later in the first year as the abnormal cells swell, rupture, and then are destroyed by the spleen creating a severe anemia. Chronic jaundice and splenomegaly also develop. Because the cells are so small, the mean corpuscular hemoglobin concentration will be increased. Gallstones may be present in older school-age children and adolescents because of the continuous hemolysis, bilirubin release, and incorporation of bilirubin into gallstones.

Infections can precipitate a crisis or cause bone marrow failure. During such a period, the anemia increases rapidly as the hemolysis continues. Blood transfusion will be necessary to maintain a sufficient number of circulating erythrocytes until the crisis passes.

The diagnosis of the disease is based on family history, the obvious hemolysis, and

the presence of the abnormal spherocytes. The treatment generally is a splenectomy at approximately 5 to 6 years. This measure will increase the number of RBCs present but will not alter their abnormal structure.

### Glucose-6-Phosphate Dehydrogenase Deficiency

The enzyme glucose-6-phosphate dehydrogenase (G6PD) is necessary for maintenance of RBC life; lack of the enzyme results in premature destruction of RBCs. The disease is an X-linked recessive trait inheritance and is found most often in persons of African, Mediterranean, or Asian descent ([Ambruso et al., 2016](#)).

G6PD disease occurs in two identifiable forms. Children with a congenital nonspherocytic type develop hemolysis, jaundice, and splenomegaly and may have aplastic crises. Other children have a drug-induced form in which the blood pattern is normal until the child is exposed to fava beans or drugs such as antipyretics, sulfonamides, antimalarials, and naphthoquinones (the most common drug in these groups is acetylsalicylic acid [aspirin]). Approximately 2 days after ingestion of such an oxidant drug, the child begins to show evidence of hemolysis, a low-grade fever, and perhaps back pain. A blood smear will show *Heinz bodies* (oddly shaped particles in RBCs).

The degree of RBC destruction depends on the drug and the extent of exposure to it. Occasionally, a newborn is seen with marked hemolysis because the mother ingested an initiating drug during pregnancy.

G6PD deficiency may be diagnosed by a rapid enzyme screening test or electrophoretic analysis of RBCs. The drug-induced type usually is self-limiting, and if a child is not exposed to substances that cause hemolysis, blood transfusions are rarely necessary. Be certain that both parents and children know about the abnormality in the child's metabolism so they can avoid common drugs such as acetylsalicylic acid.

### Sickle-Cell Anemia

Sickle-cell anemia is an autosomal recessive inherited disorder carried on the  $\beta$  chain of hemoglobin; the amino acid valine takes the place of the normally appearing glutamic acid. With this, the erythrocytes become characteristically elongated and crescent shaped (sickled) when they are submitted to low oxygen tension (less than 60% to 70%), a low blood pH (acidosis), or increased blood viscosity, such as occurs with dehydration or hypoxia. When RBCs sickle or change to an elongated shape, they cannot move freely through vessels. Stasis and further sickling occurs (a *sickle-cell crisis*). Blood flow halts and tissue distal to the blockage becomes ischemic, resulting in acute pain and cell destruction ([Ambruso et al., 2016](#)).

Because fetal hemoglobin contains a  $\gamma$ , not a  $\beta$ , chain, the disease usually will not result in clinical symptoms until a child's hemoglobin changes from the fetal to the adult form at approximately 6 months. However, the disease can be diagnosed prenatally by chorionic villi sampling or from cord blood during amniocentesis. If these

were not done, it will be identified at birth by neonatal screening (Forman, Coye, Levy-Fisch, et al., 2013).

Sickle-cell disease occurs in about 1 out of every 400 Black infants in the United States. The sickle-cell trait (a child carries a gene for the disease but does not have active symptoms) occurs in approximately 1 in 12 Blacks in the United States (Houston, Abel, Dadekian, et al., 2015).

The form of hemoglobin in this disorder is designated hemoglobin S. A child with sickle-cell disease is said to have hemoglobin SS (homozygous involvement). Both parents of the child with the disease will have a combination of usual adult and hemoglobin S types or be carriers (heterozygous) of the *sickle-cell trait* (hemoglobin AS). People with the trait produce enough normal hemoglobin to compensate for any hemoglobin that is sickled and therefore show no symptoms. A child with the disease (homozygous) produces no normal hemoglobin and so will demonstrate characteristic symptoms of sickle-cell anemia. A small number of children have combinations of hemoglobin S and hemoglobin C or E, which leads to chronic mild anemia.

### **QSEN Checkpoint Question 44.3**

#### **EVIDENCE-BASED PRACTICE**

The sickle-cell trait (hemoglobin AS) occurs in about 8% of Blacks, and although typically benign, there is some concern that intense physical exercise in such individuals could lead to cardiac deaths from occlusive crises. It has been reported that patients with sickle-cell disease are more prone to kidney and renal failure as well as rhabdomyolysis during times of extreme exertion. Controversies as to whether testing of athletes for sickle cell should be mandatory continue to exist. Although occurrences of death associated with sickle cell and exertion are rare, the National Collegiate Athletic Association (NCAA) has mandated testing for athletes (Lawrence, 2014).

Based on the previous study, which would be the best exercise for Joey, who has sickle-cell disease, and his father who has the sickle-cell trait?

- a. Playing video games with each other
- b. Joining a swimming program at their local YMCA
- c. Watching sports together on TV each evening
- d. Organizing a touch (no contact) football game each weekend

*Look in Appendix A for the best answer and rationale.*

### **Sickle-Cell Crisis**

*Sickle-cell crisis* is the term used to denote a sudden, severe onset of sickling. There is pooling of many new sickled cells in blood vessels causing consequent tissue hypoxia beyond the blockage (a *vaso-occlusive crisis*). Such a crisis is most apt to occur when a child has a gastrointestinal illness causing dehydration, a respiratory infection that

results in lowered oxygen exchange and a lowered arterial oxygen level, or after extremely strenuous exercise (enough to lead to tissue hypoxia); however, sometimes, no obvious cause of a crisis can be found (Boxes 44.6 and 44.7). Symptoms are sudden, severe, and painful (Box 44.8, an interprofessional care map for the child with sickle-cell anemia). A laboratory report will reveal a hemoglobin level of only 6 to 8 g/100 ml. A peripheral blood smear will demonstrate sickled cells. Bilirubin and reticulocyte levels will be increased and the WBC count is often elevated to 12,000 to 20,000/mm<sup>3</sup>.

### BOX 44.6

#### Nursing Care Planning Using Assessment

##### ASSESSING A CHILD WITH SICKLE-CELL CRISIS

### BOX 44.7

#### Nursing Care Planning Tips for Effective Communication

Joey, who has sickle-cell disease, is seen in the emergency department with a new vaso-occlusive crisis. His right knee is discolored by a large brush burn. He's crying from pain.

*Tip:* In an emergency room, it's important that both children and parents recognize the first priority of the nurse is to obtain an accurate history and not to blame anyone for breaking the treatment plan. The nurse will work to find ways to actively assist parents to move past a broken rule so that therapy can be started.

Children with sickle-cell anemia have to follow what seems like a great many rules to avoid clotting or bleeding episodes, such as not playing contact sports or playing too hard in the sun. The following is an example of how to facilitate a conversation when a patient has not followed the treatment plan and the caregiver is upset.

**Nurse:** Hello, Mr. Harrow. I need to ask some questions to see if anything triggered this new crisis.

**Mr. Harrow:** He better not have been doing something he's not allowed to do.

**Nurse:** His knee looks like he may have fallen. Were you running, Joey? So you got dehydrated?

**Mr. Harrow:** He better not say he was doing that.

**Nurse:** Mr. Harrow, why don't we let Joey tell us how he thinks the accident happened? Then later on, we can talk about what are good rules for him to be following.

BOX 44.8

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR A CHILD WITH SICKLE-CELL ANEMIA

Joey is a 7-year-old with sickle-cell anemia you see in the emergency room for a vaso-occlusive crisis.

**Family Assessment:** Child lives with two older brothers (10 and 12 years of age) and both parents in a three-bedroom home. Father works as a distributor for a local water bottling company. Mother, an X-ray technician, is temporarily on duty with the National Guard in the Middle East. Father rates finances as, "Not good. Medical bills are killing us."

**Patient Assessment:** Thin, early school-age child with weight at 5th percentile for age. Was screened and diagnosed with sickle-cell anemia at birth. Described as "picky eater"; has eaten little since mother was deployed because he doesn't like father's cooking. Has a history of two former vaso-occlusive crises. Missed last regularly scheduled health assessment 2 weeks ago because father had difficulty taking off from work. Was playing "tag" with older brothers this afternoon. Sclera was jaundiced and child was crying from pain by time father returned from work.

Hemoglobin 6 g/100 ml; hematocrit 31%.

**Nursing Diagnosis:** Altered tissue perfusion related to vaso-occlusive crisis

**Outcome Criteria:** Oxygen saturation level is maintained at 95% or higher, pain decreases to tolerable level, and symptoms of hemolytic crisis decrease.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess if child understands he will need to remain in bed.	Admit child to hospital unit; restrict to bed rest.	Bed rest reduces the need for oxygen in body cells.	Child complies with bed rest; plays nonaction games with parent or healthcare personnel.
<i>Teamwork and Collaboration</i>				
Nurse/primary care provider	Assess if hematology service is needed for consult.	Meet with hematology service as needed for emergency and long-range planning.	Repeated vaso-occlusive crises suggest family needs better management strategies.	Hematology service meets with parent and child as indicated.
<i>Procedures/Medications for Quality Improvement</i>				
Nurse/nurse practitioner	Assess degree of child's pain by use of FACES Pain Scale.	Administer prescribed analgesic as needed.	Vaso-occlusive crises can cause sharp pain that requires strong analgesia.	Child rates pain as no higher than 2 following analgesia administration.
Nurse	Assess oxygen saturation level by continuous pulse oximetry.	Administer oxygen by nasal prongs to keep oxygen saturation above 95% or as prescribed.	Oxygen saturation decreases because sickled cells are unable to carry a full complement of oxygen.	Child cooperates with pulse oximetry and oxygen administration. Oxygen saturation remains above 95%.
Nurse	Determine	Administer	Folic acid and	Child takes

	whether child has been taking folic acid and hydroxyurea at home.	medications to initiate red blood cell (RBC) production as prescribed.	hydroxyurea help to build new RBCs to replace those that have been hemolyzed.	medication cooperatively.
--	---	--	---	---------------------------

*Nutrition*

Nurse	Assess child's intake and output.	Begin oral rehydration or intravenous (IV) therapy as prescribed.	Restoring hydration reduces sickle-cell clotting.	Child names best hand to start IV infusion; drinks prescribed fluid.
Nurse/nutritionist	Assess child's usual nutrition intake by 24-hour dietary recall history.	Demonstrate child's reduced weight to parent. Plan ways to increase calorie intake.	Even "picky eaters" need to take in enough food daily to meet growth and maintenance needs.	Father states he will try harder to serve foods the child likes; child voices intent to eat at least one meat helping daily.

*Patient-Centered Care*

Nurse	Assess family members' understanding of the causes of sickle-cell vaso-occlusive crises.	Review with family members the importance of child avoiding dehydration and oxygen deficiency.	Dehydration leads to clumping of sickled cells, cutting off circulation in distant body parts.	Family members state they are aware they must be as responsible as the child for avoiding sickling circumstances.
-------	--	--	--	---

*Psychosocial/Spiritual/Emotional Needs*

Nurse	Assess the stress level of family in light of absent mother and child with chronic illness.	Review with family ways to maintain a tight knit family unit (e.g., game night, common activities) to maintain family unity until	When families miss a support person, they need to rally together to devise other support methods.	Father states he will try harder to meet children's needs, although worrying about keeping his job and his wife's safety are major
-------	---	---	---	--

		mother returns.		concerns.
<i>Informatics for Seamless Healthcare Planning</i>				
Nurse	Determine whether parent has any questions about care of his or her child.	Schedule a follow-up visit in 3 days following hospital discharge for evaluation as prescribed.	Care of a chronically ill child can be a major strain on a family. Follow-up visits help share responsibility for care.	Father states he understands importance of follow-up visit and will keep appointment with child.

Further complications that may occur are aseptic necrosis of the head of the femur or humerus causing sharp joint pain or a cerebrovascular accident that occurs from a blocked artery, resulting in loss of motor function, coma, seizures, or even death. If there is renal involvement, hematuria or flank pain may be present.

Other types of crisis that may occur include:

- A *sequestration crisis* occurs when there is splenic sequestration of RBCs or severe anemia occurs due to pooling and increased destruction of sickled cells in the liver and spleen. Shock symptoms occur from hypovolemia. The spleen is enlarged and tender.
- A *hyperhemolytic crisis* occurs when there is increased destruction of RBCs.
- A *megaloblastic crisis* occurs if the child has folic acid or vitamin B deficiency (new RBCs cannot be fully formed due to lack of these ingredients).
- An **aplastic crisis** (temporary cessation of RBC production) occurs when there is a sudden decrease in RBC production. This form usually occurs with infection. It creates a severe anemia.

### *Assessment for Sickle-Cell Anemia*

Sickle-cell anemia is diagnosed at birth because of required blood-spot screening. At approximately 6 months of age, children begin to show initial signs of fever and anemia. Stasis of blood and infarction may occur in a body part, leading to local pain. Some infants have swelling of the hands and feet (a hand-foot syndrome) probably caused by aseptic infarction of the bones of the hands and feet. As they grow, children tend to have a slight, thin build and characteristically long arms and legs. They may have a protruding abdomen because of an enlarged spleen and liver. In adolescence, the spleen size may decrease in size from repeated infarction and atrophy, leaving the teenager more susceptible to infection than usual because the spleen can no longer filter bacteria. *Streptococcus pneumoniae* and *meningococcus* are two common bacterial agents that frequently cause illness; the child with sickle-cell anemia needs prophylactic antibiotics and age-appropriate vaccines to prevent these and other infections (Obaro &

[Iroh Tam, 2016](#)).

During late childhood or adolescence, an acute chest syndrome with symptoms of fever, tachypnea, wheezing, or cough that leads to pneumonia may begin to occur ([Novelli & Gladwin, 2016](#)). The syndrome develops because when areas of the lung become inflamed and hypoxic, sickle cells adhere to the irritated endothelium and then fail to be reoxygenated. Blood transfusion is used to increase the oxygen-carrying capacity of the blood, and broad-spectrum antibiotics are given to resolve the pneumonia.

Another change that may occur is stasis of blood flow because of cirrhosis of the liver (fibrotic degeneration), which will eventually occur from infarcts and tissue scarring. The kidneys may have subsequent scarring also, so kidney function may be decreased. Eye sclera become icteric (yellowed) from release of bilirubin from destruction of the sickled cells; small retinal occlusions may lead to decreased vision. **Priapism**, a persistent painful erection, is a clinical manifestation of sickle cell caused by vaso-occlusion in the penis ([Ambruso et al., 2016](#)).

### *Therapeutic Management*

The child in a sickle-cell crisis has three primary needs: pain relief, adequate hydration, and oxygenation to prevent further sickling and halt the crisis.

Acetaminophen (Tylenol) may be adequate pain relief for some children; for others, a narcotic analgesic such as intravenous morphine may be necessary. Once children are pain free and able to relax, the metabolic demand for oxygen is reduced and sickling begins to end. Hydration is generally accomplished with intensive intravenous fluid replacement therapy. The acidosis that develops from tissue hypoxia must be corrected by electrolyte replacement. As a rule, because some kidney infarction may have occurred, do not administer potassium intravenously until kidney function has been determined (e.g., the child voids). Otherwise, excessive potassium levels can lead to cardiac arrhythmias. If infection appears to be the precipitator for a sickling crisis, blood and urine cultures, a chest X-ray, and a complete blood count will be taken and the infection will be treated with antibiotics. Blood transfusion (usually packed RBCs) may be necessary to prevent life-threatening complications and maintain a normal hemoglobin count ([Novelli & Gladwin, 2016](#)).

Hydroxyurea, an antineoplastic agent, has the potential to increase the strength and oxygenation capacity of sickled cells ([Ponnampalam & Thalange, 2013](#)). Given orally, a side effect of the drug is anorexia, so children need their nutrition intake monitored while taking the drug to be certain it is adequate.

If none of the previous measures appears to be effective, children may be given an exchange transfusion to remove most of the sickled cells and replace them with normal cells. Hematopoietic stem cell transplantation is a permanent solution to the disorder and is advocated for the child who does not respond to usual therapies.

### QUALITY IMPROVEMENT

Joey, who has sickle-cell anemia, is being treated for sickle-cell crisis. Which statement by his father would best assure the nurse that Joey is receiving adequate nursing care?

- “He never used to understand why he had these crises, but now, he can describe the reason.”
- “He says that his pain is actually quite manageable now.”
- “He says that the nurses he’s met so far are such nice people.”
- “He’s looking forward to getting home, but he really doesn’t mind it here.”

*Look in [Appendix A](#) for the best answer and rationale.*

## Nursing Diagnoses and Related Interventions

Because, like most anemias, sickle-cell disease is a chronic process, nursing diagnoses need to consider both short- and long-term goals.

**Nursing Diagnosis:** Ineffective tissue perfusion related to generalized infarcts due to sickling

**Outcome Evaluation:** Child’s respiratory rate is 16 to 20 breaths/min; cyanosis is absent; arterial blood gases within acceptable parameters, including  $PCO_2 = 40$  mmHg,  $PO_2 = 80$  to 90 mmHg, oxygen saturation of 95%; urine output greater than 1 ml/kg/hr.

Oxygen may be administered by either nasal cannula or mask if arterial blood gases reveal a low  $PO_2$  level. High concentrations of oxygen are used with caution because hypoxia is a stimulant to erythrocyte production, which is badly needed to replace damaged cells. Monitor the flow rate carefully, therefore, and use pulse oximetry to evaluate oxygen saturation levels for changes. Encourage bed rest to reduce oxygen expenditure.

**Nursing Diagnosis:** Ineffective health maintenance related to lack of knowledge regarding long-term needs of child with sickle-cell anemia

**Outcome Evaluation:** Parents accurately describe disease process and identify special precautions necessary to prevent a sickle-cell crisis.

In many children, episodes of sickling grow less severe as the child reaches adolescence. Other children experience such devastating episodes in early childhood that without a stem cell transplant, the disease becomes fatal at an early age.

Between crises, parents need to focus care on preventing recurring crises. Although the hemoglobin level of children may remain as low as 6 to 9 g/100 ml, children adjust well to this chronic state. Caution parents that children who receive frequent blood transfusions should not be given supplementary iron or iron-fortified formula or vitamins because they may receive too much iron; high levels of excess iron are deposited in body tissues (**hemochromatosis**) to a point of staining body tissue or being incorporated into body tissue with fibrotic scarring (hemosiderosis). Oral folic acid may be prescribed to help rebuild hemolyzed RBCs. They need to monitor urine output and may be asked to test urine for specific gravity and hematuria to detect the extent or presence of kidney damage occurring from minor infarcts. Some children who have had kidney infarcts and a lessened ability to concentrate urine have chronic nocturnal enuresis (bed-wetting).

Be certain that children receive childhood immunizations so they are not vulnerable to common childhood infections such as measles or pertussis and receive meningococcal, pneumococcal, and Hib vaccines to prevent those specific infections. If children are prescribed oral penicillin as prophylaxis against infection, help the parents determine a method to remember or remind conscientious administration of this.

Caution parents to bring their child to a healthcare facility at the first indication of infection. Some parents are reluctant to do this, afraid that they will be labeled overprotective. Assure them that healthcare personnel are knowledgeable about sickle-cell anemia and that they know that a child with even a minor infection could become very ill.

Children should attend regular school and should be allowed to participate in all school activities except contact sports (such as football), which could result in rupture of an enlarged spleen or liver. Long-distance running is also inadvisable because it can lead to dehydration. During the summer, parents need to offer the child frequent drinks to prevent dehydration, especially on long hikes and at the beach. Caution parents against taking the child on board an unpressurized aircraft in which the oxygen concentration may fall during flight.

Children with sickle-cell disease are at high risk if they need surgery because the hours of being held on nothing-by-mouth status, as well as being unable to eat afterward, may lead to dehydration; anesthesia may cause a transient hypoxia leading to sickling. Caution parents that even for a simple operation such as tooth extraction, they must alert healthcare personnel about their child's condition.

Because puberty is delayed in some children, both parents and children may need counseling to accept this; although they can be assured once puberty changes do occur, they are adequate and just appear later than usual. Children may need support and positive reinforcement during their growth years to enhance their self-esteem as they learn how to deal with the results of a chronic hematologic disorder ([Box 44.9](#)).

---

## BOX 44.9

## SCHOOL SAFETY PRECAUTIONS FOR CHILDREN WITH SICKLE-CELL DISEASE

**Q.** Joey's father says to you, "What precautions should I discuss with my son's teacher so I know he's safe at school?"

**A.** Some common suggestions include:

- Be certain your child either takes fluid with him or buys adequate fluid for lunch because he needs to maintain a high fluid intake to prevent blood from becoming thick.
- Provide additional fluid in the summer, when dehydration is more apt to happen. Anticipate ways to provide fluid during long hikes or school trips; time spent on a hot beach may need to be limited.
- Learn about sources high in folic acid, such as vegetables and fruit, and be certain these foods are included in your son's packed lunch or selected from a cafeteria every day.
- With the exception of contact sports (to avoid damage to an enlarged spleen) and long-distance running (to prevent dehydration), encourage your son to participate in normal school activities.
- Know that bed-wetting may occur as part of the illness. Encourage your son to take baths in the morning if this occurs so his clothes don't smell of urine.
- Maintain routine health care such as immunizations to prevent common childhood illnesses such as measles and mumps, which cause fever and dehydration.
- Have the school nurse call you for any sign of illness, such as an upper respiratory infection, so therapy can be started immediately.

### *What If . . . 44.2*

**Joey's father tells the nurse he restricts Joey, who has sickle-cell anemia, from drinking any fluid after 4 pm to prevent bed-wetting. What patient education would the nurse provide for this parent?**

## THALASSEMIAS

The thalassemias are autosomal recessive anemias associated with abnormalities of the b chain of adult hemoglobin (hemoglobin A). Although these anemias occur most frequently in the Mediterranean population, they also occur in children of African and Asian heritage (Ponnampalam & Thalange, 2013).

### **Thalassemia Minor (Heterozygous $\beta$ -Thalassemia)**

Children with thalassemia minor, a mild form of this anemia, produce a combination of

both defective  $\beta$  hemoglobin and normal hemoglobin. The condition represents the heterozygous form of the disorder and can be compared with children having the sickle-cell trait. Because there is some normal production, the RBC count is usually normal, but the hemoglobin concentration will be decreased by 2 to 3 g/100 ml below usual levels. The blood cells are moderately hypochromic and microcytic because of the poor hemoglobin formation.

Children may have no symptoms other than pallor. They require no treatment, and life expectancy is normal. They should not receive a routine iron supplement because their inability to incorporate it well into hemoglobin may cause them to accumulate too much iron.

### Thalassemia Major (Homozygous $\beta$ -Thalassemia)

Thalassemia major is also called Cooley anemia or Mediterranean anemia. It is diagnosed at birth by a blood spot test. Because this is a  $\beta$ -chain hemoglobin defect, symptoms do not become apparent until a child's fetal hemoglobin has largely been replaced by adult hemoglobin during the second half of the first year of life. Effects of thalassemia major on body systems are summarized in [Table 44.3](#). Unable to produce normal  $\beta$  hemoglobin, the child shows symptoms of anemia, including pallor, irritability, and anorexia ([DeLeo & Geraghty, 2016](#)).

**TABLE 44.3 EFFECTS OF THALASSEMIA MAJOR**

Body Organ or System	Effect of Abnormal Cell Production
Bone marrow	Overstimulation of bone marrow leads to bone widening, especially in the face and skull.
Skin	Bronze-colored from hemosiderosis and jaundice
Spleen	Splenomegaly
Liver and gallbladder	Cirrhosis and cholelithiasis
Pancreas	Destruction of islet cells and diabetes mellitus
Heart	Failure from circulatory overload

RBCs are both hypochromic and microcytic. Fragmented poikilocytes (abnormally shaped RBCs) and basophilic stippling (unevenness of hemoglobin concentration) are also usually present. The hemoglobin level is less than 5 g/100 ml. The serum iron level is high because iron is not being incorporated into hemoglobin; iron saturation will be 100%.

#### Assessment

To maintain a functional level of hemoglobin, the bone marrow hypertrophies in an

attempt to produce more RBCs, causing bone pain and the formation of target cells or large macrocytes that are short lived and nonfunctional. The hyperactivity of the bone marrow results in characteristic changes in the shape of the skull (parietal and frontal bossing) and protrusion of the upper teeth, with marked malocclusion. The base of the nose may be broad and flattened; the eyes may be slanted with an epicanthal fold, as in Down syndrome. An X-ray of the bone shows marked osteoporotic (of lessened density) tissue, which can lead to fractures. The child may have both an enlarged spleen and liver due to excessive iron deposits and fibrotic scarring in the liver and the spleen from increased attempts to destroy defective RBCs. Abdominal pressure from the enlarged spleen may cause anorexia and vomiting. Epistaxis is common, diabetes mellitus may result from pancreatic hemosiderosis (deposition of iron), and cardiac dilatation with arrhythmias and heart failure may result in myocardial fibrosis caused by invasion of iron.

### Therapeutic Management

Stem cell transplantation is the ultimate cure for the disorder. While waiting for a matched donor, digitalis, diuretics, and a low-sodium diet may be prescribed to prevent heart failure. Transfusion of packed RBCs every 2 to 4 weeks (hypertransfusion therapy) can be used to maintain hemoglobin between 10 and 12 g/100 ml because with this level of hemoglobin, erythropoiesis is suppressed and cosmetic facial alterations, osteoporosis, and cardiac dilatation are minimized. Hypertransfusion therapy also reduces the possibility that a splenectomy will be necessary. Frequent blood transfusions, unfortunately, increase the risk of blood-borne diseases, such as hepatitis B, and hemosiderosis, so children need an oral iron-chelating agent to remove this excessive store of iron, such as deferasirox or deferoxamine.

A splenectomy may become necessary to reduce discomfort and also to reduce the rate of RBC hemolysis and the number of transfusions needed. Bone marrow stem cell transplantation can offer a cure. Even without stem cell transplantation, the overall prognosis of thalassemia is improving, although it is still grave. Most children with the disease die of cardiac failure during adolescence or as late adolescents if they do not receive a hematopoietic stem cell transplant.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for situational low self-esteem related to changed physical appearance

**Outcome Evaluation:** Child states she can accept altered appearance and interacts with peers.

Children with thalassemia major may have delayed growth and sexual maturation. They may develop a marked change in facial appearance because of the overgrowth of marrow-producing centers of the facial bones, which will be permanent. In addition, the child who receives frequent blood transfusions may develop such hemosiderosis that skin color appears bronze.

Children should be allowed as much activity as possible and should attend regular school to maintain a nearly normal childhood. Discussions about other children's reactions to their changing facial appearance and how people are evaluated by who they are and not what they look like can be helpful.

### *What If... 44.3*

**The last time the nurse saw Lana she was fair skinned, but at a clinic visit today, the nurse notices her skin looks a lot darker. She tells the nurse she and her mother both spent time at a tanning salon to get ready for a vacation in the sun. What concerns would the nurse have about Lana using a tanning bed and vacationing in the sun?**

## **Autoimmune Acquired Hemolytic Anemia**

Occasionally, autoimmune antibodies (abnormal antibodies of the immunoglobulin [Ig]G class) attach themselves to RBCs, destroying them or causing hemolysis. This can occur at any age, and its origin is generally unknown, although the disorder is associated with malignancy, viral infections, or collagen diseases such as rheumatoid arthritis or systemic lupus erythematosus. A child may recently have had an upper respiratory infection, measles, or varicella virus infection (chickenpox). The disorder may occur after the administration of drugs such as quinine, phenacetin, sulfonamides, or penicillin (Ambruso et al., 2016).

### **Assessment**

The onset of symptoms is insidious. Children usually develop a low-grade fever, anorexia, lethargy, pallor, and icterus from release of indirect bilirubin from the hemolyzed cells. Both urine and stools appear dark as the excess bilirubin is excreted. In a few children, the illness begins abruptly with high fever, hemoglobinuria, marked jaundice, and enlarged liver and spleen.

Laboratory findings reveal RBCs have become extremely small and round (spherocytosis). The reticulocyte count will be increased as the body attempts to form replacement RBCs. A direct Coombs test result is positive, indicating the presence of antibodies attached to red cells. Hemoglobin levels may fall as low as 6 g/100 ml.

### **Therapeutic Management**

In some children, the disease process runs a limited course and no treatment is necessary. In others, a single blood transfusion may correct the disturbance. It is difficult to cross-match blood for transfusion for these children, however, because the red cell antibody tends to clump or agglutinate all blood tested. If cross-matching is impossible, the child may be given type O, Rh-negative blood, which doesn't need to match. Carefully observe the child especially during any transfusion for signs of transfusion reaction.

If anemia is persistent, corticosteroid therapy (oral prednisone) to reduce the immune response is generally effective, increasing the RBC count and hemoglobin concentration in a short period. If this is not effective, splenectomy or stronger immunosuppressive agents such as cyclophosphamide (Cytosan) or azathioprine (Imuran) are necessary to reduce antibody formation.

Often, it is difficult for parents to understand the process causing their child's condition. How could their child's body turn on itself this way? How long will this last? What will stop it from happening again? Because there are no certain answers to these questions, provide parents and children with support as they wait for this unexplainable process to run its course and for their child to be well again.

### *QSEN Checkpoint Question 44.5*

#### **TEAMWORK & COLLABORATION**

Autoimmune acquired hemolytic anemia can occur in any child. The nurse identifies which usual cause of this disorder as important for team members to know?

- a. Allergy to the protein found in fish or shrimp
- b. A mutant gene similar to sickle-cell anemia
- c. An elevated (increased) eosinophil cell count
- d. Antibody production against red blood cells

*Look in Appendix A for the best answer and rationale.*

## **POLYCYTHEMIA**

Polycythemia is an increase in the number of RBCs. The condition results from increased erythropoiesis, which occurs as a compensatory response to insufficient oxygenation of the blood in order to help supply more oxygen to body cells. Although this may occur as a hereditary form, chronic pulmonary disease and congenital heart disease are the usual causes of polycythemia in childhood. Also, it may occur from the lower oxygen level maintained during intrauterine life in newborns or with twin transfusion at birth (one twin receives excess blood, whereas a second twin is anemic).

**Plethora** (marked reddened appearance of the skin) occurs because of the increase in total RBC volume. Erythrocytes are usually macrocytic (large), and the hemoglobin content is high. This means the mean corpuscular hemoglobin will be elevated; the mean corpuscular hemoglobin concentration, however, will be normal, indicating that

although many in number, each erythrocyte is normally saturated with hemoglobin. The RBC count may be as high as 7 million/mm<sup>3</sup>. Hemoglobin levels may be as high as 23 g/100 ml.

Treatment of polycythemia involves treatment of the underlying cause. Because of the high blood viscosity from so many crowded blood cells, cerebrovascular accident or emboli may occur. The risk increases particularly if the child becomes dehydrated, such as with fever or during surgery. A program of low-dose aspirin to help prevent clotting or exchange transfusion or phlebotomy to reduce the RBC count may be necessary.

## Disorders of Blood Coagulation

Platelets are necessary for blood coagulation, so disorders that limit the number of platelets limit the effectiveness of this process. A normal platelet level is 150,000/mm<sup>3</sup>. Thrombocytopenia (decreased platelet count) is defined as a platelet count of less than 40,000/mm<sup>3</sup>. Thrombocytopenia often leads to purpura or blood seeping from vessels into the skin. In one rare disorder, children are born with thrombocytopenia and are also missing the radius bone in the forearm (thrombocytopenia-absent radius [TAR] syndrome).

### PURPURAS

**Purpura** refers to a hemorrhagic rash or small hemorrhages in the superficial layer of skin. Two main types of purpura occur in children: idiopathic thrombocytopenic purpura and Henoch–Schönlein syndrome.

#### Idiopathic Thrombocytopenic Purpura

Idiopathic thrombocytopenic purpura (ITP) is the result of a decrease in the number of circulating platelets in the presence of adequate megakaryocytes (precursors to platelets). The cause is unknown, but it is thought to result from an increased rate of platelet destruction due to an antiplatelet antibody that destroys platelets, making this an autoimmune illness.

In most instances, ITP occurs approximately 2 weeks after a viral infection such as rubella, rubeola, varicella, or an upper respiratory tract infection. Congenital ITP may occur in the newborn of a woman who has had ITP during pregnancy. An antiplatelet factor apparently crosses the placenta and causes platelet destruction in the newborn in the same way that Rh incompatibility or hemolytic disease of the newborn develops (see [Chapter 26](#)). However, in ITP, the platelets, not the RBCs, are sensitized.

#### Assessment

Manifestations often begin abruptly, first evidenced as miniature petechiae or as large areas of asymmetric ecchymosis most prominent over the legs, although they may occur anywhere on the body ([Fig. 44.3](#)). Epistaxis or bleeding into joints may be present.

**Figure 44.3** An infant with idiopathic thrombocytopenic purpura (ITP). Notice the tiny petechiae and larger ecchymotic areas. (From Zitelli, B. J., & Davis, H. W. [1997]. *Atlas of pediatric physical diagnosis* [3rd ed.]. St. Louis, MO: Mosby–Year Book.)

Laboratory studies reveal marked thrombocytopenia. The platelet count may be as low as  $20,000/\text{mm}^3$ . Bone marrow examination reveals a normal number of megakaryocytes.

### Therapeutic Management

Oral prednisone to reduce the immune response and intravenous immunoglobulin (IVIg) or, in Rh-positive children, anti-D immunoglobulin to supply anti-ITP antibodies are used to treat ITP. Platelet transfusion will temporarily increase the platelet count, but because the life span of platelets is relatively short, a platelet transfusion has only limited effect. Children with central nervous system bleeding may require a splenectomy, although this is rarely necessary.

If the child experiences joint pain from bleeding, acetaminophen (Tylenol) rather than salicylates or ibuprofen is prescribed for pain because both salicylates and ibuprofen increase the chance for bleeding as they prevent the aggregation of platelets at wound sites.

In most children, ITP runs a limited, 1- to 3-month course. A few children develop chronic ITP. A course of immunosuppressive drugs may be attempted if the chronic state persists. All children need to be vaccinated against the viral diseases of childhood so that diseases such as rubella, rubeola, and varicella are eradicated and can no longer lead to this defective coagulation process.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Health-seeking behaviors related to injury-prevention measures

**Outcome Evaluation:** Parents state precautions they will take to reduce possibility of bleeding, repeat correct dose and timing of medication therapy, child's skin is free of ecchymotic areas, and platelet count rises to normal values.

The techniques for reducing bleeding described earlier in the chapter, such as padding surfaces where the child plays (see [Box 44.3](#)), can be used to reduce the possibility of bleeding for the child with ITP. Parents cannot eliminate the possibility of a serious bleeding injury, however, until the platelet count returns to normal. The chief danger to the child from ITP, aside from the psychological stress of a perplexing illness, is intracranial hemorrhage. Although this is rare, be alert for signs such as persistent headache with vomiting, lethargy, slurred speech, weakness on one side of the body, and new onset of seizure.

**Nursing Diagnosis:** Risk for compromised family coping related to diagnosis of child's illness

**Outcome Evaluation:** Parents state that they understand the nature of their child's illness and have identified ways to carry out daily activities despite the illness.

Because symptoms such as the easy bruising of ITP mimics the beginning signs of leukemia, parents may be extremely frightened when symptoms first occur. You can assure them after the diagnosis is made that this bruising is not and will not lead to leukemia. A child may have so many bruises that the parents are initially suspected of child maltreatment. This can cause them to become very defensive and angry at healthcare personnel. Allow them time to express their anger and regain confidence in their healthcare team.

It is always bewildering for parents to be told that no one knows exactly what is causing their child's illness. To feel comfortable that healthcare personnel can manage their child's care without knowing the exact cause, parents need careful explanations of all procedures.

### Henoch–Schönlein Syndrome

Henoch–Schönlein purpura (also called anaphylactoid purpura) is caused by increased vessel permeability, which leads to bleeding in the small blood vessels. Although no definite allergic correlation can be identified, it is generally considered to be a hypersensitivity reaction to an invading allergen. It occurs most frequently in children between 2 and 8 years of age and more frequently in boys than girls ([Bluman &](#)

Goldman, 2014). Usually, there is a history of a mild infection before the outbreak of symptoms. The syndrome presents (because of the purpura) as a possible platelet disorder until a differential diagnosis is made.

### Assessment

The purpurral rash occurs typically on the buttocks, posterior thighs, and extensor surface of the arms and legs (Fig. 44.4). The tips of the ears may be involved. The rash begins as a crop of urticarial lesions that change to pink maculopapules. These become hemorrhagic (bright red) and then fade, leaving brown macular spots that remain for several weeks. The child's joints are tender and swollen. The child may have gastrointestinal symptoms such as abdominal pain, vomiting, or blood in stools. Gross or microscopic hematuria may be present from kidney involvement. A biopsy shows **granulocytes** (WBCs) in the walls of small arterioles.

**Figure 44.4** The distinctive purpurral rash of Henoch–Schönlein syndrome appearing on the legs and buttocks of a young child. (From Fleisher, G. R., Ludwig, S., & Baskin, M. N. [2004]. *Atlas of pediatric emergency medicine*. Philadelphia, PA: Lippincott Williams & Wilkins.)

Laboratory studies show a normal platelet count. The child's sedimentation rate, WBC count, and eosinophil count are elevated.

### Therapeutic Management

Treatment involves oral corticosteroid therapy (prednisone) and mild analgesics for a short period. Nose and throat cultures rule out continuing bacterial involvement. Urine should be assessed for protein and glucose to detect kidney involvement. Typically, the

disease runs a course of 4 to 6 weeks. A few children develop mildly severe chronic nephritis as a complication (Tudorache, Azema, Hogan, et al., 2015).

### **QSEN Checkpoint Question 44.6**

#### **SAFETY**

Lana develops idiopathic thrombocytopenic purpura (ITP) after a viral infection. The nurse identifies which action as most important?

- a. Caution Lana and her mother that she will bruise easily.
- b. Show Lana how to do a finger-stick test for glucose.
- c. Tell Lana to report if she develops a sharp headache.
- d. Show her mother how to test Lana's urine for protein.

*Look in Appendix A for the best answer and rationale.*

## **HEMOPHILIAS**

Hemophilias are inherited disorders of blood coagulation. There are numerous types, each involving a deficiency of a different blood coagulation factor.

### **Hemophilia A (Factor VIII Deficiency)**

The classic form of hemophilia is caused by deficiency of the coagulation component factor VIII, the antihemophilic factor, and transmitted as a sex-linked recessive trait. In the United States, the incidence is approximately 1 in 5,000 White males. A female carrier may have slightly lowered but sufficient levels of the factor VIII component so that she does not manifest a bleeding disorder. The baseline level of factor determines the occurrence of bleeding episodes and can range from mild to severe (Gupta, Garg, & Singh, 2015).

Factor VIII is an intrinsic factor of coagulation; its absence causes the intrinsic system for manufacturing thromboplastin to be incomplete. The child's coagulation ability is not totally absent because the extrinsic or tissue system remains intact. Because of this system, the child's blood will eventually coagulate after an injury.

#### **Assessment**

Hemophilia often is recognized first in the infant who bleeds excessively after circumcision. If the disease has not shown itself for several generations in a family, the parents may be unaware of its existence. For this reason, all infants need careful and thoughtful observation after circumcision. Because infants do not receive many injuries, children's bleeding tendencies may not become apparent until they become active (e.g., crawling, climbing, or walking).

Suddenly, the lower extremities (where the child bumps things) become heavily bruised. There is soft tissue bleeding and painful hemorrhage into joints, which become swollen and warm. Repeated bleeding into a joint this way causes damage to the

synovial membrane (hemarthrosis), possibly resulting in severe loss of joint mobility (Merono-Gallut & Cuesta-Barriuso, 2016).

Severe bleeding may also occur into the gastrointestinal tract, peritoneal cavity, or central nervous system. Although nosebleeds are common, they are not as severe as with the platelet deficiency syndromes. The platelet count and prothrombin time are both normal; the whole blood clotting time is either markedly prolonged or normal, depending on the level of factor VIII present. A thromboplastin generation test will be abnormal. Partial thromboplastin time (PTT) is the test that best reveals the low levels of factor VIII. It's important that children with hemophilia be identified by such tests before surgery; otherwise, fatal bleeding could occur.

### Therapeutic Management

With even minor abrasions, bleeding can be controlled by the administration of factor VIII supplied by fresh whole blood, fresh or frozen plasma, or a concentrate of factor VIII. The concentrate is supplied as a powdered form that can be stored at home and reconstituted as needed. For most bleeding episodes, one bag of concentrate per 5 kg of body weight is usually sufficient to provide protection for approximately 12 hours; another transfusion may be necessary after that time. In some children, the administration of desmopressin (DDAVP), which stimulates the release of factor VIII, may also help prevent bleeding.

In a few children, antibodies (termed *inhibitors*) to factor VIII develop, rendering the factor ineffective. If this happens,  $\epsilon$ -aminocaproic acid, a fibrinolytic enzyme that helps to stabilize clot formation and promote wound healing, can be self-administered every 6 hours if needed. Children with inhibitors to factor VIII can also be given a factor IX concentrate (Proplex or Konyne). This concentrate enters the coagulation cascade after factor VIII and halts bleeding at that point.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Parental health-seeking behaviors related to strategies for protecting child from injury

**Outcome Evaluation:** Child's skin is free of ecchymotic areas, frequent epistaxis is absent, blood pressure is within age-appropriate parameters, and swelling or warmth at joints is absent.

Parents need information both about how to prevent bleeding episodes and how to respond when one does occur. To help prevent injuries, help parents set appropriate limits for activity. An active infant, for example, may need to have crib sides padded and all toys should be inspected for sharp edges or parts. Older children need to self-

monitor activities such as roughhousing, and sports participation needs to be evaluated as to whether it will be safe. On the other hand, parents need to be certain their child is not so inactive that obesity occurs.

Parents (and the child at about age 10 years) can be taught to reconstruct and administer a replacement factor intravenously to prevent bleeding immediately after an injury. Although the child needs to be assessed by a healthcare provider, this action, combined with pressure applied to the bleeding site, immobilization of the injured extremity, and an ice pack applied locally, almost always eliminates the need for hospital admission. “Butterfly bandages” are used in place of suturing for lacerations whenever possible because sutures create additional puncture sites that could bleed.

**Nursing Diagnosis:** Pain related to joint infiltration by blood

**Outcome Evaluation:** Child states pain is at a tolerable level.

The child with hemophiliac bleeding experiences discomfort because of the bleeding into joints and may be frightened because his parents are so frightened.

Acetaminophen (Tylenol) rather than ibuprofen is ordered as an analgesic because ibuprofen may prolong bleeding. As soon as effective levels of factor VIII have been provided, the pain in the bleeding joint is generally relieved, despite the continued heat or swelling. Be certain that when joints are immobilized, they are in good alignment. As soon as the acute bleeding episode has halted (approximately 48 hours), help the child perform passive range of motion as prescribed to maintain function.

**Nursing Diagnosis:** Risk for interrupted family processes related to fears regarding child’s prognosis and long-term nature of illness

**Outcome Evaluation:** Family members voice their fear regarding illness, state they are able to cope despite stress level, and demonstrate positive coping responses.

Parents of children with hemophilia are frightened during a time of acute bleeding, not just because of what is currently happening but also because they may have seen other family members or even a previous child die of the disease. Be certain to give them a chance to talk about how the bleeding began (e.g., “I should have noticed that toy had a sharp edge,” “He fell from his bike. I should have watched him more closely”). Parents often blame themselves, so it is important to be sensitive and nonjudgmental. It is extremely important for parents to allow the child to lead a normal life, so remind them when they do this that it is impossible to prevent all injuries.

## von Willebrand Disease

von Willebrand disease, an inherited autosomal dominant disorder, affects both sexes and is most common among Whites ([Ambruso et al., 2016](#)). Along with a factor VIII

defect, there is also an inability of the platelets to aggregate and the blood vessels to constrict to aid in coagulation. Bleeding time is prolonged, with most hemorrhages occurring from mucous membrane sites.

Epistaxis is a major problem, because all children tend to rub or pick at their nose as a nervous mechanism. In girls, menstrual flow is unusually heavy and may cause embarrassment from stained clothing. Childbirth is obviously a risk for women with von Willebrand disease, so women must be monitored closely for 9 months and again during the postpartal period ([Committee on Adolescent Health Care, 2013](#)). Bleeding is controlled with factor VIII replenishment as with hemophilia, or by administration of desmopressin (DDAVP), which stimulates factor VIII release.

### **Christmas Disease (Hemophilia B, Factor IX Deficiency)**

Christmas disease, first noted in 1952 in a patient by the name of Stephen Christmas, is caused by factor IX deficiency. It is transmitted as a sex-linked recessive trait, and only approximately 15% of people with hemophilia have this form. Treatment is with a concentrate of factor IX, which is available for home administration ([Ambruso et al., 2016](#)).

### **Hemophilia C (Factor XI Deficiency)**

Hemophilia C, or plasma thromboplastin antecedent deficiency, is caused by factor XI deficiency, is transmitted as an autosomal recessive trait, and occurs in both sexes. The symptoms are generally mild compared with those in children with factor VIII or factor IX deficiencies. Bleeding episodes are treated with administration of desmopressin (DDAVP) or transfusion of fresh blood or plasma.

### **Disseminated Intravascular Coagulation**

Disseminated intravascular coagulation (DIC) is an acquired disorder of blood clotting that results from excessive trauma or some similar underlying stimulus, such as an acute infection or trauma.

A child begins to develop petechiae or have uncontrolled bleeding from puncture sites from injections or intravenous therapy. Ecchymoses and petechiae form on the skin. Observe all children with a serious illness carefully for signs such as these of increased bleeding to help identify that this is happening. DIC is also discussed in [Chapter 21](#) as a frequent complication of bleeding disorders in pregnancy.

#### *What If . . . 44.4*

**The nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to hematologic disorders and children (see [Box 44.1](#)). What would be a possible research topic to explore pertinent to this goal that would be applicable to Lana's or Joey's family and that would also**

## KEY POINTS FOR REVIEW

- Hematopoietic stem cell transplantation is the main therapy for numerous blood dyscrasias. Transplantation can be allogeneic (from a histocompatible donor), autologous (using the child's own marrow or umbilical cord blood), or syngeneic (the donor and recipient are identical twins).
- Splenectomy, another possible treatment, may increase a child's susceptibility to pneumococcal infections. Assess whether a child has received pneumococcal vaccine after a splenectomy.
- Disorders of the RBCs that commonly occur in children include acute blood loss anemia and anemia of acute infection. Aplastic and hypoplastic anemias occur from depression of hematopoietic activity in bone marrow. These anemias can be congenital or acquired.
- A major hypochromic anemia that develops in children is iron-deficiency anemia. Children invariably fatigue easily because they cannot oxygenate body cells well. Their care must include measures to keep them from tiring; oxygen administration may be necessary.
- Macrocytic anemias occur from folic acid deficiency and pernicious anemia (vitamin B<sub>12</sub> deficiency).
- Hemolytic anemias include congenital spherocytosis, G6PD, sickle-cell anemia, thalassemia, and autoimmune acquired hemolytic anemia. Sickle-cell anemia occurs most often in Black children.
- Disorders of blood coagulation include the purpuras (ITP and Henoch–Schönlein syndrome), DIC, and the hemophilias.
- Children with blood coagulation disorders must carefully guard against injury. This includes monitoring types of toys and activities. It may also include padding a crib or side rail.
- Disorders of the blood tend to be long-term illnesses. Education of the parents and child is important to promote adaptation to the condition and enhance long-term medication therapy that not only meets QSEN competencies but also best meets a family's total needs.

## CRITICAL THINKING CARE STUDY

Tooley James is a 12-year-old you meet at an emergent care clinic. Tooley has sickle-cell anemia and is awaiting a stem cell transplant. He had a splenectomy 2 years ago. He lives with his older sister Michele (18 years of age), his mother (32 years of age), and his grandmother (76 years of age). Tooley's mother works two jobs to support the family (as an assembly line worker making paper products during the day and as a waitress at a local restaurant in the evening). Tooley is responsible for taking his folic

acid and his hydroxyurea daily as well as “staying clear of infections” independently.

1. He’s at the clinic today because “a kid shoved him” on his way home from school. His sister offered to bring him to the hospital, but because she has a cold, Tooley refused to ride in the car with her. By the time his mother returned home from her second job his right knee was visibly swollen, he had pain “all over,” and was gasping for breath. Tooley knows it’s important to avoid infections, but did he make a good decision about his care?
2. Tooley needs some emergency measures in your clinic. What are the three main measures you anticipate he will need? Should you explore further how his injury happened?
3. Tooley’s mother tells you Tooley’s school grades have fallen from Bs to Cs and Ds over the past year. When you ask him why this is happening, he tells you, “If I don’t get a transplant, how will it matter what my grades are?” Is that a typical preadolescent attitude or would you worry Tooley is becoming depressed about his situation?

## Nursing Care of a Family When a Child Has a Gastrointestinal Disorder

*Barry Abraham is a 2-year-old boy with poor growth recently diagnosed with celiac disease. You see him at a birthday party, where he is having a temper tantrum because he wants to eat birthday cake like the other children. His mother gives in and says, “Well, I guess it won’t hurt him to eat a piece this one time.”*

*Previous chapters described the growth and development of well children and the nursing care for children with disorders of other systems. This chapter adds information about the dramatic changes, both physical and psychosocial, that can occur when children develop gastrointestinal disorders. Such information builds a base for care and health teaching for children with these disorders.*

**Does Barry’s mother understand her son’s disease? What could she have done differently in this situation to help him adhere to a gluten-free diet?**

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe common gastrointestinal disorders seen in children.
2. Identify 2020 National Health Goals related to gastrointestinal disorders in children that nurses can help the nation achieve.
3. Assess a child with a gastrointestinal disorder.
4. Formulate nursing diagnoses for a child with a gastrointestinal disorder.
5. Identify expected outcomes for a child with a gastrointestinal disorder as well as how to manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care for a child with a gastrointestinal disorder, such as preparing the child for surgery.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of gastrointestinal disorders in children with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

Because the gastrointestinal (GI) system is so long and so diverse, a multitude of possible disorders can occur along the tract, including both congenital disorders and acquired illnesses. Also, because the GI system is responsible for taking in and processing nutrients for all parts of the body, any problem with the system can quickly affect other body systems and, if not adequately treated, can affect overall health, growth, and development.

Because it can be difficult to appreciate the seriousness of a GI illness, parents often are surprised to learn that what they thought was a simple “stomach flu” has caused a serious electrolyte imbalance and possibly a life-threatening state for their child. Some GI disorders require both parents and the child to learn new nutritional patterns. As children grow older, counseling to help them maintain self-esteem and learn nutritional requirements so they can become independent is vital. Food poisoning and hepatitis are examples of GI illnesses that are so pervasive that 2020 National Health Goals have been set to limit their incidence ([Box 45.1](#)).

Nutrition deficiencies, unsafe food preparation, and hepatitis are three areas that could be reduced in incidence if people knew more about them and took active interventions to reduce their occurrence or spread. The 2020 National Health Goals addressing these include:

- Increase the contribution of fruits and vegetables to the diets of the population aged 2 years from 0.5 cup of fruits per 1,000 calories to 0.9 cup per 1,000 calories.
- Achieve and maintain effective vaccination coverage levels for universally recommended vaccines among young children and older (three doses of hepatitis B vaccine and two doses of hepatitis A vaccine by 19 to 35 months of age).
- Reduce infections caused by key pathogens transmitted commonly through food (including *Escherichia coli* [from 200 to 180 cases per year], *Listeria* [from 0.3 to 0.2 cases per 100,000 population per year], and *Salmonella* [from 15.2 to 11.4 cases per 100,000 population per year]).
- Increase the proportion of consumers who follow key food safety practices of “Chill: refrigerate promptly” from 88.1% to 91.1% ([U.S. Department of Health and Human Services, 2010](#); see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by counseling parents about safe food preparation and the need for children to ingest adequate fiber from fruit and vegetables for sound bowel function, by serving as consultants to day care providers to reduce the spread of stool contamination and by actively administering hepatitis A and B vaccines to infants and adolescents to eradicate these forms of the illness in another generation.

### *Nursing Process Overview*

#### FOR A CHILD WITH A GASTROINTESTINAL DISORDER

##### **ASSESSMENT**

Children with GI disorders quickly need to be assessed for signs of fluid loss, such as poor skin turgor, dry mucous membranes, or lack of tearing. When talking to parents about a child’s symptoms, ask exactly what they mean when they say “spitting up” or “a little vomiting” to be certain you’re talking about the same amount. Also, ask how many times a child has voided or how many diapers have been wet in the past 24 hours and whether this is less than usual. Compare the child’s current weight with past weight measurements, if available. Unless the child is an adolescent who has been actively dieting, there is rarely a normal reason for weight loss in children.

Most children with diarrhea have self-limited viral illness and can be treated at home. Children with severe diarrhea, especially small children, need to be seen by a healthcare provider because fluid and electrolyte changes occur rapidly in children

because of the greater percentage of fluid held extracellularly rather than intracellularly increasing the risk of dehydration.

For many children, a GI tract disorder is largely diagnosed by presenting symptoms such as those just described. In other instances, X-ray studies with a contrast medium (barium) or an endoscopic examination may be needed to confirm the presence of an anomaly. Ultrasound or magnetic resonance imaging (MRI) also may be helpful. Another important assessment area is laboratory testing for electrolyte balance through serum analysis or fluid concentration through urinalysis.

### **NURSING DIAGNOSIS**

Nursing diagnoses relevant to children with GI disorders invariably center on imbalanced nutrition because most GI diseases alter the kind and amount of nutrients ingested or absorbed into the body in some way. In addition, because feeding is one of the primary ways mothers bond with their newborns, and the process of eating and the types of food eaten are integral components of family life and culture, any disruption caused by an illness can place a strain on the entire family. Examples of nursing diagnoses include:

- Impaired parenting related to interference with establishing the parent–infant bond
- Interrupted family processes related to a chronic illness in child
- Risk for deficient fluid volume related to chronic diarrhea
- Imbalanced nutrition, less than body requirements, related to malabsorption of necessary nutrients
- Situational low self-esteem related to feelings of being different resulting from special dietary restrictions

### **OUTCOME IDENTIFICATION AND PLANNING**

Be certain when helping plan a new nutritional pattern for a child that you include the person who actually prepares or supervises the child’s nutrition. In many instances, some of the foods that a child eats are prepared by a babysitter, day care center staff, the child’s other parent, or a grandparent. Many children eat breakfast and lunch at school cafeterias. That means it may be necessary to contact school staff to ask them to make meal exceptions for a child or to supervise a choice of foods (or to see that a child eats only the packaged lunch brought to school, not extra items the child trades for with friends).

Some parents are unfamiliar with basic food categories and the importance of providing food from the MyPlate nutrition guidelines ([www.ChooseMyPlate.gov](http://www.ChooseMyPlate.gov)). When a special diet is requested, parents may have little understanding of which foods have high or low fiber content, or which foods are “bland” or “clear.” Many parents have difficulty keeping children restricted to nothing by mouth (NPO) for tests or to rest the GI tract because they know dehydration happens quickly in infants (which is true). They need support to follow the necessary restrictions when this action is so opposed to basic parenting, such as giving food.

If feedings will be given by nasogastric or gastrostomy tube, parents need enough practice to be proficient with the equipment and the technique before they are given the responsibility of doing it alone at home. If a child is going to gag or become distressed when a new oral or nasal tube is passed, parents need to have this happen where there are calm, supportive people nearby, not when they are by themselves at home.

Agencies that might be helpful for referral to parents are the Celiac Disease Foundation ([www.celiac.org](http://www.celiac.org)), the Crohn's & Colitis Foundation ([www.crohncolitisfoundation.org](http://www.crohncolitisfoundation.org)), the International Foundation for Functional Gastrointestinal Disorders ([www.iffgd.org](http://www.iffgd.org)), and the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition ([www.naspghan.org](http://www.naspghan.org)).

### **IMPLEMENTATION**

Never underestimate the difficulty family members may experience adapting to alternative nutrition methods such as total parenteral nutrition, enteric or gastrostomy feedings, or caring for a child with a colostomy. Parents need a great deal of support to adapt their busy life to these alternative methods of feeding or care.

GI disorders that occur at birth are discussed in [Chapter 27](#). Insertion of a nasogastric tube, enteral and parenteral nutrition, and administration of an enema are discussed in [Chapter 37](#). Be certain to give clear, simple explanations and praise both parents and child after they demonstrate these procedures. Children can easily interpret enemas as punishment because of the extreme intrusiveness. Provide therapeutic play before and after these procedures to reduce children's anxiety.

### **OUTCOME EVALUATION**

Recording children's height and weight is a primary method to evaluate nutritional outcomes. Even if a diet is limited in a special way, if it is adequate, children should gain weight and maintain growth.

Because children will ultimately be responsible for their own nutrition, expected outcomes should include making certain children gradually learn more about their specific nutritional measures so they can become increasingly responsible for their own intake. Often, only when they are at this stage can their parents feel secure enough to let them stay overnight with a friend, visit a relative in a distant city, or go to summer camp—activities that become important to children as they reach school age.

Children who require special nutritional plans need to be evaluated for self-esteem at periodic health visits. Do children think of themselves as inferior to or different from others because of food restrictions? What kind of positive experiences can be offered to such children, or what can parents do to provide children with experiences that would improve self-esteem?

Some examples of expected outcomes include:

- Child lists examples of gluten-free foods to select for lunch from the school cafeteria menu.

- Parent states steps she will take to seek medical care if her child has a second episode of severe diarrhea.
- Family members state they have adjusted to care of their child with liver disease.

## Anatomy and Physiology of the Gastrointestinal System

Digestion occurs the same in children and infants as it does in adults beginning with the mouth, where food is broken down into small particles and mixed with saliva. Digestion continues in the stomach and small intestine.

The esophagus pierces the diaphragm to serve as a passageway to the stomach (Fig. 45.1). At the junction of the esophagus and the stomach is the gastroesophageal (cardiac) sphincter. A sphincter is a section of circular muscle. In newborns, this sphincter is immature and allows fluid to regurgitate into the esophagus (gastroesophageal reflux). At the distal end of the stomach is the pyloric sphincter. In some infants, this muscular channel becomes narrowed (stenosed), preventing food from flowing out of the stomach freely (pyloric stenosis). Originally, it was believed that the stomach was sterile because the action of hydrochloric acid could easily kill invading organisms and limit infections. However, since the discovery that a bacterium, *Helicobacter pylori*, is the cause of peptic ulcer disease, it is now obvious that organisms can and do survive in the stomach. The small intestine is divided into three sections: the duodenum, the jejunum, and the ileum. The large intestine is divided into the cecum, the ascending colon, the transverse colon, the descending colon, the sigmoid colon, and the rectum. The appendix, which frequently becomes diseased in children, is attached to the cecum.

**Figure 45.1** The gastrointestinal tract.

## Diagnostic and Therapeutic Techniques

Several typical procedures, such as an endoscopy, small intestine wireless enteroscopy (capsule endoscopy), colonoscopy, and radiology studies, are used in the diagnosis and therapy of GI disorders. Children need good preparation for all of these procedures because they are all potentially frightening (Hardee, 2012). If children receive conscious sedation or anesthesia for a procedure, they need preparation for this as well as for the actual procedure. They should receive a clear and simple explanation of what will occur and be reassured that the parent can remain with them until they fall asleep. Involvement of child life specialists can be helpful for anxious children (Ortiz, O'Connor, Carey, et al., 2017).

Therapy may include alternative methods of feeding such as enteral (nasogastric or gastrostomy tube feedings) or nutrition sources such as total parenteral nutrition and intravenous (IV) therapy to rest the GI tract. A colostomy or ileostomy may be created to further rest the GI tract. Because these are used for other disorders as well, these procedures, their meaning, their impact on children, and nursing responsibilities are discussed in Chapters 37 and 38.

## Health Promotion and Risk Management

Health promotion related to GI disorders focuses on a wide area because the causes of

these disorders cover a wide range. Some disorders, such as appendicitis, cannot be prevented because they occur from unpredictable causes. Other disorders, such as celiac disease (sensitivity or abnormal immunologic response to gluten), involve genetic aspects that cannot be changed. Still others, such as Crohn disease and ulcerative colitis, are associated with an autoimmune response. Other conditions, such as vomiting and diarrhea, are often caused by foods that were refrigerated improperly or are spread through improper hand washing and so can be prevented. Hepatitis can be prevented through good hand washing (for hepatitis A) and immunization (for both hepatitis A and B). Vitamin and protein deficiency disorders can be prevented by educating parents about the importance of a consistently healthy diet. A vaccine to prevent rotavirus infections (taken by mouth so it is painless) is recommended for infants ([Centers for Disease Control and Prevention \[CDC\], 2016a](#)).

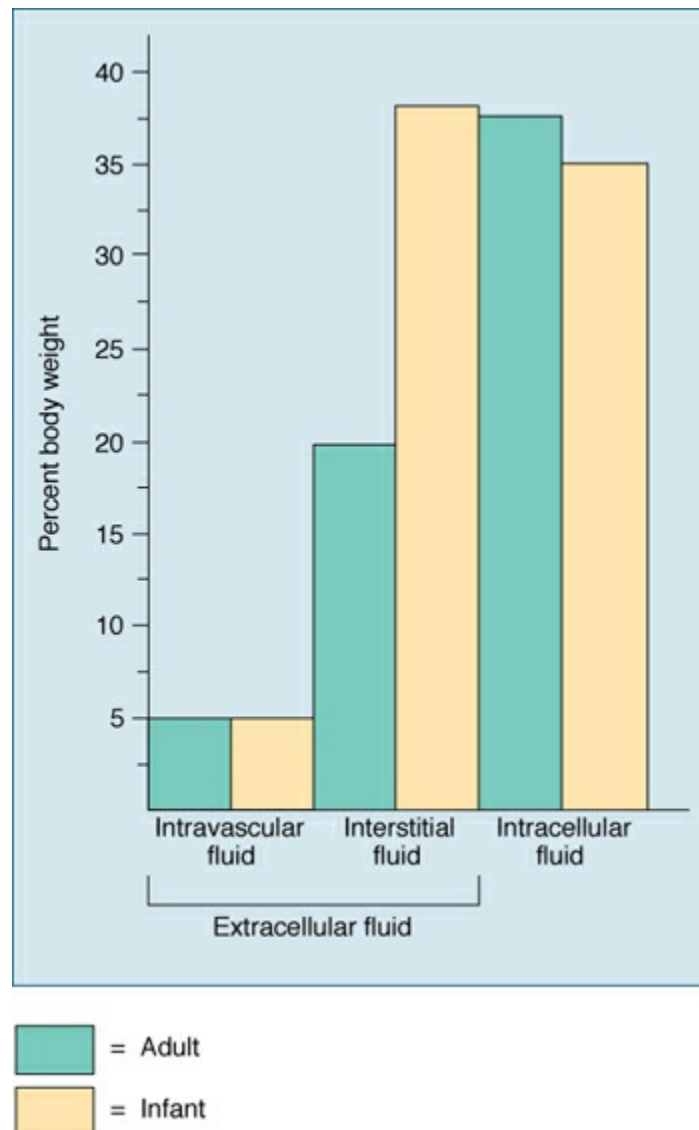

Because any interference in nutrition pervades many aspects of children's lives, families often need help with planning care. Help families plan the necessary adaptations to their lifestyle to prevent the disease from interfering with family functioning (e.g., Will day care center personnel do gastrostomy feedings? Will a nursery school accept a child with a colostomy? Can a child select a gluten-free diet at the school cafeteria?). All families should be encouraged to eat at least one meal a day together so they can have time to share experiences and “touch base” with each other. For the family with a child who has a feeding problem that requires gastrostomy feeding or total parenteral nutrition, this can be difficult. Urge such families to bring the child to the table for a social time even if the child cannot eat with the family. If watching family members eat while the child cannot eat is too difficult, urge the family to provide a “together” time in some other way so the child does not miss out on this valuable family activity.

Some GI disorders in children, such as esophagitis due to allergic disease or acid reflux, are diagnosed late because parents think the child's refusal to eat is just the sign of being a “picky eater” or a manifestation of 2-year-old autonomy. Educating parents about normal nutrition and how to distinguish things such as vomiting from illness from normal “spitting up,” or severe diarrhea from a simple GI upset, helps parents bring their children for care at the earliest possible time. Early intervention prevents the child from becoming dehydrated and seriously ill.

## **Fluid, Electrolyte, and Acid–Base Imbalances**

Because the GI system is the main route by which substances are taken into the body, it can be a major source of fluid and electrolyte loss if vomiting or diarrhea occurs ([Smith, 2011](#)). Retaining fluid is of greater importance in the body chemistry of infants than that of adults because fluid constitutes a greater fraction of the infant's total weight. In adults, body water accounts for approximately 60% of total weight. In infants, it accounts for as much as 75% to 80% of total weight; in children, it averages approximately 65% to 70%.

Fluid is distributed in three body compartments: (a) intracellular (within cells), 35% to 40% of body weight; (b) interstitial (surrounding cells), 20% of body weight; and (c) intravascular (blood plasma), 5% of body weight. Together, the interstitial and the intravascular fluid are often referred to as *extracellular fluid* (ECF), totaling 25% of body weight. In infants, the ECF portion is much greater, totaling up to 45% of total body weight (Fig. 45.2). In young children, this amount is 30%; in adolescents, it is 25%.

**Figure 45.2** The distribution of fluid in body compartments.

Fluid is normally obtained by the body through oral ingestion of fluid and by the water formed in the metabolic breakdown of food. Primarily, fluid is lost from the body in urine and feces. Minor losses (**insensible losses**) occur from evaporation from skin and lungs and from saliva, which is of little importance except in children with tracheostomies or those requiring nasopharyngeal suction. Infants do not concentrate urine as well as adults because their kidneys are immature. As a result, they have a

proportionally greater loss of fluid in their urine. In infants, the relatively greater surface area to body mass also causes a greater insensible loss. When diarrhea occurs, or when a child becomes diaphoretic because of fever, the fluid output can be markedly increased, quickly leading to **dehydration** (excessive loss of fluid) (Porth, 2011). To avoid dehydration, fluid requirements for infants and children are shown in [Table 45.1](#).

**TABLE 45.1 A METHOD TO CALCULATE FLUID REQUIREMENT**

Body Weight	Fluid Requirement per 24 Hours
Up to 10 kg	100 ml/kg
11–20 kg	1,000 ml + 50 ml/kg for each additional kilogram over 10 kg
More than 20 kg	1,500 ml + 20 ml/kg for each additional kilogram over 20 kg

## FLUID IMBALANCES

Under most circumstances, water and salt are lost in proportion to each other, termed *isotonic dehydration*. Occasionally, water is lost out of proportion to salt, and water depletion or *hypertonic dehydration* occurs. If electrolytes are lost out of proportion to water, this is termed *hypotonic dehydration*. Each of these abnormal states produces specific symptoms.

### Isotonic Dehydration

Isotonic dehydration occurs when a child’s body loses more water than it absorbs (as with diarrhea) or absorbs less fluid than it excretes (as with nausea and vomiting). The main result of isotonic dehydration is a decrease in the volume of blood serum. Typical signs and symptoms of isotonic dehydration are summarized in [Table 45.2](#).

**TABLE 45.2 SIGNS AND SYMPTOMS OF DEHYDRATION**

	Isotonic	Hypotonic	Hypertonic
Thirst	Mild	Moderate	Extreme
Skin turgor	Poor	Very poor	Moderate
Skin consistency	Dry	Clammy	Moderate
Skin temperature	Cool	Cool	Warm
Urine output	Decreased	Decreased	Decreased
Activity	Irritable	Lethargic	Very lethargic
Serum sodium level	Normal	Reduced	Increased

### What If . . . 45.1

Barry’s mother tells the nurse her primary care provider has told her to

**“force fluids” for Barry whenever he has diarrhea. She asks how much she should force the child to drink. How would the nurse best answer her?**

### **Hypertonic Dehydration**

When water is lost in a greater proportion than electrolytes, hypertonic dehydration occurs. This might occur in a child with nausea (thus preventing fluid intake) and fever (which increases fluid loss through perspiration); profuse diarrhea, where there is a greater loss of fluid than salt; or renal disease associated with polyuria such as nephrosis with diuresis. Electrolytes such as sodium, chloride, and bicarbonate concentrate in the blood. The red blood cell count and hematocrit will be elevated because the blood is more concentrated than usual. Additional signs and symptoms are summarized in [Table 45.2](#).

### **Hypotonic Dehydration**

With hypotonic dehydration, there is a disproportionately high loss of electrolytes in proportion to fluid loss. The plasma concentration of sodium and chloride are low. This could result from excessive loss of electrolytes by vomiting, from an increased loss of salt from diuresis, or from diseases such as adrenocortical insufficiency or diabetic acidosis. In order to achieve an electrolyte balance, the kidneys begin to excrete more fluid to bring the proportion of electrolytes and fluid back in balance, leading to a secondary extracellular dehydration (see [Table 45.2](#)).

### **Overhydration**

**Overhydration**, or excessive body fluid intake, can be as serious as dehydration. It generally occurs in children who are receiving IV fluid and can lead to cardiovascular and cardiac failure.

When large quantities of salt-poor fluid (hypotonic solutions) such as tap water are ingested or are given by enema, the body transfers water from the extracellular space into the intracellular space to restore normal osmotic relationships. This transfer results in intracellular edema manifested by a headache, nausea, vomiting, dimness and blurring of vision, cramps, muscle twitching, and seizures. A situation in which intracellular edema may occur is when tap water enemas are given to a child with aganglionic disease of the intestine.

## **ACID–BASE IMBALANCE**

When vomiting or diarrhea occurs, the GI system often is involved with two severe acid–base imbalances: metabolic acidosis and metabolic alkalosis. Whether body serum is becoming acidotic is determined by analyzing a sample of arterial blood for blood gases. The pH of blood is normally slightly alkaline, ranging from 7.35 to 7.45. The amount of dissolved carbon dioxide in arterial blood ( $PCO_2$ ) is normally 35 to 45

mmHg. The level of bicarbonate ( $\text{HCO}_3$ ) in arterial blood is normally 22 to 26 mEq/L.

### Metabolic Acidosis

Metabolic acidosis results from diarrhea because a great deal of sodium is lost with stool. This excessive loss of  $\text{Na}^+$  causes the body to conserve  $\text{H}^+$  ions in an attempt to keep the total number of positive and negative ions in serum balanced. With metabolic acidosis, an arterial blood gas analysis will reveal a decreased pH (under 7.35) and a low  $\text{HCO}_3$  value (near or below 22 mEq/L). The lower the  $\text{HCO}_3$  value is, the more  $\text{Na}^+$  ions that have presumably been lost or the more extensive the diarrhea has been. The child breathes rapidly (hyperpnea) to “blow off”  $\text{CO}_2$  to prevent it from combining with  $\text{H}_2\text{O}$  and reforming  $\text{HCO}_3$ . Urine becomes more acidic as ammonia formation in the urine is increased.

### Metabolic Alkalosis

With vomiting, a great deal of hydrochloric acid is lost. When  $\text{Cl}^-$  ions are lost this way, the body has to decrease the number of  $\text{H}^+$  ions present so the number of positive and negative charges remains balanced. This causes the child to become alkalotic because the number of  $\text{H}^+$  ions becomes proportionately lower than the number of  $\text{OH}^-$  ions present. The lungs attempt to conserve  $\text{CO}_2$  and water by slowing respirations (hypopnea). The excessive  $\text{CO}_2$  retained by this maneuver dissolves in the blood as carbonic acid and then is converted into excessive  $\text{H}^+$  and  $\text{HCO}_3^-$ . With metabolic alkalosis, therefore, the serum  $\text{HCO}_3$  will invariably be high. The higher the value, presumably the more  $\text{Cl}^-$  ions have been lost or the more extensive the vomiting has been. The child will breathe slowly and shallowly; pH will be elevated (near or above 7.45), and  $\text{HCO}_3$  level will be near or above 28 mEq/L.

When alkalosis occurs from vomiting, a secondary electrolyte problem often occurs. As the kidneys begin to help conserve  $\text{H}^+$  ions,  $\text{K}^+$  ions are exchanged for  $\text{H}^+$  ions—that is,  $\text{K}^+$  ions are excreted in order to retain  $\text{H}^+$  ions. As a result of this loss of  $\text{K}^+$  into the urine, low  $\text{K}^+$  levels (hypokalemia) invariably accompany metabolic alkalosis.

### *QSEN Checkpoint Question 45.1*

#### INFORMATICS

Barry has frequent bouts of vomiting. If the nurse is caring for Barry in a hospital setting after repeated bouts of vomiting, the nurse would expect the diagnostic testing to reveal which health problem?

- Respiratory acidosis
- Fluid volume excess
- Metabolic alkalosis
- Hyperchlorosis

Look in *Appendix A* for the best answer and rationale.

## Common Gastrointestinal Symptoms of Illness in Children

Vomiting and diarrhea in children commonly occur as symptoms of a GI tract disease as well as symptoms of disease in other body systems (Box 45.2). Pneumonia or otitis media, for example, may present first with vomiting or diarrhea. A danger of this is that either can lead to a disturbance in hydration, electrolyte, or acid–base balance. In many infants, vomiting and diarrhea can be more threatening to the child than the primary disease.

BOX 45.2

### Nursing Care Planning Using Assessment

#### ASSESSING A CHILD WITH ALTERED GASTROINTESTINAL FUNCTION

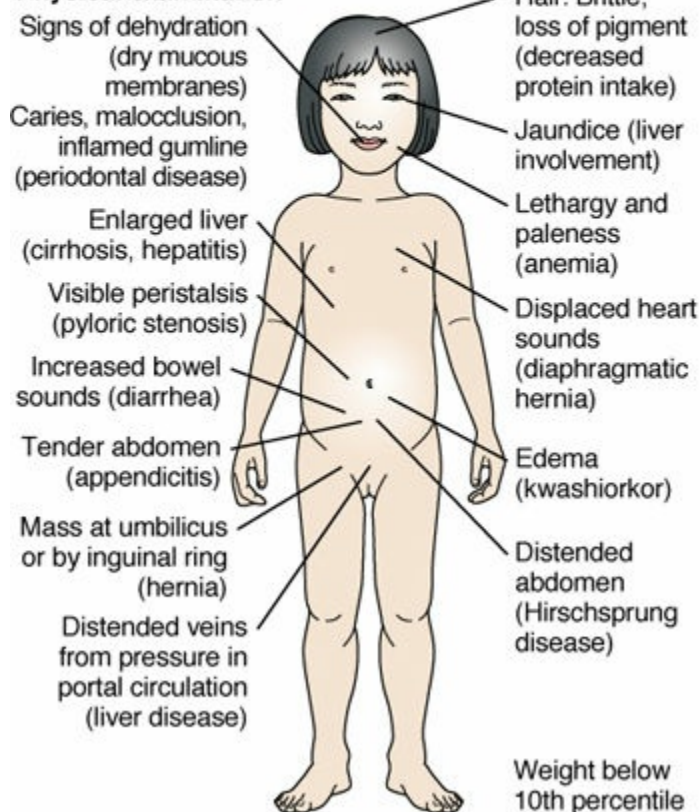

##### History

*Chief concern:* Vomiting, diarrhea, constipation, abdominal pain, abdominal distention, weight below normal standard, lethargy, paleness.

*Past medical history:* History of past vomiting or diarrhea or abdominal pain; hydramnios in pregnancy.

*Family history:* Relatives have a similar disorder; high stress level because of home or school environment.

##### Physical examination

## VOMITING

Most children with vomiting are suffering from a mild gastroenteritis (infection) due to a viral or bacterial organism, but other causes of vomiting should be considered, such as obstruction, increased intracranial pressure, and metabolic disease. The adolescent who is pregnant may mistake the normal nausea and vomiting of pregnancy for an illness. Some children develop persistent or cyclic vomiting (Lee, Abbott, Mahlangu, et al., 2012).

### Assessment

In describing symptoms of vomiting, be certain to differentiate between the various terms that are used (Table 45.3). It is important that vomiting be thoroughly described this way because different conditions are marked by different forms of vomiting, and a correct description of the child's actions can aid greatly in a diagnosis.

**TABLE 45.3 DIFFERENTIATION BETWEEN REGURGITATION AND VOMITING**

Characteristic	Regurgitation	Vomiting
Timing	Occurs with feeding	Timing unrelated to feeding
Forcefulness	Runs out of mouth with <i>little force</i>	Forceful: often projected 1 ft away from the infant; <i>projectile vomiting</i> : projected as much as 4 ft (most often associated with pyloric stenosis)
Description	Smells barely sour; only slightly curdled	Extremely sour smelling and curdled, yellow, green, clear or watery, or black or blood tinged
Distress	Nonpainful; no appearance of distress; may even smile as if sensation is enjoyable	Possible crying just before vomiting as if abdominal pain is present and after vomiting as if the force of action is frightening
Duration	Occurs once per feeding	Continuing until stomach is empty; followed by dry retching
Amount	1–2 teaspoons	Full stomach contents

### Therapeutic Management

The treatment for vomiting related to gastroenteritis is to give small amounts of fluid frequently as soon as tolerated to prevent dehydration and electrolyte imbalance. Clear liquids such as ginger ale, tea, and sports drinks can be used to maintain hydration, but

they are not suitable for rehydration. Oral rehydration solutions (ORS) such as Pedialyte should be used for infants and younger children as well as older children with dehydration. Children with intractable vomiting or severe dehydration will require IV fluids.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for deficient fluid volume related to vomiting

**Outcome Evaluation:** Skin turgor remains good; specific gravity of urine is 1.003 to 1.030, urine output is more than 1 ml/kg/hour; episodes of vomiting decrease in frequency and amount.

For the older child, start by offering a few ice chips and then water in small amounts—approximately 1 tablespoon every 15 minutes, four times, and then 2 tablespoons every half hour, four times. Popsicles can be substituted for water. If this is retained, children can be given small sips of clear liquids, such as tea, ginger ale, or an ORS. Parents are not advised to make ORS solutions at home as the recipe needs to be exact (Barros, Victoria, Forsberg, et al., 1991).

Children may become hungry and want whole glasses of fluid, but keeping the quantity to small sips prevents vomiting. Once the child is able to retain sips of clear liquids, the child can be offered portions of broth, clear soup, and skim milk in addition to clear liquids. Dry crackers or toast will help assuage hunger. By the second day, children can take a soft diet; by the third day, they should be back to their regular diet. Young infants with vomiting should be evaluated by a healthcare professional. Maintain hydration by giving 5 to 10 ml ORS every 5 to 10 minutes and gradually increase as tolerated. Once tolerating the ORS, the infant should return to breastfeeding or bottle feeding. Infants should be monitored closely for signs of dehydration. A decrease in wet diapers to one within a 6-hour period, dry mouth, and increased thirst are signs of mild dehydration. If vomiting is prolonged, infants may need IV therapy to restore hydration (Moritz & Ayus, 2011).

Assure parents that if children receive a small amount of fluid and do not vomit it, they will ultimately receive more fluid than if they take a large amount, but because of gastroenteritis, they vomit that amount. Stress that stomach secretions are lost along with vomitus each time, and the preservation of these stomach secretions is equally important. Antiemetic medicine is rarely necessary for children because acute gastroenteritis is a self-limiting condition and vomiting may actually be helpful if it rids the child's body of toxic substances. If vomiting is severe, however, an antiemetic such as promethazine (Phenergan) or ondansetron (Zofran) may be prescribed. Always ask parents if they have used an herbal remedy to stop vomiting

to be certain that any medication prescribed will be safe with the alternative treatment (Box 45.3).

### BOX 45.3

#### Nursing Care Planning to Respect Cultural Diversity

The incidence of gastrointestinal (GI) illnesses varies among communities. Vomiting and diarrhea, for example, tend to occur because of food poisoning in communities where refrigeration is less than optimal and from eating raw meat or unprocessed cheese. Celiac disease occurs most frequently in children of Northern European ancestry. Because constipation, vomiting, and diarrhea are so common, every culture has home remedies for these symptoms: cascara for constipation; psyllium for diarrhea; and ginger, peppermint, licorice, or chamomile tea for nausea or vomiting. To be certain that a child seen in a healthcare facility does not receive two forms of the same drug (one prescribed and one given in an herb form by a parent), always ask what alternative therapies or home remedies have been given and document these on the child's plan of care.

## DIARRHEA

Diarrhea that is acute is usually associated with infection; chronic diarrhea is more likely related to a malabsorptive or inflammatory cause. *Giardia lamblia* is a frequent protozoan infection that causes diarrhea. The most common viral pathogens that invade the GI tract include rotaviruses and adenoviruses. The most common bacterial pathogens include *Campylobacter jejuni*, *Salmonella*, *Clostridium difficile*, and *Escherichia coli* (Porth, 2011). Both viral and bacterial infections are easily spread in common diaper changing areas in day care centers or in public restrooms (Rimon & Freedman, 2010).

Diarrhea in infants is always serious because infants have such a small ECF reserve that sudden losses of water quickly exhaust the supply. Breastfeeding may actively prevent diarrhea by providing more antibodies and possibly an intestinal environment less friendly to invading organisms.

### Mild Diarrhea

#### Assessment

Normal and diarrheal stool characteristics are compared in Table 45.4. Children usually are anorectic, irritable, and appear unwell; a fever of 101° to 102°F (38.4° to 39.0°C) may be present. The episodes of diarrhea consist of 2 to 10 loose, watery bowel movements per day.

#### TABLE 45.4 DIFFERENTIATION BETWEEN NORMAL STOOL AND

## DIARRHEAL STOOL IN AN INFANT

Characteristic	Infant Normal Stool	Diarrheal Stool
Frequency	One to three daily	Unlimited number
Color	Yellow	Green
Effort of expulsion	Some pushing effort	Effortless; may be explosive
pH	More than 7.0 (alkaline)	Less than 7.0 (acidic)
Odor	Odorless	Sweet or foul smelling
Occult blood	Negative	Positive; blood may be overt
Reducing substances	Negative	Positive

The mucous membrane of the mouth appears dry and the skin feels warm, although skin turgor will not yet be decreased. The pulse may be rapid and out of proportion to the low-grade fever. Urine output is usually normal.

### Therapeutic Management

At this stage, diarrhea is not yet serious, and children can be cared for at home. Parents can begin to offer an ORS such as Pedialyte in small amounts on a regimen similar to that for vomiting (Smith, 2011). For breastfed infants, breastfeeding should continue. Probiotics (dietary supplements containing potentially beneficial bacteria or yeasts) to change the bacterial flora of the intestine may be administered (Guarino, Ashkenazi, Gendrel, et al., 2014). Children also may need measures to reduce their elevated temperature.

Caution parents to contact their healthcare provider prior to initiating over-the-counter drugs such as loperamide (Imodium) or bismuth subsalicylate (Kaopectate) to halt diarrhea because, as a rule, toxic levels of these can occur quickly (Karch, 2013). Caution parents to wash their hands after changing diapers to prevent the spread of infection to themselves and to notify their healthcare provider if fever, pain, or diarrhea worsens.

Infants may develop a temporary lactase deficiency after diarrhea that leads to lactose intolerance. Lactase is the enzyme that digests lactose, the sugar in milk. Lactase deficiency results in gas and diarrhea. It may appear as though the initial diarrheal illness is persisting when this occurs. It may be necessary to try using a lactose-free formula or to try having the mother withdraw dairy products from her own diet if the infant is breastfed.

### Severe Diarrhea

Severe diarrhea may result in dehydration and the need for hospitalization.

### Assessment

Infants with severe diarrhea appear obviously ill. Rectal temperature is often as high as 103° to 104°F (39.5° to 40.0°C). Both pulse and respirations are weak and rapid, and the skin is pale and cool. Infants may be apprehensive, listless, and lethargic. Obvious signs of dehydration such as a depressed fontanelle, sunken eyes, and poor skin turgor are usually present. The episodes of diarrhea usually consist of a movement of liquid green stool perhaps mixed with mucus and blood, passed with explosive force every few minutes. Urine output will be scanty and concentrated. Laboratory findings will show elevated hematocrit, hemoglobin, and serum protein levels because of the dehydration. Electrolyte determinations will indicate a metabolic acidosis (Huether, 2012).

It is difficult to measure the amount of fluid a child has lost with diarrhea, but an estimate can be derived from the loss in body weight, if known. For example, if a child weighed 10.4 kg yesterday at a health maintenance visit and today weighs 8.9 kg, the child has lost more than 10% of body weight. A loss of 2.5% to 5% of body weight suggests mild dehydration. Severe diarrhea quickly causes a 5% to 15% loss of body weight, which suggests severe dehydration. Any infant who has lost 10% or more of body weight requires immediate treatment.

### Therapeutic Management

Treatment focuses on regulating electrolyte and fluid balance by initiating oral or IV rehydration therapy and on discovering the organism responsible for the diarrhea.

All children with severe diarrhea or diarrhea that persists longer than 24 hours should have a stool culture taken to determine if infection is causing the diarrhea, and if appropriate, a definite antibiotic therapy can be prescribed. Because a side effect of many antibiotics is diarrhea, antibiotics should not routinely be used to treat diarrhea without an identifiable bacterial cause. Stool cultures may be taken from the rectum or from stool in a diaper or a bedpan.

Blood serum specimens need to be drawn for a hemoglobin level (an estimation of hydration as well as anemia); white blood cell and differential counts (to attempt to establish whether infection is present); and determinations of  $\text{PCO}_2$ ,  $\text{Cl}^-$ ,  $\text{Na}^+$ ,  $\text{K}^+$ , and pH (to establish electrolyte needs). If a child can drink, the most effective way to replace fluid is by offering oral rehydration therapy. For a child who will not drink, an IV solution such as normal saline or 5% glucose in normal saline is begun to provide replacement of fluid, sodium, and calories.

Although infants usually have a potassium depletion, potassium is not given until it is established that the child is not in renal failure because giving a potassium IV when the body has no outlet for excessive potassium can lead to excessively high potassium levels and heart block. *Before this initial IV fluid is changed to a potassium solution, therefore, be certain the infant or child has voided—proof that the kidneys are functioning.*

Enough fluid must be given not only to replace the deficit that has occurred but also

to replace the continuing loss until the diarrhea improves. If an infant has lost less than 5% of total body weight, his or her fluid deficit is approximately 50 ml/kg of body weight. If an infant has lost 10% of body weight, he or she needs approximately 100 ml/kg of body weight to replace the fluid deficit. If the weight loss suggests a 12% to 15% loss of body fluid, the infant requires 125 ml/kg of body weight to replace the fluid lost. This fluid will be given rapidly in the first 3 to 6 hours, and then it will be slowed to a maintenance rate. Once infants void, a potassium additive can be prescribed to restore serum potassium.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Deficient fluid volume related to loss of fluid through diarrhea

**Outcome Evaluation:** Skin turgor remains good; specific gravity of urine is 1.003 to 1.030; urine output is more than 1 ml/kg/hour; and bowel movements are formed and fewer than four per day. Stool tests negative for reducing substances and blood pH is 7.41.

*Promote Hydration and Comfort.* During the time an infant is NPO, wet the infant's lips with a moisturizing cream or jelly such as Vaseline if they appear to be dry. Offer a pacifier to suck if this seems to comfort him or her. (Infants want to suck because they are very thirsty and, if they have intestinal cramping with the diarrhea, they interpret this as hunger.) As the infant's condition improves, oral intake can be increased, changing to a soft then a regular diet.

If the child with severe diarrhea also has a fever, measures to reduce the fever will be necessary (see [Chapter 37](#)). Do not obtain rectal temperatures to assess fever because stimulating the anal sphincter could initiate more diarrhea. Change diapers frequently, assess perianal skin for irritation from liquid stools, and keep the skin clean and dry.

*Record Fluid Intake and Output.* Much of the nursing care of children with diarrhea focuses on careful recording of fluid intake and output. For children with severe dehydration, oral rehydration or IV therapy serves as their lifeline. Be certain to maintain proper functioning of an IV infusion and site if this is used by use of an arm board or soft restraints to prevent catheter dislodgment or interference with the infusion. If soft restraints are used, remember to release them every hour and passively exercise the child's extremities. Be certain parents understand why the IV infusion is important so they will understand the need for the soft restraints.

In children who are not toilet trained, it is important to separate urine from stool so the appearance of the stool can be accurately described and measured. Because current diapers contain a gel that quickly absorbs urine, apply a disposable urine

collection bag to the infant so you can be assured the infant is voiding, thus confirming kidney function.

For each stool passed, record its color, consistency, odor, size, and the presence of any blood or mucus. Weigh soiled diapers to reveal the number of grams of stool in the diaper (1 g = 1 ml fluid). Testing the stool for acidity and for reducing substances (e.g., sugars) indicates how quickly the stool has passed through the irritated tract. A stool that is both positive for sugar and with a pH below 7.0 (acid) indicates diarrhea is acute because so little absorption of sugar has occurred (sugar is normally absorbed rapidly from ingested food). Diarrheal stools appear green from lack of time for bile to be modified in the intestine. As diarrhea improves and stool remains in the intestine for a longer period, the stool deepens in color, and the acid and sugar contents fade.

**Nursing Diagnosis:** Risk for impaired skin integrity related to presence of diarrheal stool on skin

**Outcome Evaluation:** Skin in diaper area is not erythematous or ulcerated.

Because diarrheal stool is extremely irritating to the skin, change diapers immediately after infants pass any stool. Wash the skin of the diaper area well after each stool, and, if agency policy advises, cover it with a barrier ointment to protect it from further irritation. If the child is older, caution the child to wipe away stool thoroughly.

If infants already have skin excoriation from the number of stools they have had at home, a zinc oxide cream may help soothe the irritated skin. Exposing infants' buttocks to air also is generally helpful in healing irritations. Assure older children that a stool "accident" because of diarrhea is not "shameful" or "babyish" but to be expected because they are so ill.

**Nursing Diagnosis:** Anxiety related to traumatic experience

**Outcome Evaluation:** Child interacts with parents in age-appropriate way; can be comforted after painful procedures.

All children with diarrhea are assumed to have an infectious form of gastroenteritis and therefore need contact and standard infection precautions until their condition is ruled otherwise. To counteract the discomfort of diarrhea, children need the security of someone to stay with them. Be sure to take time during initial procedures to touch and soothe children and talk to them; once the initial admission procedures are done, sit by the bed and hold the child or gently stroke the child's head. Encourage parents to give as much care as possible. Children need this support to counteract the strange world into which they have suddenly been plunged.

## **BACTERIAL INFECTIOUS DISEASES THAT CAUSE DIARRHEA AND VOMITING**

A number of common microorganisms are responsible for the majority of diarrheal

infections in children. Common methods to prevent contracting an infection from these organisms are shown in [Box 45.4](#).

#### BOX 45.4

### Nursing Care Planning to Empower a Family

#### PREVENTING SALMONELLA- OR LISTERIA-CAUSED GASTROENTERITIS

**Q.** Barry's mother says to you, "I hear so much about food poisoning. How can I protect my family against that?"

**A.** Anyone can get food poisoning. However, it can be prevented by using the following measures:

- Wash your hands well before preparing any foods, especially chicken and eggs.
- Remember that chicken may have been contaminated with *Salmonella* at the factory where it was prepared. Wash your hands well after handling raw chicken to prevent the spread of infection to other foods being prepared.
- Clean cutting boards or food preparation surfaces with hot, soapy water and dry thoroughly after use to prevent them from becoming reservoirs of infection. Use plastic cutting boards and avoid wooden cutting boards because they may be more difficult to clean.
- Make a habit of preparing chicken last, after other foods are prepared.
- Cook eggs well (do not use raw eggs in milkshakes; cook soft-boiled or poached eggs for at least 3 minutes).
- Refrigerate chicken and eggs after preparation.
- Wash hands well after playing with or feeding a pet turtle or changing the turtle's water because turtles can also transmit *Salmonella*.
- Wash raw vegetables thoroughly before eating.
- Avoid soft cheeses such as feta, Brie, Camembert, blue-veined, and Mexican queso fresco cheese. Hard cheeses; processed cheeses, including sliced cheese, cream cheese, cheese spreads, and cottage cheese; and yogurt need not be avoided.
- Cook leftover foods or ready-to-eat foods such as hot dogs until steaming hot before eating.
- Avoid foods from delicatessen counters such as prepared salads, meats, and cheeses or heat/reheat these foods until steaming before eating.
- Avoid refrigerated pâtés and other meat spreads or heat and/or reheat these foods before eating; canned or shelf-stable pâté and meat spreads need not be avoided.
- Avoid raw or unpasteurized milk, including goat's milk, or milk products or foods that contain unpasteurized milk or milk products.

### Salmonellosis

- Causative agent: one of the *Salmonella* bacteria
- Incubation period: 6 to 72 hours for intraluminal type; 7 to 14 days for extraluminal type
- Period of communicability: as long as organisms are being excreted (may be as long as 3 months)
- Mode of transmission: ingestion of contaminated food, especially chicken and raw eggs

### Listeriosis

- Causative agent: *Listeria monocytogenes*
- Incubation period: variable, ranging from 1 day to more than 3 weeks
- Mode of transmission: ingestion of unpasteurized milk or cheeses or vegetables grown in contaminated soil. The infection is particularly important to avoid during pregnancy because infections during pregnancy can lead to miscarriage or stillbirth, prematurity, or infection of the newborn.

### Shigellosis (Dysentery)

- Causative agent: organisms of the genus *Shigella*
- Incubation period: 1 to 7 days
- Period of communicability: approximately 1 to 4 weeks
- Mode of transmission: contaminated food, water, or milk products

### Staphylococcal Food Poisoning

- Causative agent: staphylococcal enterotoxin produced by some strains of *Staphylococcus aureus*
- Incubation period: 1 to 7 hours
- Period of communicability: Carriers may contaminate food as long as they harbor the organism.
- Mode of transmission: ingestion of contaminated food such as poultry, creamed foods (e.g., potato salad), and inadequate cooking

### QSEN Checkpoint Question 45.2

#### PATIENT-CENTERED CARE

Barry's mother tells that the nurse she is anxious about the possibility of "food poisoning" and that she particularly wants to prevent *Salmonella* poisoning in her family. Which actions would the nurse suggest?

- Urge family members to keep their immunizations up to date.
- Avoid excessive intake of dairy products.
- Don't cut vegetables on a cutting board used to cut raw chicken.
- Wash fruits such as strawberries and grapes with soap and water before

eating.

Look in [Appendix A](#) for the best answer and rationale.

## PROTOZOAN OR VIRAL DIARRHEA

Most protozoan or viral diarrhea results in loose, watery stools. The chief therapy for these is ORS. Children who are cultured with *G. lamblia* may be prescribed metronidazole (Flagyl).

## Common Disorders of the Stomach and Duodenum

Disorders of the upper GI tract in children tend to involve inadequate function of the gastroesophageal valve or infection.

### GASTROESOPHAGEAL REFLUX

**Gastroesophageal reflux** is the regurgitation of stomach secretions into the esophagus through the lower esophageal (cardiac) sphincter. It is a normal physiologic process that occurs throughout the day in infants, children, and adults.

#### Gastroesophageal Reflux in Infants

Gastroesophageal reflux in infants occurs due to the immaturity of the lower esophageal sphincter, which allows easy regurgitation of gastric contents into the esophagus. It is very common during infancy, with about 70% of infants affected, and it usually requires no treatment. It usually starts within 1 week after birth and may be associated with a hiatal hernia. The emesis occurs after eating, is effortless, and most often consists of 1 to 2 oz of undigested milk.

Gastroesophageal reflux disease (GERD) may be diagnosed when infants develop complications from reflux such as irritability, failure to thrive, esophagitis, and, in severe cases, aspiration pneumonia, wheezing, and apnea. Children with cerebral palsy or other neurologic involvement are at particular risk ([Vandenplas, Rudolf, Di Lorenzo, et al., 2009](#)). Reflux is occasionally due to cow's milk protein intolerance.

#### Assessment

Diagnosis is informed by patient history, and therefore, diagnostic testing is not necessary for uncomplicated reflux. In patients with GERD, diagnostic workup may include the following:

- Upper GI series to look for anatomical abnormalities such as intestinal malrotation
- pH probe (catheter inserted through the nose into the lower esophagus) to calculate the amount of acidic reflux into the esophagus in a 24-hour period
- Esophageal manometry to assess esophageal motility to ensure there is normal

esophageal peristalsis

- Endoscopy to obtain biopsies to assess the degree of esophagitis

## Therapeutic Management

Therapeutic management options for gastroesophageal reflux in infants include conservative treatment, medication, and surgery. Conservative treatment has been shown to reduce reflux symptoms by about 60% (Orenstein & McGowan, 2008).

The traditional treatment of GI reflux is to feed infants small frequent feedings of formula thickened with rice cereal (1 tablespoon of cereal per 1 oz of breast milk or formula). The infant should be held in an upright position for 30 minutes after feedings if possible (e.g., on the parent's shoulder). The infant should not be placed in the car seat at home as this puts pressure on the stomach, making emesis more likely. Tight clothing and diapers should be avoided. Cigarette smoke should be avoided as exposure to nicotine worsens reflux. Asking the breastfeeding mother to eliminate dairy from her diet or a trial of a hypoallergenic formula for 2 weeks may be indicated (Orenstein & McGowan, 2008).

Medication is not indicated for uncomplicated reflux, but for infants experiencing irritability and poor feeding due to esophagitis, an H<sub>2</sub>-receptor antagonist such as ranitidine (Zantac) or a proton pump inhibitor such as omeprazole (Prilosec) may be prescribed daily to reduce the possibility of the stomach acid contents irritating the esophagus.

In infants, gastroesophageal reflux is usually a self-limiting condition. As the esophageal sphincter matures and the child begins to eat solid food or is maintained in a more upright position, the problem disappears.

If such medical therapy is ineffective, a laparoscopic or surgical fundoplication may be performed. The fundoplication procedure involves wrapping the upper portion of the stomach (fundus) around the lower esophagus to prevent regurgitation of stomach contents. After this procedure, the child will temporarily have a nasogastric tube attached to intermittent low suction. Assess nasogastric tube drainage and any vomitus for coffee-colored drainage after the first 24 hours (it is a normal finding in the first 24 hours), which would indicate bleeding from the surgical site. When infants are first fed after surgery, they may display signs of abdominal discomfort, such as gagging, retching, and distention, because food can no longer reflux into the esophagus as readily as it previously could. As the stomach adjusts, however, symptoms will fade. Before this happens, the distention may be so extreme that it leads to bradycardia and dyspnea. Be alert for the development of these important signs and symptoms.

## Gastrointestinal Reflux in Children and Adolescents

GERD affects about 20% of adults; few population-based studies have been done in children, but the incidence is thought to be between 1.8 and 8% (Nelson, Chen, Syniar, et al., 2000). Young children with reflux may present with vomiting. Older children and

adolescents will have similar symptoms to adults. Certain groups of children are at higher risk for reflux. These include children with cerebral palsy, Down syndrome, cystic fibrosis, and obesity. Chronic reflux is potentially dangerous because it can lead to erosion of the esophagus with perforation or stricture and is associated with the development of esophageal cancer in later life (Wang & Souza, 2011).

The typical symptoms are heartburn that occurs 30 to 60 minutes after a meal and regurgitation. Diagnosis is based on history and, if symptoms are severe, an endoscopy to reveal the irritated esophagus (esophagitis). The goal of treatment is to provide symptomatic relief and to heal any esophagitis identified. Treatment includes lifestyle changes and medication.

### Therapeutic Management

To prevent reflux, the child should avoid lying down until 3 hours after a meal and should sleep at night with their upper body elevated on a foam wedge or extra pillow. They should avoid acidic foods such as tomato products, citrus fruits, or spicy foods. Avoiding foods that delay gastric emptying such as fatty foods, chocolate, or alcohol and eating smaller portions may also be helpful. Generally, losing some weight if overweight, avoiding bending over after meals, and removing tight belts are also recommended steps.

Taking an over-the-counter antacid relieves pain immediately by decreasing the concentration of the stomach acid. H<sub>2</sub>-receptor antagonists such as famotidine (Pepcid) or ranitidine (Zantac) are also available over the counter and can be taken before meals to prevent heartburn. Proton pump inhibitors (PPIs) such as omeprazole (Prilosec) (both over-the-counter and prescription) or rabeprazole (AcipHex) (prescription), drugs that halt the release of stomach acids, offer the best long-term relief. PPIs are best taken about 30 minutes before breakfast and are generally prescribed for 8 to 12 weeks, which is usually sufficient to heal the lining of the esophagus.

As with adults, esophageal reflux in adolescents may return. Some adults require surgery in later life to relieve esophageal strictures or to prevent persistent esophagitis, which can lead to cancer if untreated.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for imbalanced nutrition, less than body requirements, related to regurgitation of food with infant esophageal reflux

**Outcome Evaluation:** Skin fold returns to place quickly when turgor is assessed, specific gravity of urine is 1.003 to 1.030; intake is appropriate for age and weight.

Teach parents the importance of monitoring intake, output (urination), and weight. Also, reinforce the need to keep the infant upright after a feeding. Be certain parents

understand how much cereal to mix with formula or breast milk. Encourage parents to feed the infant during the short time that the infant remains in the hospital after surgery so that they can regain their confidence as parents.

## PYLORIC STENOSIS

The pyloric sphincter is the opening between the lower portion of the stomach and the beginning portion of the intestine (the duodenum). If hypertrophy or hyperplasia of the muscle surrounding the sphincter occurs, it is difficult for the stomach to empty, a condition called *pyloric stenosis* (Fig. 45.3). The incidence is high, approximately 1:150 in males and 1:750 in females. It tends to occur most frequently in first-born White male infants. The exact cause is unknown, but multifactorial inheritance is the likely cause.

**Figure 45.3** Pyloric stenosis. Fluid is unable to pass easily through the stenosed and hypertrophied pyloric valve.

### Assessment

With this condition, at 4 to 6 weeks of age, infants typically begin to vomit almost immediately after each feeding. The vomiting grows increasingly forceful until it is projectile, possibly projecting as much as 3 to 4 ft (Pandya & Heiss, 2012).

Pyloric stenosis occurs less frequently in breastfed infants than in formula-fed infants. Breastfed infants begin having symptoms at 6 weeks, whereas formula-fed infants typically begin having symptoms at closer to 4 weeks of age because the curd of breast milk is smaller than that of cow's milk, and it passes through a hypertrophied muscle more easily.

Vomit usually smells sour because it has reached the stomach and has been in contact with digestive enzymes. There will never be bile in the vomitus because the feeding does not reach the duodenum to become mixed with bile. Infants are usually hungry immediately after vomiting because they are not nauseated. Although it is

difficult to assess whether nausea is present in infants, signs such as a disinterest in eating, excessive drooling, or chewing on the tongue may suggest this.

Many infants have signs of dehydration such as dry mucous membrane of the mouth, sunken fontanelles, fever, decreased urine output, poor skin turgor, and weight loss from the vomiting when they are first seen. Alkalosis may be present because of the excessive loss of chloride from the loss of stomach fluid, along with accompanying hypochloremia, hypokalemia, and starvation. Hypopnea (slowed respirations) occurs as the body attempts to compensate for the alkalosis. This will cause the  $\text{HCO}_3^-$  content of plasma generally to be above 30 mEq/L (normal levels are 22 to 28 mEq/L). Tetany may occur with alkalosis because the increased  $\text{HCO}_3^-$  ions may combine with  $\text{Ca}^{2+}$  ions in trying to affect homeostasis and thereby lowering the level of ionized calcium.

A definitive diagnosis can be made by watching the infant drink. If a pyloric stenosis is present, the sphincter feels round and firm, approximately the size of an olive in the right abdomen. As the infant drinks, gastric peristaltic waves pass from left to right across the abdomen. The olive-size lump becomes more prominent, and the infant vomits with projectile emesis. If the diagnosis is still in doubt, an ultrasound will show a hypertrophied sphincter (Iqbal, Rivard, Mortellaro, et al., 2012). An endoscopy also may be used for diagnosis by directly visualizing the hypertrophied sphincter.

### Therapeutic Management

Treatment is surgical or laparoscopic correction (a pyloromyotomy), which is performed before electrolyte imbalance occurs from the vomiting or before hypoglycemia occurs from the lack of food. Before surgery, if electrolyte imbalance, dehydration, and starvation have already occurred, these must be corrected by administration of IV fluid, usually isotonic saline or 5% glucose in saline. Oral feedings are withheld to prevent further electrolyte depletion. An infant who is receiving only IV fluid generally needs a pacifier to meet nonnutritive sucking needs and be comfortable. If tetany is present, verified by a low calcium level on blood analysis, IV calcium also must be administered. The infant usually needs additional potassium, but as a rule, this cannot be administered until it is determined the child's kidneys are functioning (e.g., the child is voiding). Otherwise, the potassium buildup could cause cardiac arrhythmias.

For surgical correction, the muscle of the pylorus is split down to the mucosa, allowing for a larger lumen. Although the procedure sounds simple, it is technically difficult to perform, and there is a high risk of infection following surgery because the abdominal incision is near the diaper area.

The overall prognosis for infants with pyloric stenosis is excellent if the condition is discovered before an electrolyte imbalance occurs.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for deficient fluid volume related to inability to retain food

**Outcome Evaluation:** Skin turgor remains good; specific gravity of urine is 1.003 to 1.030; vomiting episodes have ceased; weight is within acceptable, age-appropriate parameters.

*Preoperative Care.* Preoperative management for pyloric stenosis consists of fluid and electrolyte replacement based on laboratory determinations. Carefully note the frequency of urination, the specific gravity of the urine, and the number of stools passed to help assess dehydration and starvation. Parents may be impatient with preoperative management because it may take 24 hours or more to restore a severe fluid imbalance. They ask why their child can't have immediate surgery. Explaining that infants cannot go to surgery with an electrolyte imbalance is helpful so parents know the hours before surgery are as important to the welfare of their child as the operation itself.

*Postoperative Care.* Infants will return from surgery or laparoscopy with an IV line in place. The postoperative feeding regimen differs from one surgeon to another but usually involves frequent feedings of small amounts of fluid that are gradually increased over time as tolerated. Approximately 4 to 6 hours after surgery, infants are started on a small amount of an oral rehydrating solution by bottle. If no vomiting occurs, the amount is increased or half-strength formula or breastfeeding is begun. Finally, by 24 to 48 hours, infants can take their full formula diet or can be fully breastfed. They are usually discharged from the hospital at the end of 48 hours.

Postoperatively, it is important that infants ingest a small amount of fluid because fluid passing through the sphincter helps to keep adhesions of the sphincter from forming. At the same time, it is important that infants not be given any more than the amount of fluid prescribed at any given time so the surgical repair site is not stretched from an overdistended stomach. As the amount taken orally increases, the IV fluid will be decreased and then discontinued. Infants should be burped well after a feeding so there is no pressure from air in the stomach. Lay them on their right side after feeding so that if vomiting does occur, there is little chance of aspiration, and the flow of fluid through the pyloric valve is aided by gravity. Continue to monitor daily weights to confirm the child is receiving adequate intake. Although postoperative vomiting is commonly experienced, it should be reported immediately because the physiologic cause of the vomiting may be related to delayed gastric emptying, advancing feedings too rapidly, or edema at the operative site, all of which need to be corrected. A few infants develop short-term diarrhea (dumping syndrome) after surgery because of rapid functioning of the pyloric sphincter, but this tends to resolve without additional therapy.

**Nursing Diagnosis:** Risk for infection at site of surgical incision related to danger of contamination from feces because of proximity of incision to diaper area

**Outcome Evaluation:** Infant's temperature is not above 98.6°F (37.0°C) tympanic; incision is clean, dry, and intact without erythema or drainage.

The surgical incision for pyloric stenosis may be covered with collodion, a solution similar to clear nail polish, or a similar commercial compound to help keep urine and feces from touching it. Keep diapers folded low to prevent the incision line from being contaminated, and change diapers frequently. If the incision is exposed to feces, wash the collodion thoroughly with soap and water.

**Nursing Diagnosis:** Risk for impaired parenting related to infant's feeding difficulty and illness

**Outcome Evaluation:** Parents hold and feed infant; express positive characteristics about infant.

Encourage the parents to “room-in” with their child so they can grow comfortable and confident in caring for the child again. When the child first began vomiting so forcefully, parents may have felt they were doing something wrong and so may have lost confidence in themselves as parents. Explain to them that the vomiting was caused by a physical problem and not by anything they did.

Hospitalization often occurs near the infant's second month, when the child would normally receive diphtheria-tetanus-pertussis, rotavirus, pneumococcal, oral poliomyelitis, and *Haemophilus influenzae* immunizations. If the child is otherwise healthy, ask if they could be administered before discharge so the child's immunization status remains current. This also might serve to remind parents that getting back to normal means regular healthcare visits for vaccines and checkups.

## PEPTIC ULCER DISEASE

A *peptic ulcer* is a shallow excavation formed in the mucosal wall of the stomach, the pylorus, or the duodenum. They are rare occurring in only 1% to 2% of children and more frequently in males than females. *Peptic ulcer disease* includes gastritis (irritation of the lining of the stomach or duodenum) and is more commonly seen in childhood.

In infants, ulcers tend to occur in the stomach; in adolescents, they are usually duodenal. Such ulcers occur in a primary form caused by infection with *H. pylori* bacteria and a secondary form that follows severe stress such as burns or chronic ingestion of medications such as aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), alcohol, caffeine, and smoking cigarettes (Garrow & Delegge, 2010).

The small ulceration of the gastric or duodenal lining leads to pain, blood in the stool, and vomiting (with blood). If left uncorrected, peptic ulcer disease can lead to bowel or stomach perforation with acute hemorrhage or pyloric obstruction. A chronic ulcer condition may lead to anemia from the constant, gradual blood loss.

### Assessment

An ulcer occurring in a neonate usually presents with hematemesis (blood in vomitus) or melena (blood in the stool). Such ulcers are usually superficial and heal rapidly, although they can lead to rupture, with symptoms of respiratory distress, abdominal distention, vomiting, and, if extensive, cardiovascular collapse. If an ulcer occurs in a toddler, the first symptoms are usually anorexia or vomiting. Bleeding follows in several weeks. If an ulcer begins when children are of preschool or early school age, pain may be the presenting symptom. The child may report pain as mild, severe, colicky, or continuous. It is often poorly localized, although it may be in the epigastric area as in adults. If the pain occurs in the right lower quadrant, it may be confused with appendicitis.

In school-age children and adolescents, symptoms are generally those of the adult—a gnawing or aching pain in the epigastric area before meals that is relieved by eating. Vomiting (because of spasm and edema of the pylorus) occurs in a small number of children. On abdominal palpation, epigastric tenderness is present.

Endoscopy is the most reliable diagnostic test to confirm the diagnosis of peptic ulcer disease; it allows for visual inspection and biopsies for *H. pylori*. Children with this condition must have blood tests done periodically to be monitored for blood loss anemia.

### Therapeutic Management

Children with peptic ulcer disease due to *H. pylori* infection are treated with triple therapy, a combination of medications that is given to attempt to eradicate the bacteria from the stomach. This treatment consists of two antibiotics, usually amoxicillin and clarithromycin (Biaxin), and a PPI such as omeprazole (Prilosec). Bismuth subsalicylate (Pepto-Bismol) is soothing and mildly antibiotic and so may be prescribed concurrently. Stool can be sent for *H. pylori* stool antigen to check if the infection has cleared (Koletzko, Jones, Goodman, et al., 2011). Children with stress ulcers can be treated with a PPI alone.

## Nursing Diagnoses and Related Interventions

Having peptic ulcer disease can be difficult for children because it is painful, and remembering to take medicine daily can be a problem.

**Nursing Diagnosis:** Pain related to ulceration in intestinal tract

**Outcome Evaluation:** Child exhibits verbal and nonverbal signs of decreased pain; appears comfortable and without excessive crying.

Children with peptic ulcer disease should be able to eat a usual diet while avoiding heavily spiced food such as pizza or sausage if such food causes discomfort. Work with them to devise a schedule so they can remember to take their medications.

Be certain the outcomes planned are realistic because it may not be possible to relieve symptoms of peptic ulcers immediately. However, children can be helped immediately to understand why the pain occurs and what they can do to help relieve it.

### **QSEN Checkpoint Question 45.3**

#### **QUALITY IMPROVEMENT**

Barry's mother is concerned her new baby will develop pyloric stenosis. To detect vomiting from this, the nurse would assess the infant at what time?

- a. Immediately after feeding
- b. An hour after feeding
- c. On arising in the morning
- d. When the infant cries

*Look in [Appendix A](#) for the best answer and rationale.*

## **Hepatic Disorders**

Hepatic disorders include both congenital disorders, such as obstruction or atresia of the biliary duct, and acquired disorders, such as hepatitis or cirrhosis.

### **LIVER FUNCTION**

In infants, 1 or 2 cm of liver is readily and normally palpable under the diaphragm on the right side of their abdomen. An organ essential for the normal metabolism of carbohydrates, proteins, and fats, the liver plays a major role in the maintenance of normal blood sugar levels by changing glucose to glycogen and storing it until needed by body cells. It then reverses the process and changes glycogen back to glucose and releases it into the blood when cells need it (Huether, 2012). It assists in the catabolism of fatty acids and protein and serves as a temporary storage space for both fat and protein.

By the means of the enzyme glucuronosyltransferase, the liver is responsible for converting indirect (or unconjugated) bilirubin into direct (or conjugated) bilirubin so it can be excreted in bile and eliminated from the body. This is an important function in the newborn, and jaundice can result if the level of glucuronosyltransferase is low because of immaturity.

Lastly, the liver manufactures bile, a secretion necessary for the digestion of fat; fibrinogen and prothrombin, substances essential for blood clotting; heparin, a substance necessary to keep blood from clotting in intact vessels; and blood proteins, which are necessary for cell growth and repair. It destroys red blood cells and detoxifies many harmful absorbed substances, such as drugs. The liver is a life-sustaining organ because of all these functions; therefore, any disorder involving the liver is always

serious.

## HEPATITIS

*Hepatitis* (inflammation and infection of the liver) is caused by invasion of the hepatitis A, B, C, D, or E virus (CDC, 2016b).

### Hepatitis A

- Causative agent: a picornavirus, hepatitis A virus (HAV)
- Incubation period: 25 days on average
- Period of communicability: highest during 2 weeks preceding onset of symptoms
- Mode of transmission: in children, ingestion of fecally contaminated water or shellfish; day care center spread from contaminated changing tables
- Immunity:
  - Natural immunity: one episode induces immunity for the specific type of virus.
  - Active artificial immunity: HAV vaccine (recommended for all children 12 to 23 months of age, workers in day care centers, and certain international travelers)
  - Passive artificial immunity: immune globulin

### Hepatitis B

- Causative agent: a hepadnavirus; hepatitis B virus (HBV)
- Incubation period: 120 days on average
- Period of communicability: later part of incubation period and during the acute stage
- Mode of transmission: transfusion of contaminated blood and plasma or semen; inoculation by a contaminated syringe or needle through IV drug use; may be spread to fetus if mother has infection in third trimester of pregnancy
- Immunity:
  - Natural immunity: one episode induces immunity for the specific type of virus
  - Active artificial immunity: HBV vaccine (recommended for routine immunization beginning at birth and also to all healthcare providers) (CDC, 2016b)
  - Passive artificial immunity: specific hepatitis B immune serum globulin

### Hepatitis C, D, and E

Although hepatitis A and B are the viruses that most frequently cause hepatitis, hepatitis C, D, and E viruses may also be involved. Hepatitis C virus (HCV) is a single-strand RNA virus. Transmission, as with HBV, is primarily by blood or blood products, IV drug use, maternal–fetal transfer, or sexual contact. The virus produces mild symptoms of disease, but there is a high incidence of chronic infection with the virus.

Hepatitis D virus (HDV), or the delta form, is similar to HBV in transmission, although it apparently requires a coexisting HBV infection to be activated. Disease

symptoms are mild, but there is a high incidence of fulminant hepatitis after the initial infection.

The E form of hepatitis is enterically transmitted similarly to hepatitis A (e.g., fecally contaminated water). Disease symptoms from the E virus can range from asymptomatic to mild to chronic liver disease (Faramawi, Johnson, Chen, et al., 2011).

## Assessment

No matter which virus is involved, acute hepatitis is a generalized body infection with specific and intense liver effects. Type A occurs in children of all ages and accounts for approximately 30% of instances. Hepatitis B and C tend to occur in newborns from placental–fetal transfer and in adolescents after intimate contact or the use of contaminated syringes for drug injection.

Clinically, it is impossible to differentiate the type of hepatitis from the signs that are present. All hepatitis viruses cause liver cell destruction, leading to increased serum aspartate aminotransferase (AST), alanine aminotransferase (ALT), and alkaline phosphatase levels. Albumin synthesis decreases, and bile formation and excretion are impaired. The type of virus causing the disease can be determined by the recognition of a specific antibody against the virus such as anti-HAV immunoglobulin M (IgM) or anti-HBV IgM.

Hepatitis A is an acute self-limited illness and spread via the fecal–oral route. Symptoms include headache, fever, and anorexia. Jaundice occurs as liver function slows. This lasts for approximately 1 week and then symptoms fade with a full recovery. Rarely, children may develop fulminant liver failure. Symptoms of hepatitis B are more marked. Children report generalized aching, right upper quadrant pain, and a headache. They may have a low-grade fever. They feel ill and become fretful from pruritus (itching). After 3 to 7 days of such symptoms, the color of the urine becomes darker (brown) because of the excretion of bilirubin. In another 2 days, the sclerae of the eyes become jaundiced; soon, the child has generalized jaundice. With generalized jaundice, there is little excretion of bilirubin into the stool, so the stools become white or gray. This icteric (jaundiced) phase lasts for a few days to 2 weeks. Some children have an anicteric form of infection, in which they develop the beginning symptoms but then never develop the jaundice. However, they are as infectious as children with overt jaundice. The majority of those infected with hepatitis C will be asymptomatic, but those who become acutely ill will have similar symptoms to someone with hepatitis B.

Laboratory studies will show elevations of the liver enzymes AST (SGOT) and ALT (SGPT). Levels of bilirubin are increased in the urine. Bile pigments in the stool are decreased. Serum bilirubin levels are increased.

### *QSEN Checkpoint Question 45.4*

#### **SAFETY**

Barry's family likes to celebrate family events by eating crab, lobster, and shrimp.

The nurse recognizes which form of hepatitis is most apt to be contracted by eating contaminated shellfish?

- a. Hepatitis B
- b. Hepatitis A
- c. Hepatitis E
- d. Hepatitis C

*Look in [Appendix A](#) for the best answer and rationale.*

## Therapeutic Management

All healthcare providers should receive prophylaxis against hepatitis with the hepatitis B vaccine. Newborns should also receive routine immunization against HBV. All women should be screened during pregnancy for hepatitis B surface antigen (HBsAg). Infants born to mothers who are hepatitis B positive should receive both hepatitis B immune globulin (HBIG) and active immunization at birth to prevent them from contracting the disease ([Roznovsky, Orsagova, Kloudova, et al., 2010](#)). Hepatitis A vaccine is available for healthcare providers and included in routine immunization programs for infants beginning at 1 year of age ([CDC, 2016b](#)). The incidence of both hepatitis A and B has fallen dramatically since the introduction of routine vaccination ([Daniels, Grytdal, & Wasley, 2009](#)). Unfortunately, no vaccine for hepatitis C is yet available.

Strict hand washing and infection control precautions are mandatory when caring for children with hepatitis. Feces must be disposed of carefully because the type A virus can be cultured from feces. Syringes and needles must be disposed of with caution because the types B and C virus can be transmitted by blood. Contacts should receive immune globulin (hepatitis A) or HBIG as appropriate.

The treatment for hepatitis A is increased rest and maintenance of a good caloric intake. A low-fat diet, once recommended, is not required and, in any event, is difficult to enforce. Children are generally hungrier at breakfast than later in the day, so encourage them to eat a healthy breakfast. They should not return to school or a day care center until 2 weeks after the onset of symptoms to guard against spreading the infection. Treatment for acute hepatitis B is also supportive, as no medication is available for this stage. About 10% of children will develop chronic hepatitis B. Antiviral medications, such as interferon, entecavir, and lamivudine, have been developed for use against chronic hepatitis B and have success in eradicating the virus in some patients. Interferon and ribavirin are approved for treating hepatitis C in children. Hepatitis B is always potentially serious because newborns who contract the disease at birth have an increased risk for liver carcinoma later in life ([Bailey, Shiau, Zola, et al., 2011](#)). Because hepatitis B is a sexually transmitted disease, preadolescent children with the infection need to be screened for the possibility of sexual maltreatment ([Leder, 2012](#)).

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Pain related to pruritus of jaundice and liver inflammation

**Outcome Evaluation:** Child states level of itching is tolerable, no scratch marks on skin; reports right upper quadrant pain is minimal.

Pruritus from jaundice results in extreme discomfort for some children. A cool bath and being certain a child is not overheated and not perspiring usually reduces the itching. Skin moisturizers such as Eucerin or an antihistamine may also be helpful. Cholestyramine (Questran) is a bile acid sequestrant, which binds bile in the GI tract to prevent its reabsorption and so may be prescribed. Teaching a child distraction techniques such as putting pressure on a pruritic area or trying imagery to lessen the urge to scratch are also helpful measures.

### Chronic Hepatitis

Hepatitis is considered chronic when it persists for longer than 6 months. This is most often the result of a hepatitis B, D, or C infection. Abnormal liver enzyme levels and a liver biopsy establish the diagnosis and can also predict the severity. With chronic hepatitis, fatty infiltration and bile duct damage can occur. The disease may progress to cirrhosis and eventually liver failure. Therapy is supportive to compensate for decreased liver function (Sundaram, Hoffenberg, Kramer, et al., 2011).

### Fulminant Hepatic Failure

Fulminant hepatic failure is present when acute, massive necrosis or sudden, severe impairment of liver function occurs, leading to liver failure and hepatic encephalopathy. It can be due to infection or toxicity. Acetaminophen (Tylenol) overdose is the most likely etiology. Hepatic encephalopathy, or invasion of brain cells by ammonia, occurs because of the inability of the liver to detoxify the ammonia being constantly produced by the intestine in the process of digestion (Gluud, Vilstrup, & Morgan, 2016).

Children may show mental aberrations such as confusion, drowsiness, or disorientation. Treatment involves reducing protein intake and administering lactulose to prevent absorption of ammonia in the colon or administering nonabsorbable antibiotics such as neomycin to decrease the production of ammonia by the intestinal bacteria. **Liver transplantation** (surgical replacement of a malfunctioning liver by a donor liver) may be necessary. If a cadaver liver is not available, a lobe can be removed from a living donor such as a parent and transplanted into a child. The donor is then able to regenerate the lost lobe of the liver without long-term effects.

## OBSTRUCTION OF THE BILE DUCTS

Obstruction of the bile ducts in children generally occurs from congenital biliary atresia, stenosis, or absence of the duct. It also can occur from the plugging of biliary secretions, although this is rare. When the bile duct is obstructed, bile, unable to enter the intestinal tract, accumulates in the liver. Bile pigments (direct bilirubin) enter the bloodstream and jaundice occurs, which increases in intensity daily.

### Assessment

Although bile duct obstruction is a congenital disorder, the chief sign (jaundice) does not develop until between 2 and 6 weeks of age. This delay differentiates it clinically from physiologic jaundice, which occurs in almost all newborns on the third day of life, or the jaundice of Rh or ABO isoimmunization, which typically occurs during the first 24 hours of life. Laboratory findings will also distinguish this type of jaundice from other types because, with physiologic and isoimmunization jaundice, there is a rise in indirect bilirubin; in the jaundice of bile duct obstruction, there is a rise in direct bilirubin. Alkaline phosphatase levels will also be elevated. The AST (SGOT) level is normal in the early phase but later becomes abnormal, when prolonged obstruction and back pressure cause liver cell damage. In addition, because bile salts, which are necessary for fat and fat-soluble vitamin absorption, are not reaching the intestine, absorption of fat and fat-soluble vitamins (vitamins A, D, E, and K) becomes poor. Calcium absorption, which depends on vitamin D absorption, will fail as well. The infant's stools appear light in color from a lack of bile pigments. The pressure on the liver from the obstruction becomes so acute with time that cell destruction or cirrhosis occurs. Ultimately, without liver transplantation, death from liver failure will result (Kaido, Mori, Ogura, et al., 2012).

### Therapeutic Management

Before treatment is begun, appropriate blood work and a liver biopsy under local anesthesia may be obtained to rule out hepatitis. Duodenal secretions may be collected by endoscopy to assess for bile. Radionuclide imaging to show that bile ducts are not patent may confirm the diagnosis. If atresia of the bile duct is the problem, surgical correction is the treatment (a Kasai procedure). With this surgery, a Roux-en-Y loop of bowel is sutured directly onto the hilum of the liver so that the remaining small bile ducts will drain into the bowel. If successful, stools will become darker in color, and the jaundice will gradually resolve. Surgical correction may not be possible in all infants because the atresia may occur too far back in the liver to be in an operable area. Liver transplantation is then needed for children with extensive involvement or in whom a Kasai procedure is not successful.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for imbalanced nutrition, less than body requirements, related to inability to digest fat

**Outcome Evaluation:** Infant's weight remains in same percentile on standardized growth curve; absence of signs of vitamin deficiency such as cracked lips or altered bone growth; dietary record reflects intake of adequate nutrients.

*Preoperative Care.* Infants who are admitted for surgery for bile duct obstruction are placed on a low-fat, high-carbohydrate diet preoperatively. They are given water-soluble forms of vitamins A, D, and K to improve vitamin levels. If the vitamin K level is too low, coagulation may be affected, so vitamin K may be administered parenterally until prothrombin levels rise to normal limits. Infants will also be well hydrated with parenteral fluids.

*Postoperative Care.* Following surgery, infants return with a nasogastric tube in place attached to low intermittent suction. Observe carefully for abdominal distention because paralytic ileus, or bowel dysfunction, is a frequent complication of this type of surgery. The nasogastric tube will be left in place until peristalsis has returned. Gradually, children will be introduced to oral fluids and, eventually, to a normal diet. If the repair is successful, the child's stools change to a yellow and then brown (normal stool) color after surgery. Therefore, a description of stools is an important postoperative observation.

If bile flow is inadequate after surgery, infants will remain on a medium-fat, high-carbohydrate diet or receive total parenteral nutrition while they await transplantation surgery.

## NONALCOHOLIC FATTY LIVER DISEASE AND CIRRHOSIS

Nonalcoholic fatty liver disease (NAFLD) is the accumulation of fatty deposits in the liver and is usually associated with obesity. As obesity is increasing in school-age children and adolescents, this condition is also increasing in incidence (Vajro, Lenta, Socha, et al., 2012). NAFLD can progress to cirrhosis in rare cases.

*Cirrhosis* is fibrotic scarring of the liver. Cirrhosis means “yellow,” or the typical color of hepatic scar tissue. It rarely occurs in children, although it may be seen as a result of congenital biliary atresia or as a complication of chronic illnesses such as protracted hepatitis, sickle-cell anemia, or cystic fibrosis.

When fibrotic infiltrates replace normal liver cells, total liver function becomes impaired, resulting in a decreased ability to detoxify toxic substances, decreased protein synthesis, inability to produce prothrombin, decreased ability to produce bile, and, possibly, hypoglycemia. Children will have large, fatty stools resulting from the decrease in bile production; avitaminosis of fat-soluble vitamins; symptoms of hemorrhage from decreased clotting ability; and anemia.

Portal hypertension occurs from back pressure of blood that cannot flow readily

through the scarred organ (Fig. 45.4). This leads to compromised heart action, *ascites* (an exudate of fluid into the abdomen), possibly esophageal varices (back pressure causes them to dilate), and hypersplenism (D'Antiga, 2012).

**Figure 45.4** A distended abdomen due to ascites results in prominent veins along the abdomen. The underlying cause in this child is portal hypertension due to cirrhosis of the liver (From Salimpour, R. R., Salimpour, P., & Salimpour, P. [2013]. *Photographic atlas of pediatric disorders and diagnosis*. Philadelphia, PA: Lippincott Williams & Wilkins.)

Cholestyramine (Questran) may be prescribed to reduce reabsorption of bile into the circulation to minimize itching from cholestasis. Once fatty or fibrotic infiltration begins, however, there is no way to reverse the changes. Nursing care focuses on promoting comfort, providing adequate nutrition by a high-carbohydrate, medium-chain-triglyceride diet, and preventing further involvement until liver transplantation can be scheduled.

### **Esophageal Varices**

Esophageal varices (distended veins in the esophagus) are a frequent complication of liver disorders such as cirrhosis. They generally form at the distal end of the esophagus near the stomach because of back pressure on the veins resulting from increased portal

circulation blood pressure. Varices may bleed if children cough vigorously or strain to pass stool. Gastric reflux into the distal esophagus may irritate and erode the fine covering of the distended vessels, causing rupture.

A rupture of esophageal varices is an emergency because children can lose a large quantity of blood quickly from the engorged vessels. Octreotide or vasopressin may be given by IV to decrease blood flow to the esophagus and reduce the hemorrhage. Endoscopic variceal band ligation is the preferred method of treatment. A tight rubber band is placed around the varix, creating a clot that prevents further bleeding (Hwang, Shergill, Acosta, et al., 2014). Balloon tamponade may be used to prevent bleeding until more effective treatment can be given.

A Sengstaken–Blakemore tube or Linton-Nachlas catheter may be passed into the stomach. After insertion, balloons on the sides of these catheters are inflated to apply pressure against the bleeding vessels. As with an external tourniquet, the compression must be reduced for 5 to 10 minutes every 6 to 8 hours, or tissue necrosis can result.

Following one episode of bleeding, children must be monitored for future bleeding episodes. Frequent vital sign measurements and testing of stool and any vomitus for the presence of blood will indicate if new bleeding is occurring.

## LIVER TRANSPLANTATION

Liver transplantation is the surgical replacement of a malfunctioning liver by a donor liver. Child-size donor livers are not readily available, so the waiting time for surgery may be months. Adult livers can be reduced in size for transplantation or a lobe of a liver from a living donor can be used. Often, the child is extremely ill with ascites, GI bleeding, extreme pruritus, hepatic encephalopathy, or renal dysfunction before the surgery. This makes nursing care after liver transplantation in a child complex because it involves taking care of a child who has had major surgery and who normally would be categorized as too ill to undergo surgery.

Despite the severity of illness and the length of surgery, however, children tend to recover quickly after liver transplantation. Both children and parents must have thorough preoperative preparation, so they understand the seriousness of the surgery and the possibility that the graft will be rejected. It helps to introduce the parents to others whose children have successfully undergone the procedure so they have support people available for this critical time.

### Preoperative Management

Preoperative management consists of keeping the child in the best physiologic condition possible so that when a liver is available, the transplantation can be performed.

### Surgical Procedure

Liver transplantation is a time-consuming procedure and requires a wide subcostal incision. The vena cava is temporarily clamped during the removal of the natural liver

to prevent bleeding, which means that all IV lines must be placed in the upper extremities.

## Postoperative Management

Rejection of a liver transplant is most often because of the function of T lymphocytes. Careful tissue matching (human leukocyte antigen [HLA] matching) is necessary to reduce the possibility of stimulating T-cell rejection. To further reduce the action of T lymphocytes, children are given an immunosuppressive drug such as mycophenolate mofetil (CellCept), cyclosporine (Sandimmune), or tacrolimus (Prograf) before the transplantation.

Children may need assisted ventilation for approximately 24 hours postoperatively to prevent pulmonary complications such as atelectasis and pneumonia because the large abdominal incision makes coughing and deep breathing difficult. In addition, ascites places pressure against the diaphragm, interfering with lung expansion, and preoperative pulmonary edema may be present. After discontinuation of mechanical ventilation and extubation, chest physiotherapy may be started to mobilize lung secretions.

Advocate for adequate pain control. Frequently assess blood pressure, capillary refill, peripheral pulses, and skin color to ensure adequate cardiovascular function, which is important for good tissue perfusion of the transplanted liver. The child may have a central venous pressure line or an arterial line such as a Swan-Ganz catheter inserted to assess hemodynamic status. Assess neurologic status hourly using a modified Glasgow Coma Scale (see [Chapter 52](#)).

Usually, a child is positioned flat for the first 24 hours to prevent cerebral air emboli, which may result from any air remaining in the transplanted liver. Typically, children have a nasogastric tube inserted during surgery that is attached to low intermittent suction postoperatively. Irrigate the tube according to agency policy to maintain patency. Assess the gastric pH by aspirating stomach contents every 4 hours; based on this assessment, administer antacids or H<sub>2</sub>-receptor antagonists such as cimetidine or mucosal protectants as prescribed to help prevent a stress ulcer. If preoperative esophageal varices are present, assess nasogastric drainage carefully for frank or occult blood.

A T-tube inserted into the bile duct for drainage allows the amount of bile being produced by the new liver to be evaluated. Once bowel sounds become active, nasogastric suction and the T-tube are usually discontinued and liquids and then solid foods are introduced gradually. If vomiting occurs and is persistent, total parenteral nutrition may be used for 3 or 4 days to rest the intestinal tract before fluid is reintroduced.

Hypoglycemia is a major danger postoperatively because glucose levels are regulated by the liver, and the transplanted organ may not function efficiently at first. Assess serum glucose levels hourly by finger-stick puncture. A 10% solution of dextrose IV may be necessary to prevent hypoglycemia.

Sodium, potassium, chloride, and calcium levels are evaluated approximately every 6 to 8 hours to be certain electrolyte balance is maintained. Even if a low potassium level is detected, potassium is rarely added to IV solutions because of the risk that renal failure has occurred because of the stress of surgery. In addition, if the graft begins to become necrotic, the breakdown of cells will release potassium, elevating the level even more. Continuous cardiac monitoring is usually necessary to detect hyperkalemia (hyperkalemia causes elevation of T waves or ventricular fibrillation), hypokalemia (causes small T waves and a U wave), or other arrhythmias.

Many children develop hypertension within 72 hours after surgery. This occurs because of alterations in the renin–angiotensin system because of the not yet fully functioning transplanted liver or as a side effect of cyclosporine, tacrolimus, and steroid therapy, which is continued postoperatively to guard against transplant rejection. IV therapy with hypotensive agents such as hydralazine (Apresoline) and nitroprusside may be needed to reduce hypertension. In contrast, hypotension will occur if the transplanted liver becomes dysfunctional or if there is bleeding caused by poor blood coagulation. To help detect bleeding, observe and record abdominal girth, the incision line, and drainage from any catheters or tubes placed in the incision to allow peritoneal secretions to drain.

A warming blanket may be required postoperatively to maintain normal body temperature after the long exposure of surgery. Take axillary or tympanic, not rectal, temperatures because many children with liver damage have hemorrhoids that could rupture from the trauma of a thermometer insertion. Prevent the child from unnecessary exposure during procedures and care to help restore and maintain normal body temperature.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for infection related to administration of immunosuppressive medication

**Outcome Evaluation:** Temperature remains within normal range; no exudate or inflammation around abdominal incision is present.

Liver transplantation is possible because of the preoperative administration of an immunosuppressive agent that suppresses T lymphocytes, the lymphocytes responsible for rejecting transplanted organs. Because children are prone to infection while receiving immunosuppressive therapy, be certain to use strict aseptic technique, standard infection precautions, and careful hand washing while giving care. Clean the skin around any abdominal drains every 4 hours to avoid skin breakdown and to prevent a portal of entry for microorganisms.

Serum transaminases (AST [SGOT] and ALT [SGPT]), alkaline phosphatase, serum bilirubin, and ammonia levels are assessed at least daily to detect rejection, although children usually do not show signs of liver rejection until 5 to 7 days after surgery. In addition to changes in these laboratory values, with liver rejection, the child also may develop fever and increasing abdominal girth. Also, the urine turns orange from increased urobilinogen excretion. If signs of rejection appear to be occurring, doses of cyclosporine, tacrolimus, and a corticosteroid such as methylprednisolone are increased to maximum levels.

**Nursing Diagnosis:** Interrupted family processes related to stress of surgery and uncertainty of transplantation outcome

**Outcome Evaluation:** Child and family state that although waiting is difficult, they are able to do so; family identifies ways they have changed family life at home to accommodate child's illness and surgery.

Children and parents need continued support during the postoperative period while they wait to see if the graft will be rejected. They also need continued contact with healthcare personnel through telephone calls and clinic visits.

After successful liver transplantation, a child should be able to function with few limitations, attending school and enjoying age-appropriate activities. Be certain on hospital discharge parents have a return appointment for evaluation and are aware of the symptoms of graft rejection, such as jaundice, lethargy, and fever. Contact sports may be limited to prevent injury to the new liver, and adolescents need to be cautioned to avoid alcohol to prevent liver damage from this source.

## Intestinal Disorders

Because the intestines are a lengthy body system, several disorders, either congenital or acquired, can occur.

### INTUSSUSCEPTION

**Intussusception**, the invagination of one portion of the intestine into another (Fig. 45.5), most frequently occurs in the second half of the first year of life (Mandeville, Chien, Willyerd, et al., 2012) with 90% of cases occurring by 2 years of age. About 75% of intussusception occurs for idiopathic reasons where there is no clear cause. In other cases, a “lead point” on the intestine likely cues the invagination. Such a point might be a Meckel's diverticulum, a polyp, hypertrophy of *Peyer patches* (lymphatic tissue of the bowel that increases in size with viral diseases), or bowel tumors. The point of the invagination is generally at the juncture of the distal ileum and proximal colon.

**Figure 45.5** Intussusception. The distal ileal segment of bowel has invaginated into the cecum. A polyp serves as a lead point.

### Assessment

Children with this disorder suddenly draw up their legs and cry as if they are in severe pain, and they may also vomit. After the peristaltic wave that caused the discomfort passes, they are symptom free and play happily. In approximately 15 minutes, however, the same phenomenon of intense abdominal pain strikes again. Vomitus, which contains bile because the obstruction is invariably below the ampulla of Vater, the point in the intestine where bile empties into the duodenum, will begin. In approximately 70% of cases, frank or occult blood is seen in the stool. The stool is described as having a “red currant jelly” appearance due to the blood and mucus it contains. The abdomen becomes distended as the bowel above the intussusception distends.

If necrosis occurs in the invaginated bowel, children generally develop an elevated temperature, peritoneal irritation (their abdomen feels tender and they may “guard” it by tightening their abdominal muscles), an increased white blood cell count, and often a rapid pulse.

Diagnosis is suggested by the history. Any time a parent is describing a child who is crying, be certain to ask enough questions to recognize the possibility of intussusception. Episodes of crying are for a short time but repeat every 15 to 20 minutes; the stomach feels “full” and vomitus and diarrhea with blood may occur. The presence of the intussusception is confirmed by an abdominal X-ray, or ultrasound (Rogers, 2017).

### Therapeutic Management

The condition is a surgical emergency. Reduction of the intussusception must be done promptly by either instillation of a water-soluble solution, barium enema, or air (pneumatic insufflation) into the bowel or surgery to reduce the invagination before

necrosis of the affected portion of the bowel occurs. If there is no lead point, just the pressure of the nonsurgical techniques may reduce the intussusception. After this type of reduction, children are observed for 24 hours because some children will have a recurrence of the intussusception within this time. If this occurs, children will be scheduled for an additional reduction or surgery.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Pain related to abnormal abdominal peristalsis

**Outcome Evaluation:** Child can be comforted between spasms of pain; demonstrates interest in toys or social interactions.

Infants with intussusception are bewildered by this type of episodic pain because it is so different from any pain they have experienced before. Ordinarily, if they pinch a finger on a toy and it hurts, a parent picks them up, kisses their fingers, and the pain goes away. A parent picks them up now and the pain goes away, but it returns repeatedly. Infants need to be held, rocked, and comforted in an attempt to relieve their fright at this strange happening.

**Nursing Diagnosis:** Risk for deficient fluid volume related to bowel obstruction

**Outcome Evaluation:** Infant's skin turgor is good, pulse is 90 to 100 beats/min, amount of diarrhea and blood loss in stool are minimal; episodes of vomiting decrease in frequency.

Infants are kept on NPO status before surgery or nonsurgical reduction. Because they have abdominal pain, they may find comfort in sucking a pacifier. Because they have been vomiting, IV fluid therapy may be started to reestablish their electrolyte balance and to supply adequate fluid to hydrate them.

Following a nonsurgical reduction, infants are kept NPO for a few hours and then introduced gradually to regular feedings. Infants who have surgery will return with a nasogastric tube attached to low intermittent suction and an IV infusion in place. The nasogastric tube will remain in place until the suture line is healing, and peristaltic function has returned. Once bowel sounds are present, oral feedings can be started gradually. Encourage the parents to participate with this aspect of care because it provides them with an opportunity to regain confidence in themselves as parents. Urge them to continue to hold and be with the child as recovery proceeds to reassure themselves that the child is now once again well.

## VOLVULUS WITH MALROTATION

A **volvulus** is a twisting of the intestine (Fig. 45.6). The twist leads to obstruction of the passage of feces and to compromise of the blood supply to the loop of intestine involved. Volvulus occurs due to intestinal malrotation and may be associated with other congenital anomalies. In fetal life, a portion of the intestine first protrudes into the base of the umbilical cord at approximately 6 weeks of intrauterine life. At approximately 10 weeks of intrauterine life, it returns to the abdominal cavity. As the intestine returns, it rotates to its permanent position. After the rotation, the mesentery becomes fixed in this position. With a volvulus, this action is incomplete and the mesentery does not attach in a normal position. The bowel is left free to move and twist (Laurence & Pollock, 2012).

**Figure 45.6** Volvulus of the sigmoid colon. **(A)** The unattached loop of bowel twists. **(B)** The bowel lumen is obstructed, leading to inability of stool to pass and compression of the blood supply to the looped bowel segment.

Usually, the symptoms occur during the first 6 months of life and are those of intestinal obstruction such as intense crying and pain, pulling up the legs, abdominal distention, and vomiting. A volvulus can be differentiated from pyloric stenosis because vomiting with pyloric stenosis occurs immediately after feeding, whereas pain and vomiting from a volvulus is unrelated to feeding. The diagnosis is made based on the history and an abdominal examination, which reveals an abdominal mass. It is

confirmed by an ultrasound or lower barium X-ray. Surgery is an emergency and should be performed before necrosis of the intestine occurs from a lack of blood supply to the involved loop of bowel. Preoperative and postoperative care will be the same as for infants with intussusception.

## **NECROTIZING ENTEROCOLITIS**

**Necrotizing enterocolitis** (NEC) is a condition that develops in approximately 5% of all infants in neonatal intensive care nurseries, with premature and low-birth-weight infants at highest risk. Necrotic areas develop in the bowel that interfere with digestion and can lead to paralytic ileus, perforation, and peritonitis (Huether, 2012).

The cause of NEC is unknown and thought to be due to a variety of factors. The necrosis appears to result from ischemia or poor perfusion of blood vessels in the entire bowel or in isolated sections of the bowel. The ischemic process tends to occur from hypovolemic shock or hypoxia in which there is vasoconstriction of blood vessels to organs such as the bowel. The incidence is highest in immature infants, those who have suffered anoxia or shock, and those fed by enteral feedings. Infants with infections may develop it as a further complication of their already stressed state.

### **Assessment**

There is a lower incidence of the condition in infants who are fed breast milk than in those who are formula fed because intestinal organisms grow more profusely with cow's milk than breast milk (cow's milk lacks antibodies). A response to the foreign protein in cow's milk may also be a mechanism that starts the necrotic process. Therefore, encouraging breastfeeding may help prevent this disorder (Underwood, 2013).

Signs of NEC usually appear in the first week of life. The infant's abdomen becomes distended and tense. If stomach contents are aspirated before a feeding, a return of undigested milk of more than 2 ml will be obtained. Stool may test positive for occult blood. Periods of apnea may begin or increase in number. Signs of blood loss because of intestinal bleeding, such as lowered blood pressure and inability to stabilize temperature, also may be present.

Abdominal girth measurements made just above the umbilicus every 4 to 8 hours will show a gradual increase. Abdominal X-ray films show a characteristic picture of air invading the intestinal wall; if perforation has occurred, there will be air in the abdominal cavity.

### **Therapeutic Management**

As soon as the condition is recognized, breastfeedings or formula feedings are discontinued, and the infant is maintained on IV or total parenteral nutrition solutions to rest the GI tract except for additional supplements of enteral probiotics (Vongbhavit & Underwood, 2016). An antibiotic may be given to limit secondary infection. Handle the

infant's abdomen gently to lessen the possibility of a bowel perforation.

If the area of necrosis appears to be localized, surgery to remove that portion of the bowel may be successful. If a large portion of the bowel is removed, the infant may be prone to "short-bowel" syndrome or may have a problem with digestion of nutrients in the future. If the bowel perforates, peritoneal drainage or a laparotomy will be necessary to help remove fecal secretions from the abdomen. An infant may need a temporary colostomy performed to allow for bowel function.

NEC is a grave insult to an infant already stressed by immaturity. The prognosis is guarded until the infant can again take oral feedings without bowel complications.

## SHORT-BOWEL/SHORT-GUT SYNDROME

Short-bowel or short-gut syndrome is an absorptive disorder in which there is not sufficient bowel surface area in the small intestine for proper nutrient absorption. The condition has several causes, including surgery for NEC, volvulus, and GI tract trauma, which resulted in a large portion of the intestine being removed. The treatment includes ensuring adequate hydration and proper intake of essential vitamins and minerals. Following bowel resection surgery, total parenteral nutrition, including lipids, may be used initially until the bowel can tolerate enteral feedings. Oral or enteral feedings are then given as tolerated. If gastrostomy or nasogastric feedings are used, nonnutritive sucking should be facilitated to preserve the suck–swallow reflex. Because long-term use of total parenteral nutrition may cause liver damage, liver transplantation may be needed in the future (Bhatia, Gates, & Parish, 2010).

## APPENDICITIS

*Appendicitis* (inflammation of the appendix) is the most common cause of abdominal surgery in children. It occurs most frequently in school-age children and adolescents, although it can occur in preschoolers and even in newborns (Ladd, Neff, Becher, et al., 2012). The *appendix*, a blind-ended pouch attached to the cecum, may become inflamed because of an upper respiratory or other body infection, but the cause of appendicitis is generally obscure. In most instances, fecal material apparently enters the appendix, hardens, and obstructs the appendiceal lumen. Inflammation and edema develop, leading to compression of blood vessels and cellular malnutrition. Necrosis and pain result. If the condition is not discovered early enough, the necrotic area will rupture and fecal material will spill into the abdomen, causing peritonitis, a potentially fatal condition.

### Assessment

Most parents assume appendicitis begins with sharp pain, so they may dismiss a child's early symptoms for some time as simple gastroenteritis. In actuality, pain is a late symptom. Diagnosis is made on a cluster of symptoms: anorexia, pain or tenderness in the right lower quadrant, nausea or vomiting, elevation of temperature, and leukocytosis

(Wheeler, 2011). The history typically begins with anorexia for 12 to 24 hours. Children do not eat and do not act like their usual selves. Nausea and vomiting may then occur. The abdominal pain, when it does start, is at first diffuse. Gradually, it becomes localized to the right lower quadrant. The point of sharpest pain is often one third of the way between the anterior superior iliac crest and the umbilicus (**McBurney's point**). If the child's appendix is displaced from this usual position, the pain will not be at this typical point, so pain at any other point does not rule out appendicitis. Pregnant adolescents are apt to have displaced pain. Fever is a late symptom.

Until the pain becomes localized, appendicitis is difficult to distinguish from acute gastroenteritis. Often, it is difficult to palpate children's abdomens because they may guard their abdomen or make abdominal muscles stiff and hard by tensing them. Although this interferes with an abdominal examination, it is in itself an important sign that children have abdominal pain. To assist in a diagnosis of a painful abdomen, always palpate the anticipated tender area last.

Rebound tenderness is a phenomenon in which a child feels relatively mild pain when the area over the appendix is palpated, but, once an examiner's hand is withdrawn, the child experiences acute pain caused by abdominal contents shifting. This is diagnostic for appendicitis, but it should be done with children only when necessary because it does cause acute pain. If, on auscultation, bowel sounds are reduced (hypoactive), this suggests peritonitis or that the appendix has already ruptured.

Laboratory findings usually indicate leukocytosis (white blood cell count between 10,000 and 18,000/mm<sup>3</sup>), which is actually low for the extent of the infection that may be present. Ketone levels in the urine are inordinately elevated as a symptom of starvation from poor intestinal absorption.

An ultrasound or CT scan will reveal the swollen appendix. Pain in the right lower quadrant may also occur as a manifestation of right lower lobe pneumonia. Therefore, children may have a chest X-ray taken to rule this out as the source of pain. Because, in the past, an assessment of appendicitis depended on being able to detect abdominal pain, both parents and healthcare providers may be reluctant to administer analgesia to children with abdominal pain. Because ultrasound can successfully reveal appendicitis, however, analgesia to make the child comfortable can be given (Bansal, Banever, Karrer, et al., 2012).

## Therapeutic Management

Therapy for appendicitis is surgical removal of the appendix by laparoscopy before it ruptures. Achieving this is easier in older than younger children because they are more capable of relating the progression of symptoms. Also, the wall of the appendix is thinner and perforates more readily in young children.

## Nursing Diagnoses and Related Interventions

Priorities for nursing care must be established quickly because this is an emergency, and the child must be prepared immediately for surgery. [Box 45.5](#) shows an interprofessional care map illustrating both nursing and team planning for a child with appendicitis.

## BOX 45.5

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR A CHILD WITH APPENDICITIS

Barry’s parents bring his older sister, 10-year-old Addie, to the emergency department because of nausea, vomiting, and abdominal pain since yesterday. Father states, “We thought it was just an upset stomach, but it isn’t getting any better, and the pain is much worse now.”

**Family Assessment:** Child lives with two younger siblings (2 years and 12 months of age) and both parents on a rural horse farm. Father works as a newspaper printer in town; mother cares for horses and stable. Mother reports finances as, “Good. We’re enjoying this time of life.”

**Patient Assessment:** Thin-appearing 10-year-old female with a history of inflammatory bowel disease. Temperature, 101.2°F; pulse rate, 100 beats/min; respirations, 24 breaths/min. Mother reports that yesterday the child stated she was not feeling well. “She wasn’t eating, and she had pains in her stomach. Last night, the pain got worse, and she started vomiting.” Pain now localized in right lower quadrant. Legs drawn up against abdomen. Bowel sounds sluggish. Rebound tenderness present. White blood cell count of 17,000/mm<sup>3</sup>. Ultrasound confirms appendicitis. Child is scheduled for emergency appendectomy.

**Nursing Diagnosis:** Pain related to presence of appendicitis

**Outcome Criteria:** Child states pain is not above a 2 on 1–10 numeric pain scale.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess what is child’s most comfortable position.	Do not palpate child’s abdomen.	Palpating could rupture inflamed appendix.	Child states s knows not to pressure on abdomen.

Reinforcing that parents acted with good judgment can increase self-esteem and ability to accept new developments.	Child and parents state that although their stress level is high, they are able to cope with the developments.

### *Informatics for Seamless Healthcare Planning*

Nurse	Assess if child and parents have any questions prior to leaving for operating room.	Review what will happen in the operating room and immediate postoperative course.	The better informed child and parents are of happenings, the better they will be able to cooperate.	Child and parents state they feel prepared for the next step in treatment for child's condition.
-------	---	---	---	--

**Nursing Diagnosis:** Fear related to pain and the emergency nature of disorder and immediate surgery

**Outcome Evaluation:** Parents and child state that they understand what interventions are necessary and cooperate as necessary; child states level of pain is tolerable.

Admission to a hospital for appendicitis often occurs rapidly. A parent telephones a primary care provider, who recommends the child be seen in the emergency room. Surgery is scheduled as soon as it can be arranged or a mere 30 minutes may have passed from the time of the first phone call to when the child is wheeled into surgery. During this time, the parent and child both need to be told exactly what is happening (e.g., "I'm going to take some blood; I'm putting your name tag on your arm") and who the people are who are caring for them (e.g., "This is Dr. Brown, the anesthesiologist. I'm Ms. Henry, a registered nurse."). Remember, parents may not think clearly in this type of emergency so their reactions to situations may not be their usual ones (e.g., they leave food cooking on the stove, they leave their car in the middle of the street, which causes a traffic jam, rather than pulling it into the parking lot). Explain that the procedures being done for their child, such as blood studies, or the short wait while an operating room is prepared are necessary for safe surgery, and the danger of the appendix rupturing is not as acute a danger as they may have believed under these controlled circumstances. Praise them for the things they did well, such as recognizing that the child was ill and bringing the child immediately for

care, to help offer a sense of control.

Once a diagnosis is made by ultrasound, a child needs an analgesic for pain. Cathartics and heat to the abdomen are contraindicated to relieve pain because these increase the possibility of rupture of the appendix. If you are assisting with washing the abdomen with an antiseptic solution immediately before surgery, be certain to do this gently because the abdomen is tender, and compression could cause the appendix to rupture. Likewise, use lukewarm, not hot water, because heat can increase the possibility of appendix rupture by increasing edema in the appendix. Urge the child to find the best position of comfort and assure both parents and the child that surgery is being scheduled as soon as possible.

**Nursing Diagnosis:** Risk for deficient fluid volume related to NPO status presurgery and postsurgery

**Outcome Evaluation:** Child's skin fold returns to place quickly when turgor is assessed, pulse and blood pressure are within normal age limits; weight is maintained.

Preoperatively, obtain a urine sample for urinalysis and blood for a complete blood count. IV fluid therapy may be initiated to hydrate a child who has been vomiting a great deal. Postoperatively, children may have a nasogastric tube in place, and they will be maintained on IV fluids until they can take adequate oral feedings (approximately 24 hours). With unruptured appendicitis, the postoperative course is uneventful and children are up a few hours after surgery and discharged within several days. They generally return to school in another week.

### *QSEN Checkpoint Question 45.5*

#### **EVIDENCE-BASED PRACTICE**

The onset of appendicitis is sudden and parents may be unable to arrange to room-in with their hospitalized child. Despite being encouraged and often included in medical rounds as a means to improve communication and increase their knowledge of and participation in their child's care, work responsibilities, care of siblings, a long commute to the hospital, and other types of situations may prevent parents from being with their child during the entire stay. Having daily interaction with the healthcare team lessens parental anxiety about their child's health (Yager, Clark, Cummings, et al., 2017). A study conducted by Yager et al. (2017) found that providing access to medical rounds through telemedicine to parents had a positive effect. It offered them reassurance regarding their child's care and increased their communication with the healthcare team.

Based on this study, the nurse determines which strategy is most effective to decrease parental anxiety when parents are unable to stay with their child for several hours during the day?

- a. Offer to take notes on the medical rounds and verbally provide them to the

- parents when they arrive.
- b. Offer to call them during medical team rounds, so they can participate.
  - c. Reassure them their child may receive more attentive care than a child whose parent is present.
  - d. Ensure the parents their child will be well cared for and they can call anytime to check on them.

Look in *Appendix A* for the best answer and rationale.

## Ruptured Appendix

If a child's appendix has already ruptured when the child is seen in the emergency department, the potential for peritonitis increases greatly. Children generally appear severely ill. Their white blood cell count is apt to be more than  $20,000/\text{mm}^3$ . Position the child in a semi-Fowler's position, if possible, so that infected drainage from the cecum drains downward into the pelvis rather than upward toward the lungs. The child needs an IV fluid line inserted for hydration. Antibiotics will be begun preoperatively or as soon as the ruptured appendix is confirmed (Hung, Lin, & Chen, 2012).

During surgery, the child will have drains placed beside the surgery incision so any infectious material in the abdomen can continue to drain. Warm soaks to the incision line may be prescribed three or four times a day to encourage drainage. Examine the wound carefully at each dressing change. Be certain not to dislodge drains while removing soiled dressings. Report immediately any drain that is expelled because the surgeon may want to replace it to ensure a patent drainage route. Often, drains are shortened with each dressing change to encourage initially deep areas, then areas closer to the skin to drain. IV fluid and antibiotic therapy are continued until full bowel function is restored.

When changing dressings, also assess for signs of peritonitis such as a boardlike (rigid) abdomen, generally shallow respirations (because deep breathing puts pressure on the abdomen and causes pain), and increased temperature. Although the postoperative course is slower (approximately 3 weeks) after a ruptured appendix, the prognosis is still good. A local abscess or intestinal adhesions may result. Adhesion formation, a long-term effect, could interfere with fertility in girls or cause bowel obstruction in both sexes later in life.

### *What If . . . 45.2*

**Barry's older sister develops appendicitis, and the nurse meets them in the emergency room. Her parent tells the nurse she "dropped everything" to rush her there. What questions would the nurse want to ask to see if she has thought through the situation?**

## MECKEL'S DIVERTICULUM

In embryonic life, the intestine is attached to the umbilicus by the omphalomesenteric (vitelline) duct. This duct becomes a vestigial ligament as infants reach term. In 2% or 3% of all infants, however, a small pouch of this duct remains, located off the ileum, approximately 18 in. from the ileum–colon junction: a **Meckel’s diverticulum** (Kloss, Branton, & Sullivan, 2010). The structure often contains some misplaced gastric mucosa, which secretes gastric acids that flow into the intestine and irritate the bowel wall, leading to ulceration and bleeding. Children will have painless, tarry (black) stools or grossly bloody stools. On occasion, the diverticulum may serve as the lead point, causing an intussusception. In some instances, a fibrous band extending from the diverticulum pouch to the umbilicus acts as a constricting band, causing bowel obstruction.

The history of the child suggests the diagnosis. Because the pouch is small, it does not fill, and therefore, it may not be evident on X-ray or ultrasound. A nuclear medicine test called a Meckel’s scan is used to identify the area of gastric mucosa in the intestine. Treatment is laparoscopy exploration and removal of the vestigial structure.

### **CELIAC DISEASE (MALABSORPTION SYNDROME, GLUTEN-INDUCED ENTEROPATHY, CELIAC SPRUE)**

Celiac disease is an immune-mediated abnormal response to gluten, the protein in wheat, and related proteins in rye, barley and possibly oats, in a genetically susceptible individual. When children with the disorder ingest gluten, flattening of the fingerlike projections (villi) of the small intestine occurs, preventing the absorption of foods, especially fat, into the body. If the disease goes undiagnosed, children develop **steatorrhea** (bulky, foul-smelling, fatty stools), failure to thrive, and malnutrition. The classic picture of a child with celiac disease—a thin child with a distended abdomen (Fig. 45.7)—is rarely seen today as testing has improved and children are being diagnosed more promptly.

**Figure 45.7** A child with celiac disease. Typically, the child's abdomen will be distended from the fat, bulky stools. A wasted appearance (often of the buttocks) is no longer commonly seen.

The illness occurs most frequently in children of a Northern European background, those with a first-degree relative with celiac disease, and those who have type 1 diabetes mellitus, IgA deficiency, and Down syndrome, suggesting an associated immune response. In Europe and the United States, prevalence estimates range from 1:80 to 1:300 children (Hill, Dirks, Liptak, et al., 2005). Although it is a relatively rare condition, early recognition is essential so treatment can be provided, along with early support and nutritional guidance for the parents.

### Assessment

The diagnosis is based on the history; clinical symptoms such as poor growth, bulky stools, malnutrition, distended abdomen, and anemia, which usually become noticeable between 6 and 18 months of age, after the introduction of gluten into the diet. However, celiac disease can be diagnosed at any age. Serum analysis of antibodies against gluten (endomysial antibody, tissue transglutaminase is obtained) and biopsies of the small intestinal mucosa (done by endoscopy), which are the gold standards, establish the

typical changes in intestinal villi. In addition, the child's response to gluten is observed by placing the child on a gluten-free diet. In most instances, the response to this diet is dramatic: The child begins to gain weight, steatorrhea improves, and irritability fades.

## Therapeutic Management

Treatment is to continue the gluten-free diet for life because there is an associated slightly increased risk of malignancy in those who are diagnosed with celiac disease as adults. There does not appear to be the same risk in those diagnosed in childhood, possibly due to early introduction of a gluten-free diet (Hill et al., 2005). Correction of any vitamin and mineral deficiencies may be necessary.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Imbalanced nutrition, less than body requirements, related to malabsorption of food

**Outcome Evaluation:** Child's weight is maintained on a percentile curve on a growth chart, skin turgor is good, stool pattern and consistency is normal; parents verbalize appropriate gluten-free food choices.

Parents need a great deal of nutritional counseling when their child is first placed on a gluten-free diet so they can recognize foods that contain gluten (e.g., wheat, rye, oats, and barley products) and if possible, they should meet with a registered dietitian. They need to recognize that because gluten is a part of wheat flour, gravy, soups, and sauces as well as packaged and frozen foods. Because children are anorectic when they are first introduced to the new diet, getting them to eat it may be a problem. Remember that toddlers often eat small servings more readily than larger ones. Help parents create incentives to eat, such as inviting dolls to "tea" or having a picnic outside.

As children reach school age, preparing a gluten-free diet grows more and more difficult because favorite school-age foods such as spaghetti, pizza, hot dogs, cake, and cookies are not allowed. Selecting a diet in a school cafeteria may be tricky. Holidays pose additional problems as wheat-based birthday cakes, turkey stuffing, and holiday cookies are prohibited. Parents can learn to prepare gluten-free foods, and gluten-free foods have become more available in supermarkets and on restaurant menus. A Pavlova (made with meringue) can be substituted for a birthday cake and crushed potato chips are a good substitute for flour in many recipes. Until children can recognize which foods they can or cannot eat, parents often find it difficult to let them stay at friends' houses or go to summer camp, activities that are important to children learning independence. Eating gluten-free foods is a current food fad, so

parents need to make it clear to school officials and friends that their child is not eating gluten free as a fad but because a gluten-free diet is lifesaving for their child (Pietzak, 2012).

## Disorders of the Lower Bowel

In children, disorders of the lower bowel mainly create problems with evacuation.

### CONSTIPATION

*Functional constipation*, or constipation without an underlying medical disease, is a very common problem in childhood, often starting in the first year of life. The definition of constipation is based on the Rome III Criteria (Box 45.6) and differs with the child's age (Tabbers, Dilozeno, Berger, et al., 2014), but it is generally defined as either two or less bowel movements per week that cause distress to the child. Stools are often large, hard, and painful to pass. Anal fissures may develop. As passing stool is painful, the child represses the next urge to defecate to avoid pain. This is known as stool holding. The rectum gradually becomes distended and adjusts to the ever-present bulk of stool, and the urge to defecate becomes less frequent. When the child does pass stool, it is larger and even more firm than before and causes even more anal pain. This vicious cycle continues until the child becomes severely constipated. Children may have leakage of liquid stool or *encopresis* (involuntary release of stool) when their rectum can hold no more (see Chapter 54). This is sometimes confused with diarrhea. The child may complain of abdominal pain and may have a decreased appetite.

#### BOX 45.6

#### Rome III Diagnostic Criteria for Functional Constipation

In the absence of organic pathology,  $\geq 2$  of the following must occur:

##### FOR A CHILD WITH A DEVELOPMENTAL AGE <4 YEARS\*

1.  $\leq 2$  defecations per week
2. At least 1 episode of incontinence per week after the acquisition of toileting skills
3. History of excessive stool retention
4. History of painful or hard bowel movements
5. Presence of a large fecal mass in the rectum
6. History of large-diameter stools that may obstruct the toilet

Accompanying symptoms may include irritability, decreased appetite, and/or early satiety, which may disappear immediately following passage of a large stool

##### FOR A CHILD WITH A DEVELOPMENTAL AGE $\geq 4$ YEARS WITH INSUFFICIENT CRITERIA FOR IRRITABLE BOWEL SYNDROME<sup>†</sup>

1.  $\leq 2$  defecations in the toilet per week
2. At least 1 episode of fecal incontinence per week

3. History of retentive posturing or excessive volitional stool retention
4. History of painful or hard bowel movements
5. Presence of a large fecal mass in the rectum
6. History of large-diameter stools that may obstruct the toilet

\*Criteria fulfilled for at least 1 month. Adapted from Hyman, P. E., Milla, P. J., Benninga, M. A., et al. (2006). Childhood functional gastrointestinal disorders: Neonate/toddler. *Gastroenterology*, 130(5), 1519–1526.

†Criteria fulfilled at least once per week for at least 2 months before diagnosis. Adapted from Rasquin, A., Di Lorenzo, C., Forbes, D., et al. (2006). Childhood functional gastrointestinal disorders: Child/adolescent. *Gastroenterology*, 130(5), 1527–1537.

Source: Tabbers, M. M., Dilozenzo, C., Berger, M. Y., et al. (2014). Evaluation and treatment of functional constipation in infants and children: Evidence-based recommendations from ESPGHAN and NASPGHAN. *Journal of Pediatric Gastroenterology and Nutrition*, 58(2), 258–274.

Some children begin holding stool for psychological reasons. Once the process begins, however, the hardened stool, the anal fissures, and the pain on defecation soon occur, and what began for an emotional reason becomes a physical ailment. This is important to understand because with such children, therapy involves both counseling to correct the initial problem and treatment of the physical symptoms.

## Assessment

When taking a history, be certain to have parents describe what they mean by constipation. Some children normally pass stool only every other day or every 3 days. As long as the stool is not hard and there is no discomfort associated with passing stool, it is not considered constipation. Examine the circumstances that may have led to constipation (e.g., diet low in fiber, little privacy in bathroom, family stress). It is also important to know the age of onset of the constipation, whether or not they are toilet trained, and if they exhibit stool withholding behaviors. Young children may hide when they need to defecate and may cry and turn red in the face with the effort of holding back the stool. In children who failed to pass meconium within the 48 hours of life, it is important to differentiate constipation from Hirschsprung disease. Other indications of an underlying problem include poor growth, congenital abnormalities, and a family history of GI disorders.

## Therapeutic Management

Treatment of chronic constipation is aimed at softening stool so it will pass painlessly. Bowel cleansing to remove retained stool with weight-appropriate doses of polyethylene glycol is recommended before beginning daily treatment. Enemas are avoided if possible (Tabbers et al., 2014). After this, a stool softener such as polyethylene glycol is prescribed daily. Polyethylene glycol (Miralax) has been found to be the most effective medication for treating constipation. Normal fiber intake is recommended. There is no evidence that a high-fiber diet improves stool frequency in children (Chmielewska, Horvath, Dziechciarz, et al., 2011). Children should be encouraged to sit on the toilet after meals to attempt defecation. Young children respond well to positive

reinforcement, and parents can use a sticker chart or other small rewards as motivation.

## INGUINAL HERNIA

**Inguinal hernia** is a protrusion of a section of the bowel into the inguinal ring. It usually occurs in boys (9:1) because, as the testes descend from the abdominal cavity into the scrotum late in fetal life, a fold of parietal peritoneum also descends, forming a tube from the abdomen to the scrotum (García-Hernández, Carvajal-Figueroa, Suarez-Gutiérrez, et al., 2012). In most infants, this tube closes completely. If it fails to close, intestinal descent into it (hernia) may occur at any time when there is an increase in intra-abdominal pressure. In girls, the round ligament extends from the uterus into the inguinal canal to its attachment on the abdominal wall. In girls, an inguinal hernia may occur because of a weakness of the muscle surrounding the round ligament.

### Assessment

A hernia appears as a lump in the left or right groin. In some instances, the hernia is apparent only on crying (when abdominal pressure increases) and not when children are less active. Inguinal hernias are painless. Pain at the site implies that the bowel has become incarcerated in the sac, which is an emergency that requires immediate action to prevent bowel obstruction and ischemia.

The diagnosis is established by a history and physical appearance. When taking a history of a well child, be certain to ask parents whether they have ever noticed any lumps in the child's groin area. The hernia may not be noticeable at the time of a healthcare visit, so, unless asked specifically, parents may not mention it. If present, the herniated intestine can be palpated in the inguinal ring on physical examination.

### Therapeutic Management

Treatment of inguinal hernia is laparoscopy surgery. The bowel is returned to the abdominal cavity and retained there by sealing the inguinal ring. Pneumoperitoneum (instillation of carbon dioxide into the perineal cavity) during surgery may be performed to reveal the presence of an enlarged inguinal ring on the opposite side. If this is present, both sides may be repaired, and the child will return from surgery with dressings on both groins.

Formerly, surgery for inguinal hernia was delayed until the child was 3 or 4 years of age. Today, to prevent the complication of bowel strangulation—a surgical emergency—infants with inguinal hernia may have surgery before 1 year of age. If surgery is proposed as a prophylactic measure, setting outcomes may be difficult for parents as they weigh the value of surgical repair against the risk of anesthesia and surgery.

After surgery, keep the suture line dry and free of urine or feces to prevent infection. Most incisions in this area are closed by a tissue adhesive, which is waterproof and seals the incision from urine and feces. Even so, the infant will need frequent diaper changes and good diaper-area care. Assess circulation in the leg on the side of the surgical repair

to be certain that edema of the groin is not compressing blood vessels and obstructing blood flow to the leg.

## **HIRSCHSPRUNG DISEASE (AGANGLIONIC MEGACOLON)**

Hirschsprung disease, or *aganglionic megacolon*, is an absence of ganglionic innervation to the muscle of a section of the bowel—in most instances, the lower portion of the sigmoid colon just above the anus (Pakarinen, Kurvinen, Koivusalo, et al., 2013). The absence of nerve cells means there are no peristaltic waves in this section to move fecal material through the segment of intestine. This results in chronic constipation or ribbonlike stools (stools passing through such a small, narrow segment look like ribbons). The portion of the bowel proximal to the obstruction dilates, thus distending the abdomen (Fig. 45.8).

**Figure 45.8** Aganglionic megacolon (Hirschsprung disease). The distal portion of the bowel lacks nerve innervation. Because there is no peristalsis in this narrowed segment, the bowel proximal to it distends markedly.

The incidence of aganglionic disease is higher in the siblings of a child with the disorder than in other children. It also occurs more often in males than in females. It is caused by an abnormal gene on chromosome 10. The incidence is approximately 1 in 5,000 live births (Stensrud, Emblem, & Bjørnland, 2012).

### **Assessment**

Occasionally, infants are born with such an extensive section of bowel involved that even meconium cannot pass. Because newborn stools are normally soft, however,

symptoms of aganglionic megacolon generally do not become apparent until 6 to 12 months of age. By this time, children appear thin and undernourished (sometimes deceptively so because their abdomen is large and distended) and have a history of not having a bowel movement more than once a week of ribbonlike or watery stools.

The diagnosis is suggested by a rectal exam; if a gloved finger is inserted into the rectum of a child with true constipation, the examining finger will touch hard, caked stool. With aganglionic colon disease, the rectum is empty because fecal material cannot pass into the rectum through the obstructed portion. A barium enema or ultrasound with contrast medium is generally prescribed to substantiate the diagnosis. The contrast mediums will outline the narrow, nerveless portion and the large proximal distended portion of the bowel. Enemas must be used cautiously, however, because children cannot expel this afterward any more effectively than they can stool. A definitive diagnosis is by a biopsy of the affected segment to show the lack of innervation or by anorectal manometry, a technique that tests the strength or innervation of the internal rectal sphincter by inserting a balloon catheter into the rectum and measuring the pressure exerted against it.

### Therapeutic Management

Repair of aganglionic megacolon involves dissection and removal of the affected section, with anastomosis of the intestine (termed a pull-through operation). Because this is a technically difficult operation to perform in a small abdomen, the condition is generally treated in infants by two-stage surgery: First, a temporary colostomy is established, followed by bowel repair at 12 to 18 months of age. After the final surgery, children should have a functioning, normal bowel. In the few instances in which the anus is deprived of nerve endings, a permanent colostomy will need to be established.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Imbalanced nutrition, less than body requirements, related to reduced bowel function

**Outcome Evaluation:** Child ingests a low-residue diet; weight follows a percentile curve on a growth chart.

Preoperatively, older children may be in poor health from poor food intake over a long period of time. If this is so, they may be placed on a minimal-residue diet, stool softeners, vitamin supplements, and perhaps daily enemas until their condition improves. Total parenteral nutrition can offer another source of nutrition. If a child is to be cared for at home, help the parents learn about a minimal-residue diet or one that is low in indigestible fiber and residue. Fried foods and highly seasoned foods

are omitted as well to eliminate chemical irritants in the intestinal tract.

Parents may need to create a reminder sheet for the stool softener so it is given daily. When children are beginning a special diet, it may be advisable to have parents refrain from introducing new feeding methods, such as a cup or spoon, unless children are at the developmental point where they will quickly adapt to the new procedure and are, in fact, so eager to feed themselves that they will actually eat better this way.

Postoperatively, after removal of the aganglionic portion and anastomosis of the colon at the second step of the repair, infants will return with a nasogastric tube in place attached to low suction, an IV infusion, and probably an indwelling urinary (Foley) catheter. Observe the infant for abdominal distention. Assess bowel sounds and observe also for passage of flatus and stools. As soon as peristalsis has returned (approximately 24 hours after surgery), the nasogastric tube can be removed, and the child can be offered small, frequent feedings of fluids, such as water or gelatin. The child is then gradually introduced to full fluids, a soft diet, a minimal-residue diet, and, finally, a normal diet for age. Caring for a child with a colostomy is discussed in [Chapter 37](#).

**Nursing Diagnosis:** Constipation related to reduced bowel function

**Outcome Evaluation** Child has a daily bowel movement through either a colostomy or by enema.

Before surgery, the child may be prescribed daily enemas to achieve bowel movements. Remind parents that the fluid used for enemas must be normal saline (0.9% NaCl) and not tap water. Because tap water is hypotonic, if it is instilled into the bowel, it moves rapidly across the intestinal wall into interstitial and intravascular fluid compartments to equalize osmotic pressure. This has led to death of infants from cardiac congestion or cerebral edema (water intoxication). To use for enemas, parents can buy a ready-made saline preparation at a pharmacy, or they can prepare their own by mixing 2 teaspoon of noniodized salt to 1 qt of water. Although adding salt to water does not seem important, be certain parents understand the rationale for doing this so they conscientiously add the right proportion of salt to water.

**Nursing Diagnosis:** Risk for compromised family coping related to chronic illness in child

**Outcome Evaluation:** Parents state they are able to cope with the level of stress present from their child's condition.

Most parents feel tremendous relief after the second-stage surgery is complete. Caution parents that the child may still remain a “fussy eater” for a few months because feeding problems that begin for physical reasons can continue for emotional or psychological reasons. Help parents to diminish the importance of meals gradually; to schedule periods during the day when they give their full and positive attention to the child, such as reading a story or putting a puzzle together; and to offer

praise for pleasant, not difficult, behavior. These measures will help mealtime problems gradually diminish.

## **INFLAMMATORY BOWEL DISEASE: ULCERATIVE COLITIS AND CROHN DISEASE**

Two conditions are categorized as inflammatory bowel disease (IBD): *ulcerative colitis* and *Crohn disease* (Danese & Fiocchi, 2011). These disorders have some separate as well as some overlapping characteristics. Both involve the development of inflammation in the intestine. Ulcerative colitis (UC) affects only the mucosal lining of the colon, whereas Crohn disease (CD) can affect any part of the GI tract from the mouth to the anus. The area most commonly involved in CD is the last part of the small intestine known as the terminal ileum. The inflammation in CD can extend through the wall of the intestine and cause abscesses and fistulae. About 25 % of IBD cases are diagnosed in children younger than 20 years of age. The incidence in United States has been increasing (Kappelman, Moore, Allen, et al., 2013). The cause of IBD is unknown but thought to be multifactorial and due to an abnormal response by the immune system to an environmental trigger in a genetically susceptible individual.

Psychological factors have not been supported as a primary contributory factor to IBD, but psychological problems often occur secondary to the disease, possibly intensifying symptoms. Smoking has been shown to be a precipitating factor in CD (Ananthakrishnan, 2013).

### **Ulcerative Colitis**

Children with UC develop crampy abdominal pain, urgency, tenesmus, and frequent bloody stools. Anemia and hypoalbuminemia due to losses in the stool may be present. It is treated with oral and sometimes IV medications such as infliximab (Remicade). If it does not respond to medical therapy, surgery to remove the colon is performed, which is curative for UC. There is an association between UC and colon carcinoma if the disease persists over 10 years. Yearly colonoscopy should be performed once the patient has reached 8 to 10 years from the date of diagnosis (Sengupta, Yee, & Feuerstein, 2016).

### **Crohn Disease**

The symptoms of CD depend on the severity and location of the inflammation. Abdominal pain, diarrhea with or without blood, and weight loss may be present. The inflamed area may become narrowed causing a stricture of the bowel, and a bowel obstruction may develop if this goes untreated. Fistulae, small tunnels that run either from the bowel to the skin or to another organ, can develop. These most commonly involve the perianal area. CD is also treated with oral and IV medications depending on the severity of the disease. Remission has also been achieved with exclusive enteral feeding (Gupta, Nobel, Kachelries, et al., 2013). Surgery may be necessary to remove

strictures or repair fistulae, but the disease can redevelop in other areas of the bowel. There are periods of exacerbations and remissions in both disorders. As inflammation becomes acute, children develop abdominal pain. Because the inflamed areas do not absorb nutrients or fluid well, diarrhea and malnutrition develop. To reduce abdominal pain, which is most acute after eating, when the bowel becomes active, children begin to skip meals. This can cause them to become malnourished and develop a vitamin or iron deficiency.

### Assessment

In both conditions, diarrhea and steatorrhea develop from the irritation and the unabsorbed fluid. If inflamed portions ulcerate, there will be blood in the stool. Weight loss occurs; in prepubertal children, growth failure can occur. A recurring fever may be present (Table 45.5).

**TABLE 45.5 COMPARISON OF CROHN DISEASE AND ULCERATIVE COLITIS**

Comparison Factor	Crohn Disease	Ulcerative Colitis
Part of bowel affected	Ileum	Colon and rectum
Nature of lesions	Intermittent	Continuous
Diarrhea	Moderate	Severe and bloody
Anorexia	Severe	Mild
Weight loss	Severe	Mild
Growth retardation	Marked	Mild
Anal and perianal lesions	Common	None
Association with carcinoma	Rare	Common

Diagnosis is established by endoscopy and colonoscopy. Small biopsies with very low risk of bleeding are taken from multiple areas in the upper and lower GI tract. Inflammation, friability, and bleeding may be seen. The histology report shows chronic inflammation and sometimes granulomas in CD. A radiology study such as an MRI is usually obtained to examine the parts of the small bowel that can't be reached with an endoscope.

### Therapeutic Management

In mild to moderate cases, oral medications are usually sufficient to control the symptoms. Vitamin and mineral deficiencies should be corrected. In more severe cases, bowel rest may be indicated to allow the bowel to heal. Enteral or total parenteral nutrition, therefore, is usually provided for nutrition during the resting period. A child can remain home during this period as long as parents have thorough education about

the child's nutritional needs (see [Chapter 37](#)).

When food is reintroduced after the resting period, a high-protein, high-carbohydrate, and high-vitamin diet is prescribed to replace nutrients. Children may eat cautiously at first to avoid reintroducing diarrhea, so assess intake and output carefully. The treatment regimen depends on the child's condition. In more severe cases, remission is usually achieved with corticosteroids or infliximab (Remicade), an antibody to the inflammatory cytokine tumor necrosis factor alpha. Maintenance therapy may be with infliximab or mercaptopurine (immunomodulator) or mesalamine alone or a combination of medications ([Box 45.7](#)). If surgery for UC becomes necessary, the procedure is performed in two stages. During the first stage, total colectomy is performed and an ileostomy created. Several months later, an ileoanal pouch is created and the ileostomy is taken down ([Fig. 45.9](#)). This allows the child to be continent of stool.

#### BOX 45.7

### Nursing Care Planning Based on Responsibility for Pharmacology

#### 5-AMINOSALICYLATES (MESALAMINE, SULFASALAZINE, BALSALAZIDE)

**Classification:** anti-inflammatory agent

**Mechanism of Action:** Unknown, but it is thought that it acts topically in the bowel to reduce inflammation.

**Pregnancy Risk Category:** C (D at term)

**Dosage:** 50 mg/kg/day given either divided into two to four doses. Rectal formulation usually given 1–2 times daily.

**Possible Adverse Effects:** sensitivity to sunlight, dizziness, drowsiness, nausea, abdominal pains, crystalluria, and hematuria

#### Nursing Implications

- Caution the parents and child that the drug may turn urine orange-red and soft contact lenses yellow.
- Advise children to take with or just after meals to avoid GI irritation.
- Ensure adequate fluid intake to avoid crystallization of sulfa component in urine.
- Anticipate prescription for folic acid concurrently if sulfasalazine used. Drug decreases folic acid absorption.
- Instruct the child and parents about the need to use sunscreens and protective clothing while outside.

**Figure 45.9** Ileoanal pouch. (From Craven, R. F., Hirnle, C. J., & Henshaw, C. M. [2017]. *Fundamentals of nursing: Human health and function* [8th ed.]. Philadelphia, PA: Wolters Kluwer.)

Bowel surgery is always a serious step, but because it reduces the possibility of the child developing colon cancer in association with UC, it may be necessary in children whose disease is running a long-term, debilitating course that does not improve (Danese & Fiocchi, 2011). Caution parents, although they want their children to be independent with regard to bathroom use, to always report if change in the color or consistency of bowel movements does occur so a relapse can be detected.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Imbalanced nutrition related to poor absorption because of disease process

**Outcome Evaluation:** Child's weight follows a percentile growth curve; urine specific gravity is 1.003 to 1.030; child states that alternative feeding method is tolerable.

Nutrition is a priority concern for children with IBD, especially those with CD, because malnutrition can occur from the combination of poor intestinal absorption and chronic diarrhea. If the disease is not well controlled and inflammation persists, children can be left both short in stature and light in weight. Treatment with steroids can also cause growth retardation. The advent of biologic medications such as infliximab has greatly decreased the need to use long courses of prednisone. Active disease can result in protein, vitamin, fat, and mineral deficiencies.

When nutrition is supplied by enteral or total parenteral nutrition solutions, allowing the enteral infusion to flow during the night and removing the tube during the day can make feedings more tolerable. Remember that food provides social experiences as well as nutrition. Help parents provide opportunities for usual mealtime stimulation in other ways.

**Nursing Diagnosis:** Risk for ineffective coping related to chronic illness

**Outcome Evaluation:** Child expresses feelings, states she understands the disease and therapy; suggests ways to minimize stress.

Caution children about possible side effects, such as excessive weight gain, a round facial appearance, and facial acne, which may occur if corticosteroid therapy, such as prednisone, is used so they are not surprised by this. Assess blood pressure, intake and output, weight, and sleep patterns for any child taking steroids. Provide time to listen so children have someone outside their family to talk to about their symptoms and family or stress problems (Box 45.8). The disorder follows a chronic course and can involve embarrassing episodes of diarrhea or acute abdominal pain.

#### BOX 45.8

#### Nursing Care Planning Tips for Effective Communication

Barry's older sister Addie has Crohn disease. Her primary care provider has informed her parents she won't need surgery but will need long-term treatment that will include both medical and nutritional therapy. You see Mrs. Abraham filling out forms by Addie's bedside.

*Tip:* Explore the parents' understanding of any instructions and help them receive more accurate information when needed. People under stress often do not hear instructions well. When this happens, they may need instructions repeated several times before they truly comprehend what was said.

Be careful not to ignore situations that arise where a parent may not have heard everything they were told about their child's condition and the full implications. In the following scenario, Mrs. Abraham does not realize Addie will need ongoing treatment.

**Nurse:** Mrs. Abraham, can I help you with anything?

**Mrs. Abraham:** No. I'm filling out forms for Addie to go back to school since she'll be well again in a short time.

**Nurse:** Do you mean Addie doesn't need parenteral nutrition?

**Mrs. Abraham:** She needs to eat, sure. But no surgery.

**Nurse:** Addie needs to regain her strength before she goes back to school. Do you know what is meant by parenteral nutrition?

### *What If . . . 45.3*

**Barry's older sister, who has Crohn disease, is being cared for at home with total parenteral nutrition. How can the nurse help her keep pace with her friends at school? How can the nurse help her maintain a sense of high self-esteem in light of her many hospitalizations, total parenteral nutrition, and home care?**

## **IRRITABLE BOWEL SYNDROME**

Irritable bowel syndrome (IBS) is a functional bowel disorder that typically causes symptoms of abdominal pain and altered bowel habits with no underlying organic cause. It should not be confused with IBD. It may be either constipation or diarrhea predominant or there may be a mixed picture (Chiou & Nurko, 2010). Diagnosis is based on the Rome III Criteria (see Box 45.6). It is a common disorder in adolescents and adults and thought to affect 15% of the population with a 2:1 female to male predominance (Brandt, Chey, Foxx-Orenstein, et al., 2009). The symptoms can adversely affect quality of life and cause children to miss school (Youssef, Murphy, Langseder, et al., 2006).

The cause is unknown. The onset of loose stools can follow an infection and may be due to an alteration in the intestinal flora. Other studies have looked at intestinal bacterial overgrowth, food sensitivities, visceral hyperalgesia (heightened sensitivity to bowel distension), and psychosocial factors.

Antidepressants, anticholinergics, and antibiotics that work to reduce bacteria in the gut such as rifaximin may be prescribed to treat the symptoms of IBS (Chiou & Nurko, 2010).

## **CHRONIC RECURRENT ABDOMINAL PAIN**

Chronic recurrent abdominal pain is also a functional disorder. The pain is episodic to continuous, and the cause is unknown (Collins & Lin, 2010). Children who experience this are commonly 6 or 7 years of age or in prepuberty (11 to 12 years of age). The pain is not accompanied by a change in bowel habits. There is no association with meals. It is also generally poorly localized, although children may point to the umbilicus as the primary site. On physical examination, there is no abdominal tenderness, distention,

guarding, or muscle spasm. Symptoms of stress such as sleep disturbances, fears, or eating problems may be present. A family history may indicate problems in the family such as marital discord, financial problems, or physical illness in parents or siblings.

Although the cause of the pain cannot be identified, the pain is real. Treatment for functional abdominal pain and IBS are similar and includes dietary changes such as increased fiber and probiotics, medications, behavioral, and complementary therapy (Chiou & Nurko, 2010). Cognitive behavioral therapy teaches the child coping strategies, such as distraction techniques and relaxation, and has been shown to reduce abdominal pain in at least 70% of children (Duarte, Penna, Andrade, et al., 2006). Parents are trained to redirect the child after pain complaints and use positive reinforcement. Hypnosis has also been shown to be an effective adjunct therapy (Vlieger, Menko-Frankenhuis, Wolfkamp, et al., 2007).

## Disorders Caused by Food, Vitamin, and Mineral Deficiencies

There are many underfed and malnourished children in every part of the world. Although extreme diseases of food or vitamin deprivation are rare in the United States, they do exist. Such children need early identification so they can receive better nutrition before permanent damage occurs.

The average child does not develop a deficient intake of essential nutrients because, even if the child is occasionally a fussy eater, over the space of a week, a child does ingest foods containing the necessary nutrients. Carefully assess any child who has an interference in nutrition such as a GI illness or a child is receiving enteric feedings or total parenteral nutrition to make sure that nutrient deficiencies do not exist. Assess children who have been maltreated or neglected closely for nutritional deficiencies because they may not have been given adequate food.

### KWASHIORKOR

**Kwashiorkor**, a disease caused by protein deficiency, occurs most frequently in children ages 1 to 3 years because this age group requires a high-protein intake. It is a disease found almost exclusively in developing countries in Africa, Asia, and Latin America, although it does occur in the United States (Boyd, Andea, & Hughey, 2013). It tends to occur after weaning, when children change from breast milk to a diet consisting mainly of carbohydrates. Growth failure is a major symptom. Because edema is also a symptom, however, children may not appear light in weight until the edema is relieved. There is a severe wasting of muscles, but, again, this is masked by the edema.

Edema results from hypoproteinemia, which causes a shift of body fluid from the intravascular compartments to the interstitial space, causing ascites. The edema tends to be dependent, so it is first noted in the lower extremities. Children are generally irritable and uninterested in their surroundings. They fall behind other children of the same age

in motor development.

If the child had a period of good protein intake, then poor protein intake, and then good intake again, hair shafts develop a striped appearance of brown, then white, and so on—a “zebra sign.” Children also have diarrhea, iron-deficiency anemia, and enlarged livers.

Without treatment, kwashiorkor is fatal. For therapy, a diet rich in protein is essential. Even so, there is evidence to suggest that protein malnutrition early in life, even if corrected later, may result in failure of children to reach their full potential of intellectual and psychological development.

### **QSEN Checkpoint Question 45.6**

#### **TEAMWORK & COLLABORATION**

Barry’s aunt and uncle adopted a toddler from a developing country. The nurse learns that a dietitian has been working with the family because of the child’s history of kwashiorkor. The nurse would expect the dietitian to prioritize what nutrient in this child’s diet?

- a. Water-soluble vitamins
- b. Fats and triglycerides
- c. Quality protein
- d. Vitamin K

*Look in [Appendix A](#) for the best answer and rationale.*

## **NUTRITIONAL MARASMUS**

**Nutritional marasmus** is caused by a deficiency of all food groups—basically, a form of starvation. Although it is seen most commonly in developing countries where food supplies are scarce, it can be seen in the United States in grossly neglected children or those with failure to thrive (see [Chapter 55](#)). These children are most commonly younger than 1 year of age. They have many of the same symptoms as children with kwashiorkor, including growth failure, muscle wasting, irritability, iron-deficiency anemia, and diarrhea. Whereas children with kwashiorkor are anorectic, children with nutritional marasmus are invariably hungry (starving) and will suck at any object offered to them, such as a finger or their clothing. Treatment is a diet rich in all nutrients. Like children with kwashiorkor, they may suffer cognitive challenges that persist throughout life ([Galler, Bryce, Waber, et al., 2012](#)).

## **VITAMIN AND MINERAL DEFICIENCIES**

Both vitamin and mineral deficiencies occur at a low rate in children of the United States because so many foods are enriched (restoration of ingredients removed by processing) or fortified (additional vitamins and minerals not normally present have been added). Milk, for example, is fortified with vitamins D and A. Orange juice is

fortified with calcium. White bread is enriched with B vitamins. Vitamin deficiency diseases are summarized in [Table 45.6](#).

**TABLE 45.6 VITAMIN DEFICIENCY DISORDERS**

Vitamin	Cause of Deficiency	Signs and Symptoms
Vitamin A	Lack of yellow vegetables in diet	Tender tongue, cracks at corners of mouth, night blindness <b>Xerophthalmia</b> (dry and lusterless conjunctivae) <b>Keratomalacia</b> (necrosis of the cornea with perforation, loss of ocular fluid, and blindness)
Vitamin B <sub>1</sub>	Most common in children who eat polished rice as dietary staple because B <sub>1</sub> is contained in hull of rice	<b>Beriberi</b> (tingling and numbness of extremities, heart palpitations, exhaustion) Diarrhea and vomiting Aphonia (crying without sound) Anesthesia of feet
Niacin	Common in children who eat corn as dietary staple because corn is low in niacin	<b>Pellagra</b> (dermatitis, resembles a sunburn), diarrhea, mental confusion (dementia)
Vitamin C	Lack of fresh fruits in diet	<b>Scurvy</b> (muscle tenderness, petechiae)
Vitamin D	Lack of sunlight	Poor muscle tone, delayed tooth formation <b>Rickets</b> (poor bone formation) Craniotabes (softening of the skull) Swelling at joints, particularly of wrists and cartilage of ribs Bowed legs, tetany (muscle spasms)

*What If . . . 45.4*

The nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to GI disorders in children (see [Box 45.1](#)). What would be a possible research topic to explore pertinent to this goal that would be applicable to the Abraham family and that would also advance evidence-based practice?

## KEY POINTS FOR REVIEW

- Some GI disorders lead to long-term therapies such as colostomy or gastrostomy feedings. Because these disorders interfere with common body functions such as eating and elimination, they are difficult for children to accept without the support of concerned healthcare providers.
- Children lose proportionately more fluid with vomiting and diarrhea than adults, so they need rapid assessment and interventions to avoid dehydration.
- Fluid, electrolyte, and acid–base imbalances tend to occur rapidly with vomiting and diarrhea. Vomiting leads to alkalosis. Diarrhea leads to acidosis.
- GI disorders almost always interfere with nutrition to some degree. This is a greater problem in children than adults because children need to ingest adequate nutrients and fluid daily for growth as well as body maintenance.
- Gastroesophageal reflux is the passage of gastric contents into the esophagus with or without regurgitation and vomiting. In infants, it is treated by feeding a thickened formula and keeping the infant upright after feedings. Adolescents are prescribed a proton pump inhibitor and advised to sleep with two pillows.
- Pyloric stenosis is hypertrophy of the valve between the stomach and duodenum. It impedes the passage of feedings, leading to vomiting, and is repaired by surgery.
- Peptic ulcer disease may occur in children of all ages. The disorder causes a shallow excavation to form in the mucosal wall of the stomach. It is treated, like adult ulcers, with antibiotics and agents to suppress gastric acidity.
- Forms of hepatitis seen in children include hepatitis A (fecal–oral transmission) and hepatitis B, C, D, and E (caused by contaminated blood or body fluids and IV drug use). Vaccines to hepatitis A and B are available and are routinely given to children.
- Biliary atresia is an obliterative disorder of the extrahepatic biliary tree that occurs within the first 2 months of life. This can lead to fibrotic scarring of the liver (cirrhosis). Most of these children need a liver transplant to restore liver function.
- Intussusception is the invagination of one portion of the intestine into another. Volvulus is a twisting of intestine. Both may lead to bowel obstruction.
- Necrotizing enterocolitis is the development of necrotic patches in the intestine. It occurs almost exclusively in preterm infants.
- Appendicitis is inflammation of the appendix. It is always an emergency and is the most common reason for abdominal surgery in children. A laparoscopy is done to remove the appendix, ideally before it ruptures.
- Celiac disease (gluten-induced enteropathy) is a change in the ability of the intestinal villi to absorb nutrients. Children must follow a gluten-free diet for life.
- Inguinal hernia can occur in children. It is surgically corrected when recognized.
- Hirschsprung disease (aganglionic megacolon) is absence of ganglionic innervation in a section of the lower bowel. Therapy may involve a temporary colostomy followed by surgery in 6 to 12 months to remove the affected bowel portion.
- Inflammatory bowel disease can occur as either ulcerative colitis or Crohn disease, both chronic conditions. Therapy is long term. If medical therapy is unsuccessful,

portions of the bowel may be surgically removed. Ulcerative colitis is associated with the development of colon cancer later in life.

- Kwashiorkor (protein deficiency), nutritional marasmus (starvation), vitamins A and D (rickets), vitamin B<sub>1</sub> (beriberi), and vitamin C (scurvy) deficiencies occur in children when they are not provided or cannot absorb adequate nutrients. Although more common in developing countries, they can occur in a child in any community.
- Children with GI disorders should join the family for mealtimes if possible. Even if they cannot eat the same foods as other family members, this helps not only meet QSEN competencies but also allows children to benefit from the social interaction.

### CRITICAL THINKING CARE STUDY

Shanita is a 3-year-old you see in the emergency room because she has had 12 diarrheal stools in the past 8 hours. She lives with her single mother in a rented apartment in the inner city. Her mother works in the local potato chip factory. Because it was such a hot day, Shanita spent the day at the park with a playmate (Dwight, also 2 years of age) and his mother Iris. Iris called Shanita's mother at 2 PM to come home because Shanita was feeding their new puppy some hard dog food and Iris was afraid Shanita might have eaten some herself because she began to have diarrhea.

1. Shanita's mother is worried that because her clothes always smell of hot grease, this has made Shanita sick. Is it more likely the smell of grease; possibly eating some hard dog food; or eating a packed lunch of a hotdog, potato salad, and a soda is the main cause of the diarrhea?
2. Shanita is not yet toilet trained. If you need to separate Shanita's urine from stool so you can better evaluate the consistency of her stool, would you ask her to void frequently or try not to void when she has a bowel movement?
3. What point of care tests could you do to evaluate whether Shanita's diarrhea is improving?

## 46

# Nursing Care of a Family When a Child Has a Renal or Urinary Tract Disorder

*Carey Hendricks is a 4-year-old girl admitted to the hospital with marked ascites and edema from nephrotic syndrome. She lives with her grandparents because her mother is incarcerated on a drug charge. “She’s been gaining weight yet doesn’t eat anything,” her grandmother tells you. “She drank part of a beer I left on the coffee table last week. Could that be what caused this? What if she needs a kidney transplant? Will I be allowed to give a kidney to her?”*

*Previous chapters described the growth and development of well children and the nursing care of children with disorders of other systems. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur when children develop urinary tract or renal disorders. This information builds a base for assessment, care, and health teaching.*

**How would you answer Carey’s grandmother? What information does she need to better understand her grandchild’s condition?**

## KEY TERMS

**Alport syndrome**  
**azotemia**  
**dialysis**  
**dysfunctional elimination syndrome (DES)**  
**enuresis**  
**epispadias**  
**extrophy of the bladder**  
**glomerular filtration rate**  
**glomerulonephritis**  
**hydronephrosis**  
**hypospadias**  
**nephrosis**

patent urachus  
polycystic kidney  
postural proteinuria  
prune belly syndrome (PBS)  
vesicoureteral reflux

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe common renal and urinary disorders that occur in children.
2. Identify 2020 National Health Goals related to renal or urinary tract disorders in children that nurses can help the nation achieve.
3. Assess a child for a renal or urinary tract disorder.
4. Formulate nursing diagnoses related to renal or urinary disorders in children.
5. Understand expected outcomes for a child with a renal or urinary tract disorder in order to most effectively assist families in managing transitions throughout their child's healthcare experience.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Describe the process of implementation of nursing care for a child with a renal, bladder, or urinary tract disorder.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of renal and urinary tract disorders with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

Normally, the urinary system maintains the proper balance of fluid and electrolytes in the blood. When disease occurs, such as with structural abnormalities or kidney malfunction, children may be left with excessive amounts of fluid in the body or with an imbalance of electrolytes essential to body functioning that becomes long term (Ring & Huether, 2013).

Unfortunately, because symptoms may be vague, or because children or parents do not realize the seriousness of urinary tract disease (or are embarrassed to discuss it), children may not be evaluated at the first sign of illness. Therefore, health education aimed at increasing awareness of symptoms of urinary tract and kidney disorders is an important area of family health teaching. Box 46.1 shows 2020 National Health Goals related to renal disorders and children.

Renal disease can lead to long-term illness, so preventing it is important to improving the health of the nation. 2020 National Health Goals that address this concern are:

- Reduce the rate of new cases of end-stage renal disease from a baseline of 300 per 1 million population to a target rate of 221 per 1 million population.
- Increase the proportion of patients with treated chronic kidney failure who receive a transplant within 3 years of end-stage renal disease from a baseline of 17.1% to 18.8% (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by educating parents to give antibiotics conscientiously for streptococcal throat infections and being active advocates for organ transplant procedures.

### *Nursing Process Overview*

## FOR CARE OF A CHILD WITH A RENAL OR URINARY TRACT DISORDER

### ASSESSMENT

Because the symptoms of many urinary tract and renal disorders, such as mild abdominal pain, slowly increasing edema, or low-grade fever, are subtle, school nurses play an important role in recognizing the seriousness of such minor symptoms and making referrals for care.

Pain can be, but is not always, a symptom of kidney or bladder infection. Be sure to assess the degree of any pain, including its location and intensity, before administering an analgesic or antispasmodic to aid with diagnosis or prognosis. Assisting patients with properly procuring a urine specimen is another important means of ensuring accurate assessment of the patient.

### NURSING DIAGNOSIS

Nursing diagnoses used with children with urinary tract or renal disorders are related to the symptoms these disorders cause plus the effect chronic disease can have on a family. Some examples include:

- Pain related to bladder irritation from urinary tract infection
- Excess fluid volume related to decreased kidney function and fluid accumulation
- Fear related to renal transplantation
- Imbalanced nutrition, less than body requirements, related to effects of dietary restrictions
- Social isolation related to immunosuppressant therapy

- Interrupted family processes related to the stress of a child's chronic illness
- Compromised family coping related to the chronic nature of a child's illness

## **OUTCOME IDENTIFICATION AND PLANNING**

Be certain that outcomes established for care are relevant to a child's age and condition. If renal disease becomes chronic, expected outcomes may need to be modified frequently to meet the evolving needs of both the child and the family unit.

Planning for a child with a urinary tract or renal disorder often involves helping parents develop a reliable system to remember to give medicine. A child with nephrotic syndrome or a renal transplant, for example, may need to take three or four different types of medicine every day, often at different times. Be certain parents understand the types of medicine prescribed and the expected action and side effects of each. Parents should receive this information both verbally and in written form so that they have easy-to-access information at home. If the school a child attends has a zero tolerance policy for taking medication at school, the child will need proper documentation from his or her medical provider in order for the school to make accommodations.

It is important to assist parents in scheduling times for hemodialysis or peritoneal dialysis as well as planning for care of their other children and around their work schedules. This should help them achieve balance among all tasks that need to be done. If a child develops severe renal impairment, parents may be asked to make a decision regarding kidney removal and transplantation. Provide them with ample time and resources for discussion about this because offering to be a living kidney donor is a major life step. Examples of organizations that are helpful for referral include the National Kidney Foundation ([www.kidney.org](http://www.kidney.org)), the Polycystic Kidney Disease Foundation ([www.pkdcure.org](http://www.pkdcure.org)), the Urology Care Foundation ([www.urologyhealth.org](http://www.urologyhealth.org)), and the Kidney Dialysis Foundation ([www.kdf.org.sg](http://www.kdf.org.sg)).

## **IMPLEMENTATION**

Neither parents nor children may fully understand the function of the urinary system because it is not a system that receives much discussion. For example, they may confuse the words "ureter" and "urethra." Nurses should be knowledgeable resources, explaining anatomy, tests and procedures, and the rationale for various testing. In addition, nurses should be patient advocates and facilitate opportunities for family/provider discussions when indicated.

Many children with kidney disease take a corticosteroid for immunosuppression and so develop a typical cushingoid appearance with edema or ascites, making them appear obese. This can lead to teasing or bullying by classmates because of their "different" appearance. Contacting the school (with the child's and parents' permission) to assist with appropriate education of classmates can facilitate peer understanding and foster support in the school environment. Frequent contact and discussion with the child's siblings is also important to help them understand their sibling's medical situation, the reasons for so many tests and healthcare visits, and

why their sibling is receiving so much attention. It is important to recognize that a chronic health condition affects the entire family, and each member of the family unit deserves care and understanding.

If kidney damage becomes extensive and the child's kidneys fail or a transplant is rejected, nursing care needs to be refocused on helping the family to face the possibility of the child's death. Caring for children with a near-fatal or fatal diagnosis is discussed in [Chapter 56](#).

### **OUTCOME EVALUATION**

Children with urinary or renal disease often require long-term follow-up care after their acute illness to monitor their renal and bladder function. Even though their child is being followed by a specialty renal group or clinic, remind parents that routine health maintenance such as routine childhood immunizations (although children taking steroids or other immunosuppressive therapy should not receive live-virus vaccines) remains important.

Examples suggesting achievement of outcomes are:

- Child reports that pain is at a tolerable level and decreasing in intensity after treatment.
- Family members state they are able to cope with long-term illness in their child.
- Child states the purpose of a low-sodium diet and lists the ingredients of a low-sodium meal.
- Child states he or she can accept the need for kidney transplantation.
- Child states the precautions he or she must follow to reduce possibility of infection while on immunosuppressive therapy.

## **Anatomy and Physiology of the Kidneys**

Embryonic development of the urinary tract is discussed in [Chapter 9](#). [Figure 46.1](#) identifies the structures of the tract. Kidneys in children are located slightly lower in relation to the ribs than in adults. They also do not have as much perinephric fat to pad them, making their kidneys more vulnerable to trauma than in an adult.

**Figure 46.1** The urinary system.

## KIDNEY FILTRATION

The glomeruli in the kidney filter water and solutes from the blood. The process is only effective, however, if the blood pressure is higher in the arteries going into the kidneys than in the internal tubular arteries. Urine production is also dependent on the blood pressure being lower in the arteries leaving the kidneys than in the internal tubular arteries. For this reason, renal function must be assessed carefully in children who present with either decreased or increased blood pressure. Whereas hypertension in adults is most often associated with cardiac dysfunction or disease, in pediatric patients, hypertension is most often associated with renal dysfunction.

## URINE

Approximate urine output from different age groups is shown in [Table 46.1](#). A significant decrease in urine production is *oliguria*; absence of urine production is *anuria*.

**TABLE 46.1 CHILD'S AVERAGE URINE OUTPUT IN 24 HOURS**

Age	Amount of Urine (ml)
6 months–2 years	540–600
2–5 years	500–780
5–8 years	600–1,200
8–14 years	1,000–1,500
Over 14 years	1,500

When renal disease occurs and glomerular or tubular function becomes impaired, nonprotein nitrogenous substances such as creatinine, urea, ammonia, and purine bodies are retained in the blood rather than being excreted. The amount of urea in urine is an indirect indication of kidney and liver function.

Creatinine is a product released during muscle cell metabolism. The amount excreted in urine normally remains constant regardless of the amount of protein in the diet or body processes. When it is less in amount, therefore, it means kidneys are not functioning as well as usual. *Casts* are formed when there is an abnormal condition that causes the kidney tubule to become lined with protein formed from red and white blood cells, epithelial cells, or fatty cells that harden into the shape of the tubule. After urine washes the casts out, they can be detected by microscopic examination of urine. Because protein deposits in this way only when fluid is slow-moving, their presence suggests slow filtration.

## Assessment of Renal and Urinary Tract Dysfunction

Assessment of urinary or renal tract disorders is based on history, physical examination, and laboratory/diagnostic tests (Box 46.2). Remember when taking the history of a child with a urinary or renal disorder that discussing this area of the body may not be comfortable for the child or parents (Box 46.3).

BOX 46.2

### Nursing Care Planning Using Assessment

#### ASSESSING A CHILD FOR RENAL AND URINARY TRACT DYSFUNCTION

### History

**Chief concern:** Child reports burning or cries on urination; bloody or "dark" urine, frequency of urination; abdominal pain, flank pain, enuresis. Parents report increase in size of abdomen, periorbital edema, poor appetite, frequent thirst, weight gain, strong odor to urine; diaper rash in infants. A school-age child may be described as a behavior problem because he or she frequently asks to use the bathroom.

**Family history:** History of renal disease, such as polycystic kidney, enuresis; hypertension.

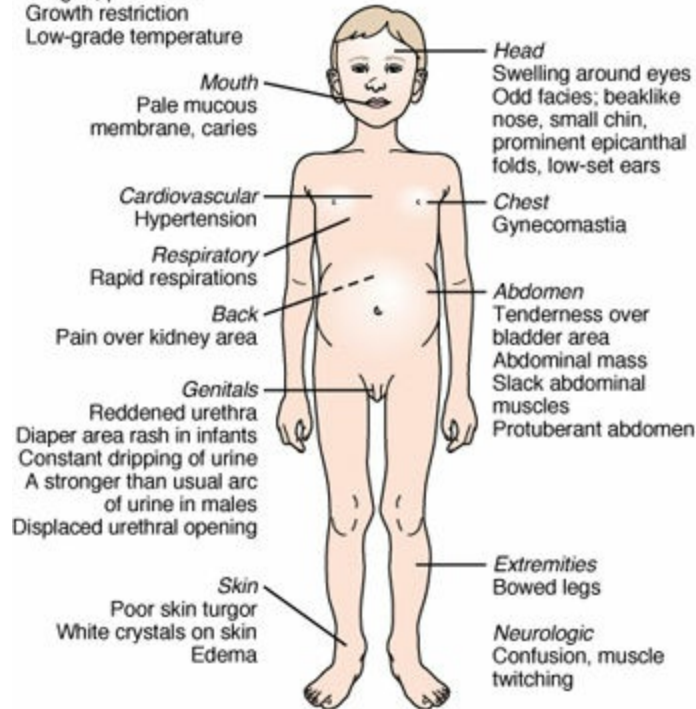

**Pregnancy history:** Exposure to nephrotoxic drugs (antibiotics) during pregnancy. Oligohydramnios at birth.

**Past illness history:** Child recently had a throat or skin infection.

### Physical assessment

#### General appearance

Fatigue, paleness  
Growth restriction  
Low-grade temperature

BOX 46.3

### Nursing Care Planning to Respect Cultural Diversity

As a general rule, because elimination functions are typically regarded as private, this is not a body system that all people discuss as comfortably as they do illnesses of other body systems. The more modesty is stressed in a culture, the more difficult it may be for people to ask questions about this system's disorders. By being aware that this is a difficult area for parents to discuss, healthcare personnel can better observe whether added health education is needed when caring for a child with one of these disorders.

### LABORATORY/DIAGNOSTIC TESTS

A variety of diagnostic tests may be performed, either in an ambulatory department or in an inpatient basis, to document renal or urinary tract disease.

## Urinalysis

Urinalysis is not only one of the most revealing tests of kidney function but also one of the simplest. For best results, specimens collected should be fresh because urine that stands at room temperature for any length of time changes composition. Techniques for obtaining urine samples such as clean-catch, catheterization, 24-hour collections, and suprapubic aspiration are described in [Chapter 37](#). A chemical reagent strip can be used to detect glucose, protein, and occult blood and to measure pH. Specific gravity is best determined by use of a refractometer (requires only a single drop; see [Chapter 37](#)).

## Urine Culture

A urinary tract infection (UTI), or the presence of bacteria in urine, is diagnosed by urine culture. Urine for culture can be obtained by several techniques including midstream clean-catch, catheterization, or sterile suprapubic aspiration (see [Chapter 37](#)). The technique used should be determined by the provider and will be influenced by the patient's age, medical history, toilet training status, and cooperation. The test result interpretation varies depending on the technique. For example, a positive result from a clean-catch sample is  $>50,000$  CFU/ml, whereas the positive threshold for a sterile catheterized sample or suprapubic aspirate is  $>10,000$  CFU/ml ([Roberts, Downs, Finnell, et al., 2011](#)).

## Radioisotope Scanning

The administration of radioisotopes (a technetium scan) is another way to assess glomeruli filtration ability. For this, radioactively tagged substances are given intravenously; the rate at which these substances flow through the kidney and are excreted in urine is then determined. The level of radioisotopes used in these studies is small, and urinating removes the substance from the body immediately afterward. You can assure parents that children do not remain radioactive after the procedure so that parents are not afraid to stay near their children or to hold them.

## Blood Studies

A blood urea nitrogen (BUN) test measures the level of urea in blood or how well the kidneys can clear urea from the bloodstream. A normal value is 5 to 20 mg/100 ml.

**Glomerular filtration rate** is the rate at which substances are filtered from the blood to the urine. It is measured by the amount of creatinine (the breakdown product of creatine from muscle contraction) in blood serum or excreted in 24 hours as determined by a 24-hour urine sample. A normal creatinine clearance rate is 100 ml/min. A normal urine creatinine level is 0.7 to 1.5 mg/100 ml; creatinine in blood serum rarely exceeds 1 mg/dl ([Huether, 2013](#)).

## Ultrasonography and Magnetic Resonance Imaging

Either a *sonogram* or *magnetic resonance imaging* (MRI) can show differing sizes of kidneys or ureters and illustrate the difference between solid or cystic kidney masses. Because they do not involve X-rays, both ultrasound and MRI may be repeated at frequent intervals for follow-up without danger of radiation exposure (Nelson, Chow, Rosoklija, et al., 2012). When explaining ultrasound and MRI tests, compare the machines used to a camera so it's an object familiar to children and not as frightening.

## X-Ray Studies

A flat-plate abdominal radiograph can provide information about the size and contour of the kidneys and may be referred to as a *KUB* (*kidney, ureters, and bladder*). *Computed tomography* (CT) scans of the kidneys reveal both the size and density of kidney structures and adequacy of urine flow. Conscious sedation may be given before a CT scan because the size of a CT scanner can be frightening and a child must lie still for an extended time during the procedure. However, many children's hospitals are now staffed by child life specialists who can often prepare and support a child through a CT scan without sedation. If a contrast medium will be injected to better outline urine flow, be certain to ask about allergy to iodine before the study because the injected medium is iodine based and is therefore contraindicated in a person with an iodine allergy. As with MRI, explaining to the child that the machine used is much like a large camera can help reduce fear. When preparing a child for a test with an injected medium, caution children that they may experience flushing of the face, warmth, and a salty taste in their mouth after the injection of the "medicine."

### Intravenous Pyelogram

An *intravenous pyelogram* (IVP) is an X-ray study of the upper urinary tract. For the procedure, a radiopaque dye is injected into a peripheral vein, circulates through the bloodstream, and is almost immediately identified as a foreign substance by the kidneys and filtered out into the urine by the glomeruli. Radiographs taken at frequent intervals during the test show the outline of collecting systems in the kidney and of the ureters as the radiopaque dye passes through them.

### Voiding Cystourethrogram

A *voiding cystourethrogram* (VCUG), a study of the lower urinary tract, reveals the structure of the urethra and bladder and the presence of reflux into the ureters (Lum, 2012). After bladder catheterization, a radiopaque dye is injected into the bladder, and the catheter is then removed. The child is asked to void into a bedpan while serial X-ray films are taken. Although the catheterization can be unpleasant, being asked to void while supine and being observed may be the most stressful part of the procedure for children because they have been taught that voiding is a private act. Be sure children are told in advance that they will be asked to do this and that it is all right if a stranger watches them (something they have been taught to avoid as well). The first void after

catheterization may be painful, but you can assure the child that this is usually only a one-time occurrence and that drinking plenty of water following the test dilutes the urine and decreases dysuria. Pouring warm water over the perineal area while sitting on a toilet or sitting in a bathtub of warm water and voiding into the water can also be helpful but is rarely necessary.

A VCUG should not be done if a child has an active UTI because there is danger the radiopaque material injected into the bladder could spread bacteria from the bladder, up the ureters to the kidneys, causing pyelonephritis. Therefore, report any symptoms of a UTI, such as urinary frequency, dysuria, or low-back pain, to the radiologic service before the procedure so that the child can be properly evaluated and the test rescheduled if necessary.

## Cystoscopy

*Cystoscopy*, or examination of the bladder and ureter openings by direct examination with a cystoscope introduced into the bladder through the urethra, may be done to evaluate for possible vesicoureteral reflux or urethral stenosis. Radiopaque dye may be introduced into the bladder at the time of cystoscopy so the bladder can be visualized on X-ray. During the procedure, small catheters can be threaded into the ureters for the introduction of dye to outline them (retrograde pyelography). Because the procedure is painful and requires a child to lie still, it is usually done under anesthesia. As with catheterization for VCUG, the first void after cystoscopy may be uncomfortable, and the child should be adequately prepared for this.

### QSEN Checkpoint Question 46.1

#### TEAMWORK & COLLABORATION

Carey is undergoing a VCUG to help diagnose whether she has vesicoureteral reflux. A nurse collaborates with the radiology technician to ensure an accurate test that does not cause distress for Carey. What should the nurse emphasize in order to achieve these goals?

- The technician will have to read the instructions for the test to Carey.
- Lying in a large, metal tube is frightening for most children.
- Children often feel uncomfortable voiding in public.
- The dye capsules may be too large for Carey to swallow.

Look in [Appendix A](#) for the best answer and rationale.

## Renal Biopsy

*Renal biopsy* involves passing a thin biopsy needle into the kidney through the skin over the kidney. The procedure is used to diagnose the extent of renal disease and thereby predict disease outcome or progress or reveal beginning rejection of a transplanted kidney (Tse, Yadav, Herrema, et al., 2013).

Renal biopsy may be done in an older child under only local anesthesia, but conscious sedation may be necessary for a younger child who cannot cooperate easily. The kidney is located first by ultrasound to accurately locate the best place for the biopsy. The child lies prone with a sandbag under the abdomen for firmness. If the procedure is done under a local anesthetic, prepare children for the feel of a pinprick as the local anesthetic is injected; after this, they should not feel any further pain. They will feel pressure, however, as the biopsy needle is inserted. Caution children they need to lie still while the biopsy specimen is taken (if the child moves suddenly, the needle might puncture a renal artery or vein or tear vital glomeruli). Be certain children have support people to remain with them for this procedure, so they have someone to hold their hand or comfort them when they feel the pressure of the needle.

After the biopsy, press a sterile square gauze against the biopsy site for approximately 15 minutes to halt bleeding and then apply a pressure dressing. Caution parents beforehand that a large dressing will be used, so they don't think the size of the dressing reflects the size of the specimen taken (the amount of tissue removed is actually no more than the lumen of the needle used, or about the size of a pencil lead).

Measure vital signs and observe the biopsy site every 15 minutes for at least the first hour afterward. Do not lift the dressing to assess bleeding because doing so destroys the protective function of the pressure dressing. If the procedure is done on an ambulatory basis, children can be discharged 2 to 4 hours after the procedure if vital signs are stable and they have voided. Encourage children to drink a considerable amount of fluid (a glass every hour while awake) during the first 24 hours to keep urine flowing freely and prevent blood from clotting in the kidney tubules and blocking urine flow. Play games with the child, if necessary, to encourage a high fluid intake (the child must take a drink each time before a turn at a game, or play "Simon Says" and have Simon frequently say, "Drink").

The first void after renal biopsy is invariably tinged with blood. Advise parents to restrict their child's activity for 24 hours or until no more blood (hematuria) is present. Instruct parents how to properly obtain and view serial urine samples, comparing each specimen with the previous one, to detect whether hematuria is increasing or decreasing. When urine no longer appears bloody, they can test it for occult blood a final time to confirm that all bleeding has stopped. The treating provider may order hematocrit to be tested 24 hours after the procedure in order to confirm that bleeding has ceased.

### *What If... 46.1*

**Carey's grandmother telephones the nurse after a kidney biopsy and says Carey is voiding black urine. She asks whether there is a possibility Carey is voiding blood. What recommendations should the nurse make to the grandmother?**

## Therapeutic Measures for the Management of Renal Disease

Because kidney function is necessary for life, if it deteriorates, therapies to replace renal function must be instituted.

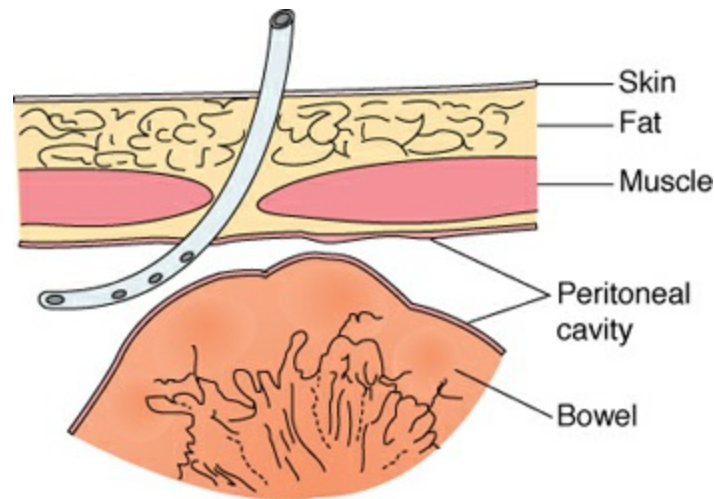

### PERITONEAL DIALYSIS

**Dialysis** is the separation and removal of solutes from body fluid by diffusion through a semipermeable membrane. *Peritoneal dialysis* uses the membrane of the peritoneal cavity to do this. Hemodialysis circulates blood through an outside synthetic membrane to do this. Unlike hemodialysis, peritoneal dialysis does not require elaborate equipment or expense, but it does take more time. Peritoneal dialysis may be used as a temporary measure for children who experience sudden renal failure caused by trauma or shock. It is also used for fairly long periods with children with chronic renal disease to allow them to live until kidney transplantation can be arranged (Issa, Lankireddy, & Kukla, 2012).

It is usually begun when the serum creatinine level reaches 10 mg/100 ml. Other indications are congestive heart failure, BUN of more than 100 mg/100 ml, hyperkalemia (potassium level of more than 6 mEq/L), and uremic encephalopathy (confusion or coma). Continuous peritoneal dialysis allows the procedure to be done at home because less rigorous monitoring of the procedure is necessary.

### Performing Peritoneal Dialysis

Before peritoneal dialysis begins, a child's weight and vital signs need to be obtained to provide baseline information. Ask the child to void to reduce bladder size, so the bladder occupies as little anterior space as possible; if a child cannot void, catheterization may be necessary. Following this, the child's abdomen is cleaned just below the umbilicus with an antiseptic solution and covered with a sterile drape; a local anesthetic is injected into the abdominal wall, and a large-bore needle is inserted into the peritoneal cavity. If ascites fluid is present, a quantity of this fluid is removed and then a warmed hypertonic glucose solution (approximately 50 to 100 ml/kg of body weight) or a commercial dialysis solution is infused by gravity flow into the peritoneal cavity. This distends the abdominal wall and allows safe insertion of a peritoneal catheter, which is sutured into place and covered with a sterile dressing (Fig. 46.2). This catheter will remain in place for the duration of dialysis.

**Figure 46.2** Insertion site for a peritoneal dialysis catheter.

As for any procedure, children need to be well prepared for peritoneal dialysis, but if the procedure is presented in a matter-of-fact way, children usually accept it with no more apprehension than IV therapy as both procedures involve a needle penetration. Caution children they will feel the initial prick of the needle that administers the local anesthetic but then will feel only pressure after that as the peritoneal needle or catheter is inserted. The procedure is intrusive, however, and can therefore be frightening. Provide opportunities for therapeutic play such as letting the child handle a cloth doll, a dialysis tube, IV tubing, a doll's bed, or syringes as they become familiar with the procedure.

With the dialysis tube in place, a prescribed amount of dialysis solution is infused into the peritoneal cavity by gravity drainage. This takes approximately 10 minutes and is recorded as *inflow* time. Be certain the infusion fluid is warmed to room temperature to prevent the child from becoming chilled; warming the solution in a basin of warm water or with the use of commercial warm packs so it is near body temperature also appears to improve diffusion efficiency. Heparin may be added to the first infusion to keep any initial bleeding from the abdominal puncture from plugging the tube.

The infused fluid is allowed to remain in the child's peritoneal cavity for 15 to 60 minutes (called the *equilibrium* or *dwell time*) while fluid, urea, and electrolytes move by osmosis from extracellular spaces into the hypertonic solution. After the designated equilibrium time has passed, drain the fluid from the peritoneal catheter into a collecting bottle (this takes approximately 10 minutes and is recorded as *outflow* time). More fluid generally drains from the peritoneal cavity than was infused because excessive fluid has diffused across the peritoneum, reducing accumulated peritoneal or ascitic fluid.

Peritoneal dialysis may be conducted continuously for periods of 12 to 72 hours, depending on the effectiveness of the procedure in restoring serum creatinine and BUN levels to normal.

Monitor vital signs at least every hour, or per the provider's order, while children are undergoing peritoneal dialysis. Frequent blood studies are necessary during periods

of peritoneal dialysis to determine electrolyte concentrations. If electrolyte imbalances occur, electrolytes may be added to the infusion solution or administered IV. During each new infusion period and while the solution is in the abdomen, carefully observe for shortness of breath because the fluid exerts upward pressure on the diaphragm. Elevating the head of the bed a little usually helps to increase breathing space and ease respirations. If either tachycardia or hypotension occurs, this suggests that hypovolemia is occurring or fluid is moving too rapidly into the peritoneal cavity. An increasing temperature (after 24 hours) suggests peritoneal infection (Sayed, Abu-Aisha, Ahmed, et al., 2013).

Follow the agency's policy for cleaning and covering the end of the peritoneal catheter if there are periods when dialysis is halted (Fig. 46.3). The longer the peritoneal catheter remains in place, the greater is the risk of infection. Always assess the tube insertion site daily for redness or drainage. Use palpation to assess the abdomen for guarding or tenderness (rigidity suggest peritonitis or infection). Ask children to report any abdominal pain or diarrhea.

**Figure 46.3** Peritoneal catheter inserted into a child's abdomen. A secure dressing surrounds the insertion site to prevent infection. (Courtesy of Karen M. Polise, MSN, RN, Division of Nephrology, The Children's Hospital of Philadelphia.)

Once cycles of dialysis begin, children often grow bored lying in bed waiting for this procedure to be finished. Plan interaction for these times—perhaps a toy or game that is allowed only during the procedure so that the time remains special. Children generally do not feel hungry while having peritoneal dialysis because the bulk of peritoneal fluid causes pressure on the stomach and makes them feel uncomfortably full, so they usually prefer a liquid diet or small frequent feedings during this time. So that children can feel they have a sense of control over what is happening, let them help with the procedure by doing such things as recording the amount of solution infused and drained and allowing them to select liquids they like for meals.

Peritoneal dialysis is a simple yet important procedure. Help parents understand its importance for their child, so they can demonstrate a positive attitude toward it because their acceptance of the procedure helps the child accept it as well.

### Continuous Cycling Peritoneal Dialysis

Continuous cycling peritoneal dialysis (CCPD) allows a child to go to school or participate in other activities while receiving dialysis (Davenport, 2012). With CCPD, a permanent dialysis catheter is inserted and sutured into place at the abdomen. Although commercial devices may be used, for the simplest method, the child or parent attaches a bag of dialysis fluid and tubing to this and infuses a prescribed dialysis solution by gravity drainage; the bag and tubing are then rolled into a compact square under the child's clothes. The infused solution remains in the child for 4 to 6 hours during the day (8 hours at night); the dialysate bag is then lowered, and the solution drains from the peritoneal cavity into it. The bag and fluid are then discarded and a new bag of dialysate solution is attached and raised, and new solution is infused.

CCPD requires careful monitoring and attention by the child or family, so there is a record of the amount of fluid infused. Children on CCPD can participate in gym programs but should not participate in contact sports or swimming. Teach parents to think ahead for holidays or family trips so they do not run short of supplies.

Because CCPD is continuous, electrolytes in the bloodstream are maintained at more constant levels than when intermittent dialysis is used. A great deal of potassium is removed, however, so caution is needed or children may become hypokalemic (Lum, 2012). The main advantage is that CCPD allows greater freedom for children to attend school. There are disadvantages, however, such as infection resulting from the long-term placement of the catheter and dehydration or hypernatremia resulting from excess fluid removal. Because the tube remains in place at all times and the peritoneal solution constantly distends the abdomen, the child appears obese and clothing is difficult to fit, frequently reminding the child of the illness. Possible complications of CCPD are summarized in Table 46.2.

**TABLE 46.2 POSSIBLE COMPLICATIONS OF CONTINUOUS CYCLING PERITONEAL DIALYSIS**

Assessment	Problem	Interventions
Redness, pain, or swelling at tube insertion site	Infection	Report findings; take culture of site; administer antibiotics or other site care as prescribed.
Abdominal pain, increased temperature, nausea and vomiting, cloudy return in drainage solution	Peritonitis	Report findings; administer antibiotics as prescribed; auscultate for bowel sounds with vital sign assessment.

Cramps as fluid is infused	Irritation of peritoneal cavity	Infuse solutions more slowly; warm temperature of solution to body temperature.
Difficulty with infusion or drainage of fluid	Kinked or clotted tubing; malpositioned catheter	Assess tubing for kinking; change position of child; ask child to cough to increase abdominal pressure; add prescribed amount of heparin to dialysate bag (prevents clotting).
Weight increase; moist cough, shortness of breath	Fluid overload	Assess blood pressure and weight; decrease sodium and fluid oral intake as prescribed; possibly decrease strength of dialysis fluid as prescribed.
Weight loss, hypotension, poor skin turgor, tachycardia	Fluid loss	Assess blood pressure and weight; increase fluid and sodium intake as prescribed.
Blood-tinged dialysis return	Ruptured capillary vessel	Report findings; assess pulse and blood pressure; observe for further bleeding in drainage; flush catheter with prescribed amount of heparin to keep clots from forming.

### *What If . . . 46.2*

**Carey, who receives CCPD, wants to go to her church camp this summer. Her grandmother asks the nurse whether this would be a good experience for Carey. What factors would the nurse want to know about the camp? About Carey? About her dialysis regimen?**

## HEMODIALYSIS

*Hemodialysis* removes body wastes by using an external membrane as the diffusion surface. For hemodialysis, a catheter is inserted into an artery and blood is removed from the child and circulated through a dialysis coil. Urea and electrolytes in the blood diffuse into the surrounding fluid bath as the blood passes through the coil (Hothi, Stronach, & Harvey, 2013). After diffusion is complete, the blood is returned to the child's venous circulation (Fig. 46.4).

**Figure 46.4** A nurse preparing a 10-year-old girl for a hemodialysis session. A subclavian catheter from the child is connected to the hemodialysis equipment (in the background). Blood flows from the child through the catheter to the hemodialysis equipment and is then returned to the child's venous circulation. (© Life in View/Science Source.)

Hemodialysis can be done as a continuous process, but it is so effective that 3 hours of hemodialysis accomplish as much as 12 hours of peritoneal dialysis. Children who have renal failure or whose kidneys have been removed while they await a kidney transplant can be maintained almost indefinitely by hemodialysis sessions two or three times a week or by continuous ultrafiltration or continuous arteriovenous hemofiltration. It can be used in infants as well as older children (Quinlan, Bates, Sheils, et al., 2013).

To establish a site for initial blood removal, children may have a double-lumen central catheter inserted into a central vein, such as the subclavian or internal jugular vein. A permanent technique is subcutaneous anastomosis of a vein and artery, creating an arteriovenous fistula (usually the brachial artery and brachiocephalic vein; Fig. 46.5A) or internal anastomosis of the artery and vein using a subcutaneous graft (see Fig. 46.5B). The possibility of infection is reduced with internal anastomosis, although, unfortunately, two venipunctures, one from a low point in the shunt to remove blood and one high in the shunt to return it, are necessary for dialysis (use an anesthetic cream beforehand to reduce pain). The ability to feel a thrill (vibration) or hear a bruit over the fistula or graft site is proof that the connection is patent.

**Figure 46.5** (A) An internal arteriovenous fistula. (B) An internal arteriovenous graft.

The risks of hemodialysis include infection introduced by venipuncture (severe because the infection immediately causes septicemia) and clotting of the access site, which can lead to emboli. During hemodialysis, if too much sodium is removed, muscle cramping may occur. A “first use” syndrome or symptoms such as dizziness or muscle cramping can occur from a reaction to the fibers in the dialysis machine coil. If urea is moved from the blood at too rapid rate—faster than urea can be shifted from the brain into the blood—children may begin to show signs of confusion, vomiting, dizziness, visual blurring, or hallucinations from a *dialysis disequilibrium syndrome*. This occurs because, as osmotic pressure is greater in the brain than the blood, fluid shifts into the brain, resulting in cerebral edema. Hemodialysis must be temporarily halted if these symptoms occur to allow equalization.

Children grow as bored during hemodialysis as they do during peritoneal dialysis. Help parents provide stimulating activities such as playing a board game or reading a favorite story, which are only used during that time period. When children’s kidneys are removed prior to transplantation, they must remain on a continuous program of hemodialysis. These children may come to resent a machine as “owning” or “controlling” them as they become aware they cannot exist apart from it (Bayhakki & Hatthakit, 2012). Allowing them to plan special activities to do during hemodialysis time can help not only to pass the time but also to give them a feeling of control.

## Health Promotion and Risk Management

Several important interventions can help prevent urinary and renal disease in children. The first intervention is to educate parents and caregivers about wiping from front to back when changing diapers of female infants. The second intervention is to prevent UTI in girls by beginning education about perineal hygiene measures from the time they are first toilet trained. Remind parents of simple ways to prevent UTI, such as not allowing children to bathe with bubble bath. Teach parents to recognize that abnormally colored urine (red, black, or cloudy) should not be dismissed because this could be the beginning of a UTI or kidney disease.

Educating parents about the importance of giving the full course of antibiotics prescribed for UTIs can help prevent return reinfection; giving the full course of antibiotics after a streptococcal infection can help prevent acute glomerulonephritis.

## Structural Abnormalities of the Urinary Tract

Because the urinary tract is a system of hollow tubes, congenital disorders can rise from faulty recanalization in intrauterine life.

### PATENT URACHUS

When the bladder first forms in utero, it is joined to the umbilicus by a narrow tube, the *urachus*. If this fails to close during embryologic development, a fistula is left between

the bladder and umbilicus (**patent urachus**). This occurs more commonly in males than in females. Nurses are frequently the ones to discover this condition as they notice clear fluid draining from the base of the umbilical cord while changing a newborn's diaper. If you test the fluid with Nitrazine paper for pH, its acid content will identify it as urine. An ultrasound will confirm the patent connection.

A few patent urachus abnormalities heal spontaneously, but most require surgical correction to prevent pathogens from entering the fistula site and causing persistent bladder infection. This is done in the immediate neonatal period using only a small subumbilical incision (M. S. Tsai & Yeh, 2011).

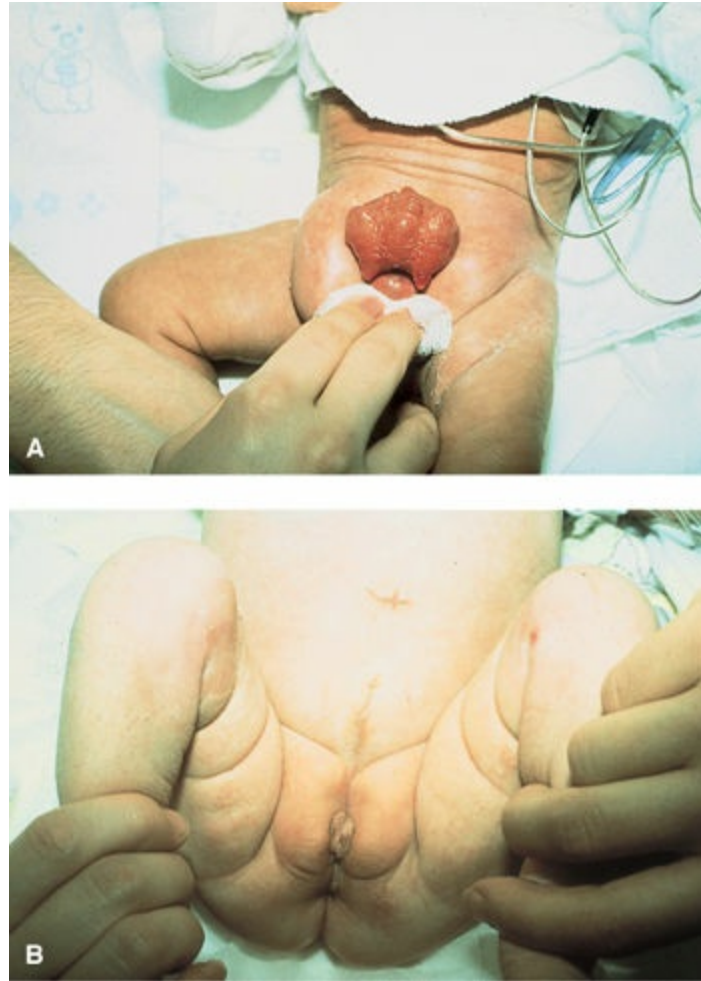

## EXSTROPHY OF THE BLADDER

**Exstrophy of the bladder** is a midline closure defect that occurs during the 10th week of pregnancy. As a result, at birth, the bladder lies exposed on the anterior abdominal wall. The latest population-based studies have shown the incidence to be between 2 and 3 per 100,000 live births, with almost identical incidence between males and females (Purves & Gearhart, 2010).

### Assessment

Exstrophy is often, but not always, detected by fetal ultrasound, which reveals the lack of an anterior wall of the bladder and a lack of anterior skin covering the lower anterior abdomen (Fig. 46.6A). A skilled ultrasonographer may pick up on possible exstrophy when they do not observe a typical bladder-filling cycle during the prenatal ultrasound. At birth, the bladder appears bright red and continually drains urine from the open surface. In both sexes, pelvic bone defects, particularly a wide pubic diastasis, are a hallmark of exstrophy. In males, the genital defect is severe because the anterior corporal length is 50% shorter, and the diameter of the posterior corporal segment is 40% larger than in males without exstrophy. This leads to the appearance of a dramatically short, wide penis. In females, the urethra may be abnormally formed, and the vagina is approximately 50% shorter and 30% wider than females without exstrophy, frequently requiring vaginoplasty after puberty in order to allow sexual intercourse and tampon use without pain (Purves & Gearhart, 2010). Urethral defects in males, such as **epispadias**—the opening of the urinary meatus on the dorsal or superior surface of the penis—are also common. The skin around the bladder quickly becomes excoriated because of constant exposure to acid urine. Kidney infection can occur from ascending organisms from the open bladder. When children with this disorder begin to walk, they may demonstrate a “waddling” gait caused by the wide pubic diastasis.

**Figure 46.6** Bladder exstrophy. **(A)** Prior to surgical reconstruction. Note the bright-red color of the bladder. **(B)** Following surgical reconstruction. (Courtesy of Karen M. Polise, MSN, RN, Division of Nephrology, The Children’s Hospital of Philadelphia.)

### Therapeutic Management

The treatment of bladder exstrophy begins with surgical closure of the bladder and the anterior abdominal wall, and construction of a urethra (see Fig. 46.6B). Because of the severe nature of the defect and the high potential for initial closure failure, and the lifelong negative sequelae of such a failure, children born with bladder exstrophy should immediately be referred to a pediatric urologist at a major children’s center who has undergone fellowship training in bladder exstrophy treatment. If the bladder is of suitable size and quality, an ideal timeline for closure is in the first 24 to 72 hours of life. If the bladder template is too small, however, the bladder can be left to grow for 3 to 6 months before closure. In such instances, the bladder mucosa should be kept moist and covered with plastic wrap to prevent the bladder surface both from drying out and from adhering to bedclothes or diapers and being injured. To prevent the skin of the abdomen from excoriation, consult a wound, ostomy, and continence nurse for the best approach, which usually involves a protective topical application such as A&D

Ointment, Karaya Gum, or Maalox. If this is done, do not separate the infant's legs to apply diapers; just place them under the child instead. Be certain to change diapers promptly after defecation so feces are not brought forward to the open bladder. Position the infant on the back so urine drains freely. Sponge bathe rather than tub bathe the infant to prevent water from entering the ureters and becoming a source of infection.

It is important to help parents to view their child as healthy in every aspect other than his or her bladder defect. When a child with bladder exstrophy is received into your care, remember to congratulate the parents on the birth of their baby. Bladder exstrophy affects only urinary elimination, and in most cases, these children are otherwise extremely healthy. With modern-day surgical approaches, these children can lead normal, healthy lives, and it is important for the emotional well-being of the family to focus on these positive aspects. In instances when the bladder closure is to be delayed, teaching the parents to properly care for the bladder at home is imperative.

### Postoperative

Surgery is completed as either a one-step or staged repair. After bladder closure, a suprapubic tube is placed for urine drainage and will typically remain in place for 4 to 6 weeks to allow the bladder to drain continuously and the surgical anastomoses to heal. The infant should be positioned on the back with the legs raised in traction at 90 degrees. This position is maintained for 4 to 6 weeks after surgery and is essential to prevent failure of the closure. Approximately 30% of patients with bladder exstrophy at children's medical centers worldwide also undergo osteotomy at the time of their bladder closure. Immediately after surgery, urine draining from the catheter may be tinged with blood, but this should clear after the first few days. Children may experience sharp, painful bladder spasms after surgery. Such spasms are often the most painful and prominent source of discomfort for the recovering child. Working with the pain team to provide adequate analgesia and anticholinergic therapy is imperative for both the comfort of the child and the proper healing of the bladder.

For some children, so little bladder tissue is present that surgical reconstruction isn't possible, and a *continent urinary reservoir* (or artificial neobladder) is constructed (Purves & Gearhart, 2010) (Fig. 46.7).

**Figure 46.7** A continent urine reservoir. A portion of intestine is isolated; the attached ureters drain into it. The appendix creates an abdominal stoma for catheterization.

For continent urinary diversion, a small segment of the intestine is separated from the intestinal tract. The intestinal tract is then reanastomosed so the gastrointestinal tract is unaffected. The separated segment is made into a bladder-like reservoir, and then the appendix is tubularized to create a continent channel extending from the dome of the bladder reservoir to a continent stoma at the site where the umbilicus would normally lie.

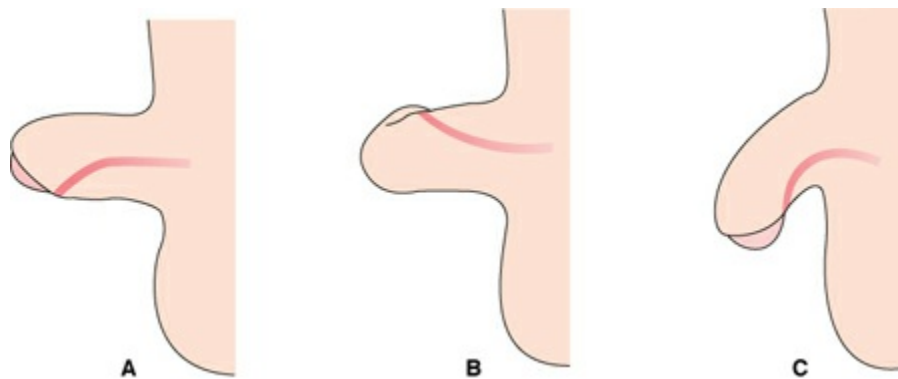

Urine drains from the kidneys into the ureters and then into the collecting bowel segment. The parent or child catheterizes the abdominal stoma every 3 to 4 hours throughout the day to empty urine. The procedure is theoretically simple, but it is technically difficult to accomplish. Parents need a good review of anatomy to aid their understanding of the procedure. As the child reaches school age and begins school activities that expose the condition to others, such as showering, adjusting to a continent urinary reservoir can be difficult. Ensure that the child has a plan and support for peer disclosure, maintenance, and follow-up care during the school years and adolescence so the function of the reservoir and also the child's adjustment can continue to be assessed and supported.

For children who have a successful initial closure, adequate bladder capacity, pelvic floor function, and bladder contractility, an alternate continence procedure, called a bladder neck reconstruction (BNR), may be an option. This is ideally undertaken in the

mid to late elementary school years or later and requires significant preparation that often takes place over a number of months or years under a specialist's care. A BNR reconstructs the bladder neck and urethra and allows the child to void via the urethra and achieve continence.

## HYPOSPADIAS

**Hypospadias** is a urethral defect in which the urethral opening is not at the end of the penis but on the ventral (lower) aspect of the penis (Fig. 46.8A) (Spinoit, Poelaert, Groen, et al., 2013). It is a fairly common anomaly, occurring in approximately 1 in 300 male newborns. It tends to be familial or may occur from a multifactorial genetic focus. Epispadias is a far more severe defect and results from a defect in the dorsal wall of the urethra, resulting in a dorsally located ectopic meatus. The most extreme cases in males result in a penopubic location of the meatus and complete incontinence (see Fig. 46.8B).

**Figure 46.8** Urethral defects. (A) Hypospadias. (B) Epispadias. (C) Hypospadias with chordee.

### Assessment

Be certain to inspect all male newborns at birth for hypospadias or epispadias as part of a routine physical examination. The degree of hypospadias may be minimal (on the glans but inferior in site) or maximal (at the midshaft or at the penal-scrotal junction). Many newborns with hypospadias have an accompanying short *chordee*—a fibrous band that causes the penis to curve downward (often called a cobra-head appearance; see Fig. 46.8C). Also inspect carefully for *cryptorchidism* (undescended testes), which is often found in conjunction with hypospadias.

If the penis defect is so extensive that sex determination is unclear, sex cell karyotyping or DNA analysis (see Chapter 8) should be done. Parents may have difficulty discussing this condition with relatives or healthcare personnel because it is a sensitive topic for them. Help parents work through these feelings by allowing them to talk about the disorder, by answering honestly and openly their questions about what the condition includes, and by assisting the family in receiving professional support when necessary.

## Therapeutic Management

Children with hypospadias should not be circumcised because, at the time of the repair, the surgeon may wish to use a portion of the foreskin for the repair. In the newborn, the surgical procedure may be a *meatotomy*—a procedure in which the urethra is extended to a usual position—to establish better urinary function. When the child is older (age 12 to 18 months), adherent chordee can be released. If the repair will be extensive, all surgery may be delayed until the child is 3 to 4 years of age. To encourage penis growth and make the procedure easier, the child may have testosterone cream applied to the penis or receive testosterone injections until surgery. It's important that hypospadias be corrected before school age if at all possible so the child looks and feels like other males. If left uncorrected, in later years, a meatal opening at an inferior penile site may interfere with fertility because it does not allow sperm to be deposited close to the female cervix during coitus (Vidal, Gorduza, Haraux, et al., 2010).

After surgical repair, a urethral urinary drainage catheter will be inserted to allow urine output without putting tension against the urethral sutures. The child may notice painful bladder spasms as long as the catheter is in place (3 to 7 days), so an analgesic such as acetaminophen (Tylenol) and an anticholinergic medication such as oxybutynin (Ditropan) may be prescribed for pain relief. After hypospadias repair, children can be expected to have usual urinary and reproductive function unless accompanying anomalies of the penis are present.

## Infections of the Urinary System and Related Disorders

As the urinary system drains to the outside of the body, infection can easily spread to the bladder or kidneys.

### URINARY TRACT INFECTION

UTI occurs more often in females than in males: about 8% in girls and 2% in boys (Lum, 2012). Urinary pathogens seem to enter the urinary tract most often as an ascending infection from the perineum and are gram-negative rods such as *Escherichia coli*. UTIs also occur as a health care–acquired infection in children who have urinary catheters.

UTIs occur more often in girls than boys because the urethra is shorter in girls, and because it is located close to the vagina and anus, vulvovaginitis or rectal bacteria can easily spread to the urethra. Changing diapers frequently can help reduce the risk for infection in infants. Girls should be taught early (when they are toilet-trained) to wipe themselves from front to back after voiding and defecating to avoid contaminating the urethra. There is a suggested correlation between the use of products such as bubble bath, feminine hygiene sprays, and hot tubs and UTI in girls, so use of these should be discouraged or minimized (Gaylord & Peterson-Smith, 2012). Additional measures to prevent UTIs are summarized in [Box 46.4](#).

**PREVENTING URINARY TRACT INFECTION IN FEMALES**

**Q.** Carey’s grandmother tells you, “Carey had two urinary tract infections last year. How can we prevent that from happening again?”

**A.** Here are some important tips to help prevent urinary tract infection (UTI):

- Encourage your granddaughter to drink fluid periodically during the day, especially in warm weather or during exercise, to keep urine flowing freely and prevent stasis of urine in bladder.
- Urge her to urinate at least every 2 to 3 hours to prevent stasis of urine in the bladder.
- Teach her not to bathe with bubble bath; this can cause vulvar and urethral irritation.
- Help your granddaughter learn to wipe from front to back after moving her bowels or urinating to prevent moving rectal contamination forward to the urethra.
- Have your granddaughter wear cotton, not synthetic, underwear to decrease perineal irritation.
- Instruct your granddaughter to wash her vulva daily to lower the bacterial count on the perineum.
- When your granddaughter begins menstruating, encourage her to change sanitary pads at least every 4 hours to reduce the possible growth of bacteria near the urethra.
- If symptoms of UTI should occur (pain on urination, frequency, blood in urine), call your primary healthcare provider. If an antibiotic is prescribed, make sure that your granddaughter takes it for the full prescribed course, so all bacteria are completely eradicated. Otherwise, after a short time, bacteria will grow stronger, and the infection will recur and be more difficult to treat.
- When your granddaughter becomes sexually active, teach her to urinate immediately after intercourse to flush out any bacteria introduced into the urethra during intercourse.

It’s important that UTIs are treated so they do not damage the bladder lining and/or spread to involve the kidneys (pyelonephritis) and cause permanent damage. Girls who have one UTI should be thoughtfully assessed and, if a second UTI occurs, should be referred to a fellowship-trained pediatric urologist to determine whether any congenital urologic anomaly such as an urethral stenosis or vesicoureteral reflux exists. Any male older than the age of 3 months who presents with UTI should also be evaluated by a pediatric urologist.

**Assessment**

Although it may be possible to locate a UTI precisely as urethritis, cystitis, ureteritis, or pyelonephritis, the signs and symptoms in young children often are not clear-cut, so all types are lumped together and referred to as UTIs. The typical symptoms that occur in older children or in adults—pain on urination, frequency, burning, and hematuria—may not be present in young children, so UTI is suspected when a child has a fever with no demonstrable cause on physical examination. If the infection is confined to the bladder (cystitis), the child may have a low-grade fever, mild abdominal pain, and day- or nighttime enuresis. If the infection progresses to pyelonephritis, the symptoms are generally more acute, with high fever, abdominal or flank pain, vomiting, and malaise.

Urine for culture can be collected using a clean-catch technique, suprapubic aspiration, or catheterization, so bacteria from the vulva or foreskin do not contaminate the sample and give a false result. Suprapubic aspiration is generally limited to infants. Catheterization, also frightening and a potential source of infection, is limited in children of all ages.

Urine obtained from suprapubic aspiration is generally sterile, so any growth from this source is significant. A clean-catch urine specimen is said to be positive for bacteriuria if the bacterial colony count is more than 100,000 per milliliter. A count of less than 10,000 per milliliter is considered a negative culture. If the count is between 10,000 and 100,000 per milliliter or if the urine is positive for proteinuria (which could happen because of the presence of bacteria), the count is usually repeated. In addition to identifying the responsible organism, microscopic examination of the urine specimen may indicate the presence of red blood cells (hematuria) caused by bacterial irritation of the bladder mucosa. The presence of either red or white blood cells or bacteria tends to make urine more alkaline, so the pH of the sample will be elevated (>7). Surveillance urine cultures, once a common practice, are no longer recommended. The American Academy of Pediatrics (AAP) released in 2011 its updated guidelines for UTI management in children aged 2 to 24 months and encourage providers to make careful assessments and culture only in symptomatic patients ([Roberts et al., 2011](#)).

## Therapeutic Management

The medical treatment for UTI is the oral administration of a broad-spectrum antibiotic such as sulfamethoxazole-trimethoprim (Bactrim) or amoxicillin, or an antibiotic specific to the causative organism that is cultured ([Paintsil, 2013](#)). Nitrofurantoin is also a good choice for UTIs because it is a broad-spectrum antibiotic that concentrates in the urine and can be used for both treatment and prophylaxis. In addition to the antibiotic, a child needs to drink a large quantity of fluid to “flush” the infection out of the urinary tract, particularly if a sulfa drug is prescribed because these can cause urinary crystals in concentrated urine. Cranberry juice is often recommended as being highly effective in acidifying urine and making it more resistant to bacterial growth. In actual practice, little evidence of its effectiveness exists, so water is the best choice; fluids with artificial coloring and carbonation should be avoided because they irritate the bladder and can cause further discomfort. If the child experiences moderate to severe pain on urination

that interferes with the ability to void, suggest the child sit in a bathtub of warm water and void into the water. A mild analgesic, such as acetaminophen (Tylenol), may help reduce pain enough to allow voiding.

Remind parents that with a UTI, treatment with antibiotics must be continued for the full prescription or the infection will return. Help parents create a reminder system, such as a sheet of paper for the refrigerator door or a reminder on their smartphone, to help ensure adherence. A repeat clean-catch urine sample obtained after approximately 7 days of antibiotic dosing is indicated for some children who have had multiple recurrent UTIs. This is referred to as a “test of cure,” and the goal is to confirm that the bacterial infection has been obliterated and is not simply being partially suppressed while the child is on antibiotics and will surge back to culture-positive levels when the antibiotics are discontinued.

After recurrent UTIs, children may be prescribed a prophylactic antibiotic for 6 months while measures are taken to optimize voiding habits and hydration.

## “HONEYMOON” CYSTITIS

*Honeymoon cystitis* refers to UTI seen in young women shortly after they initiate a first sexual relationship caused by the local irritation and inflammation that results from coitus.

Like most UTIs, these respond quickly to antibiotic therapy. Voiding as soon as possible after coitus may help to flush pathogenic organisms from the urethra and prevent such infections. When cystitis first occurs in an adolescent girl, it is an alert that she may be sexually active. In addition to the need for counseling about personal hygiene measures to prevent UTI, the girl may need information about safer sex, reproductive planning, and symptoms of sexually transmitted infections. Recurrent UTIs in a school-age or preschool girl may suggest sexual maltreatment (Beck, Bekker, & Van Driel, 2010).

### QSEN Checkpoint Question 46.2

#### QUALITY IMPROVEMENT

Carey’s grandmother is concerned because Carey had two UTIs last year. Which of the following statements best shows that Carey’s grandmother received adequate patient education on the prevention of UTIs?

- “I won’t allow Carey to drink too much milk or eat foods like yogurt.”
- “I’ll try to have Carey bathe with bath salts to discourage bacteria in her groin area.”
- “I’ll be certain to administer all of the antibiotic pills that the doctor prescribes.”
- “I’ll make sure that Carey doesn’t overexert herself when she’s playing with her friends.”

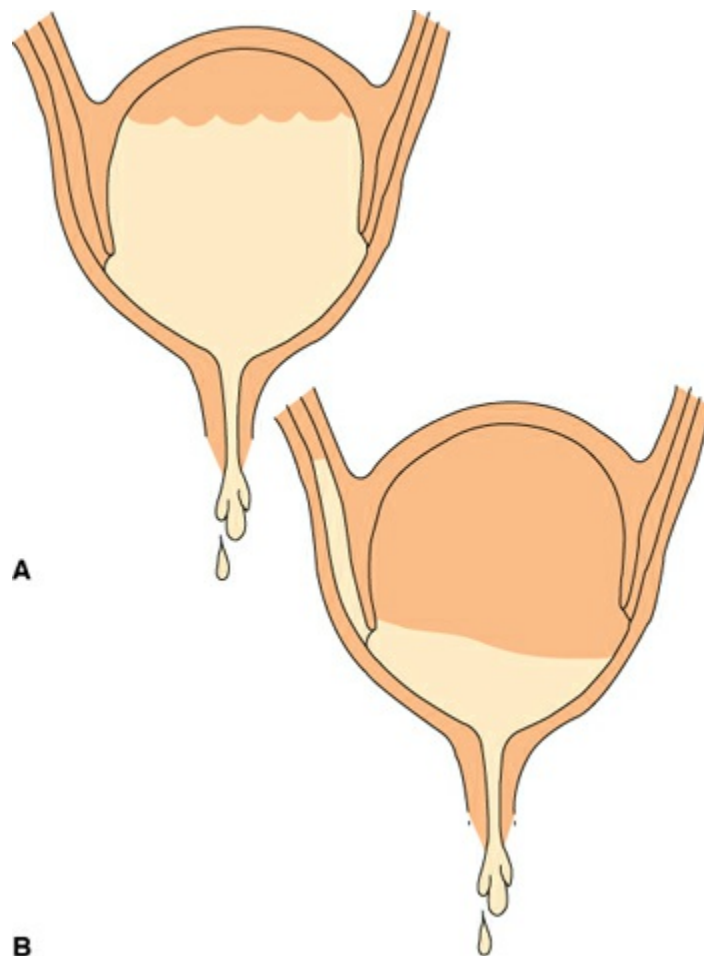

Look in [Appendix A](#) for the best answer and rationale.

## VESICoureTERAL REFLUX

Normally, urine flows from the ureters into the bladder, with almost no flow reentering the ureters from the bladder because the ureters enter the bladder obliquely and a bladder skin flap or “valve” obscures the end of the ureter, preventing backflow.

**Vesicoureteral reflux** refers to retrograde flow of urine from the bladder into the ureters (Batinic, Milošević, Topalovic-Grkovic, et al., 2013). This reflux of urine occurs with micturition (voiding) when the bladder contracts (Fig. 46.9) because the valve that guards the entrance from the bladder to the ureter is defective either from birth or because of scarring from repeated UTIs; bladder pressure is stronger than usual; or ureters are implanted at unusual angles or too low on the bladder wall.

**Figure 46.9** Vesicoureteral reflux. (A) Normal voiding pattern. (B) Reflux into ureters with voiding.

Reflux has the potential to lead to bladder infection because urine is retained in the ureters after voiding and then drains back into the bladder after the child is finished voiding where it remains. Stasis of any fluid is subject to infection. The capacity for normal bladder tissue to lyse bacteria also becomes reduced because of the large residual urine volume that is always present. If the reflux is enough that it leads to back

pressure on the kidneys, it has the potential to lead to nephron destruction and, subsequently, hydronephrosis or dilatation of the renal pelvis. As the condition tends to appear in families, it is most likely caused by a heterogeneous gene disorder ([Hunziker & Puri, 2012](#)).

### Assessment

A child with reflux is usually first seen by healthcare personnel because of a history of repeated UTIs. A VCUG, CT scan, MRI, cystoscopy, or cystography with contrast material will show the ureteral reflux. Based on diagnostic studies, reflux is graded from I to V by degree of reflux, with grade V being the most serious.

### Therapeutic Management

The majority of instances of vesicoureteral reflux resolve with maturity without a need for surgery. Until this normal growth occurs, however, the condition must be treated to decrease the possibility of glomerular scarring from infection or back pressure ([Passamanek, 2011](#)). Teaching double voiding (having the child void and then in a few minutes attempt to void again) may help to empty the bladder more fully and prevent recurrent infection from urinary stasis. Some girls need to remain on prophylactic antibiotics for a lengthy time to prevent bladder infection from reoccurring.

If continuous antibiotic therapy does not prevent recurrent UTIs or the reflux is initially identified as severe, it can be corrected by cystoscopy. Under general anesthesia or conscious sedation, a cystoscope is passed into the bladder through the urethra and an agent such as dextranomer–hyaluronic acid (Deflux) is injected to stabilize the ureter valves ([Puri, Kutasy, Colhoun, et al., 2012](#)). To correct the implantation site of ureters, laparoscopic surgery can be scheduled to reinsert the ureters at a more oblique angle.

After surgery, a suprapubic catheter will remain in place to keep the bladder empty and prevent pressure against the surgical area. Two ureteral catheters (stents), threaded into the ureters to drain urine directly from the kidney pelvis, also exit at the suprapubic tube site. All three tubes are attached to a closed drainage system. Sterile gauze dressings and antibiotic cream are placed around the tube insertion site to keep it free of infection.

In preparing children for this type of surgery, be certain to prepare them for the number of tubes they will have afterward. Explain that even with the tubes in place, the child will be allowed to walk and move about soon after the operation (and should do so). Be sure that the child and parents understand the importance of not raising the collection system above the child's bladder level when helping the child out of bed. This helps prevent potentially contaminated urine from flowing from the tubes back into the bladder or ureters.

Urine will drain primarily from the kidney stents for approximately the first 3 days after surgery; thereafter, drainage will flow around the stents and will be mainly from the suprapubic tube. As long as they are in place, it's important to assess that both stents

are draining to ensure kidney production is equal on both sides. Observe the suprapubic tube and stent drainage closely for color or clots (should not be over pinpoint in size) and measure the amount and record it every hour for the first 24 hours and then about every 4 hours following that. Initially, drainage from the bladder catheter will be bloody, but this should clear in 2 to 3 days. To show that urine is clear of blood, obtain serial urine specimens each time collecting bags are emptied and label them with the time of removal. Comparing the color of these samples will show that urine is clearing of blood. School-age children can help label the containers, which can help add to their sense of accomplishment and control over the situation.

To help keep the ends of stents or the suprapubic tube from becoming contaminated, care should be taken to maintain aseptic technique when emptying drainage bags. Once drainage occurs primarily from the suprapubic tube, and renal status and good drainage are ensured, the stents are removed. In most cases, this is done before discharge from the hospital, but the process varies by both technique and provider. Many children are frightened because they worry this will be painful. You can assure them this is a simple procedure, and most children are not even aware when the stent is removed. This is done easily and without the need for anesthesia.

Incisional pain and painful bladder spasms may be present for the first 3 days after surgery, so antispasmodics are usually prescribed to reduce bladder spasm. Not touching or moving the suprapubic tube also helps to reduce spasms because this limits bladder irritation. The suprapubic tube is typically removed between 4 and 7 days after surgery (again, a nearly painless procedure). There may be slight urine leakage from the puncture site of the tube for 1 or 2 days after removal of the tube. Keep a sterile dressing in place to absorb the leaking urine. Remind the child and parents to avoid tub baths until the suprapubic tube site has closed completely.

A few children continue to have bladder reflux after ureter reimplantation. All children need follow-up care such as repeat VCUG and/or ultrasound at a later date in order to establish that surgery was effective in halting the reflux.

## HYDRONEPHROSIS

**Hydronephrosis** is enlargement of the pelvis of the kidney with urine as a result of back pressure in the ureter. The back-pressure is generally caused by obstruction, either of the ureter or of the point where the ureter joins the bladder, as with vesicoureteral reflux. Although this may occur at any age, it occurs most often in the first 6 months of life and is often diagnosed by ultrasound during intrauterine life ([Yamaçake & Nguyen, 2013](#)).

The condition is usually asymptomatic. The infant may have repeated UTIs caused by urinary stasis (difficult to detect in a young child except as general irritability or crying on voiding). Elevated blood pressure caused by increasing tubular pressure (which activates the renin–angiotensin system) may be detected on a routine health assessment, although blood pressure is not taken routinely in infants. With severe back pressure, the infant will eventually experience flank or abdominal pain. Abdominal

palpation may reveal an abdominal mass (the dilated kidney pelvis). An IVP or ultrasound will reveal the enlarged pelvis and the point of obstruction.

Hydronephrosis is a serious disorder because if the pressure in the pelvis becomes too acute, back pressure on the kidney can interfere with tubular function or destroy the nephrons. The treatment is surgical correction of the obstruction before glomerular or tubular destruction occurs.

## Disorders Affecting Normal Urinary Elimination

Common disorders can interfere with urine elimination, such as **dysfunctional elimination syndrome (DES)**, including enuresis, and rarer disorders such as kidney agenesis. DES is an abnormal pattern of elimination of unknown cause, characterized by both urine and stool and by bladder and/or bowel incontinence. It occurs in a previously toilet trained child without anatomic or neurologic abnormalities.

### ENURESIS

**Enuresis** is involuntary passage of urine past the age when a child should be expected to have attained bladder control (Fleming, 2012). Because this is expected at 2 to 3 years of age for daytime and age 4 to 6 years for nighttime, enuresis is said to occur at approximately 7 years. Enuresis may be nocturnal (occurs only at night), diurnal (occurs during the day), or both. It is primary if bladder training was never achieved and is considered acquired or secondary if control was established but has now been lost.

Most enuresis is nocturnal; however, many children who present for treatment of nocturnal enuresis are also found to have some diurnal enuresis or DES as well. These factors are often the root cause of the nocturnal issues. Voiding dysfunction should be managed in an interdisciplinary setting that includes medicine, nursing, behavioral psychology, and nutrition, as indicated. Single treatment modalities are rarely successful long term, and management should include a multimodal approach, including bowel management, timed voiding, hydration management, improved fiber intake, behavioral management, biofeedback (when appropriate), and drug therapy when necessary (Eldridge & Lakshmanan, 2011). It occurs more frequently in boys than in girls. It also tends to be familial (if it is present in a child, one of the parents probably experienced it, too).

### Assessment

Children with enuresis who are older than 5 years of age need an evaluation to determine whether there is an organic cause for the disorder. During history taking, ask how parents have tried to correct the problem; identify whether it is primarily a problem for the child or the parents (treatment will be most effective if the child wants the situation corrected). Assess whether there are stresses in the family, such as parents who expect more mature behavior of a child than the child can manage, the introduction of a

new brother or sister, an uncomfortable school situation such as bullying, or marital discord.

If children wet only on nights when they are exceptionally tired or troubled, a functional rather than an organic cause is suggested. If children wet only when they are engrossed in an interesting activity, they may simply need more reminders to empty their bladder. If children have symptoms other than bed-wetting, such as abdominal pain, burning, or frequency, UTI is suggested. It is a common practice for many parents to lift children out of bed every night and take them to the bathroom so they don't wet the bed. This can be a stop gap and is not harmful. However, it does not help develop the child's arousal response, which will improve the situation long term. For this practice to be meaningful and purposeful, the child should be brought to full awareness when they are woken up at night. They should walk to the bathroom under their own power (a parent can assist to avoid any accidents given their fatigued state) and should be told that they are going to sit on the toilet because their bladder is full and the toilet is the proper place to empty.

Some children with enuresis have abnormal electroencephalographic patterns. Other children with the same abnormal patterns do not have enuresis, however, so this by itself is not a sufficiently specific finding to be helpful. In others, bed-wetting seems to occur as children pass from a period of rapid eye movement sleep pattern to a type IV level, or it is primarily a sleep disorder. It may be associated with small bladder capacity (which would explain why the condition is familial).

Although usually not necessary to aid diagnosis, an ultrasound, pre–post bladder scan, or urodynamic testing may be prescribed to rule out organic disease, and a clean-catch urine specimen may be prescribed to rule out bacteriuria if other possible symptoms are present. Assess specific gravity, protein, and glucose of urine to rule out a defect in urine concentration or reveal evidence of nephron disease.

## **Therapeutic Management**

The treatment of enuresis can be complex because the cause is often unknown. If stress factors have been identified, not all of these can be eliminated because certain circumstances, such as the birth of a new sibling, cannot be changed, but frank discussion with children regarding what causes the stress and attempts to help them cope better with their daytime activities may lessen incidents.

In many children, it helps to limit fluids during the 2 hours before bed. Remind parents, however, that not all children are able to go without a drink from dinner until breakfast. For instance, for a child with sickle-cell anemia, restricting fluid in this way may cause increased sickling of cells as a result of dehydration and should be avoided.

Alarm bells that ring when children wet at night can be effective in some children. This type of system does not actually stop bed-wetting, but a sensor registers wetness and wakes the child and then the child stops voiding and gets up and uses the bathroom. Over time, this type of conditioning may be effective, but once the urine alarm is removed, children may relapse. Bladder-stretching exercises—drinking a large quantity

of water and then refraining from voiding as long as possible—to increase the functional size of the bladder are contraindicated and can cause both dysfunctional voiding and renal damage. Parents should be strongly cautioned against this.

In some cases, a synthetic antidiuretic hormone (desmopressin [DDAVP]) administered orally is the drug of choice to reduce urinary output and nocturnal enuresis in cases of primary nocturnal enuresis (Deshpande, Caldwell, & Sureshkumar, 2012). However, most children who wet at night do not have primary nocturnal enuresis and have some daytime symptoms of habits that are causing the nighttime problems. Children should be evaluated and treated in a clinic focused on DES and voiding dysfunction (Box 46.5).

## BOX 46.5

### Nursing Care Planning Based on Responsibility for Pharmacology

#### DESMOPRESSIN ACETATE (DDAVP)

**Classification:** a synthetic form of human antidiuretic hormone

**Action:** promotes resorption of water in the renal tubule or decreases bladder filling; drug of choice for primary nocturnal enuresis (Karch, 2013)

**Pregnancy Risk Category:** B

**Dosage:** In children 6 years of age and older, 0.2 mg orally at bedtime, titrated up to 0.6 mg to obtain the desired response. Intranasal preparations are no longer recommended.

**Possible Adverse Effects:** transient headache, nausea, flushing, mild abdominal cramps, fluid retention

#### Nursing Implications

- Instruct parents and child that child should restrict fluid after dinnertime in addition to taking medication.

Enuresis can become a major problem for children as well as family dynamics and deserves appropriate medical attention in a child after the seventh birthday. As a general measure, children who wet their beds need to take baths in the morning rather than at bedtime to minimize urine odor and avoid bullying. Parents may find planning a vacation with hotel stays difficult. They may resent the daily linen washing. Children may exclude themselves from activities such as slumber parties or camping trips with friends to avoid embarrassment.

Enuresis may occur in hospitalized children because of the stress of their new surroundings. Preschool children may experience it because they are uncomfortable using strange bathrooms or do not understand which bathroom is theirs to use. As a rule, place as little stress or importance on enuresis as possible during an illness and encourage parents to do the same.

## POSTURAL (ORTHOSTATIC) PROTEINURIA

A few children will spill albumin into the urine when they stand upright for an extended period (**postural proteinuria**, also called postural albuminuria). The amount of spilling decreases when they rest in a supine position. To identify a possible cause for the condition, an MRI of kidneys and ureters may be prescribed. To document that the proteinuria is related to posture, collect urine after the child has been recumbent during the night (a first-voided specimen) and then again after the child has been up and active for several hours. Make certain when collecting these urine specimens to record the child's activity accurately. If the child stood by the crib rail crying for a parent or was held in a nurse's lap for most of the night, the urine may show protein in the morning specimen because it is not truly a "resting specimen." Likewise, the "active" specimen should be collected after the child was truly active, not lying in a supine position reading a book for most of the time. Play a game if necessary, such as follow the leader, so the child is active.

Unless the MRI reveals an obstructive cause, postural proteinuria apparently results from the effect of gravity and thus needs no therapy. However, be certain to document the condition because some of these children do have obstructive disorders that need further identification (Milani, Mazzoni, Burdick, et al., 2010).

## KIDNEY AGENESIS

*Agensis* means lack of growth (literally, lack of a beginning) or that no organ formed in utero. Absence of kidneys in a newborn is suggested when the volume of amniotic fluid on ultrasound or at birth is severely less than usual (oligohydramnios), indicating that fetal urine was not added to the volume of amniotic fluid. The infant often has *Potter syndrome* or accompanying misshapen, low-set ears and hypoplastic (stiff, inflexible) lungs from compression caused by the lack of amniotic fluid in utero (A. C. Tsai, Manchester, & Elias, 2012). Bilateral absence of kidneys is obviously incompatible with life unless a renal transplantation can be accomplished; the associated condition of nonfunctioning lungs, however, lessens the infant's eligibility for a successful transplantation.

## POLYCYSTIC KIDNEY

**Polycystic kidney** implies that large, fluid-filled cysts have formed in place of normal kidney tissue. The most frequent type of polycystic kidney seen in children is inherited as an autosomal recessive trait. A more rare form is inherited as an autosomal dominant trait (Mahan, 2011). With either type, there is abnormal development of the collecting tubules. The kidneys grow large and feel soft and spongy. If the disorder is bilateral, an infant will not be able to pass urine so the mother will develop oligohydramnios during pregnancy. The newborn can have a flattened nose or *micrognathia* (small jaw), findings of Potter syndrome. A sonogram during pregnancy or at birth will reveal the fluid-filled cysts.

If the condition is unilateral, urine production will be decreased (oliguria), not absent. For this reason and because kidneys are difficult to locate in newborns, a unilateral polycystic kidney may be missed until later in life, when, with increased kidney growth, an abdominal mass can be palpated. The cystic growth offers such resistance to blood circulation that systemic hypertension often results by school age.

In many children, the condition is associated with a cerebral aneurysm, and the liver is filled with identical cysts. This is most evident later in life when increased difficulty with portal circulation occurs (blood cannot perfuse the cystic liver structures either).

The treatment for polycystic formation is surgical removal of the diseased kidney if only one is cystic. If both kidneys are cystic, treatment is renal transplantation (difficult in the young child because few infant kidneys are available for transplantation and because of the technical challenge presented by such small blood vessels). Because this kidney disease is inherited, parents and children at adolescence need genetic counseling to inform them that future children may have this problem.

## RENAL HYPOPLASIA

*Hypoplasia* means reduced growth, so hypoplastic kidneys are small and underdeveloped and contain fewer lobes than usual. In addition to having poor kidney function, hypertension from stenosis of the renal arteries may develop. If hypoplasia is bilateral, the child may need a kidney transplant in later life to maintain kidney function and prevent extreme hypertension.

## PRUNE BELLY SYNDROME

**Prune belly syndrome (PBS)** is a syndrome with a broad spectrum of severity. The most common abnormalities associated with PBS are cardiac, pulmonary, orthopedic, and urologic. Renal dysplasia occurs in about 50% of cases ([Hassett, Smith, & Holland, 2012](#)). Occurring mainly in boys, the severe dilation of ureters and the bladder causes back pressure and destruction of kidneys.

The condition is typically marked by the presence of three main urologic symptoms: bilateral undescended testes, the dilated faulty development of the bladder and upper urinary tract, and renal dysplasia. The infant's abdomen appears wrinkled (like a prune) because of the poorly developed abdominal muscles ([Fig. 46.10](#)). Without surgical remodeling, the infant will develop repeated UTIs, leading eventually to end-stage renal disease. Teach parents to protect their child's abdomen from trauma, such as can happen from lap belts or baby walkers because their child lacks abdominal support, while waiting for muscle transplant procedures to create more abdominal support ([Fearon & Varkarakis, 2012](#)). Some children need kidney transplants as they reach school age because of destruction of glomeruli from continual back pressure of urine on nephrons.

**Figure 46.10** Prune belly syndrome. (Courtesy of Karen M. Polise, MSN, RN, Division of Nephrology, The Children’s Hospital of Philadelphia.)

## ACUTE POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

**Glomerulonephritis**, inflammation of the glomeruli of the kidney, may occur as a separate entity but usually occurs in children as an immune complex disease after infection with nephritogenic streptococci (most commonly subtypes of group A beta-hemolytic streptococci) where complement, a cascade of proteins activated by antigen–antibody reactions, plugs or obstructs glomeruli. Immunoglobulin G (IgG) antibodies against streptococci can be detected in the bloodstream of children with acute glomerulonephritis, proof the illness follows a streptococcal infection (Kambham, 2012).

Intravascular coagulation occurs in the minute renal vessels; ischemic damage from this leads to scarring and decreased glomerular function. The glomerular filtration rate decreases, leading to an accumulation of sodium and water in the bloodstream. The inflammation of the glomeruli allows protein molecules to escape into the urine.

### Assessment

Acute glomerulonephritis is most common in children between the ages of 5 and 10 years, the age group most susceptible to streptococcal infections. Boys appear to develop the disease more often than girls; it occurs more often during the winter and spring, as do pharyngeal streptococcal infections. The child typically has a history of a recent respiratory infection (within 7 to 14 days) or impetigo (within 3 weeks). All children who have had a “strep” throat, tonsillitis, otitis media, or impetigo caused by a streptococcal infection, ideally, should have a urinalysis 2 weeks after the infection to evaluate that glomerulonephritis is not occurring. Many children do not receive this follow-up step, however, because of lack of health insurance coverage or compliance.

The disorder is announced by a sudden onset of hematuria and proteinuria. Urinary sediment will contain white blood cells, epithelial cells, and hyaline, granular, and red blood cell casts. Testing a single specimen of urine will show 1+ to 4+ protein; a 24-hour urine specimen may contain as much as 1 g of protein (normally, urine contains none).

The hematuria is usually so extreme that the child's urine appears tea-colored, reddish-brown, or smoky. After these initial urine changes, the child develops oliguria. Specific gravity of urine becomes elevated. Hypertension from hypervolemia occurs. The child may have abdominal pain, a low-grade fever, edema, anorexia, vomiting, or headache. There may be cardiac involvement such as orthopnea, cardiac enlargement, enlarged liver, pulmonary edema, a galloping heart rhythm, or heart failure because of the difficulty in managing the excessive plasma fluid.

Blood analysis will indicate a lowered blood protein level (hypoalbuminemia) caused by the massive proteinuria. As the child's blood volume expands, a mild anemia will also develop. As in all inflammatory diseases, the erythrocyte sedimentation rate will increase. Because the glomeruli cannot filter properly, concentrations of urea, nonprotein nitrogen (BUN), and creatinine in blood will increase.

If blood pressure reaches 160/100 mmHg as part of the expanding circulatory volume, encephalopathy may occur, with symptoms of headache, irritability, seizures, vomiting, coma or lethargy, and perhaps transitory paralysis, symptoms all caused by *cerebral ischemia* (vasoconstriction of cerebral vessels that occurs to reduce cranial pressure).

## Therapeutic Management

In most children, acute glomerulonephritis runs a limited, short-term, 1- to 2-week, benign course, and during this time, there is little specific therapy other than to alleviate symptoms of the disorder. A course of antibiotics may be prescribed to be certain all streptococci are removed from the child's system. Diuretics are of little value because obstructed glomeruli cannot be made to function, although a course of ethacrynic acid or furosemide (Lasix) may be tried. If heart failure occurs, keeping the child in a semi-Fowler's position, digitalization, and oxygen administration are helpful. If diastolic blood pressure rises to more than 90 mmHg, antihypertensive therapy with an antihypertensive such as labetalol will be prescribed. Phosphate binders, such as aluminum hydroxide to reduce phosphate absorption in the gastrointestinal tract, or a potassium-removing resin agent, such as sodium polystyrene sulfonate (Kayexalate), may be necessary in children who have rising phosphate and potassium levels because the kidneys are unable to clear these from the circulation.

Diet is controversial. Although restricting salt may limit edema and limiting protein intake may reduce the amount of protein lost in urine, most children who are losing large quantities of protein actually need more protein to supplement this loss. Most children do well, therefore, on a usual diet for their age. Weighing the child every day and calculating intake and output are important assessments to follow the course and extent of the disease.

Bed rest is unnecessary, although it's good to encourage children to participate in quiet play activities rather than active exercise. After 1 or 2 weeks, they can attend school and engage in their usual activities, although competitive activity is limited until kidney function has returned to normal (about 2 months). Caution parents that the

results of a urine protein test may remain abnormal for up to a year, so if their child has this test done as a routine screening procedure at a health checkup, they don't worry that the finding means reinfection or the beginning of further disease.

A few children will not completely recover from acute glomerulonephritis but will develop chronic nephritis. These children apparently suffer destruction from the initial inflammation that destroys renal function (Praga & Morales, 2013).

## Nursing Diagnoses and Related Interventions

Nursing care for the child with glomerulonephritis centers on helping alleviate symptoms and allowing the child to adjust to his or her sudden change in appearance.

**Nursing Diagnosis:** Situational low self-esteem, related to feelings of responsibility for onset of serious illness

**Outcome Evaluation:** Child (parent) admits feeling guilty about inadequate treatment of initial infection; discusses plans and ways to maintain health at this point; participates in care.

Glomerulonephritis is a frightening disease for both children and their parents because it begins so abruptly. Children may be frightened by the initial hematuria and upset at the appearance of periorbital edema, which makes their reflection in the mirror seem strange and often frightening to them. Children as young as early school age are aware that kidneys are necessary for life and thus appreciate the seriousness of kidney disease.

If children were prescribed penicillin for pharyngitis 2 weeks before the development of the condition but refused to take it, they and their parents often need to talk about their feelings. To help them understand that the outcome of the original neglected therapy does not have to result in a bad outcome, provide frequent reports of subtle positive changes in the child's condition, such as "Her blood pressure is not as high as before; she doesn't need medicine for that anymore." or "She weighs 2 pounds less today than 4 days ago; that generally means her kidneys are beginning to function more efficiently."

Be certain that parents know the date and place of a return visit for follow-up care. Because this is a perplexing disease, be certain they have a telephone number to call if they have questions about their child's care or condition. Acute glomerulonephritis tends not to recur with subsequent streptococcal infections, so prophylactic penicillin to prevent further streptococcal infections is not necessary.

*QSEN Checkpoint Question 46.3*

**PATIENT-CENTERED CARE**

Carey's grandmother tells the nurse that Carey had symptoms of acute glomerulonephritis last week that were greatly distressing. The nurse identifies which reported symptom as a typical first symptom of glomerulonephritis?

- a. Carey said her left knee hurt, although she didn't remember bumping it.
- b. Carey asked her grandmother why there was blood in the toilet bowl.
- c. Carey cried because she was starting to experience cramps.
- d. Carey told her grandmother her stomach hurt after using the bathroom.

---

*Look in [Appendix A](#) for the best answer and rationale.*

---

## CHRONIC GLOMERULONEPHRITIS

Although chronic glomerulonephritis occasionally follows acute glomerulonephritis or nephrotic syndrome, it also occurs as a primary disease (or after acute glomerulonephritis that was clinically so mild it was undiagnosed). The child is found to have proteinuria at a routine health assessment. Further investigation indicates hypertension and the presence of red cell or white cell casts and occult blood in urine with low specific gravity (below 1.003). Blood studies may indicate an increased BUN or creatinine levels. An MRI or a renal biopsy will reveal permanent destruction of glomerular membranes.

The disorder may result in either diffuse or local nephron damage. In both instances, the undamaged nephrons increase their glomerular filtration rate to compensate for the damaged nephrons. At some point in this chronic disease destruction process, however, compensatory mechanisms begin to fail, and renal insufficiency or failure results.

**Alport syndrome**, which also includes hearing loss and ocular changes, is progressive chronic glomerulonephritis inherited as an X-linked or autosomal recessive disorder (Kruegel, Rubel, & Gross, 2013).

With chronic glomerulonephritis, if the child has acute symptoms of edema, hematuria, hypertension, or oliguria, bed rest may be necessary. If children have only a chronic manifestation, such as proteinuria, and continue to feel well, they can maintain normal activity, including school attendance. Children should not engage in competitive activities such as contact sports, however, because of the risk of kidney injury.

Therapy is nonspecific and directed at symptom relief rather than the disease process or its cause, which is unknown. Therapy with antihypertensive drugs such as hydralazine (Apresoline) or with diuretics to increase urine output such as ethacrynic acid (Edecrin) can be helpful. Corticosteroid therapy may reduce or halt the progress of the disorder by reducing inflammation. Children have difficulty accepting long-term corticosteroid therapy because of the side effects, in particular the typical "moon face" and extra body hair (Cushing syndrome) that develop. Talk with them about these body changes and assure them that these changes will reverse when the drug is discontinued.

Children receiving corticosteroids are at an increased risk for developing infections because of the immunosuppressive activity of these drugs. Be certain parents know how to take their child's temperature and to report the earliest signs of infection as well as

shield their child from other children (and healthcare personnel) with infections.

Generally, the prognosis for children with chronic glomerulonephritis is not encouraging because, although the illness runs a long-term course, eventually it leads to renal insufficiency and renal failure (Kraut, 2013). Kidney transplantation is a possibility to replace a diseased kidney. Children can be maintained for long periods by peritoneal dialysis or hemodialysis while waiting for a transplant.

Although most children are adolescents or young adults before the disease runs its ultimate course, because children as young as early school age are aware of the importance of kidney function, most are aware of the likely outcome of their disease at an early age. They indicate that they appreciate having healthcare personnel face this outcome with them honestly while they wait for kidney transplantation to prolong their life.

## NEPHROTIC SYNDROME (NEPHROSIS)

**Nephrosis** is altered glomerular permeability apparently due to an autoimmune process or a T-lymphocyte dysfunction that results in fusion of the glomeruli membrane surfaces, which, in turn, leads to abnormal loss of protein in urine. The highest incidence is at 3 years of age, and it occurs more often in boys than in girls (Mahan, 2011).

Nephrotic syndrome occurs in three forms: (a) congenital, as an autosomal recessive disorder; (b) secondary, as a progression of glomerulonephritis or in connection with systemic diseases such as sickle-cell anemia or systemic lupus erythematosus (SLE); and (c) idiopathic (primary). The congenital form is rare; the idiopathic form is most common (Praga & Morales, 2013).

Nephrosis can be further classified according to the amount of membrane destruction: minimal change nephrotic syndrome (MCNS), focal glomerulosclerosis (FGS), and membranoproliferative glomerulonephritis (MPGN). MCNS is the type most often seen in children (80%). As the name implies, with this type, little scarring of glomeruli occurs. Both of the other types involve scarring of glomeruli, and these children will have a poorer response to therapy (Hodson & Craig, 2013).

The four characteristic symptoms of nephrotic syndrome are proteinuria, edema, hypoalbuminemia (low serum albumin level), and hyperlipidemia (increased blood lipid level) (Richardson, 2012). Proteinuria occurs because increased glomerular permeability leads to protein loss in the urine and, subsequently, hypoalbuminemia. With a low level of protein in the bloodstream, osmotic pressure causes fluid to shift from the bloodstream into interstitial tissue, causing the edema. As the blood volume decreases, the kidneys begin to conserve sodium and water, adding to the potential for edema. The hyperlipidemia occurs because the liver increases production of lipoproteins to try to compensate for protein loss. Lipids are too large to be lost in urine, so they rise to high levels in the blood serum. Some children have such high lipid levels that, when blood is drawn and placed into a test tube, a circle of white fat forms across the top. Figure 46.11 illustrates the process that leads to these usual symptoms.

**Figure 46.11** The process that results in the signs and symptoms of nephrotic syndrome.

### Assessment

Symptoms invariably begin insidiously. Edema tends to be dependent or occur in the lower parts of the body. Children develop swelling around the eyes (periorbital edema) upon waking in the morning after sleeping with their head flat on a bed. Parents may notice that clothing no longer fits a child around the waist because edematous fluid is beginning to collect in the abdominal cavity (ascites). It is easy for parents to dismiss these first symptoms as those of an upper respiratory tract infection and the normal “paunchy” belly of a toddler or preschooler. As edema progresses, however, the child’s skin becomes pale, stretched, and taut. In boys, scrotal edema becomes extremely marked. Ascites may become so extensive that the resultant pressure on the stomach and intestine leads to anorexia, vomiting, or diarrhea. Because of poor nutrition, the child’s growth may decline, and the child may become malnourished, yet the child will appear deceptively obese because of the extensive abdominal edema. When the abdominal ascites presses against the diaphragm, children may develop difficulty breathing. Parents report that children are irritable and fussy, probably from the feeling of abdominal fullness and generalized edema (Fig. 46.12). In addition, an increased risk for clotting can occur from the decreased intravascular fluid volume.

**Figure 46.12** A young child with edema of the face and abdomen due to nephrotic syndrome. (From Salimpour, R. R., Salimpour, P., & Salimpour, P. [2013]. *Photographic atlas of pediatric disorders and diagnosis*. Philadelphia, PA: Lippincott Williams & Wilkins.)

Laboratory studies will reveal marked proteinuria. A single test will show a 1+ to 4+ protein; a 24-hour total urine test will show up to 15 g of protein (normally, urine contains no protein). The protein loss with nephrotic syndrome is almost entirely albumin, differentiating it from the proteinuria of glomerulonephritis, in which protein loss tends to be nonspecific. Some children with nephrotic syndrome exhibit hematuria at the onset, but it is minimal in contrast to that seen with acute glomerulonephritis. The erythrocyte sedimentation rate (demonstrating the inflammation of the glomeruli membrane) is elevated. Features of acute glomerulonephritis and nephrotic syndrome are compared in [Table 46.3](#). An MRI or renal biopsy may be done to determine whether there is scarring of the glomerular membrane and to document the type of nephrotic syndrome present.

**TABLE 46.3 COMPARISON OF FEATURES OF ACUTE**

## GLOMERULONEPHRITIS AND NEPHROTIC SYNDROME

Factor	Acute Glomerulonephritis	Nephrotic Syndrome
Cause	Immune reaction to group A beta-hemolytic streptococcal infection	Idiopathic or an autoimmune process or a congenital inherited type
Onset	Abrupt	Insidious
Hematuria	Profuse	Rare
Edema	Mild	Extreme
Hypertension	Marked	Mild
Hyperlipidemia	Rare or mild	Marked
Peak age frequency	5–10 years	2–3 years
Interventions	Limited activity; antihypertensives as needed; symptomatic therapy for congestive heart failure	Corticosteroid and cyclophosphamide administration; possibly diuretic and potassium supplements
Diet	Normal for age	Normal for age with some salt restriction
Prevention	Prevention or thorough treatment of group A beta-hemolytic streptococcal infections	None known

### Therapeutic Management

Therapy for nephrotic syndrome is directed toward reducing the proteinuria and subsequent edema. This is typically achieved through a course of corticosteroids, such as IV methylprednisolone or oral prednisone, and keeping the child free of infection while the immune system is suppressed by these drugs. An initial dose of prednisone is given until diuresis without protein loss is accomplished; the dosage is then reduced for maintenance and continued for as long as 1 to 2 months.

Instruct parents to test the first urine specimen of the day for protein with a chemical reagent strip and keep an accurate chart showing the pattern of protein loss. Approximately once a week, parents are usually asked to collect a 24-hour urine specimen so total protein loss can be measured.

After an initial 4 weeks of therapy, prednisone is generally given every other day rather than every day. This is because prednisone has the potential to halt growth and to suppress adrenal gland secretion, side effects which can be reduced if the drug is given on alternate days, resulting in less alteration of adrenal steroid production (Karch, 2013). Parents may need to be assured that alternate-day therapy is best to keep them

from changing the schedule to every day or giving twice the calculated dose by adding extra tablets on alternate days as an attempt to make their child well sooner. Prednisone tastes bitter, so parents may welcome suggestions regarding how to disguise the taste, such as by mixing it with applesauce or flavored syrup.

Be certain that both the parents and the child are aware long-term administration of prednisone will cause a cushingoid appearance or a “moon face,” extra fat at the base of the neck, and increased body hair. Be certain also that parents know to plan ahead for pharmacy refills so prednisone therapy is not stopped abruptly because an abrupt stop can lead to adrenal insufficiency.

Diuretics are not commonly used to reduce the edema of nephrosis because they tend to decrease blood volume, which is already decreased, possibly leading to acute renal failure. Children who respond poorly to prednisone alone, however, may need diuretic therapy with a drug such as furosemide (Lasix) to initiate more kidney function. When children are taking furosemide for extended periods, there is always a danger that too much potassium will be excreted, causing hypokalemia. Children on long-term diuretic therapy, therefore, usually need frequent blood studies to determine that their electrolyte levels, especially potassium, are adequate. They may need supplemental potassium and should eat foods high in potassium such as bananas and milk. IV albumin may be administered to temporarily correct hypoalbuminemia. This causes edema to lessen because, as the serum albumin level rises, fluid shifts from subcutaneous spaces into the bloodstream. If the child is then administered a rapid-acting diuretic, the extra fluid in the bloodstream will be removed as urine. It's important that the diuretic be administered after the albumin infusion or the child could develop a fluid overload and, subsequently, heart failure.

Some children are prednisone-resistant or do not respond to corticosteroid therapy. With these children, a course of a cytotoxic agent, such as cyclophosphamide (Cytosan) or cyclosporine (Sandimmune), or a stronger immunosuppressant agent, such as mycophenolate mofetil, may be effective in reducing symptoms or preventing further relapses of the disease ([Banaszak & Banaszak, 2012](#)). It is important to ensure children take in an adequate fluid intake with these drugs to prevent bladder irritation and bleeding. Cyclophosphamide is also used in chemotherapy for malignancy (see [Chapter 53](#)), so be certain parents are not misled into believing their child has cancer because their child is receiving a chemotherapeutic drug.

The prognosis for children with nephrotic syndrome varies. Almost all children with MCNS respond initially to steroid therapy and remain free of the disease. Those with FGS and MPGN types tend to have relapses at frequent or infrequent intervals over the next several years. Children who have frequent relapses this way have a relatively poorer chance of ever being free of the disorder, and many will require renal transplant later in life. All children and families need and deserve emotional support while the disease runs a long-term course.

***QSEN Checkpoint Question 46.4***

## SAFETY

Carey is subsequently diagnosed with nephrotic syndrome. The nurse determines which action is best to provide patient education for the grandmother?

- Caution her grandmother to not feed her foods high in salt because salt irritates glomeruli.
- Encourage her to walk to school daily for exercise.
- Teach her grandmother to test Carey's urine for protein using a dipstick.
- Teach her grandmother how to take Carey's tympanic temperature daily.

Look in *Appendix A* for the best answer and rationale.

## Nursing Diagnoses and Related Interventions

Nursing interventions with nephrotic syndrome center on diminishing symptoms such as edema and proteinuria.

**Nursing Diagnosis:** Imbalanced nutrition, less than body requirements, related to poor appetite, restricted diet, and protein loss

**Outcome Evaluation:** Child follows normal growth curve on standard growth chart.

With nephrosis, a good protein intake is necessary to offset protein loss. A good potassium intake through consumption of fruits and fruit juices, particularly bananas, is necessary to maintain sufficient serum potassium levels, if the child is receiving a potassium-losing diuretic (Table 46.4). Although important, eating sufficient protein may be difficult because abdominal ascites can lead to a poor appetite. During acute phases of the disease, fluid or sodium may be temporarily restricted. If this is so, most children are happiest with many small glasses of fluid spaced throughout the day rather than several large drinks. It may help to make a chart showing the amount of fluid a child can drink each day. As fluid is given, color in a portion of the chart corresponding to the amount given to allow the child to tell from the uncolored portion how much more fluid is allowed that day, a much easier method for toddlers and preschoolers (the age group usually affected by this disease) to understand rather than hearing fluid measured in milliliters or even glassfuls.

**TABLE 46.4 FOODS HIGH IN POTASSIUM**

Food Group	Examples
Fruits	Bananas, peaches, prunes, raisins, oranges, orange juice
Vegetables	Carrots, celery, lima beans, potatoes, collards, dandelion greens, spinach

Protein	Nuts, peanuts, red meat
Dairy products	Milk, whole or skim; low-sodium milk products
Miscellaneous	Salt substitutes, chocolate and cocoa, bran

Children need to be weighed daily to detect if fluid accumulation is continuing (caution parents to use the same scale with the child in the same clothing and measure at the same time of day for best accuracy). Review with them how to measure intake and output as well. If the child is hospitalized, taking pulse rate and blood pressure every 4 hours will help detect hypovolemia from excessive fluid shifts to interstitial tissue.

**Nursing Diagnosis:** Risk for impaired skin integrity related to edema

**Outcome Evaluation:** Child’s skin is intact without erythema.

Edematous skin tends to break down easily, so children with nephrotic syndrome need frequent position changes while in bed. Check clothing to make certain an elastic band at the waist of pajamas or other constricting parts is not too tight. Place soft gauze between skin surfaces, especially around the scrotum, to help prevent skin irritation. Remember edematous tissue does not heal well, so breaks in the skin can easily become secondarily infected. Change frequently the diapers of children who are not toilet-trained and thoroughly clean their skin with each change to prevent skin breakdown and infection in the diaper area. Because medications are poorly absorbed from edematous skin areas, keep intramuscular or subcutaneous injections to a minimum. Advocate for oral medication if at all possible (see [Box 46.6](#), an interprofessional care map illustrating both nursing and team planning for a child with nephrotic syndrome).

## BOX 46.6

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR A CHILD WITH NEPHROTIC SYNDROME

Carey is a 4-year-old girl admitted to the hospital with nephrotic syndrome. Her grandmother asks you, “Could this have happened because she drank part of a beer I left on the coffee table?”

**Family Assessment:** Child lives with grandparents in a trailer park while mother is incarcerated on a drug charge. Grandparents are both retired. Grandfather rates finances as, “Okay. I saved some money, and we both get Social Security.”

**Patient Assessment:** Child began “gaining weight” and becoming irritable a week ago. Yesterday, her face appeared “very puffy.” Appetite has declined sharply in last

2 weeks. States she's "always full." Marked dependent edema (4+ over tibia) present. Urine tested and found to be 4+ for protein.

**Nursing Diagnosis:** Excess fluid volume related to decreased kidney function and fluid accumulation

**Outcome Criteria:** Child's edema decreases; urine proteinuria is less than 2+.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess whether child is able to carry out routine activities with extensive ascites or edema.	Review with grandparents advantage of allowing child to continue usual activities.	Child's mobility may interfere with physical tasks; other children may make fun of her.	Child and grandparents state that child is able to continue with usual activities; will report bullying.
<i>Teamwork and Collaboration</i>				
Nurse/primary care provider	Assess whether grandparents have legal guardianship for child and can give permission for health care.	Contact renal service to evaluate whether child should be admitted to service for evaluation.	Nephrotic syndrome is a chronic disorder that requires conscientious, specialized health supervision.	Grandparents state they have legal guardianship; renal service personnel meet with child and grandparents for consultation.
<i>Procedures/Medications for Quality Improvement</i>				
Nurse	Assess if child has experience with oral medication; if grandparents will be able to do dipstick urine testing and 24-hour urine collection.	Administer oral prednisone as prescribed. Review techniques for dipstick urine testing and urine collection.	Prednisone, a corticosteroid, reduces immune response and proteinuria. Urine testing measures extent of protein loss.	Child accepts oral prednisone. Grandparents demonstrate technique of urine testing and urine collection.

*Nutrition*

Nurse/nutritionist	Assess child's food intake for last 24 hours.	Suggest ways grandmother can include all food groups in child's diet even though child takes in a reduced amount.	Ascites crowds stomach, so it can give a feeling of fullness and cause undernutrition.	Child describes yesterday's intake; grandmother voices intent to devise a way to ensure child's intake remains nutritious.
--------------------	---	---	--	--

*Patient-Centered Care*

Nurse	Assess grandparents' knowledge about kidney function and kidney disease.	Teach grandparents about kidney function and disease process as needed.	Understanding disease process can help grandparents to better carry out therapy.	Grandparents state they understand why edema has occurred and describe action of medicine to reverse this.
-------	--	---	--	--

*Psychosocial/Spiritual/Emotional Needs*

Nurse	Assess whether grandparents are having childrearing concerns.	Review natural inquisitiveness of preschool children, which can lead them into unsafe areas.	Grandparent states she didn't supervise child well so child drank beer off coffee table.	Grandparent states that although caring for a preschooler is difficult, she feels adequate to give care.
-------	---	--	--	--

*Informatics for Seamless Healthcare Planning*

Nurse	Assess if grandparents have transportation to return for follow-up appointment.	Schedule return appointment for 1 week at kidney clinic.	Because nephrotic syndrome is a long-term disorder, child will need continued follow-up for months to	Grandparents state they are aware of long-term nature of disorder and will keep follow-up appointments.
-------	---	--	---	---

come.

Children are generally more comfortable if they sleep with their head elevated in a semi-Fowler's position rather than a supine or prone position because this reduces periorbital edema. If children do sleep in a head-flat position, edema can be so severe in the morning, their eyes are swollen completely shut or their tongues are so swollen that they cannot speak. Suggest ways parents can provide a semi-Fowler's position at home, such as by placing extra pillows on the child's bed or slipping a cardboard box under the head of the mattress to raise that end of the mattress.

### *What If... 46.3*

A nurse needs to give an intramuscular injection to Carey, who has extensive dependent edema from nephrotic syndrome. Would it be best to inject into a thigh or deltoid muscle? Why?

## **HENOCH–SCHÖNLEIN SYNDROME NEPHRITIS**

Henoch–Schönlein purpura is discussed in [Chapter 44](#). Approximately one quarter of the children who develop this type of purpura develop renal disease as a secondary complication. The renal involvement becomes apparent within a few days after the manifestations of purpuric symptoms. Children will show either urinary abnormalities such as proteinuria or a rapidly progressing glomerulonephritis. Most children recover completely. A few will develop chronic symptoms and long-term kidney disease ([Jauhola, Ronkainen, Koskimies, et al., 2012](#)).

## **SYSTEMIC LUPUS ERYTHEMATOSUS**

SLE is an autoimmune disease in which, when autoantibodies and antigens meet, they cause deposits of complement in the kidney glomerulus (see [Chapter 20](#)). As a result, some children with SLE develop symptoms of acute or chronic glomerulonephritis; glomerulonephritis or heart disease is the ultimate cause of death in many adults with SLE ([Lateef & Petri, 2012](#)). Therapy with corticosteroids or cytotoxic agents may be effective to stop the renal destruction. If kidney transplantation is required, the transplant should be successful because the same damage rarely occurs in the transplanted kidney.

## **HEMOLYTIC-UREMIC SYNDROME**

With hemolytic-uremic syndrome, the lining of glomerular arterioles becomes inflamed, swollen, and occluded with particles of platelets and fibrin. The child's red blood cells and platelets become damaged as they flow through the partially occluded blood vessels. As the damaged cells reach the spleen, they are destroyed by the spleen and

removed from circulation, leading to a hemolytic anemia.

Ninety percent of children who develop this syndrome have recently experienced an *E. coli* gastrointestinal infection from a source such as undercooked hamburger (*E. coli* is found in the intestine of beef cattle). Whether to treat *E. coli* infections with antibiotics is controversial because some children who have their initial *E. coli* infection treated with an antibiotic appear to have a more serious form of anemia than those not treated (Geerdes-Fenge, Löbermann, Nürnberg, et al., 2013).

### Assessment

The syndrome occurs most often during the summer months and in children 6 months to 4 years of age. Children usually develop only a transient diarrhea from the *E. coli* infection, although this can progress to severe fluid loss and bowel wall necrosis. Fever may become so elevated that the child experiences stupor and hallucinations. Oliguria accompanied by proteinuria, hematuria, and urinary casts in urine follows. The oliguria will lead to increased serum creatinine and BUN and extensive edema. Children appear pale from anemia; easy bruising or petechiae may be present from *thrombocytopenia* (reduced platelet level). Laboratory studies will show fibrin split products in the serum as the fibrin deposits in glomerular vessels are degraded. Thrombocytopenia will be present because platelets are damaged by the irregular blood vessels.

### Therapeutic Management

The child needs renal replacement therapy (supportive therapy) to maintain kidney and heart function. The extreme oliguria can be treated with peritoneal dialysis; anemia can be corrected by careful transfusion of packed red cells.

Ensure that parents understand the importance of follow-up care and have an appointment for this. Help them begin to view the child as well again so they do not continue to shelter the child unnecessarily but allow for normal growth and development.

Despite the extent of the illness, most infants with hemolytic-uremic syndrome recover completely. Some children, however, die of the acute illness or continue to have chronic renal involvement.

## ACUTE RENAL FAILURE

Renal failure occurs in either an acute or chronic form. The acute form most often occurs because of a sudden body insult, such as severe dehydration. The chronic form results from extensive kidney disease, such as hemolytic-uremic syndrome or glomerulonephritis (Lum, 2012).

Other causes of acute renal failure include prolonged anesthesia, hemorrhage, shock, severe diarrhea, or sudden traumatic injury. It also can occur in children who are placed on cardiopulmonary bypass while undergoing heart surgery, who receive common antibiotics (aminoglycosides, penicillin, cephalosporins, and sulfonamides), who

swallow a poison such as arsenic (found in rat poison), or who are exposed to industrial wastes such as mercury. All of these conditions appear to lead to renal ischemia, which ultimately leads to acute renal failure.

## Assessment

One of the first symptoms noted with acute renal failure is *oliguria*, a urine output of less than 1 ml/kg of the child's body weight per hour. An indwelling urinary catheter may be inserted to rule out the possibility that urinary retention in the bladder, rather than kidney dysfunction, is causing the severe oliguria.

Both **azotemia** (accumulation of nitrogen waste from the breakdown of protein in the bloodstream) and *uremia* (extra accumulation of nitrogen wastes in the blood, with additional toxic symptoms such as cerebral irritation) will occur because of the oliguria. The BUN level rises progressively as renal insufficiency continues and fewer and fewer breakdown products of protein can be excreted. As the kidneys become unable to dilute or concentrate urine, the specific gravity of urine often becomes "fixed" at 1.010. A BUN level greater than 80 to 100 mg/100 ml is a toxic level and needs correction, usually by dialysis. Urine creatinine is another measure that can be used as an indicator of function because it is normally excreted at a uniform rate. A rate of less than 10 mg/100 ml indicates severe renal failure.

*Hyperkalemia* (elevated potassium level), manifested by a weak, irregular pulse, abdominal cramps, lowered blood pressure, and muscle weakness, begins to occur as potassium can no longer be excreted. Acidosis will follow shortly from the inability of H<sup>+</sup> ions to be excreted. As the total output decreases, phosphorus levels rise in the bloodstream. A high serum phosphorus level leads to a low calcium serum level because phosphorus and calcium have an inverse proportional relationship. Severe hypocalcemia leads to muscle twitching and seizures (*tetany*); chronic hypocalcemia leads to withdrawal of calcium from bones (*osteodystrophy*) (Wesseling-Perry, 2013).

An IVP, MRI, or radioactive uptake scan is used to substantiate the lack of kidney function. Parents and children need support for this type of study because the results may be disappointing and so different from what they hoped they would be.

## Therapeutic Management

Because acute renal failure is a reaction to body stress caused by acute disease or insult, attempts to treat it focus on supporting the child's body systems while correcting the underlying condition. If the child is dehydrated (as with diarrhea or hemorrhage), IV fluid is needed to replace plasma volume. Administer such fluid slowly, however, to avoid heart failure because extra fluid cannot be removed by the nonfunctioning kidneys. Be certain the fluid prescribed does not contain potassium until it is established that kidney function is adequate; otherwise, the buildup of potassium could cause heart block. Potassium levels greater than 6 mEq/L are corrected by the IV administration of calcium gluconate (as the glucose moves into cells, it carries potassium with it), by the

oral administration of a cation exchange resin such as sodium polystyrene (Kayexalate), or by dialysis. Administering sodium bicarbonate is another method for causing a shift of potassium from the bloodstream into cells, temporarily reducing the circulating potassium level. Administration of a combination of IV glucose and insulin may also be effective (insulin helps glucose move into cells and potassium is carried with it).

A diuretic such as furosemide (Lasix) may be prescribed in an attempt to increase urine production. The child's diet should be low in protein, potassium, and sodium and high in carbohydrate to supply enough calories for metabolism yet limit urea production and control serum potassium levels. Oral fluid intake may be limited to prevent heart failure due to accumulating fluid that cannot be excreted. Weigh children daily (same scale, same clothing, same time of day) and maintain accurate intake and output recordings to help evaluate fluid status. If children are so ill they cannot eat, total parenteral nutrition may be necessary. Again, regulate amounts carefully to prevent fluid overload (see [Chapter 37](#) for administration techniques).

When recovery from acute renal failure begins, children generally have a degree of diuresis as the extra fluid accumulated by the body begins to clear. It's important that this increase in urine production is noted because children may need additional fluid intake at this point to prevent hypovolemia, which could lead once more to renal failure. Being told their child has acute renal failure is a harrowing time for parents. They usually remain anxious for an extended period after an episode of acute renal failure because they fear that the restoration of kidney function is only temporary. Reassure them that urine output is remaining at a normal level so they can relax and interact effectively with their child.

## **CHRONIC KIDNEY DISEASE (END-STAGE KIDNEY DISEASE)**

Chronic renal failure results from developmental abnormalities, when acute failure becomes long term, or when chronic kidney disease has caused extensive nephron destruction ([Braun, Sood, Hogue, et al., 2012](#)). The nephrons that are not destroyed appear to function as usual; they simply are inadequate in number to sustain kidney function. Beginning approximately when 50% of nephrons are destroyed, kidney function diminishes by degree until the child develops end-stage kidney disease (the point when kidneys can no longer effectively evacuate waste products from the body).

### **Assessment**

With loss of nephron function, the ability to concentrate urine halts, resulting in polyuria, possibly manifested as enuresis. The few functioning nephrons present cannot reabsorb enough sodium to maintain a functioning serum level of body fluid, so dehydration occurs. As additional nephrons are lost, the polyuria decreases, and oliguria and anuria occur. Inability to excrete H<sup>+</sup> ions leads to acidosis. Hypocalcemia and hyperphosphatemia occur from the kidney's inability to excrete phosphate. Osteodystrophy occurs as calcium is withdrawn from bones to compensate for the low

level of calcium. In addition, because kidneys are responsible for synthesizing vitamin D to its active form, vitamin D cannot be produced. Without this, calcium cannot be absorbed from the gastrointestinal tract and deposited in bones. Bones become so calcium depleted that growth halts and the bones lose strength (renal rickets).

Erythropoietin, formed by the kidneys, stimulates red cell production. With decreased erythropoietin production, anemia develops. Pruritus may be present from skin irritation due to excretion of nitrogenous wastes. These changes are summarized in Figure 46.13.

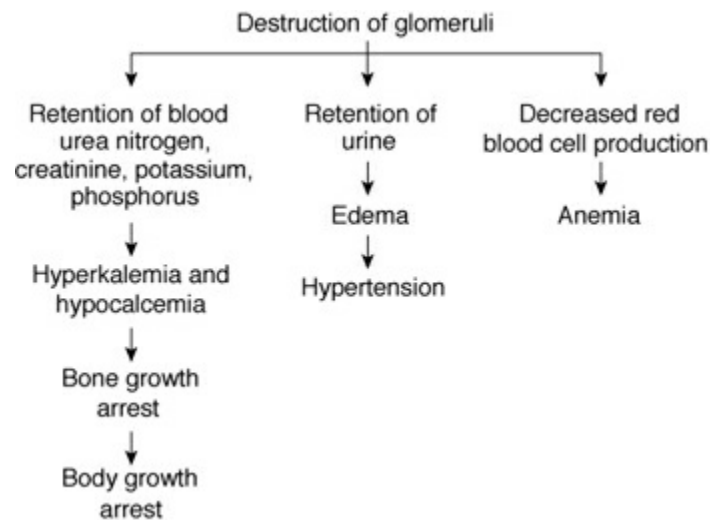

Figure 46.13 Pathology of chronic renal failure.

### Therapeutic Management

Children with chronic renal failure are generally placed on a low-protein, low-phosphorus, low-potassium diet to prevent rapid urea and phosphate buildup. Children may be prescribed aluminum hydroxide gel to take with meals to bind phosphorus in the intestines and prevent absorption. Milk usually is not given because it is high in sodium, potassium, and phosphate—electrolytes children may have difficulty clearing. Meat is restricted, and even beans are high enough in protein to be eliminated, making this a difficult diet for children to follow over an extended period. Letting children have some choice about what foods they eat each day helps to promote adjustment to such a restricted diet. Whoever will be preparing meals at home needs good instructions on selecting low-protein foods. Low-electrolyte, low-protein formulas are commercially available for infants with renal failure.

Total daily fluid intake may need to be restricted, although restriction should be as minimal as possible, or it can present an area of tremendous conflict between the child and parents. Many children need sodium intake restricted, and others need a normal sodium intake (but no excessively salty foods such as lunch meats, potato chips, or pretzels). In contrast, other children may actually need additional salt because, due to poor tubular reabsorption, they dump sodium in urine. Low-sodium formulas such as Lonalac are recommended for children with heart failure who need a low-sodium

intake. These must be used cautiously in children with renal insufficiency, however, because their high-potassium content can lead to toxic potassium blood levels. Diuretics may be prescribed to help children regulate sodium and fluid levels and prevent edema.

As renal failure becomes prolonged, a child needs supplemental calcium to prevent muscle cramping, rickets, tetany, or seizures. As hypertension becomes more and more acute from the accumulating blood volume, a daily antihypertensive drug may be prescribed. Recombinant human erythropoietin to stimulate red blood cell formation or packed red cells may be needed to correct anemia. Like all fluid, administer blood transfusions cautiously so volume overload does not occur. Dialysis is the answer to effective excretion of urea while children wait for a kidney transplant to replace their nonfunctioning kidneys.

## Nursing Diagnoses and Related Interventions

Nursing diagnoses with chronic or end-stage kidney disease must address both the physical and psychological aspects of the illness and long-term care.

**Nursing Diagnosis:** Risk for interrupted family processes related to chronically ill family member

**Outcome Evaluation:** Family members express feelings about illness to each other and to healthcare providers; participate in care of ill member.

It is easy for children to become depressed because of chronic fatigue and an unappetizing diet (Tong, Henning, Wong, et al., 2013). They begin to grow poorly because of the alteration in calcium metabolism, and if they are taking corticosteroids or other immunosuppressive drugs because of glomerulonephritis, they may be angry or disheartened about their change in appearance from taller and thin to shorter and heavier. Help them stay as active as possible to discourage boredom by suggesting age-appropriate activities. Because adolescence is an age at which recreational drug use is common, ask if teenagers are using a recreational drug as a method to relieve their anxiety or boredom (Steele, Belostotsky, & Lau, 2012).

Caring for a child with chronic renal disease is time-consuming and can be financially and socially devastating for parents. Parents caring for such children at home need opportunities at periodic health assessments to voice their frustrations, fears, and anxieties. They need time to do those things important to them as individuals whether taking a weekend trip or attending an evening movie. Ask parents at clinic or follow-up visits, “Do you ever get out of the house or have the opportunity to do anything for yourself?” “What can we do for *you*?” Help of this kind ultimately improves children’s care because it improves the lives and mental attitudes of those around them.

### **INFORMATICS**

Carey's grandmother is deeply concerned that Carey will develop chronic kidney disease later in life. What findings in Carey's laboratory workup would suggest that her kidneys are failing? (Select all that apply.)

- a. She has an elevated serum phosphorus level.
- b. She is developing a normocytic anemia.
- c. Her serum vitamin D level is below normal.
- d. Her serum creatinine level is steadily falling.
- e. Her blood pressure is steadily increasing.

*Look in [Appendix A](#) for the best answer and rationale.*

## **Kidney Transplantation**

The ultimate possibility for prolonging the life of children with renal failure is kidney transplantation. With complete renal failure, children who have extensive hypertension may have their damaged kidneys removed and be placed on hemodialysis or CCPD to await kidney transplantation. Kidney removal this way is an important step for both the parents and the child because although parents realize their child's kidneys are no longer functioning, this step removes all hope that a miracle might make them function once more. Parents may ask whether it is possible to leave one of the child's kidneys because only one kidney will be transplanted (not recommended because the hypertension would continue). Be certain that parents have a thorough explanation of why hypertension is destructive and that it could lead to a cerebrovascular accident or coronary artery disease. Help them understand that their child's renal biopsy shows that, short of a miracle, their child's kidneys will not function again, and so their removal is not a loss but only recognition of a loss.

### **PREOPERATIVE CARE**

Kidney transplantation is most effective (the kidney is less likely to be rejected) if the kidney is taken from a living twin, parent, or sibling ([Butani, Troppmann, & Perez, 2013](#)). Rejection occurs at a higher incidence if a kidney comes from a cadaver or recently deceased child. Most people consider that children should be of legal age to give consent to supply a kidney for transplantation, so few children have a sibling who is eligible to donate a kidney. Transplanted kidneys are placed in the abdomen, not the usual kidney space. Transplantation of a kidney from an adult into a child who weighs less than 10 kg can be difficult because of the difference in the size of the arteries and veins, which must be matched, and because of the possibility of hypertension, excessive diuresis, and abdominal complications (from the lack of space).

Many children anticipate that the characteristics of the donor will be transmitted to

them by the kidney, so they are reluctant to accept the kidney of a family member with a character trait they do not like (perhaps a bad temper). You can assure them that transplanted organs do not transplant character traits with them.

People who are ineligible to donate a kidney include those with multiple bilateral small renal arteries, bilateral renal disease, renal infection, advanced medical illness, severe obesity, or hypertension. Although kidney removal can be done by laparoscopy, donors must understand that removal of a kidney involves major surgery. Tests kidney donors can expect to have preoperatively include human leukocyte antigen (HLA) typing, electrolyte blood analysis, complete blood count, bleeding time, urinalysis and urine culture, 24-hour urine sample for protein, a renal arteriogram, and IV pyelography. Donors will have urine samples collected after surgery to assess that their remaining kidney is capable of maintaining full function and that they are still in good health.

Before surgery, children who are to receive a transplant may be dialyzed to clear their body of excessive potassium and fluid. If the donated kidney will be from a relative, there is adequate time for thorough preoperative preparation of this type. If the donor kidney is from a cadaver, the announcement of surgery will be sudden, and time for preoperative instruction and procedures may be limited. The family should be prepared for this possibility well in advance, and teaching should occur before a cadaver kidney becomes available.

### ***QSEN Checkpoint Question 46.6***

#### **EVIDENCE-BASED PRACTICE**

When kidney disease becomes chronic, it places a great burden on caregivers' energy and finances. To investigate how parents feel about caring for a child with chronic kidney disease, researchers interviewed parents of 20 children with chronic kidney disease recruited from two pediatric hospitals. Results of the study revealed four major themes: parents had to struggle to accept the diagnosis and permanence of their child's disorder; parents found continuous caregiving stressful, exhausting, and overwhelming; spousal tension and sibling neglect occurred; and parents felt they needed support from their healthcare providers (Tong, Lowe, Sainsbury, et al., 2010). In addition, a recent first-of-its-kind meta-analysis examining caregiver stress in pediatric chronic conditions indicates that caregivers of children with chronic illness endorse greater general parenting stress than caregivers of healthy children (Cousino & Hazen, 2013).

Based on these studies, if Carey developed chronic kidney disease, which action by a nurse would be most helpful?

- a. Assure the grandmother she can call the clinic at any time if she has a concern.
- b. Ask the grandmother to keep a daily record of conversations she has with Carey.

- c. Review with the grandmother ways that Carey will require even more care in the future.
- d. Help the grandmother learn to say “no” when other family members ask her to help them.

---

*Look in [Appendix A](#) for the best answer and rationale.*

## Human Leukocyte Antigen Typing

HLAs are a group of antigens found on the surfaces of all cells with a nucleus, including blood components such as leukocytes and platelets. The name is derived from the fact they were first identified on white blood cells. Such antigens are inherited from both parents and are specific for each individual. They are carried on the short arm of chromosome 6 in each cell and denote tissue type or determine which tissue the immune system will identify as foreign tissue. They also serve as the basis for paternity typing and may cause reactions to blood product transfusions and bone marrow and organ transplants.

When two people have the same, or mostly the same, HLA antigens, they are said to be *histocompatible*. Identical twins have complete histocompatibility; family members have partial histocompatibility; any two people can have histocompatibility on at least one antigen site.

Children who are awaiting kidney transplantation are HLA typed, and this information is circulated to major medical centers. When a kidney is available for transplantation, the child’s tissue type is compared with the donor kidney, and factors such as “best match,” general condition, size of the child, and length of time the child has been on the waiting list are considered. The chance of receiving a kidney is increased today because, with new immunosuppressive drugs, even donor kidneys that are not fully matched have a chance to successfully graft.

## POSTOPERATIVE CARE

After renal transplantation, children are cared for in an environment that is as sterile as possible as they are placed on immunosuppressive therapy such as cyclosporine, azathioprine (Imuran), and methylprednisolone (Solu-Medrol), and possibly antilymphocyte globulin and antithymocyte globulin to reduce the possibility of kidney rejection. Although some transplanted kidneys begin to function immediately, hemodialysis may be continued until the implanted kidney can fully function after recovering from the initial insult of transplantation.

Children may pass through a “honeymoon” period after the transplantation or a period during which a child models perfect behavior on the belief the success of the transplant depends on good behavior rather than the condition of renal veins and arteries, the transplanted kidney, or antigen–antibody formation ([Box 46.7](#)).

BOX 46.7

## Nursing Care Planning Tips for Effective Communication

Carey's grandmother tells you Carey has "changed completely" since she became ill with acute glomerulonephritis.

*Tip:* Use therapeutic communication and ask specific follow-up questions. In the following scenario, the grandmother describes a "honeymoon" period that children may pass through after being told their kidneys are injured because they know how important kidneys are for life. Parents often need help seeing this for what it is, so they can begin to reassure children that behaving perfectly will not influence the outcome of their illness and that, because they loved them as they were, they will continue to love them regardless.

**Nurse:** Mrs. Hendricks, in what way has Carey changed?

**Mrs. Hendricks:** She used to whine all the time and constantly ask for things. Now, she entertains herself. It's like heaven.

**Nurse:** Do you think she's acting a little too perfect?

**Mrs. Hendricks:** Well, it does seem a bit strange.

**Nurse:** Do you think she feels responsible for being sick? Could she be worrying that if she misbehaves, her medicine will stop working?

**Mrs. Hendricks:** I never thought of that. I would feel better if she started to act like her old self.

Children with end-stage renal disease are usually behind in growth at the time of a transplant. Although the rate of growth will be improved after kidney transplantation, they may never reach full height, related to the already lost growth plus need for corticosteroid maintenance therapy to continue immunosuppression long term.

### Transplant Rejection

Acute transplant rejection, if it occurs, usually develops within the first 3 months after transplantation. Children begin to develop fever, proteinuria, oliguria, weight gain, hypertension, and tenderness over the kidney. Serum creatinine and BUN levels will rise. Increasing the dose of immunosuppressants may be effective in stopping this type of rejection.

Rejection may also be *chronic*, in which the transplanted kidney gradually loses function after the first 6 months. Hypertension and anemia result. An MRI or a biopsy will show vascular changes such as narrowing of arterial lumens and interstitial changes such as fibrosis and tubular atrophy. This type of rejection is difficult to halt, although it may be such a slow, steady process that it will be 2 or 3 years before the kidney actually fails. If a kidney is rejected, it is removed, and a child is returned to a program of hemodialysis. Because one kidney was rejected does not mean a second transplant will also be rejected. Unfortunately, because the number of kidneys available for transplantation is limited, kidney rejection of this type becomes an ominous sign for the

child's long-term survival.

Malignant disease is more common in transplantation recipients than in the normal population probably because of the long-term immunosuppression (Ponticelli & Graziani, 2012). The original disease for which the child underwent transplantation, such as glomerulonephritis, may also recur in the transplanted kidney. During adolescence, typically an age of poor adherence to medication regimens, monitor kidney recipients closely to be certain they are taking their immunosuppressive therapy. Parents cannot help but overprotect the child after a kidney transplant; they worry a roughhousing session with a sibling or playing a game such as baseball may injure the transplanted kidney. The child may be afraid to engage in any activity for the same reason. Ask at healthcare visits if the family needs help to return to a healthy lifestyle after this major life change.

#### *What If . . . 46.4*

**A nurse is particularly interested in exploring one of the 2020 National Health Goals regarding renal disorders of children (see Box 46.1). What would be a possible research topic pertinent to this goal that would be applicable to Carey's family and also advance evidence-based practice?**

### **KEY POINTS FOR REVIEW**

- Many urinary tract disorders, such as polycystic kidneys, urethral obstruction, and bladder exstrophy, are often evident on a prenatal ultrasound. Early identification on fetal ultrasound allows therapy to begin in utero or immediately after birth.
- Many urinary tract disorders, such as polycystic kidneys or chronic renal failure, are long-term conditions requiring years of therapy. Be certain parents are well informed about their child's condition so they can continue to participate in planning their child's care that not only meets QSEN competencies but also best meets the family's total needs.
- Congenital structural abnormalities of the urinary tract include patent urachus, exstrophy of the bladder, hypospadias, and epispadias. Surgical correction is required for all of these, but the outcome should be favorable. In the case of epispadias and exstrophy, referral to a pediatric urologist trained in these conditions through a fellowship should be facilitated to support the best possible outcome.
- UTI tends to occur more often in girls than boys. "Honeymoon cystitis" refers to a UTI occurring after the first instance of sexual intercourse. Preventing recurrent infections is important in order to prevent damage to the lining of the bladder, bacterial colonization of the bladder, and long-term renal damage.
- Vesicoureteral reflux is the backflow of urine into one or both ureters with voiding because the valve that guards the entrance to the ureters is lax or the ureters insert too low in the bladder. Surgical correction may be necessary to prevent renal

damage, but proper voiding habits, constipation management, and hydration should be emphasized because optimization of these key factors often decreases or, in some cases, abates vesicoureteral reflux.

- Kidney dysfunction can occur for structural reasons such as kidney agenesis, polycystic kidney, and renal hypoplasia, all conditions that limit kidney function.
- Acute poststreptococcal glomerulonephritis is inflammation of the glomeruli after a streptococcal infection. It is characterized by an acute episode of hematuria and proteinuria but typically runs a short-term course.
- Nephrotic syndrome is an immunologic process that results in altered glomerular permeability and can lead to a self-limiting or long-term course.
- Diminished kidney function leads to both fluid and electrolyte imbalances. Creative techniques are necessary to encourage children to continue to ingest a restricted-protein diet.
- When renal failure is either acute or chronic, peritoneal dialysis or hemodialysis may be used to remove body wastes until kidney function can be restored.
- Kidney transplantation is often the only long-term option for children with kidney failure. It requires extensive surgery and requires the child to remain on immunosuppressive therapy long term in order to prevent transplant rejection.

### CRITICAL THINKING CARE STUDY

Jamie is a 16-year-old teenager with chronic kidney disease. He lives with his mother and a younger sister, 10 years old. He's homeschooled because he has to miss 3 days of school each week for hemodialysis.

1. You notice that although Jamie is supposed to limit the amount of potassium he ingests, when offered a choice between popcorn with orange juice or raisins and milk for an afternoon snack he chose the raisins and milk. Was that his best choice?
2. Jamie appears obese because of the long-term use of immunosuppressants. You hear him brag to his girlfriend that he has lost more weight than her as part of a New Year's resolution pact. You also notice, according to Jamie's medicine reminder sheet, that he has missed taking two doses of prednisone. Would omitting taking prednisone cause him to lose weight? What could be the effect of omitting his prescribed prednisone?
3. Jamie's mother wants him to learn to drive so he can travel to the dialysis center by himself. Jamie says he can't do that because dialysis makes him feel dizzy and nauseated. Are those common symptoms of dialysis? As his dialysis nurse, what could you do to reduce his symptoms?

## Nursing Care of a Family When a Child Has a Reproductive Disorder

*Navi is a 15-year-old girl you meet in a pediatric clinic. She has a purulent vaginal discharge and burning on urination; she is diagnosed with gonorrhea. When you ask her if she is sexually active, she says no; she thinks she contracted the infection from sharing a towel in a locker room. As she leaves the clinic, you hear her tell the receptionist, "I'm glad I got this early in life. Now I won't have to worry about getting it again."*

*Previous chapters described the growth and development of well children and health concerns that occur in other body systems. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur when children develop reproductive disorders. Such information forms the basis for care and health teaching in this area.*

**What kind of health education does Navi need?**

### KEY TERMS

**amenorrhea**  
**anovulatory**  
**cryptorchidism**  
**dysmenorrhea**  
**endometriosis**  
**fibrocystic breast disease**  
**gynecomastia**  
**hydrocele**  
**intersexed**  
**menorrhagia**  
**metrorrhagia**  
**mittelschmerz**  
**orchiectomy**  
**orchiopexy**  
**pelvic inflammatory disease (PID)**

**premenstrual dysphoric disorder (PDD)**  
**sexually transmitted infection (STI)**  
**varicocele**  
**vulvovaginitis**

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe common reproductive disorders in children.
2. Identify 2020 National Health Goals related to reproductive disorders that nurses can help the nation achieve.
3. Assess a child with a reproductive disorder.
4. Formulate nursing diagnoses for a child with a reproductive disorder.
5. Establish expected outcomes for a child with a reproductive disorder that help children and parents manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care for a child with a reproductive disorder, such as teaching about normal menstruation.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of children's reproductive disorders with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

Reproductive disorders in children range from mild infections to serious anatomic malformations. All of these disorders require prompt and careful treatment so children can reach adulthood in good reproductive health, with unaltered fertility, and with a positive sense of sexuality. Reproductive infections may suggest child maltreatment, so children with these also need careful assessment to rule out this possibility (Dubowitz, 2013) (see Chapter 55). The 2020 National Health Goals related to reproductive disorders in children are highlighted in Box 47.1.

### BOX 47.1

#### Nursing Care Planning Based on 2020 National Health Goals

Because sexually transmitted infections (STIs) not only cause short-term distress as a result of painful lesions but also can have long-term implications for fertility and

future childbearing, several 2020 National Health Goals specifically address these and include:

- Reduce the proportion of adolescents with *Chlamydia trachomatis* infections seen in family planning clinics from a baseline of 7.4% to a target of 6.7%.
- Reduce the annual incidence of new cases of gonorrhea in adolescent females from a baseline of 285/100,000 cases to no more than 257/100,000 cases and in adolescent males from 220/100,000 cases to 198/100,000 cases.
- Reduce the incidence of primary syphilis in adolescent females from a baseline of 1.5/100,000 cases to no more than 1.4/100,000 cases and in adolescent males from 7.6/100,000 cases to 6.8/100,000 cases.
- Reduce the incidence of congenital syphilis from a baseline of 10.1/100,000 live births to 9.1/100,000 live births.
- Reduce the incidence of genital herpes from a baseline of 10.5% to no more than 9.5%.
- Reduce the proportion of females with human papillomavirus (HPV) infection (developmental).
- Reduce the incidence of pelvic inflammatory disease among women aged 15 through 44 years from a baseline of 3.9% to no more than 3.5% (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by educating adolescents about effective ways to prevent STIs and how to recognize the signs and symptoms of these illnesses.

### *Nursing Process Overview*

## FOR CARE OF A CHILD WITH A REPRODUCTIVE DISORDER

### **ASSESSMENT**

Assessment of reproductive health begins with the first physical examination at birth and continues at health assessments throughout childhood and adolescence. Because this is a sensitive area for many people to discuss, parents may not be as comfortable inquiring about or describing disorders of the reproductive tract as they are about discussing other areas. Unless they have clear, thorough explanations of the condition and prescribed therapy, their reluctance to pursue the subject may leave them confused or misinformed. Even young children can sense that a health problem affecting genitalia is viewed by some adults as different from other disorders and so may not ask as many questions as they do about other concerns.

### **NURSING DIAGNOSIS**

Nursing diagnoses formulated for reproductive illnesses in children focus not only on the result of the disease symptoms but also on the anxiety this type of disorder can cause. Examples of nursing diagnoses include:

- Risk for infection transmission related to lack of knowledge of safer sex

practices

- Pain related to symptoms of vaginal infection
- Disturbed body image related to fibrocystic breast disease
- Anxiety related to absence or irregularity of menstrual periods in adolescent
- Fear related to surgery on genital organs

## **OUTCOME IDENTIFICATION AND PLANNING**

An assessment of a child's knowledge about the reproductive system and ways illness can affect reproductive and sexual functioning forms the foundation for developing appropriate outcomes. Educating the child about reproductive health may be one of the first areas to plan. When establishing expected outcomes with adolescents, work with them to establish a plan that will involve them in the decision-making process.

Organizations helpful for referral to parents or adolescents include the National Women's Health Network ([www.nwhn.org](http://www.nwhn.org)), the National Adolescent and Young Adult Health Information Center ([nahic.ucsf.edu](http://nahic.ucsf.edu)), the Office of Adolescent Health ([www.hhs.gov/ash/oah/](http://www.hhs.gov/ash/oah/)), and the Centers for Disease Control and Prevention ([www.cdc.gov](http://www.cdc.gov)).

## **IMPLEMENTATION**

Interventions for children with reproductive disorders should always include education about reproductive functioning and measures for maintaining reproductive and sexual health. Health education regarding the importance of testicular self-examination for adolescent males should be stressed at healthcare visits (see [Chapter 34](#)). Guidelines for teaching about menstrual health and safer sex to protect against unintended pregnancy or sexually transmitted infections (STIs) (covered in [Chapter 5](#)) are also important.

Essential nursing interventions also include supporting parents and children through difficult decisions about procedures and providing close observation and empathic counseling after surgery. For example, surgery for undescended testes is a procedure that can be traumatic for a child, especially if it is performed during a developmental stage in which a boy views such surgery as castrating (a psychological reason in addition to a physical reason as to why it is done early in life). As all children with any reproductive disorder reach puberty, they need honest explanations about any effect such a condition will have on interpersonal relationships, sexual functioning, or childbearing.

## **OUTCOME EVALUATION**

The responses of children to reproductive dysfunction vary both with the severity of the condition and with the specific age and fears of the child. It is safe to assume, however, that children who have experienced such a health problem are at risk for a loss of self-esteem or confusion about their body image. Therefore, outcome evaluation should include a long-term evaluation of the child's coping abilities and self-image. If a child contracts an STI, the evaluation should also address the child's knowledge about avoiding STIs in the future and willingness to seek help should an

infection recur.

The following are examples suggesting achievement of outcomes:

- Adolescent states discomfort from vaginal infection is tolerable after beginning medication.
- Adolescent states she is able to view self as competent despite fibrocystic breast disease.
- Child states that she is able to wait 6 months without worrying about not yet beginning her menstrual periods.
- Child states he feels less fearful about impending surgery after talking with his healthcare provider.

## Assessing Reproductive Disorders in Children

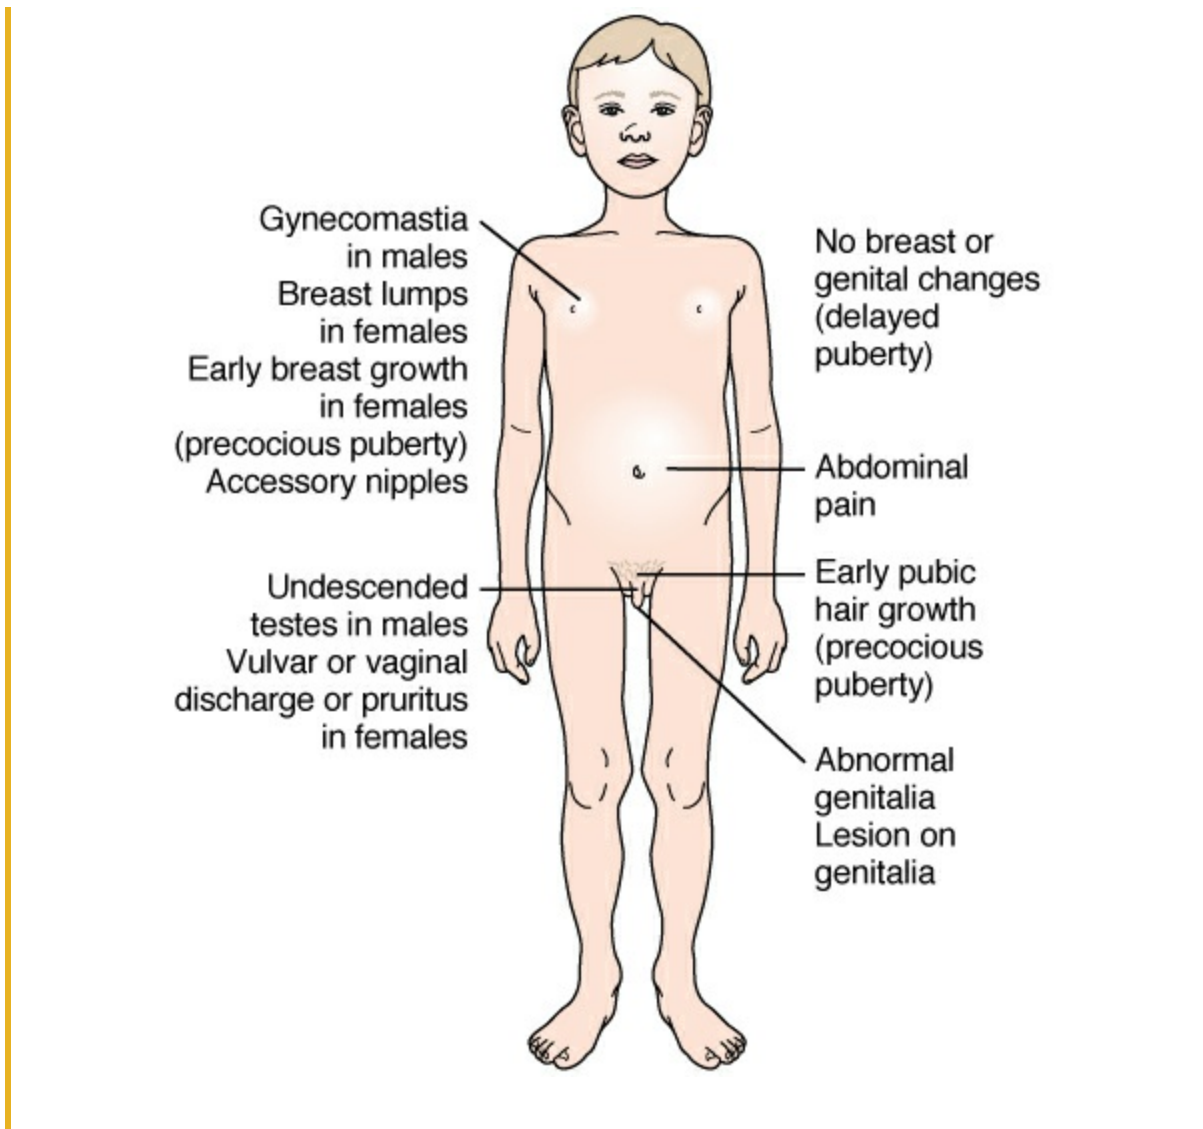

Reproductive disorders in children may be congenital or acquired, so assessments for these must be ongoing throughout childhood ([Box 47.2](#)).

BOX 47.2

### Nursing Care Planning Using Assessment

#### ASSESSING A CHILD WITH A REPRODUCTIVE DISORDER

As with other parts of a health interview, questions regarding reproductive health are generally addressed to the parents until the child is able to answer history questions reliably and independently. Once a girl has reached adolescence, a gynecologic history (Box 47.3) should be included in the health assessment. To preserve their privacy, adolescents of both genders may prefer to not be accompanied by a parent during a physical examination for a reproductive disorder. It is also appropriate to ask the parent to step out of the room during the assessment; however, the parent has to leave willingly and cannot be made to leave.

### BOX 47.3

#### Taking a Gynecologic History

When assessing an adolescent for a gynecologic health history, be especially conscious of an adolescent's sense of modesty and need for privacy.

#### MENSTRUAL HISTORY

At what age did you begin menstruating? When was your last menstrual period?  
How often do your menstrual periods occur? How long do they usually last?  
What is the amount of menstrual flow? (Document by number of pads or tampons used.)

Do you experience discomfort? (Document if discomfort occurs on first day or all days and action taken to relieve it.)

Do any sisters or your mother have discomfort or pain during their menstrual periods (endometriosis is familial)?

Do you experience any symptoms of irritability, moodiness, headache, or diarrhea (premenstrual dysphoric disorder) 1 or 2 days before menses?

#### **REPRODUCTIVE TRACT HISTORY**

Have you or do you have a vaginal discharge? (Document amount and whether pad is necessary; include duration, frequency, description, associated symptoms, and actions taken.)

Is there vaginal itching (pruritus)? Or vaginal odor?

Have you had reproductive tract surgery? Have you ever been pregnant? Have you ever had an abortion or miscarriage?

#### **SEXUAL HISTORY**

Are you currently sexually active (oral or vaginal)? What is the gender of your partner?

Have you had a sexually transmitted infection such as herpes, gonorrhea, or syphilis?

Do you experience any discomfort during sexual activity (dyspareunia) or any spotting afterward (postcoital spotting)?

Do you have any concerns about frequency, position, or partner's satisfaction with coitus? Do you experience orgasm?

#### **CONTRACEPTION HISTORY**

Do you use any type of birth control? If so, what contraceptive do you use? (Document length of time used, satisfaction, and any problems.)

#### **BREAST HEALTH**

Have you ever noticed any abnormality such as a lump, discharge, or pain in your breasts?

Have you ever had breast surgery?

Have you breastfed a child?

Do you have a yearly breast examination by a healthcare provider?

Adolescents who are worried that they may have contracted a sexually transmitted infection or suspect they have become pregnant often visit healthcare facilities without parents. Before they can admit this chief concern, however, they may “test” a healthcare provider by eliciting a reaction to a minor problem. Be aware that an adolescent who consults a healthcare provider with a seemingly minor concern may be simply misinterpreting symptoms, and the adolescent actually may be seeking help for another problem. Asking the adolescent “Is there anything else that worries you? Is there any

other way we can help you today?” may help you elicit the adolescent’s primary concern (Box 47.4).

#### BOX 47.4

### Nursing Care Planning Tips for Effective Communication

Navi, age 15 years, is seen at your pediatric clinic. She has mild symptoms of an upper respiratory tract infection.

*Tip:* Adolescents can have difficulty discussing symptoms of a reproductive tract infection. In this scenario, an adolescent tries to obtain an antibiotic by describing respiratory or abdominal symptoms. Be alert to this possibility to aid in recognizing a “growing” history of this type.

**Nurse:** Navi? Doctor Jensen doesn’t believe you need anything for your cold. Just drink a little extra fluid and take it easy for a couple days.

**Navi:** Don’t I need a prescription? Some penicillin or something?

**Nurse:** No. Colds are caused by viruses. Penicillin isn’t necessary.

**Navi:** I want to be sure I get over this. I’d really like an antibiotic of some kind.

**Nurse:** One really isn’t necessary.

**Navi:** I have a bad cough. I don’t think I mentioned that.

**Nurse:** Doctor Jensen listened to your chest. You don’t have anything serious there.

**Navi:** My stomach doesn’t feel very good either. Can’t I have something?

**Nurse:** It seems you’re having more symptoms than you originally mentioned. Are you worried about something other than cold symptoms?

**Navi:** Well, I have this rash and . . .

**Nurse:** And . . . ?

**Navi:** I’m scared I might have a sex disease.

A pelvic examination is unnecessary for girls who have not yet reached adolescence. However, if vaginal walls need to be inspected (because of an inflammation, infection, or the suspicion of sexual maltreatment), an otoscope and ear tip can be used in place of a speculum. Cotton-tipped applicators can be used to take culture specimens without causing discomfort.

For adolescent girls, a pelvic examination should become part of routine health care around the age of 18 to 20 years or at the point when she becomes sexually active. Because the first pelvic examination can be stressful, spend time with the girl before the procedure to teach her about what is being assessed. A three-dimensional model of internal organs and some representative instruments may be more useful when describing the examination than a verbal description of anatomy.

Healthcare facilities should have a small speculum for examining young girls. For their comfort, warm the speculum first. Let the girl look at and handle a speculum

before one is used. Remember that different cultures have different attitudes toward reproductive disorders. Adolescents from Middle Eastern countries, for example, are extremely modest, and so may be extremely uncomfortable having pelvic examinations. Girls from these countries may be more comfortable if the examiner is a woman. Remaining beside an adolescent as a support person also helps to reduce the stress the teen may be experiencing. To protect her self-esteem, be sure she meets the person who will examine her before she is placed in a lithotomy position.

If a young adolescent is uncomfortable in a lithotomy position, she can be examined in a dorsal recumbent position instead (see [Chapter 11](#) for information on assisting with a pelvic examination). Allow an adolescent to choose whether she wants a parent to remain in the room with her.

## Health Promotion and Risk Management

Newborns need a thorough examination at birth to rule out congenital reproductive disorders so these can be diagnosed and management can begin. All children need education about how to make sexually healthy decisions and how to care for their bodies ([Bakke, 2016](#)). Adolescents may state they are not interested in this information because they are choosing abstinence. It is still important to provide the education with regard to making sexually healthy decisions and reward positive choices for staying healthy. School-health nurses are located in high schools and are considered effective at delivering preventive reproductive health education to adolescents ([Smith & Stepanov, 2014](#)).

## Disorders Caused by Altered Reproductive Development

Sex chromosomes (XX or XY) develop at conception. However, development of the reproductive system, including external genitalia, occurs over two distinct periods. Reproductive organs and genitalia begin to differentiate in utero by the eighth week, with growth and refinement occurring over the next several months. A second phase occurs with specific endocrine changes triggered during puberty and is the period of maturation of primary and secondary sexual characteristics.

Ambiguous genitalia, a rare condition that occurs during fetal development, is an example of a first-stage disorder; precocious puberty or delayed puberty are examples of second-phase disorders.

### AMBIGUOUS GENITALIA

Ambiguous genitalia refers to genitalia that are not defined as male or female and the presence or absence of gonadal tissue is unknown ([Lathrop, Cheney, & Hayman, 2014](#)). Although external sexual structures generally follow from the presence of the XX or XY chromosomes, a diagnosis of ambiguous genitalia means external sexual organs in the child did not follow this normal course of development, so that, at birth, they are so

incompletely or abnormally formed that it is impossible to clearly determine the child's gender by simple observation. For instance, a male infant with *hypospadias* (urethral opening on the underside of the penis) and cryptorchidism (undescended testes) may appear more female than male on first inspection (see [Chapter 46](#) for a discussion of hypospadias).

A female fetus can become “masculinized” if exposed to androgen in utero. The most common cause of this is *congenital adrenocortical syndrome*. The adrenal gland produces androgen instead of adequate cortisone, causing the clitoris to become the size of a typical newborn male's penis ([Marcdante & Kliegman, 2015c](#)) (see [Chapter 48](#)).

If testosterone was produced in utero but development of the müllerian duct (female) was not suppressed, a child may be **intersexed** (formerly termed *hermaphrodite*), with both ovaries and testes and either male or female external genitalia. Children with ambiguous genitalia are often termed *pseudointersexed* because, as infants, they have some external features of both sexes, although only either ovaries or testes (or neither) are present.

### Assessment

If there is any question about a child's gender, karyotyping or a DNA analysis establishes whether the child is genetically male or female (see [Chapter 8](#)). *Laparoscopy* (introduction of a narrow laparoscope into the abdominal cavity through a half-inch incision under the umbilicus) or possibly exploratory surgery may be necessary to determine if ovaries or undescended testes are present. Intravenous pyelography or ultrasound can be used to establish whether a complete urinary tract is present.

### Therapeutic Management

Once the child's true chromosomal gender has been documented by chromosome or DNA analysis, the extent of necessary reconstructive surgery is determined in consultation with the parents. This may involve correction of a hypospadias or cryptorchidism, removal of labial adhesions, or surgical removal of an enlarged clitoris. If removal of an enlarged clitoris seems necessary, parents must consider what the absence of this organ will mean to the girl in terms of later sexual enjoyment. Parents are well advised to delay this type of surgery until adolescence when the girl can decide for herself whether she wants this done. If a vagina will be constructed, surgery for this is usually delayed until the child is well adjusted and psychologically stable as well as when growth is complete ([Lathrop et al., 2014](#)).

If an infant is chromosomally male but does not have an adequate penis, a decision to raise the child as a female might be made, although construction of an artificial penis is more likely. Nonfunctioning ovaries or testes are generally removed to prevent malignancy later in life.

## Nursing Diagnoses and Related Interventions

The birth of a child with a perplexing disorder produces a particularly high level of stress, possibly hampering parents' ability to think calmly about their situation and make plans.

**Nursing Diagnosis:** Anxiety related to ambiguous gender of child at birth

**Outcome Evaluation:** Parents voice willingness to support treatment plan, including additional necessary tests, and state they are prepared to make decisions with guidance from healthcare team.

If the gender of a child is unclear, the parents should be told this immediately. If first told their child is a boy, only to be told 24 hours later that the child is chromosomally a girl, then parents may find this difficult to accept. During this period when the baby's gender is yet to be determined, avoid calling the baby "it." Rather, say "the baby" or "your child." Explain how sexual organs form in utero and that every child has the potential to be externally female or male.

To promote bonding, help parents understand that their child is otherwise perfect (assuming this is true). As the child grows, additional counseling may be needed for both the parents and the child to provide education about the full meaning of the congenital disorder.

## PRECOCIOUS PUBERTY

Although precocious puberty (the development of breasts or pubic hair before 8 years of age in girls and 9 years of age in boys) can occur in both sexes, the condition is most often seen in girls. Such early development may be only a reflection of early maturation but is traditionally considered precocious sexual development (Marcdante & Kliegman, 2015b). Development may be limited to just breast tissue but can proceed to complete secondary sex characteristics, spermatogenesis, or menstrual function.

The condition is caused by the early production of gonadotropins by the pituitary gland; gonadotropins then stimulate the ovaries or testes to produce sex hormones. Such stimulation can occur because of a pituitary tumor, cyst, or traumatic injury to the third ventricle next to the pituitary gland. It also can occur because of estrogen-secreting cysts or tumors of the ovary or testosterone-secreting cysts of the testes. In rare instances, it occurs because of an estrogen- or testosterone-secreting adrenal tumor. In girls, ingestion of a mother's oral contraceptive pills can initiate menarche-like changes. Exogenous androgen exposure, typically through medications, and central nervous system infections are also common causes (Menon & Vijayakumar, 2014).

In children with precocious puberty, a pituitary tumor must be ruled out. If no physical cause, such as a tumor, is detected, the phenomenon appears to occur only because the *gonadostat* of the hypothalamus (the trigger that begins the development of secondary sex characteristics) has turned on several years too early.

### Assessment

With precocious puberty, children have accelerated skeletal maturation as well as increased breast and genital development. Girls have menstrual bleeding yet have little pubic or axillary hair because of still low androgen secretion. Boys have obvious genital growth. The diagnosis of early puberty is confirmed by serum analysis for estrogen or androgen, which will be at adult levels.

## Therapeutic Management

Children need therapy not only because of their outward appearance but also because if epiphyseal lines of long bones close early, they will be left unnecessarily short in stature. A synthetic analog to gonadotropin-releasing hormone (GnRH) is available as leuprolide acetate (Lupron) (Box 47.5). Administration of this analog desensitizes GnRH receptors, making stimulation by GnRH ineffective and halting sexual maturation at the point to which it has advanced (Karch, 2013). Therapy may also include medroxyprogesterone or cyproterone acetate during the initial 3 months to prevent flare up response from the GnRH (Menon & Vijayakumar, 2014).

### BOX 47.5

#### Nursing Care Planning Based on Responsibility for Pharmacology

#### LEUPROLIDE ACETATE (LUPRON DEPOT-PED)

**Classification:** Leuprolide is a hormonal agent, specifically a luteinizing hormone–releasing hormone (LH-RH) agonist.

**Action:** occupies pituitary gonadotropin-releasing hormone (GnRH) receptors, preventing GnRH from functioning, thereby reducing the level of testosterone or estrogen in the body (Karch, 2013)

**Pregnancy Risk Category:** X

**Dosage:** intramuscular (IM) injection every 3 months

**Possible Adverse Effects:** nausea, vomiting, anorexia, hot flashes, headache, pain at injection site

#### Nursing Implications

- Administer only with the syringe supplied with the drug.
- Vary injection sites to decrease local irritation.
- Monitor injection sites for bruising and rash.
- Because injections are given only every 3 months, assist parents with preparing a calendar so they know when the next injection will be due.

#### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Disturbed body image related to precocious puberty

**Outcome Evaluation:** Child voices an understanding of what is happening and does not evidence excessive shyness or reluctance to interact with peers.

Children who develop precociously may have difficulty interacting with peers because they appear so different from other members of their age group. Parents may worry about a child becoming sexually active and particularly about girls becoming pregnant. Both parents and children need reassurance that, after reaching the age of normal puberty, the child will maintain normal growth, development, and appearance.

Help parents to understand that their child is fully fertile and able to inseminate or conceive. Oral contraceptives, however, are not advisable for girls this young because the estrogen in them also causes early closure of epiphyseal lines, possibly stunting the child's growth further.

Parents may need to be reminded also that, although their child appears to be much older, the changes are only in sexual characteristics. Household tasks, responsibility, and expectations must be geared to the child's chronologic age, not to his or her outward appearance.

## DELAYED PUBERTY

Secondary sex characteristics are normally present by age 14 years in girls and 15 years in boys. Delayed puberty, as the name implies, is the failure of pubertal changes to occur at the usual age. The family history of many of these children reveals a family tendency for late maturation. If so, the child needs a thorough physical examination to disclose whether some secondary sex characteristics are present or endocrine stimulation is beginning.

Most girls worry considerably about delayed menstruation, but, once reassured that their development is merely delayed, they are usually willing to wait for menarche to occur on its own. If girls have not begun to menstruate by age 17 years and pathology has been ruled out, menstrual cycles can be initiated by administering estrogen. Similarly, boys who are distressed by their lack of development may receive testosterone supplements to stimulate pubic hair and genital growth, but again, patience may allow usual maturation to occur.

### *QSEN Checkpoint Question 47.1*

#### INFORMATICS

Suppose Navi, 15 years of age, had undergone diagnostic testing and been diagnosed with precocious puberty. What advice would a nurse give her parents?

- a. Restrict the amount of physical and mental stimulation she receives daily to halt abnormal growth.
- b. Although her sexual appearance is advanced, she is not able to conceive.

- c. Treat her appropriately for her chronologic age rather than her physical appearance.
- d. Do not allow her to eat processed meats, which contain growth hormones.

Look in [Appendix A](#) for the best answer and rationale.

## Reproductive Disorders in Males

Common reproductive disorders in males include structural alterations in the penis or testes such as phimosis and cryptorchidism, inflammation such as balanoposthitis, and, in adolescents, testicular cancer.

### BALANITIS (BALANOPOSTHITIS)

*Balanoposthitis* is inflammation of the glans and prepuce of the penis. It tends to occur in uncircumcised boys, is usually caused by poor hygiene, or may accompany a urethritis or a regional dermatitis (Morris, Waskett, Banerjee, et al., 2012).

#### Assessment

The prepuce and glans appear red and swollen, and there may be a purulent discharge. The boy may have difficulty voiding because of crusting at the meatal opening and because acidic urine touching the denuded surface of the glans causes pain.

#### Therapeutic Management

Any discharge should be cultured to rule out a sexually transmitted infection such as gonorrhea. Medical treatment involves local application of heat by warm wet soaks or warm baths. A local antibiotic ointment may be prescribed. If *phimosis* (a tight foreskin) appears to be contributing to the condition, circumcision may be advocated after the inflammation subsides to prevent the condition from recurring.

Although balanoposthitis is painful, a boy may tolerate the discomfort for several days because he may be worried it was caused by masturbation (which can contribute to the irritation) or by sexual activity and may be reluctant to seek help for fear of being criticized. He can be reassured that the problem is local and will have no long-range effect.

### PHIMOSIS AND PARAPHIMOSIS

Phimosis is the inability to retract the foreskin from the glans of the penis. The foreskin is tight at birth and may even be held fast by adhesions and so, in newborns, cannot (and should not) be retracted. After a few months, the adhesions dissolve and the foreskin becomes retractable; if it does not, the infant has phimosis (Shahid, 2012). If a foreskin is extremely tight, it can interfere with voiding. Balanoposthitis may develop because the foreskin cannot be retracted for cleaning. Circumcision of newborns (discussed in

Chapter 18) is no longer routinely advised but is used to relieve phimosis. Paraphimosis is the inability to replace the prepuce over the glans once it has been retracted. This is an emergency situation to address before circulation to the glans is impaired.

## CRYPTORCHIDISM

**Cryptorchidism** is failure of one or both testes to descend from the abdominal cavity into the scrotum (Braga & Lorenzo, 2017). Normally, testes descend into the scrotal sac during months 7 to 9 of intrauterine life. They may descend any time up to 6 months after birth, but they rarely descend after that time and a referral to specialist is warranted (Fantasia, Aidlen, Lathrop, et al., 2015).

The cause of undescended testes is unclear. Testes apparently descend because of stimulation by testosterone; hence, a lower than usual level of testosterone production may prevent descent. Fibrous bands at the inguinal ring or inadequate length of spermatic vessels may prevent descent. The condition is found in about 3 out of every 1,000 male newborns; it occurs most often in premature or low-birth-weight babies (Gaylord & Petersen-Smith, 2013).

### Assessment

Early detection of undescended testes is important because the warmth of the abdominal cavity may inhibit development of the testes, ultimately affecting spermatogenesis. After the age of 1 year, sperm production deteriorates rapidly in undescended testes, and the testes may even undergo a malignant change (Braga & Lorenzo, 2017). Anchoring the testes in the scrotal sac does not guarantee malignancy can be prevented, but it will allow the boy to perform preventive measures such as testicular self-examination.

Some boys may be diagnosed with undescended testes when, if an examining room is chilly, the testes have retracted to make palpation assessment difficult. Excessive palpation or stroking of the inner thigh may also stimulate the cremasteric reflex and cause retraction. In these instances, testes descend when the child is standing or after a warm bath.

Laparoscopy is effective at identifying whether an undescended testis is at the inguinal ring (true undescended testis) or ectopic (still in the abdomen). Because testes arise from the same germ tissue as the kidneys, the kidney function of a child with ectopic testes is usually evaluated as well. If undescended testes and other factors such as ambiguous genitals pose questions about the child's gender, a *karyotype* may be done to determine the child's true gender.

### Therapeutic Management

Because the testes sometimes descend spontaneously during the first year of life, treatment is usually delayed for 1 year, possibly 2 years. Boys may be given a short course of chorionic gonadotropin hormone for about 5 days to see if testicular descent can be stimulated. If this is not successful, surgery (**orchiopexy**) by laparoscopy will

then correct the condition (McIntosh, Scrimgeour, Youngson, et al., 2013).

## Nursing Diagnoses and Related Interventions

If an orchiopexy is scheduled, the focus is on parent and child teaching, preoperative preparation, and postoperative care.

**Nursing Diagnosis:** Deficient knowledge related to parents' and child's inexperience with surgical procedure and postoperative treatment plan

**Outcome Evaluation:** Parents (and child, if old enough) accurately describe what will be accomplished by surgery.

Boys who are old enough to understand why they need surgery need good preparation for this. Use an anatomically correct picture to point out the exact site where surgery will be performed. Reassure the boy that the penis itself will not be cut. Although the child may not voice a fear of mutilation, you can assume it exists, especially in preschool children.

During surgery, internal sutures may be inserted to hold the testis in place. Although the child may be discharged from the hospital on the same day, his activity will be limited until approximately the second day after surgery to ensure the internal suture line remains intact.

**Nursing Diagnosis:** Disturbed body image related to change in physical appearance

**Outcome Evaluation:** Child (if verbal) states he views himself as a whole person and interacts with peers without excessive shyness or hesitancy.

The postoperative evaluation should reveal that the suture line is healing well and that both testes can be palpated in the scrotum. It should also address the boy's feelings about the surgery and the changes in his body. He may need an opportunity to express his fears about mutilation or castration by playing with puppets or dolls after surgery. In years to come, even after a repair, boys who had bilateral cryptorchidism may be less fertile. When boys reach puberty, teach testicular self-examination to assess any early symptoms of malignancy, such as nodules or abnormal growth (see [Chapter 34](#)).

## HYDROCELE

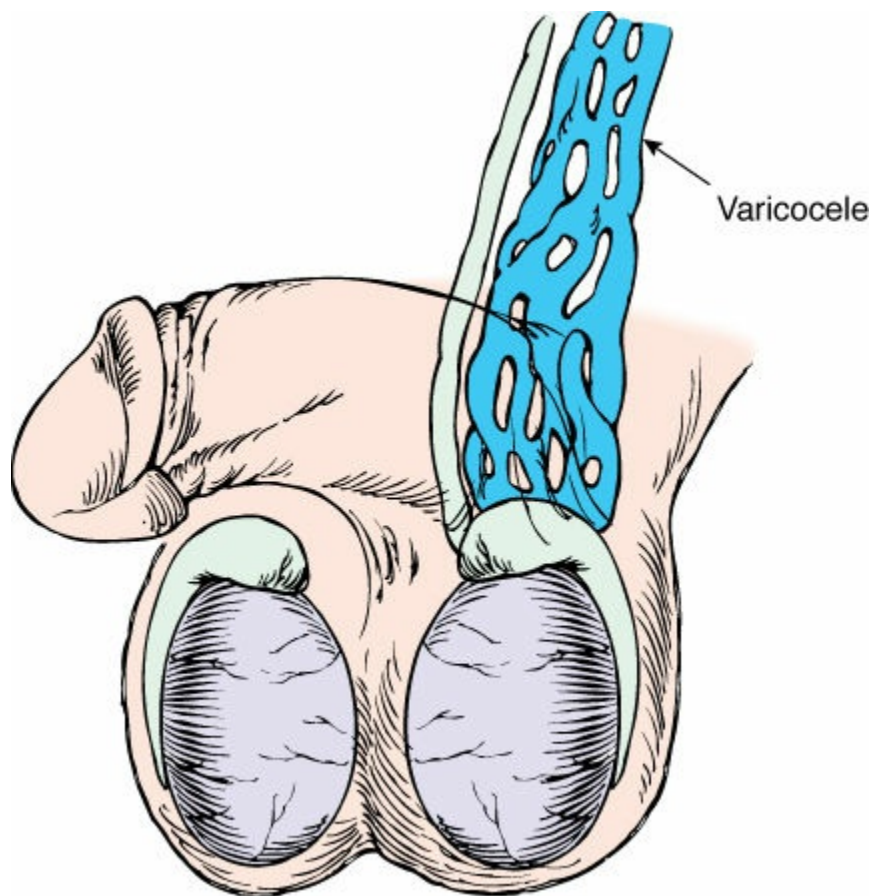

When a testis descends into the scrotum in utero, it is preceded by a fold of tissue, the *processus vaginalis*. Occasionally, fluid (termed a **hydrocele**) collects in this fold. In utero, the fluid can be revealed by ultrasound. At birth, the fluid causes the scrotum of the newborn to appear enlarged (Panabokke, Clifford, Craig, et al., 2016). Its presence can be revealed by ultrasound or *transillumination* (the shining of a light through the

scrotal sac causes the area to glow). If the hydrocele is uncomplicated, the fluid will gradually be reabsorbed, so no treatment is necessary. The child's parents can be assured that the hydrocele is only excess fluid and the scrotal enlargement is not caused by an abnormal testis, tumor, or hernia.

Hydroceles may form later in life due to *inguinal hernias* (abdominal contents extruding into the scrotum through the inguinal ring, with accompanying fluid). If this happens, when the hernia is repaired, the hydrocele will be reabsorbed (see [Chapter 45](#)). Injection of a drug to decrease fluid production (*sclerotherapy*) may also be effective for older youths.

## VARICOCELE

A **varicocele** is abnormal dilation of the veins of the spermatic cord ([Fig. 47.1](#)). It is important to identify varicoceles in adolescents because, although it may not cause a difference, the increased heat and congestion in the testicles is a possible cause of subfertility ([Fine & Poppas, 2012](#)). If fertility becomes a concern, the varicocele can be surgically removed. The adolescent will experience some local tenderness and edema for a few days after surgery. This can be minimized by applying ice for the first few hours postoperatively.

**Figure 47.1** A varicocele. Identifying a varicocele in adolescent males is important because the condition may be associated with subfertility.

### *What If . . . 47.1*

**Ryan, Navi's boyfriend, was born with undescended testes. He had surgery for this when he was 2 years old. He's concerned now that he is at high risk for testicular cancer. What patient education would the nurse best provide?**

## TESTICULAR TORSION

Testicular torsion (twisting of the spermatic cord) is a surgical emergency. Although it can be present in newborns, it occurs most frequently during early adolescence (Colaco, Heavner, Sunaryo, et al., 2015). Less than normal testicular support apparently allows the spermatic cord to twist.

The boy experiences immediate severe scrotal pain and perhaps nausea and vomiting from the extent of the pain. The testis feels tender to palpation, and edema begins to develop. If the condition is not recognized promptly (within 4 hours), irreversible change in the testis can occur from lack of circulation to the organ. Boys need to be educated about the phenomenon so that they report symptoms promptly. Fortunately, the torsion can usually be reduced manually under ultrasound guidance (Sung, Setty, & Castro-Aragon, 2012). Laparoscopic surgery, however, may be necessary to reduce the torsion and to reestablish circulation.

## TESTICULAR CANCER

Testicular cancer is rare (only 1% of all malignancies) but can be an adolescent concern because it tends to occur between ages 15 and 35 years (Russell, 2014). Symptoms include painless testicular enlargement and a feeling of heaviness in the scrotum. The disease metastasizes rapidly, leading to abdominal and back pain due to retroperitoneal node extension as well as weight loss and general weakness. Human chorionic gonadotropin (hCG) and  $\alpha$ -fetoprotein (AFP), tumor markers, will be detected in blood serum. **Gynecomastia** (enlargement of the breasts) may arise because of hCG produced by the tumor.

Therapy for testicular malignancy is **orchiectomy** (removal of the testis) followed by radiation or chemotherapy (Haugnes, Bosl, Boer, et al., 2012). At the time of surgery, a gel-filled prosthesis is inserted to provide a symmetric appearance to the scrotum. "Sperm banking," or preserving frozen sperm before the procedure, can be presented as an option for future family planning (Kelvin, 2015). Teaching all males to perform testicular self-examination for early cancer detection is important to help detect signs and symptoms of testicular cancer at an early point when the prognosis will be favorable (see Chapter 34).

## Reproductive Disorders in Females

The most frequent reproductive disorders in females involve vaginal or menstrual irregularities. Other disorders are caused by physiologic or structural alterations of the reproductive organs such as imperforate hymen, pelvic inflammatory disease, or infections caused by sexually transmitted infections.

## MENSTRUAL DISORDERS

Because menstruation is an ongoing process throughout half of a woman's life, an irregularity such as painful cycles can exert a major influence on her daily activities and life plans. Menstrual disorders in adolescents fall into two categories: (a) menstruation that is painful or uncomfortable and (b) infrequent or too frequent cycles (Gerlt & Starr, 2013).

### Mittelschmerz

Some adolescents experience abdominal pain during ovulation from the release of accompanying prostaglandins. Pain at this time may also be caused by a drop or two of follicular fluid or blood spilling into the abdominal cavity. Called **mittelschmerz**, the pain can range from a few sharp cramps to several hours of discomfort. It is typically felt on one side of the abdomen (near an ovary) and may be accompanied by scant vaginal spotting.

An advantage of mittelschmerz is that it clearly marks ovulation. If pain is felt in the right lower quadrant, it should be differentiated from appendicitis; a lack of associated appendicitis symptoms such as nausea, vomiting, fever, abdominal guarding, and rebound tenderness does this. Mittelschmerz can be relieved by a mild analgesic such as acetaminophen.

### Dysmenorrhea

**Dysmenorrhea** is painful menstruation (Munro, 2012). The pain is caused by the release of prostaglandins in response to tissue destruction during the ischemic phase of the menstrual cycle, which leads to smooth muscle contraction and uterine pain.

Although dysmenorrhea is exceedingly common, it needs to be investigated because it can also be a preliminary symptom of an underlying disorder such as pelvic inflammatory disease, uterine myomas (tumors), or endometriosis (abnormal formation of endometrial tissue).

### Assessment

During the first year or two of menstruation, dysmenorrhea rarely occurs because early menstrual cycles are usually **anovulatory** (without ovulation). As ovulation begins, typical menstrual discomfort also begins. The actual percentage of adolescents affected by dysmenorrhea is between 64% and 93%; however, the majority of adolescents experience pain with menstruation periodically (Aktaş, 2015).

It is categorized as *primary* if it occurs in the absence of organic disease; it is

*secondary* if it occurs as a result of organic disease. Symptoms each month may begin with a “bloated” feeling and light cramping 24 hours before a menstrual flow. Colicky (sharp) pain is superimposed on a dull, nagging pain across the lower abdomen, and an “aching, pulling” sensation of the vulva and inner thighs when the flow begins. Some adolescents have mild diarrhea as well. Mild breast tenderness, abdominal distention, nausea, vomiting, and headache are other symptoms that may also be present.

### Therapeutic Management

Dysmenorrhea can usually be controlled by a nonsteroidal anti-inflammatory drug (NSAID) such as ibuprofen (Advil, Motrin). Be certain girls know not to take these drugs on an empty stomach because they can be extremely irritating to gastric mucosa. If symptoms do not respond to NSAIDs, hormonal treatment, such as combined estrogen and progestin oral contraceptive pills (COCs), can be tried. These prevent pain by preventing ovulation, which was the cause of the pain. If preferred, adolescents can choose to be prescribed long-acting oral contraceptives so that they have menstrual periods only every 3 months. One disadvantage of COC therapy is the possible adverse effects of long-term estrogen administration such as thrombophlebitis or early closure of epiphyseal lines of long bones.

A patient with dysmenorrhea that does not improve with the use of NSAIDs and COCs should be further evaluated for endometriosis, which is characterized by dysmenorrhea and non-menstrual pelvic pain (Facchin, Barbara, Saita, et al., 2015).

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Pain related to menstrual period

**Outcome Evaluation:** Patient states she feels some control over pain through nonpharmacologic or pharmacologic methods.

Several nonpharmacologic solutions such as yoga and exercise may help relieve dysmenorrhea (Chien, Chang, & Liu, 2013). Decreasing sodium intake for a few days before an expected menstrual flow by omitting salty foods such as potato chips and luncheon meats may help reduce “bloated” feelings. Abdominal breathing (breathing in and out slowly, allowing the abdominal wall to rise with each inhalation) may also be helpful. Applying heat to the abdomen with a heating pad or taking a hot shower or bath may relax muscle tension and relieve pain (Navvabi Rigi, Kermansaravi, Navidian, et al., 2012). Abdominal massages (effleurage or light massage) or acupressures are still other options (Gharloghi, Torkzahrani, Akbarzadeh, et al., 2012). Adolescents who remain sexually active during their menses may discover an orgasm helps relieve pelvic engorgement and cramping.

If girls are going to apply heat to their abdomen, caution them not to do this until

their menstrual flow actually begins because if the pain is actually from an inflamed appendix, heat could cause rupture of the appendix and life-threatening peritonitis.

### *QSEN Checkpoint Question 47.2*

#### **EVIDENCE-BASED PRACTICE**

Nonpharmacologic interventions are being used with increasing frequency to help reduce the pain of dysmenorrhea. To discover whether participating in a yoga program could decrease the symptoms related to primary dysmenorrhea, a research team recruited 40 undergraduate female students. Half were in a control group, and the other half were assigned to the exercise group. Those in the exercise group participated in an hour-long yoga session once a week for 12 weeks. Results of the study showed that a yoga program can improve menstrual pain intensity and menstrual distress (Yang & Kim, 2016).

Based on this study, what would the nurse recommend to Navi?

- a. Make a list of menstrual symptoms each month because listing them helps reduce discomfort.
- b. Nonpharmacologic measures can help with coping psychologically with pain.
- c. Some exercise programs can genuinely help reduce menstrual pain.
- d. The more vigorous the exercise, the less pain the patient is likely to have.

*Look in Appendix A for the best answer and rationale.*

## **Menorrhagia**

**Menorrhagia** is an abnormally heavy menstrual flow, usually defined as greater than 80 ml per menses or a flow that soaks more than one pad or tampon an hour. It tends to occur in girls close to puberty because, without ovulation and subsequent progesterone secretion, estrogen secretion causes extreme proliferation of endometrium. There is often also an unusual amount of menstrual flow in girls using intrauterine devices (IUDs). With oral contraceptives, the flow is often light; for this reason, it may seem alarmingly heavy once pills are discontinued, when this is just a return of the adolescent's normal flow.

Heavy flows need to be investigated, however, because they also can indicate endometriosis (see later discussion), a systemic disease (anemia), a blood dyscrasia such as a clotting defect, or a uterine abnormality such as a myoma (fibroid) tumor. It can be a symptom of infection such as pelvic inflammatory disease, an indication of early pregnancy loss that is coincidentally occurring at the time of an expected menstrual period, or can occur from breakthrough bleeding from an oral contraceptive.

### **Assessment and Therapy**

It is difficult to determine when a menstrual flow is abnormally heavy, but because a

sanitary pad or tampon holds approximately 25 ml of fluid, if a pad or tampon is saturated in less than 1 hour, the flow is heavier than usual.

The adolescent who is losing excessive blood because of anovulatory cycles may be prescribed progesterone during the luteal phase to prevent proliferative growth during this phase of the cycle; if the ability to conceive is unimportant, adolescents may be prescribed a low-dose oral contraceptive or GnRH inhibitor to decrease the flow. If anemia is occurring from the heavy blood loss, an iron supplementation may be necessary to restore sufficient hemoglobin formation (Rydz & Jamieson, 2013).

### **Metrorrhagia**

**Metrorrhagia** is abnormal uterine bleeding (AUB) between menstrual periods (Matteson, Raker, Clark, et al., 2013). This is normal in some adolescents who have spotting at the time of ovulation (“mittelstaining”). It may also occur in teenagers taking oral contraceptives (breakthrough bleeding) during the first 3 or 4 months of use. It also can occur from vaginal irritation caused by infection or spotting from a temporarily low level of progesterone production, which leads to endometrial sloughing (dysfunctional uterine bleeding or a luteal phase defect), although this condition most often occurs near the end of the reproductive years, not the beginning.

If AUB occurs for more than one menstrual cycle in a teenager who is not taking oral contraceptives, she needs to be referred to her primary care provider for examination because abnormal vaginal bleeding is an early sign of uterine or cervical carcinoma or an ovarian cyst (Twiss, 2013). Prescription of a COC and NSAIDs that will reduce the amount of a menstrual flow is recommended instead (Gerlt & Starr, 2013).

### **Menstrual Migraine**

A *menstrual migraine headache* refers to a sharp, disabling headache, often accompanied by nausea or vomiting or vision changes, which occurs at the same time as a menstrual flow (Karlı, Baykan, Ertaş, et al., 2012). This is probably caused by the drop in estrogen, which occurs immediately prior to a menstrual flow. Therapy is NSAIDs, which decrease inflammation, or sumatriptan (triptan), which reduces swollen blood vessels. Menstrual migraines seem to be more intense in adolescents taking birth control pills so those who tend to have these should be counseled to use another form of reproductive planning (Hershey, 2012). Any form of migraine headache is frightening because of its sharp intensity; assure girls this is not an uncommon symptom to accompany menstrual flows. Although this doesn't relieve the pain, it can help adolescents not read more into the symptom than it warrants.

### **Endometriosis**

**Endometriosis** is the abnormal growth of extrauterine endometrial cells, often in the cul-de-sac of the peritoneal cavity or on the uterine ligaments or ovaries, and is one of

the main causes of dysmenorrhea in adolescents (Facchin et al., 2015; Kennedy & Koninckx, 2012). This abnormal tissue results from excessive endometrial production and a reflux of blood and tissue through the fallopian tubes during a menstrual flow. The condition tends to occur most often in White nulliparous women, but there is also a familial tendency in which daughters of women with endometriosis develop symptoms of dysmenorrhea early in life.

The excessive production of endometrial tissue can be related to a deficient immunologic response. In many women, it appears to be related to excess estrogen production or a failed luteal menstrual phase caused by not ovulating or ovulating irregularly. The resulting proliferation of tissue forces the menstrual flow into the fallopian tubes.

Dysmenorrhea occurs as the abnormal tissue begins to slough in the same manner as the uterine lining in response to estrogen and progesterone stimulation and withdrawal. This causes inflammation of surrounding tissue in the abdominal cavity and a release of prostaglandins. Abnormal tissue in the pelvic cul-de-sac can cause *dyspareunia* (painful coitus) because it puts pressure on the posterior vagina. Subfertility may result if the fallopian tubes become immobilized and blocked by tissue implants or adhesions, preventing peristaltic motion and transport of ova (see Chapter 9). Adolescents with endometritis may want to consider having children early in life before overgrowth of the endometrium becomes so extensive that it begins to interfere with conception.

### Assessment

Pelvic examination may show the uterus is displaced by tender, fixed, palpable nodules. Nodules in the cul-de-sac or on an ovary may be palpable and painful.

### Therapeutic Management

Treatment for endometriosis can be medical or surgical, depending on the extent of the condition. Estrogen/progesterone-based oral contraceptives may reduce the amount of extrusion into the peritoneal cavity because the tissue sloughs under the influence of the progesterone. Danazol (Danocrine), a synthetic androgen, can be prescribed to help shrink the abnormal tissue. Administration of a GnRH agonist, such as leuprolide acetate (Lupron), can reduce hormone stimulation and cause the same effect (see Box 47.5). Aromatase inhibitors, which reduce estrogen levels, are still another solution (Agarwal & Foster, 2015). A laparotomy with excision by laser surgery is the most effective measure, but, because this is a highly invasive procedure, a course of conservative medical treatment may be tried first.

### Amenorrhea

**Amenorrhea**, or absence of a menstrual flow, strongly suggests pregnancy but is by no means definitive because it can also result from tension, anxiety, fatigue, chronic illness, extreme dieting, or strenuous exercise. Amenorrhea as a sign of pregnancy is discussed

in [Chapter 10](#). Competitive swimmers, long-distance runners (50 to 75 miles weekly), and ballet dancers may notice their intensive training causes menstrual periods to become scant and irregular, a phenomenon related to their low ratio of body fat to body muscle; this leads to excessive secretion of prolactin. An elevation in prolactin then causes a decrease in GnRH from the hypothalamus, followed by declines in follicle-stimulating hormone (FSH), follicular development, and estrogen secretion. Menstrual cycles usually return to normal within a few months after discontinuation of strenuous training and conditioning and an increase in caloric intake ([Weiss Kelly & Hecht, 2016](#)).

Adolescents who wish to maintain a normal cycle while training for a sports event may take bromocriptine (Parlodel), which reduces high prolactin levels by its action on the hypothalamus. Many adolescents, however, view the absence of menstrual periods as a benefit of sports training. If a menstrual flow is delayed and pregnancy is suspected, bromocriptine should be discontinued because it is potentially teratogenic.

Amenorrhea also occurs among females who diet excessively, partially as a natural defense mechanism to limit ovulation and also probably as a means of conserving body fluid. Adolescents with *anorexia nervosa* or *bulimia* (eating disorders described in [Chapter 54](#)) often develop amenorrhea after approximately 3 months of excessive dieting or bingeing and dieting; as in athletes, this is caused by an increase in prolactin ([Dominé, Dadoumont, & Bourguignon, 2012](#)).

### *What If . . . 47.2*

**Navi returns to the clinic in 6 months and tells the nurse she hasn't had a menstrual flow for 3 months. What would the nurse first suspect as Navi's condition? What questions should the nurse ask Navi?**

## **Premenstrual Dysphoric Disorder**

**Premenstrual dysphoric disorder (PDD)** is a condition that occurs in the luteal phase of the menstrual cycle and is relieved by the onset of menses. Because of the variety of possible symptoms, as many as 3% to 8% of women experience some degree of PDD, such as anxiety, fatigue, abdominal bloating, headache, irritability, or depression, and these may begin as early as adolescence. For a small subset of these women, these symptoms become so extreme that they are incapacitating ([Hofmeister & Bodden, 2016](#)).

The cause of PDD is unproven, but, contrary to previous beliefs, it must be due to more than a drop in progesterone just before menses. A syndrome similar to PDD can occur in women after tubal ligation; with this, apparently a decrease in the blood supply to the ovary results in decreased luteal function. In some women, a vitamin B-complex deficiency may lead to estrogen excess, causing an abnormal ratio of estrogen to progesterone. Other related causes may be poor renal clearance leading to water

retention, or hypoglycemia leading to a surge of epinephrine and low calcium levels and interference with serotonin synthesis.

Because symptoms of PDD vary from cycle to cycle and throughout life, therapy is aimed at correcting specific symptoms (Steinberg, Cardoso, Martinez, et al., 2012). Adolescents who think they have PDD should keep a diary of when symptoms occur. They should be certain their diet is high in vitamins and calcium and low in salt. Agents that suppress ovarian function, such as oral contraceptives or the GnRH agonist leuprolide, may be prescribed. If depression is a major symptom, an antidepressant may be prescribed, although antidepressants (especially serotonin-reuptake inhibitors) are prescribed with caution in adolescents because they may be responsible for an increase in suicidal behavior (Adegbite-Adeniyi, Gron, Rowles, et al., 2012).

## ADDITIONAL REPRODUCTIVE DISORDERS IN FEMALES

### Female Circumcision

Female circumcision is the incision and removal of the clitoris (Gele, Johansen, & Sundby, 2012). There is no medical reason or advantage of the procedure, but, performed just prior to puberty, it is regarded as a coming of age ritual or religious practice in some cultures. Both a painful and mutilating procedure, it is not legal in the United States. You may, however, see adolescents or women in gynecology and pregnancy care settings who have had this done in another country. A major complication of the procedure is that women may have difficulty with conception or childbirth because of vulvar scarring and perineal contraction.

### Imperforate Hymen

The *hymen* is the membranous ring of tissue that partly obstructs the vaginal opening. An *imperforate hymen* totally occludes the vagina, preventing the escape of vaginal secretions and menstrual blood (Cetin, Soysal, Khatib, et al., 2016).

Before menarche, a girl with an imperforate hymen usually has no symptoms. With the onset of menstruation, however, the menstrual flow builds up in the vagina, causing increased pressure in the vagina and uterus and, eventually, abdominal pain. Palpation of the abdomen reveals a lower abdominal mass. On vaginal examination, an intact, bulging hymen is evident. The treatment is surgical incision or removal of the hymenal tissue. The girl may have local pain after the incision, which can be relieved by a mild analgesic and warm baths.

Because most girls of early menstrual age have scant knowledge of anatomy, pictures of the reproductive tract can help to explain that this is a local and minor problem. Once relieved, it will not interfere with sexual relations or future childbearing.

### Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is the most frequent cause of ovulation failure seen today. It is found in about 10% of women of childbearing age (Connor, 2012).

Adolescents with the syndrome begin to develop an increased androgen (male hormone) level, which then prevents follicular ovarian cysts from maturing, a situation that leads to typical symptoms of irregular or missed menstrual cycles, acne, excessive hair growth (hirsutism), being overweight, male pattern baldness, type 2 diabetes, and, most important, an absence of ovulation. The androgen increase is usually directly related to obesity and further exacerbates insulin resistance (Spritzer & Motta, 2015).

Assessment for the disorder includes a thorough history and physical exam, a pelvic exam to determine the consistency and size of ovaries, and perhaps an ovarian ultrasound for the same purpose. Serum androgen and glucose levels will also be assessed.

Because the exact cause of polycystic ovaries is not known, treatment is aimed at relieving the symptoms. Many adolescents with the syndrome are obese, therefore, weight loss by increasing lean meat, fruits, and vegetables and decreasing the amount of concentrated carbohydrates in their diet is encouraged. This eating pattern also lowers blood glucose levels, improves the body's use of insulin, and helps to normalize testosterone secretion. If a woman is morbidly obese, bariatric surgery may be recommended because this will achieve the same result.

A COC may be prescribed because this changes the ratio of estrogen and testosterone produced, leading to better regulated menstrual cycles. To prevent type 2 diabetes from developing, metformin (Glucophage) may be prescribed, which is yet another method to reduce blood glucose levels. If the adolescent or woman wants to become pregnant, fertility medications such as a course of clomiphene (Clomid) to stimulate ovulation may be suggested. Two final therapies to help achieve pregnancy are in vitro fertilization (IVF) (see Chapter 7) and ovarian drilling, a surgery technique done by laparoscopy that reduces the size of the ovaries and limits the amount of testosterone the ovaries are able to produce. To decrease hair growth and reduce acne symptoms, antiandrogens such as spironolactone (Aldactone) or finasteride (Propecia) can be tried. Caution women that finasteride is teratogenic and so should not be used if they intend to become pregnant, and it should be discontinued during pregnancy (Mysore & Shashikumar, 2016).

PCOS is a perplexing disorder because it produces such a wide range of symptoms, and responses to therapy may not be immediate. Support from healthcare providers is important, especially if the woman wants to become pregnant and realizes her condition is not going to readily allow this to happen.

### ***QSEN Checkpoint Question 47.3***

#### **QUALITY IMPROVEMENT**

The symptoms of PCOS can begin with adolescence. If Navi had this, which of the following facts would a nurse want her to describe after an educational session?

- a. PCOS can be easily treated with an antibiotic.
- b. This condition can cause both obesity and interfere with future fertility.

- c. The condition usually fades with full maturity at the end of adolescence.
- d. Polycystic ovaries are easy to identify because they are so painful.

Look in [Appendix A](#) for the best answer and rationale.

## Toxic Shock Syndrome

Toxic shock syndrome (TSS) is an infection that is usually caused by toxin-producing strains of *Staphylococcus aureus*. Although organisms can enter the body by other means, they typically enter through vaginal walls that have been damaged by the insertion of tampons at the time of a menstrual period (Edmonds, 2012). Once occurring at epidemic proportions because of superabsorbent tampons, it now can be prevented by simple steps (Box 47.6).

### BOX 47.6

#### Nursing Care Planning to Empower a Family

##### MEASURES TO PREVENT TOXIC SHOCK SYNDROME

**Q.** Navi says to you, “I use tampons. How can I make sure I don’t get toxic shock syndrome?”

**A.** The following measures can help prevent the syndrome:

- Use the lowest absorbency tampon possible that is still adequate for your individual flow.
- Alternate use of tampons with use of sanitary pads. Change tampons at least every 4 hours.
- Avoid handling the portion of the tampon that will be inserted vaginally.
- Do not use tampons near the end of a menstrual flow, when excessive vaginal dryness can result from scant flow.
- Do not insert more than one tampon at a time to avoid abrasions and to keep the vaginal walls from becoming too dry.
- Avoid deodorant tampons, deodorant sanitary pads, and feminine hygiene sprays; these products can irritate the vulvar–vaginal lining.
- If fever, vomiting, or diarrhea occurs during a menstrual period, discontinue tampon use and immediately consult your healthcare provider because these are symptoms of TSS.
- Anyone who has had one episode of TSS is well advised not to use tampons again until two vaginal cultures for *Staphylococcus aureus*, the bacteria usually responsible for TSS, are negative.

## Assessment

The symptoms of TSS are a high temperature (over 102°F [38.9°C]), vomiting and diarrhea, hypotension, severe muscle pain, decreased platelet count, and a macular

(sunburn-like) rash that desquamates on palms and soles. As the infection progresses, septic shock develops; renal, liver, and central nervous system functions fail, leading to disorientation and confusion.

Some adolescents have mild diarrhea as a normal accompaniment to dysmenorrhea, but any female who develops fever with diarrhea and vomiting during a menstrual period should suspect TSS and telephone her primary care provider.

### Therapeutic Management

Women or adolescents with suspected TSS need a careful vaginal examination and removal of any tampon particles as well as cervical and vaginal cultures for *S. aureus*. Iodine douches may reduce the number of organisms present vaginally. A penicillinase-resistant antibiotic such as the cephalosporins, oxacillins, or clindamycins is prescribed. Intravenous fluid therapy to restore circulating fluid volume or a vasopressor such as dopamine (Intropin) may be necessary to increase blood pressure. Osmotic therapy to shift fluid back into the intravascular circulation is important to prevent renal and cardiac failure. Recovery occurs in 7 to 10 days with adequate therapy; however, fatigue and weakness may last for months.

TSS recurrence can occur probably because the organism was not completely eliminated from the body. That makes it important for girls to complete their entire antibiotic prescription and in the future to use the lowest absorbency tampon appropriate for their individual flow.

### Vulvovaginitis

In **vulvovaginitis**, inflammation of the vulva or vagina is accompanied by pain, odor, pruritus, and a vaginal discharge (Rome, 2012). Vaginal bleeding may also be present. The condition may occur in a girl of any age, but it tends to be more frequent as girls reach puberty probably because the change to adult pH and the presence of vaginal secretions make the vagina more receptive to infections. Box 47.7 discusses common measures to relieve vulvovaginal discomfort.

#### BOX 47.7

#### Nursing Care Planning Based on Family Teaching

#### TIPS FOR RELIEVING THE PAIN OF VULVOVAGINITIS

**Q.** Navi says to you, “My bottom is irritated from my vaginal discharge. What can I do to relieve that?”

**A.** Here are some tips that might help:

- Wash the area twice a day with mild, nonperfumed soap and water, and pat dry to remove secretions and decrease irritation. Always wash and dry from front to back to prevent spreading rectal contamination forward.
- Take a tub bath or apply warm, moist compresses three times a day to soothe the

area and to keep it free of irritating drainage.

- After drying the cleansed area, apply cornstarch for comfort and to absorb residual moisture.
- Avoid bubble baths and feminine hygiene sprays because the ingredients in these may cause additional local irritation as well as may contribute to urinary tract infections.
- Take acetaminophen (Tylenol) or a nonsteroidal anti-inflammatory drug (NSAID) such as ibuprofen every 4 hours. These are both analgesics and so relieve pain and reduce itching, a mild pain sensation.
- Avoid scratching, which may increase abrasions and introduce a secondary infection. Instead, apply a cold compress to relieve the itching sensation.
- Wear cotton underwear, which allows air to circulate and moisture to evaporate rather than nylon or silk, which prevents air circulation and retains moisture.
- Sleep without underwear.
- Use an anesthetic spray or hydrocortisone cream if prescribed.
- If an antibiotic has been prescribed for a vaginal infection, take it conscientiously because only after the infection subsides will the vaginal discharge and itching clear.

## Preschool- and School-Age Children

Vaginal discharge may occur before menarche, but bleeding is rarely seen at this age. If vaginal bleeding does occur, it is usually caused by irritation caused by an inserted foreign object into the vagina, infestation of pinworms, or daily bubble baths (which can lead to urinary tract infections [UTIs] as well as vulvar irritation). It could also be due to urethral bleeding from cystitis (bladder infection) or rectal pruritus, which has led to scratching and rectal bleeding. Precocious puberty is yet another disorder that must be ruled out. Finally, whether sexual maltreatment has occurred must be investigated because it could be a cause of any bleeding, tenderness, or infection (see [Chapter 55](#)).

Treatment for pinworm is discussed in [Chapter 43](#). If there is a foreign body in the vagina, it obviously should be removed by a vaginal examination. This may be difficult for young girls to accept because, unless a small speculum is used, vaginal manipulation and stretching can be painful. Application of a local antibiotic ointment or warm baths afterward may be prescribed to prevent infection and inflammation after removal of the object.

A few preschool- or school-age children develop a vaginitis due to *Streptococcus* or to *Escherichia coli* introduced from the anus by improper perineal care after voiding or bowel movements. A tight hymen then traps the microorganisms in the vagina and leads to infection. The girl may need an antibiotic prescribed for this and needs to be reminded to wipe from front to back after voiding or bowel movements to help prevent this from occurring again.

## Adolescents

As a girl enters puberty, she may notice a slight vaginal discharge caused by increased vaginal secretions. As long as she has no other symptoms, you can reassure her this is normal. To keep from developing vulvar irritation, caution girls to wear cotton underpants rather than nylon (so that moisture is absorbed better) and to dry the vulva thoroughly after bathing or swimming. Daily washing of the perineum and frequent changing of tampons or sanitary pads during menstruation helps prevent chafing or stasis of menstrual blood and so helps prevent irritation and odor.

## Pelvic Inflammatory Disease

**Pelvic inflammatory disease (PID)** refers to various inflammatory conditions of the genital tract in females: the uterus, fallopian tubes, ovaries, and their supporting structures (Black, 2014). The infection can extend so far it causes pelvic peritonitis. Although sexual transmission accounts for approximately 75% of all instances of PID (gonorrheal and chlamydial organisms are frequently responsible), infections from other causes such as *E. coli* or *Streptococcus* can occur and may be as severe. Adolescents, those with multiple sexual partners, and those who don't use condoms have a higher incidence of PID than other groups (Ross, 2012).

PID usually begins with a cervical infection that then spreads by surface invasion along the uterine endometrium and then out to the fallopian tubes and ovaries. It is most likely to occur at the end of a menstrual period because menstrual blood provides an excellent growth medium for bacteria and there is loss of the normal barrier of cervical mucus during this time.

## Assessment

With acute PID, a woman or adolescent notices severe pain in the lower abdomen. She may have an accompanying heavy, purulent discharge. As the infection progresses, she develops a fever, and leukocytosis and an elevated erythrocyte sedimentation rate will be present. During a pelvic examination, any manipulation of the cervix causes severe pain, making it difficult to palpate the ovaries because of tenderness and abdominal guarding. As peritoneal tissue becomes inflamed and edematous, a purulent exudate forms in the tubes. If the process is untreated, it enters a chronic phase and fibrotic scarring with stricture of the fallopian tubes results. With this chronic phase, the abdominal pain lessens but dyspareunia and dysmenorrhea may be extreme. If the ovaries are affected, intermenstrual spotting may occur. A diagnosis can be aided by ultrasound or laparoscopy.

## Therapeutic Management

Therapy involves administration of analgesia for comfort plus a broad-spectrum antibiotic such as doxycycline (Vibramycin) or clindamycin (Cleocin). In some women, a pelvic abscess forms and must be drained through the cul-de-sac before healing can

occur. Women who have IUDs in place do not need to have them removed because these do not interfere with therapy (Tepper, Steenland, Gaffield, et al., 2013).

Women who have had one episode of PID have an increased chance of a second occurrence because the immune protection of the tubes and ovaries may have been damaged. They should avoid coitus during menstruation, when their protective mechanisms are lowest, and be certain their sexual partner is also not infected with the organism that caused the original infection. Early childbearing or IVF may be necessary for some women because extensive tubal scarring impaired their fertility. It is important for adolescents to recognize the symptoms of PID and to seek early help to avoid these worst case outcomes.

## Breast Disorders

Although males have few breast disorders, they can occur in either males or females.

Gynecomastia (enlarged breast tissue) may occur temporarily in preadolescent boys in response to a rising estrogen level. Particularly noticeable in obese males, this enlargement fades with a normal increase in testosterone production with puberty (Dickson, 2012). It may also occur in teens who participate in body-building sports as a result of steroid use. If this is the cause, counseling regarding the danger of performance-enhancing drug use is crucial.

### ACCESSORY (SUPERNUMERARY) NIPPLES

As the name implies, *accessory nipples* are additional breast nipples (Marcdante & Kliegman, 2015a). They tend to occur along the mammary lines and can be present in either male or female (Fig. 47.2). They are present from birth but usually are not as protuberant as true nipples; they also lack areolar pigmentation. Parents should be told what they are so they can inform their child later about this because some growth in accessory nipples may occur at puberty or during pregnancy in response to estrogen stimulation. If girls are unaware they have an accessory nipple and think it is a large mole, they may be worried they have skin cancer when these changes occur.

**Figure 47.2** Nipple lines, along which accessory nipples occur.

In a few instances, actual breast tissue is present beneath the accessory nipple. If so, it is subject to the same diseases as other breast tissue such as fibrocystic disease or breast cancer (Valeur, Rahbar, & Chapman, 2015). If the accessory nipple or accessory breast tissue is cosmetically distressing to an adolescent, it can be removed by simple surgical excision.

## **BREAST HYPERTROPHY**

*Breast hypertrophy (macromastia)* is abnormal enlargement of breast tissue. In the average girl, progesterone levels are low until menstruation cycles are fully established. Breast development halts after puberty, as soon as progesterone levels rise to mature strength. If the time span between puberty and maturation is a lengthy one, breast growth lasts for longer than usual, resulting in larger than usual breasts.

Breast hypertrophy can lead to both physical and emotional stress because a girl

may feel pain and fatigue in her back or shoulders from the weight of heavy breast tissue. In addition, she may feel self-conscious and try to minimize her breast size by slouching, resulting in poor posture or rounded shoulders. Pregnancy and lactation may be particularly difficult times because breasts that are already large become even heavier with milk formation. Hearing comments such as “I wish I had your problem” rather than receiving support and understanding from parents, peers, and healthcare providers does not relieve her concerns.

Be certain adolescents with large breasts conscientiously schedule a yearly breast examination with their healthcare provider because it is easier for a cancerous lesion to escape detection in large amounts of breast tissue than in smaller breasts.

If breast hypertrophy is so extreme that it interferes with a girl’s physical and emotional well-being, surgical breast reduction is a possibility (Srinivasaiah, Iwuchukwu, Stanley, et al., 2014). Adolescents need to seriously consider the consequences of this procedure, however, before undertaking it at this early age. If a large amount of glandular tissue is removed, breastfeeding might no longer be an option. The adolescent also needs to be told realistically that changing her physical appearance will reduce physical discomfort, but changing her self-concept must come from within.

## **BREAST HYPOPLASIA**

*Breast hypoplasia* is less-than-average breast size. In most instances, this does not represent a decreased amount of glandular or functional breast tissue but a reduced amount of fatty tissue. If having small breasts interferes with self-esteem, a girl can have surgical augmentation by a silicon or a saline implant inserted under the breast tissue to increase breast size, but, again, this needs careful consideration regarding whether it is necessary at this young age. Be certain the girl understands that her breast tissue is not replaced by the implant, and that she still needs breast examinations because she could still develop breast cancer in later years.

Breasts with implants in place may feel firmer than usual on palpation due to the formation of a fibrotic band or capsule around the implant. Decreased nipple sensation may be present for approximately 1 year after the procedure.

Breast implants do not interfere with breastfeeding because they are placed behind the milk glands. A traumatic blow to the breast, such as one that could occur from an automobile accident, requires examination by the augmentation surgeon to be certain the implant did not rupture, causing its contents to leak into the bloodstream or breast tissue.

## **FAT NECROSIS**

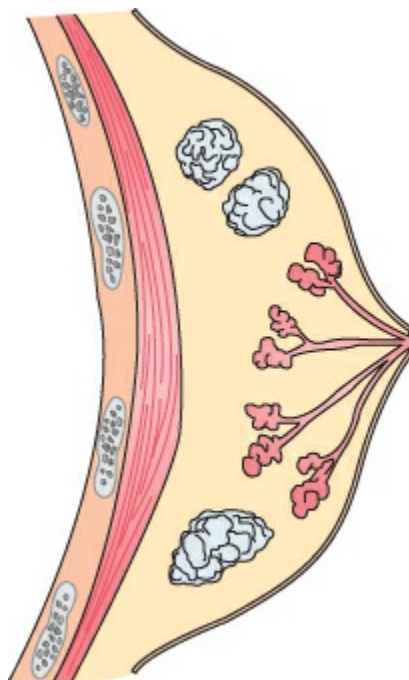

If breast tissue is struck during a fall or other traumatic injury such as injury from a seatbelt, it can become tender, painful, inflamed, or reddened (Alvarez & Jacobs, 2011). A few days after the injury, necrosis or disintegration occurs in the fatty layer. As the

area heals, fibrotic scar tissue forms leaving a firm, palpable lump in the breast. It is not freely movable; it can, however, cause skin or nipple retraction or dimpling on the skin surface. Unlike malignant breast growths that also show this “orange peel” sign, posttraumatic breast lumps tend to be well delineated because of the scar tissue.

It is generally recommended that such fibrotic areas be biopsied and then excised. The procedure is a minor one, usually leaves little scarring, and the adolescent no longer needs to worry about the lump in her breast afterward.

## FIBROCYSTIC BREAST DISEASE

**Fibrocystic breast disease** is the most common benign breast condition in women of all ages (De Silva, 2012). It can occur as early as puberty, when estrogen rises to adult levels. More commonly, however, it is found in older adolescents. Round, fluid-filled, and freely movable cysts form in the connective breast tissue (Fig. 47.3). The consistency of these lesions varies with the menstrual cycle, changing from firm to soft, depending on the amount of serous fluid present. The lesions tend to shrink or disappear during pregnancy and lactation, and they tend to fade with menopause.

**Figure 47.3** Round, fluid-filled cysts form in breast tissue in fibrocystic breast disease.

Decreased sodium intake or short-term use of a mild diuretic just before menses can reduce fluid retention and the size of the cysts. Discontinuing smoking can help as well. Because fibrocystic breasts feel tender and “stretched,” this can interfere with active sports and other strenuous activity. This discomfort can usually be relieved with a simple analgesic, such as acetaminophen (Tylenol), an NSAID, or warm compresses, avoidance of trauma, and firm bra support. The formation of fibrocystic lesions may be

increased in some women with the use of methylxanthines found in caffeine, theophylline, and theobromine, so avoiding foods such as coffee, cola drinks, tea, chocolate, some toffee candy, and medications that contain caffeine helps reduce pain.

If these measures do not decrease fibrocystic symptoms, cysts may be aspirated under a local anesthetic by injection of a thin sterile needle attached to a small syringe. This procedure not only reduces the size of the cyst but also provides fluid for biopsy (Alvarez & Jacobs, 2011).

In addition to being physically distressed, women with fibrocystic breasts may worry that each lump could be malignant. Breast carcinoma does occur in women with fibrocystic breast disease, but fibrocystic lesions do not directly lead to this. Breast cancer, however, may not be discovered before a woman seeks a health consultation because a woman assumes all her breast lesions are benign. Therefore, in addition to a yearly breast examination, women with fibrocystic breast disease need an annual breast ultrasound or magnetic resonance imaging (MRI) to efficiently locate and identify that the cysts are benign.

## FIBROADENOMA

*Fibroadenomas* are tumors that consist of both fibrotic and glandular components that occur in response to estrogen stimulation (Valeur et al., 2015). They may increase in size during adolescence, during pregnancy and lactation, or when a woman takes an estrogen source such as an oral contraceptive.

Unlike fibrocystic lesions, fibroadenomas feel round and well delineated, are painless and freely movable, and do not tend to cause skin retraction. Occasionally, they calcify and feel extremely hard. Like fibrocystic lesions, the presence of them can be distressing, but they do not appear to become malignant.

Such tumors can be surgically excised so a woman no longer has to worry about them. Because the incision is small, it leaves little scarring at the site.

### QSEN Checkpoint Question 47.4

#### SAFETY

Navi, 15 years of age, asks whether it would be safe for her to have breast augmentation. What advice should the nurse give her?

- She would not likely be able to breastfeed after undergoing augmentation.
- Breast implants increase her risk of developing fibrocystic disease.
- It is safe for girls her age to have this surgery, but careful consideration is needed.
- Implants increase her risk of breast cancer in later life.

Look in *Appendix A* for the best answer and rationale.

## MASTITIS

Mastitis is inflammation or infection of the breast. Because this usually occurs as a complication of breastfeeding, it is discussed in [Chapter 19](#).

## Sexually Transmitted Infections

**Sexually transmitted infections (STIs)** are diseases that are spread through sexual contact with an infected partner. They range in severity from easily treated infections, such as trichomoniasis, to HIV infection, which, despite advances in therapy, is life threatening. If these diseases are discovered in young children, the possibility of sexual maltreatment has to be considered ([Hornor, 2017](#)). Adolescents account for almost half of the new cases of STIs each year, which includes heterosexual and same-sex transmission ([Goyal, Shea, Hayes, et al., 2016](#)).

Abstinence or condom use provides the best protection against STIs. Additional measures include voiding immediately and washing genitals well with soap and water after coitus as well as choosing sexual partners who are at low risk for infection (i.e., avoiding persons who are intravenous drug users or those with multiple sexual partners). Educating adolescents about safer sex practices, including the need for condom use (see [Chapter 5](#)) and the importance of health screening for these disorders, is an important nursing responsibility. Pay particular attention to adolescents who do not have a strong family support system because it may be particularly difficult for these youth to receive correct information about preventing STIs ([Hudson, 2012](#)).

STIs are becoming more difficult to treat because the causative organisms are becoming increasingly resistant to antibiotics. Always reinforce the fact that little immunity develops from STIs, so such diseases can be contracted repeatedly. In most instances, an infected partner should also be treated or the disease can recur from cross infection.

Several STIs, such as syphilis, are known to be teratogenic. All of them are suspected of being a causative factor of preterm birth. [Chapter 12](#) discusses care for the newborn affected by such diseases.

## CANDIDIASIS

Candidiasis is a vaginal infection spread by the fungus *Candida*, an organism that thrives on glycogen ([Rome, 2012](#)). Candidiasis is so common that as many as 90% of women will have it sometime in their life. Because oral contraceptives produce a pseudopregnancy state, adolescents using oral contraceptives tend to have frequent vaginal candidal infections. If being treated with an antibiotic for another infection (which destroys normal vaginal flora and lets fungal organisms grow more readily), they are also particularly susceptible to this infection. Incidence is also strongly associated with immune suppression and diabetes mellitus because hyperglycemia provides the perfect glucose-rich environment for candidal growth.

## Assessment

Because of the scant mucus production in the period before menses, symptoms may be most acute at this time. The adolescent will notice vulvar and vaginal reddening, burning and itching, and even bleeding from hairline fissures. A thick, cream cheese–like discharge can usually be observed at the vaginal outlet. Internally, the vagina shows white “patches” that cannot be scraped away without bleeding on the walls. There may be accompanying pain on coitus or on tampon insertion. Candidal infections can also be present at other body sites, such as the oral cavity or a moist area such as the umbilicus. In immunosuppressed individuals, candidal infections can become systemic (Edmonds, 2012).

Candidal infections are diagnosed by removing a sample of the discharge from the vaginal wall and placing it on a glass slide. Three or four drops of a 20% potassium hydroxide (KOH) solution are then added, and the mixture is protected by a coverslip. Under a microscope, typical fungal hyphae indicate the presence of *Candida* organisms (Table 47.1). An at-home test kit (Vagisil Screening Kit) is available, which gives results instantly. A woman inserts a pH wand into her vagina and in a few seconds compares the color of the swab to a pH color chart. If the reading is above 5.0, it suggests she may have a bacterial infection and should see her healthcare provider. A pH level of 4.5 plus itching and/or burning, unusual discharge, or a yeasty odor suggests a yeast infection, and it would be all right for her to use an over-the-counter treatment.

**TABLE 47.1 COMMON VULVOVAGINAL INFECTIONS**

<b>Causative Agent</b>	<b>Symptoms</b>	<b>Common Therapy</b>
<i>Candida albicans</i>	Vulvar reddening and pruritus; thick, white, cheese-like vaginal discharge	Clotrimazole (Lotrimin) or miconazole (Monistat) vaginal suppositories or fluconazole (Diflucan) orally; bathing with dilute sodium bicarbonate solution may relieve pruritus
<i>Trichomonas</i>	Thin, irritating, frothy, gray-green discharge; strong, putrid odor; itching	Metronidazole (Flagyl) or tinidazole (Tindamax) orally; douching with weak vinegar solution to reduce pruritus
Herpesvirus type 2	Painful pinpoint vesicles on an erythematous base with a watery vaginal discharge possible; voiding may be irritating and painful	Bathing with dilute sodium bicarbonate solution, applying lubricating jelly to lesions, or an oral analgesic such as ibuprofen may be necessary for pain relief; topically applied acyclovir (Zovirax) helps heal lesions
<i>Gardnerella</i>	Edema and reddening of vulva; milky gray	Metronidazole (Flagyl) or clindamycin

	discharge; fishlike odor	
<i>Chlamydia trachomatis</i>	Watery, gray-white vaginal discharge; vulvar itching	Tetracycline or doxycycline; erythromycin during pregnancy
<i>Neisseria gonorrhoeae</i>	Possibly symptomless; may have profuse yellow-green vaginal discharge	Ceftriaxone and doxycycline
<i>Enterobius vermicularis</i> (pinworm)	Rectal pruritus, especially on rising in the morning	Oral administration of an anthelmintic, such as mebendazole (Vermox)
<i>Treponema pallidum</i> (syphilis)	Painless ulcer on vulva or vagina	Benzathine penicillin, administered intramuscularly
<i>Streptococcus</i>	Vaginitis, vulvar itching; edema and reddening of vulva	Antibiotic such as amoxicillin
Foreign body	Vaginal discharge; odor	Removal of foreign body during pelvic examination

## Therapeutic Management

Therapy for candidal infections includes vaginal tablets or cream applications of antifungal preparations such as over-the-counter miconazole (Monistat) or clotrimazole (Lotrimin) once a day for 3 to 7 days. Oral fluconazole (Diflucan) can be administered as a one-time dose. Teach women to insert antifungal tablets or creams at bedtime, so the drug does not drain from the vagina immediately afterward. Treatment should not be interrupted until it is complete, even during a menstrual period.

If a girl has frequent candidal infections, her urine should be tested for glucose to rule out diabetes mellitus. If she is using an oral contraceptive, she might be counseled to use another reproductive planning method. If an adolescent is sexually active, treatment of the male partner may be necessary to break a reinfection cycle ([McGreal & Wood, 2013](#)).

## Pregnancy and Candidiasis

Candidiasis occurs more frequently during pregnancy than usual because the increased estrogen level present during pregnancy causes the vaginal pH to be less acidic and even more favorable for yeast growth. Women with repeated infections should have their urine tested for glucose to determine whether gestational diabetes is present.

Both miconazole (Monistat) for 7 days or a single dose of oral fluconazole

(Diflucan) are approved for use during pregnancy. Treating the infection during pregnancy is important not only because the profuse vaginal discharge and pruritus is uncomfortable but also because if the infection is present in the vagina at the time of childbirth, it may cause a candidal infection, or *thrush*, in the newborn (see [Chapter 43](#)). Caution pregnant women to call their primary healthcare providers before using an over-the-counter product to double-check that the product is safe to use during pregnancy and also so the primary care provider can know a vaginal infection is occurring ([Mashburn, 2012](#)).

### What If... 47.3

**Navi tells the nurse she feels protected from contracting an STI because she knows she is up to date with her immunizations. What patient education would the nurse best provide?**

## TRICHOMONIASIS

*Trichomonas vaginalis* is a curable STI and has the highest prevalence among adolescents ([Swartzendruber, Sales, Brown, et al., 2014](#)). The incubation period is 4 to 20 days. A serious consequence of trichomoniasis is that infection can cause such genital inflammation that it makes it easier for the person to be infected with the HIV virus or to pass the HIV virus on to a sex partner ([Centers for Disease Control and Prevention \[CDC\], 2017](#)).

### Assessment

With a trichomonal infection, females may notice only a slight vaginal discharge or else notice extreme vaginal itching and a frothy white or grayish-green vaginal discharge. The upper vagina looks reddened and may have pinpoint petechiae. In some women, these changes can be so extreme, a Pap test taken during this time may be misinterpreted as showing abnormal tissue. Males with the same infection tend not to report any symptoms.

The infection is diagnosed by microscopic examination of a sample of the vaginal discharge; trichomonads typically appear as rounded, mobile structures.

### Therapeutic Management

Oral metronidazole (Flagyl) or tinidazole (Tindamax) eradicates trichomonal infections. Use of condoms by sexual partners help prevent recurrence of *Trichomonas* in both parties. Because metronidazole interacts with alcohol (to cause acute nausea and vomiting), caution older adolescents and women to not drink alcoholic beverages during the course of treatment with this drug.

### Pregnancy and Trichomoniasis

Trichomoniasis infections are associated with preterm labor, premature rupture of membranes, and postcesarean infection. The drug of choice during pregnancy is single-dose oral metronidazole. Although classified as a Class B pregnancy drug, it may not be prescribed during the first semester of pregnancy to avoid detrimental fetal effects (Karch, 2013).

## BACTERIAL VAGINOSIS

*Bacterial vaginosis* is defined as the absence or deficiency of lactobacilli in the vaginal flora and it occurs frequently among woman of childbearing age (Parma, Vanni, Bertini, et al., 2014). An intensely pruritic vaginal discharge appears milky-white to gray and has a fishlike odor. Microscopic examination of the discharge shows gram-negative rods adhering to vaginal epithelial cells (termed *clue cells*). Like trichomoniasis, bacterial vaginosis can increase a woman's susceptibility to other STIs, such as herpes simplex virus (HSV), chlamydia, and gonorrhea, as well as HIV (Bautista, Wurapa, Sateren, et al., 2016).

The treatment is oral or vaginal metronidazole for 7 days. The woman's sexual partner should also be treated to prevent recurrence of the infection. Therapy with probiotic lactobacilli to change vaginal organisms is a future possibility for prevention (Parma et al., 2014).

### Pregnancy and Bacterial Vaginosis

The treatment during pregnancy is oral metronidazole or clindamycin for 7 days in order to prevent preterm labor as well as premature rupture of the membranes (Bennett, 2012).

### QSEN Checkpoint Question 47.5

#### TEAMWORK & COLLABORATION

Candidal vaginal infections can occur as an opportunistic infection when adolescents are prescribed antibiotics. A nurse would refer an adolescent for medical treatment of this problem if she reported which of the following?

- a. Many yellow pinpoint vaginal lesions
- b. Green-tinged pruritic vaginal walls
- c. White, cheese-like vaginal discharge
- d. Vaginal atrophy with final scarring

Look in *Appendix A* for the best answer and rationale.

## CHLAMYDIA TRACHOMATIS INFECTION

*Chlamydia trachomatis* infections have become the most commonly reported bacterial cause of STIs in the United States (Pearson, Gift, Leichter, et al., 2015). The incubation period is 1 to 5 weeks; symptoms include a heavy, grayish-white discharge

and vulvar itching. Diagnosis is made by identification of the organism, which can be done at the point of care with a urethra or cervix swab. A urine specimen can be used as an alternative screening method. Therapy is oral doxycycline for 7 days or azithromycin as a single dose. Because the infection has become so common, most public health departments require that the infection be reported to the health department the same as other STIs such as gonorrhea. Because there is a strong association between gonorrhea and *Chlamydia*, if a chlamydial infection is documented, women are usually tested for gonorrhea as well. Long-term effects of chlamydial infections are PID, possibly leading to subfertility.

### **Pregnancy and *Chlamydia***

Screening for *Chlamydia* via a vaginal culture is usually done during a woman's first prenatal visit. If a woman has multiple sexual partners, screening may be repeated again in the third trimester. Doxycycline (Vibramycin), the therapy for nonpregnant women, is contraindicated during pregnancy because of possible fetal long-bone deformities; azithromycin (Zithromax) or amoxicillin (Amoxil) are used instead. A woman's partner also should be treated to prevent her from becoming reinfected.

It's important that chlamydial infections be treated during pregnancy because they are associated with premature rupture of the membranes, preterm labor, and endometritis in the postpartum period. An infant who is born while a chlamydial infection is present can develop conjunctivitis or pneumonia after birth (see [Chapters 40 and 50](#)).

## **HUMAN PAPILLOMAVIRUS**

The human papillomavirus (HPV) causes fibrous tissue overgrowth (sometimes called genital warts) on the external vulva, vagina, or cervix (condyloma acuminatum). At first, lesions appear as discrete papillary structures; they then spread, enlarge, and coalesce to form large, cauliflower-like lesions. The infection may be present in as many as 10% to 30% of women and is most common in women who have multiple sexual partners. Children (both male and female) who develop an HPV infection should be further investigated for sexual maltreatment ([Francis & Katz, 2013](#)). Therapy for such lesions is aimed at dissolving the lesions and also ending any secondary infection present. Small growths often fade by themselves, although they can be removed by applying podophyllin (Podofin), a wart removal medication. Large lesions are removed by laser therapy, cryocautery, laser, or knife excision. With cryocautery, edema at the site is evident immediately; lesions become gangrenous, and sloughing occurs in 7 days, with healing complete in 4 to 6 weeks with only slight depigmentation at the site. Warm baths and a lidocaine cream may be soothing during the healing period.

HPV infections are serious because they are associated with the development of penile and cervical cancer later in life ([D'Hauwers, Depuydt, Bogers, et al., 2012](#)). Related to this, women who have had one episode of infection should be conscientious

about having yearly Pap tests for the rest of their lives, and men should conscientiously inspect their penis for any abnormal growths or ulcers. The vaccines, Gardasil or Cervarix, are recommended as part of routine administration to both early teenage girls and boys to prevent such infections. Approach the subject of immunization with parents and teenagers with sensitivity because some parents and children are not ready to admit they might be or will soon become sexually active and need this protection (Katz, Oldach, Goodwin, et al., 2014). Immunizing teenagers against an HPV infection should reduce not only the incidence of HPV infections in the future but also the rate of cervical and penile cancer as well (Markman, 2013).

### **Pregnancy and Human Papillomavirus Infection**

HPV lesions tend to increase in size during pregnancy because of the high vascular flow in the pelvic area. They may become secondarily ulcerated and infected; when this occurs, a foul vulvar odor may develop.

Podophyllum is contraindicated during pregnancy because of possible toxic effects on the fetus. Trichloroacetic acid (TCA) or bichloroacetic acid (BCA) applied to the lesions weekly may be effective and can be used during pregnancy. Women who do not find the lesions bothersome may choose to leave them in place until the postpartum period and have them removed then. Remind them, in the meantime, that the lesions are infectious and can spread to a sexual partner.

The presence of vulvar lesions appears to have no effect on the fetus during pregnancy, but if they are so large they obstruct the birth canal for birth, a cesarean birth may be scheduled.

### **HERPES GENITALIS (HERPES SIMPLEX TYPE 2)**

Genital herpes is caused by *herpesvirus hominis* type 2 (also called herpes simplex virus type 2 or HSV-2). This is one of four similar herpesviruses: cytomegalovirus, Epstein–Barr, varicella zoster, and herpes type 1 (HSV-1) and type 2 (HSV-2). Genital herpes occurs in epidemic proportions in the United States, and HSV-1 is becoming more commonly the cause of primary genital infections (Groves, 2016). Although the virus can be contained, unlike most other STIs, there is no known cure. The disease involves a lifelong process, therefore, and, although it may not be a direct precursor to cervical cancer, women with cervical cancer tend to have more antibodies against herpes genitalis than others or probably have been exposed to the virus more than others. The virus is spread by skin-to-skin contact, entering through a break in the skin or mucous membrane. In the newborn, acquired at birth, the virus can be systemic or even fatal (see Chapter 26).

### **Assessment**

Herpes is diagnosed by culture of the lesion secretion from its location on the vulva, vagina, cervix, or penis or by isolation of HSV antibodies in blood serum. The

incubation period is 3 to 14 days. On first contact, extensive primary lesions originate as a group of pinpoint vesicles on an erythematous base. Within a few days, the vesicles ulcerate and become moist, painful, draining, and open lesions. An adolescent may have accompanying flu-like symptoms with increased temperature; vaginal lesions may cause a profuse discharge. Pain is intense on contact with clothing or acidic urine. Diagnosis of the disorder is made by the appearance of the lesions and on the results of a Pap smear and an enzyme-linked immunosorbent assay (ELISA).

After this primary stage, which lasts approximately 1 week, lesions heal but the virus lingers in a latent form in the sensory nerve ganglia. The condition can flare up and become an active infection again during illness, just prior to menstruation, fever, overexposure to sunlight, or stress. This secondary response usually produces only local lesions rather than systemic symptoms.

### Therapeutic Management

Both acyclovir (Zovirax) and valacyclovir (Valtrex) are examples of antivirals that can control the virus by interfering with DNA reproduction and decreasing symptoms (Groves, 2016). Topical imiquimod (Aldara) or foscarnet (Foscavir) may be prescribed for resistant lesions. If applying a topical ointment or vaginal gel to a patient, be certain to protect yourself with a finger cot or glove so you do not contract the virus or absorb the drug. Warm baths three times a day may be helpful to reduce discomfort for the patient. An emollient (A&D Ointment) can also reduce discomfort, although its moisture tends to prolong the active period of the lesions. Infected people need to inform their partners when they have any active lesions and either avoid sexual contact or use a condom to decrease the danger of spreading the virus.

Because of the possible association with cervical cancer, any female with genital herpes should have yearly Pap tests for the rest of her life, and men need to self-inspect for recurrent lesions.

### Pregnancy and Herpes Simplex Virus Type 2 Infection

If a woman contracts an HSV-2 infection during pregnancy, herpes can be transmitted across the placenta to cause congenital infection in the newborn. If primary or secondary active lesions in the vagina or on the vulva are present at the time of birth, herpes infection can be transmitted to the newborn at birth. When this occurs, a severe systemic infection that is often fatal can result (see Chapter 26). To help avoid transmission, women with active lesions are usually scheduled for cesarean birth (Groves, 2016).

The drug of choice for the treatment of herpes infection during pregnancy is the same as for nonpregnant women (acyclovir [Zovirax] or valacyclovir [Valtrex]) (Karch, 2013). Women can reduce the pain of the lesions by taking baths or applying warm, moist tea bags to the area.

## HEPATITIS B AND HEPATITIS C

Both hepatitis B and hepatitis C can be spread by semen as well as blood and therefore are considered STIs. These are discussed in [Chapter 45](#), with other forms of hepatitis. Because hepatitis B can be spread by sexual intercourse, adolescents who did not receive immunization against this as an infant and who are sexually active need immunization.

## GONORRHEA

Gonorrhea is transmitted by *Neisseria gonorrhoeae*, a gram-positive diplococcus, which thrives on the mucous membrane of the vagina or penis ([O'Connor & Shubkin, 2012](#)). In males, symptoms include *urethritis* (pain on urination and frequency of urination) and a urethral discharge, which appear after a 2- to 7-day incubation period. Untreated, the infection spreads easily among sexual partners and may spread to the testes, scarring the tubules and causing permanent sterility. It often occurs concurrently with a chlamydial infection.

Although symptoms of gonorrhea in females are not as visible, there may be a slight yellowish vaginal discharge. The Bartholin glands may become inflamed and painful. If left untreated, the infection can spread to pelvic organs, most notably the fallopian tubes, can cause PID, and, as in males, tubal scarring with permanent sterility. In both males and females, if systemic involvement occurs, arthritis or heart disease can develop.

### Assessment

A urine culture for the gonococcal bacillus, in addition to vaginal, urethral, and perhaps anal and oral cultures, should be obtained on all children with vulvovaginitis or a urethral discharge to rule out gonorrhea because, if gonorrhea is detected, child maltreatment needs to be ruled out.

### Therapeutic Management

One intramuscular injection of ceftriaxone (Rocephin) plus 7 days of oral doxycycline (Vibramycin) or azithromycin (Zithromax) is the current recommended therapy because this treatment regimen is effective for gonorrhea, chlamydia, and syphilis ([Kransdorf, Kling, & Mayer, 2014](#)). Sexual partners should receive the same treatment ([Box 47.8](#), an interprofessional care map for an adolescent with an STI).

BOX 47.8

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR AN ADOLESCENT WITH GONORRHEA

Navi is a 15-year-old female high school student you meet at a pediatric clinic. She

describes intense vulvar irritation from a yellowish-green vaginal discharge.

**Family Assessment:** Navi lives with mother in a studio apartment in inner city. Mother works at home as a freelance journalist. Mother describes finances as “good.”

**Patient Assessment:** Well-proportioned female; sexual maturity Tanner stage 3. Menarche at 12 years; periods every 30 days; duration 6 days. Sexually active for approximately 1 year with same partner. “He doesn’t use a condom anymore because I’m the only one he’s dating.”

Vulva reddened and excoriated. Yellow-green discharge noted at vaginal introitus. Reddened areas noted on vaginal walls. One dose of intramuscular (IM) ceftriaxone (Rocephin), plus oral doxycycline (Vibramycin) prescribed for 7 days. She says, “I think I got this from a towel I borrowed in gym class. Does my boyfriend need treated too?”

**Nursing Diagnosis:** Deficient knowledge related to cause and treatment of sexually transmitted infection (STI)

**Outcome Evaluation:** Adolescent states she understands cause of STI; reports boyfriend has an appointment within 48 hours for evaluation.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess whether adolescent understands importance of washing hands after using bathroom and avoiding sexual intercourse during treatment.	Discuss how disease can be spread to boyfriend or to other body parts by unclean hands.	Gonorrhea is particularly hazardous because it can cause eye infections with corneal scarring.	Adolescent states she will take precautions to wash hands well; will avoid sexual intercourse until repeat culture.
<i>Teamwork and Collaboration</i>				
Nurse/STI counselor	Confer with STI counselor as to whether disease is a reportable one.	Meet with STI counselor regarding procedure for STI contacts.	Gonorrhea is a reportable disease.	STI counselor assumes responsibility for securing STI contacts.
<i>Procedures/Medications for Quality Improvement</i>				
Nurse	Assess whether adolescent has experience with	Administer ceftriaxone (Rocephin) IM;	The antibiotics chosen for gonorrhea	Adolescent accepts IM injection; states

	taking medicine. Assess if a reminder sheet would be helpful.	give instructions for oral doxycycline (Vibramycin) for 7 days as prescribed.	treatment are also effective against chlamydia, which is frequently associated with gonorrhea.	she understands importance of taking oral antibiotic for full 7 days.
Nurse	Assess whether adolescent has access to a bathtub at home.	Recommend the use of warm bath before and after school.	Warm baths are soothing and help keep the vulva free of irritation.	Adolescent states she will use home bathtub for sitz baths twice daily and will wash tub well after use.
<i>Nutrition</i>				
Not applicable (N/A)	N/A	N/A	N/A	N/A
<i>Patient-Centered Care</i>				
Nurse	Assess whether adolescent is aware STIs are spread through sexual intercourse not towel exchange.	Teach adolescent about the cause, means of spread, and a treatment for gonorrhea.	Adolescent must be aware of the spread of STIs to prevent them in the future.	Adolescent states she understands STIs are spread by sexual relations.
<i>Psychosocial/Spiritual/Emotional Needs</i>				
Nurse	Assess intensity of adolescent's pruritus or pain from vulvitis on a scale of 1 to 10.	Discuss the use of acetaminophen or ibuprofen for pain and pruritus as needed.	Acetaminophen and ibuprofen are effective analgesics for mild pain and itching.	Adolescent describes correct dosage of analgesics and states intention to use them.
Nurse/STI counselor	Assess whether adolescent has had sexual contacts other	Ask adolescent to name any additional sexual contacts.	Sexual contacts need to be notified so they can also receive	Adolescent names any other sexual contacts; possibility of

	than current boyfriend.		treatment.	rape or sexual maltreatment is ruled out.
<i>Informatics for Seamless Healthcare Planning</i>				
Nurse	Assess whether adolescent understands, in the light of contracting this disease, that she must ask boyfriend to use a condom for sexual relations.	Discuss the possibility that because he contracted an STI, his relationship with her may not be monogamous.	STI was spread to her by a sexual contact.	Adolescent states she will be more conscientious about insisting boyfriend use a condom.
Nurse	Assess whether adolescent or parent has any questions about disease or therapy.	Schedule adolescent for a return appointment in 1 week for repeat culture.	A repeat culture will reveal whether antibiotic therapy has been effective.	Child and parent state they understand the importance of a repeat culture and return appointment.

Approximately 24 hours after beginning treatment, gonorrhea is no longer infectious. Approximately 7 days after treatment, however, a patient should return for a follow-up culture to verify the disease has been completely eradicated (few adolescents take this precaution without urging). Most states require gonorrhea be reported to the health department; adolescents are asked to name sexual contacts to help prevent the disease spread. Without being told who put them at risk, these people can then be notified by a health department investigator that they have been exposed to a particular STI and need treatment.

### Pregnancy and Gonorrhea

Gonorrhea is associated with spontaneous miscarriage, preterm birth, and endometritis in the postpartum period. Pregnant women cannot be administered doxycycline because it has the potential to be teratogenic. Instead, they are prescribed azithromycin. It is important that gonorrhea is identified and treated during pregnancy because, if the infection is present at the time of birth, it can cause a severe eye infection, which can lead to blindness in the newborn (ophthalmia neonatorum; see [Chapter 26](#)).

### PATIENT-CENTERED CARE

Navi does not seem concerned about the possibility she could contract gonorrhea again. What additional health teaching does she need to better understand how this disease is spread?

- a. The microorganism of gonorrhea can be spread via anal, oral, and vaginal intercourse.
- b. It is possible for the gonorrhea organism to be spread by anal/penile contact.
- c. The low pH of saliva prevents this from being spread by oral/penile contact.
- d. Gonorrhea is a virus that can be treated effectively if diagnosed early.

Look in [Appendix A](#) for the best answer and rationale.

## SYPHILIS

*Syphilis* is a systemic disease transmitted by the spirochete *Treponema pallidum* (O'Connor & Shubkin, 2012). Like gonorrhea and chlamydia, its occurrence must be reported to public health departments.

After an incubation period of 10 to 90 days, a deep ulcer (termed a *chancre*), which is usually painless despite its size, appears usually on the genitalia (penis or labia) or in the vagina, on the mouth, lips, or rectal area from oral–genital or genital–anal contact. Swollen lymph nodes may also be present, but these are likely to be less noticed by the affected person. Without treatment, a chancre lasts approximately 6 weeks and then fades.

About 2 to 4 weeks after the chancre disappears, a generalized, macular, copper-colored rash appears. Rare among rashes, it covers the soles and the palms as well as extremities and the body. There may be secondary symptoms of generalized illness, such as a low-grade fever. A serologic test for syphilis taken at this time yields a positive result. With or without treatment, this stage of syphilis also fades.

The next stage is a latency period that may last from only a few years to several decades. The only indication of the disease at this point is a serologic test, which continues to yield a positive result.

The final stage of syphilis is a destructive neurologic disease that involves major body organs, such as the heart and the nervous system, with symptoms such as blindness, paralysis, mental confusion, slurred speech, and lack of coordination. If this third stage is not identified and treated, it can become fatal.

### Assessment

Syphilis is diagnosed by recognition of the various symptoms of the three stages and by serologic serum tests, such as the Venereal Disease Research Laboratory (VDRL) test, the automated reagin test (ART), the rapid plasma reagin (RPR) test, or the fluorescent treponemal antibody–absorption test (FTA-ABS).

## Therapeutic Management

Benzathine penicillin G, given intramuscularly in two sites, is effective therapy. For the adolescent who is sensitive to penicillin, either oral erythromycin or tetracycline can be given for 10 to 15 days. Sexual partners are treated in the same way as the person with an active infection. Therapy effectively arrests the disease at whatever stage it has reached. After therapy, adolescents may experience a sudden episode of hypotension, fever, tachycardia, and muscle aches (a Jarisch-Herxheimer reaction caused by the sudden destruction of spirochetes). The reaction lasts about 24 hours and then fades. Because syphilis can be treated so easily, one would think it would be easy to eradicate. In reality, however, because the primary chancre is painless, many people are either unaware of it or choose to ignore it, thereby transmitting the disease to unsuspecting sexual partners. Be certain adolescent are screened for all STIs with both a history and a physical examination, and that sexuality is discussed at healthcare visits (Hsu & Burstein, 2016). They also need to be assured they can report the disease to healthcare personnel and name sexual contacts without fear of being criticized.

## Pregnancy and Syphilis

Early in pregnancy (before week 18), the placenta appears to provide some protection against syphilis. After this time, however, the spirochete crosses the placenta freely and may be responsible for spontaneous miscarriage, preterm labor, stillbirth, or congenital anomalies in the newborn (see Chapter 12). All pregnant women are screened for syphilis at a first prenatal visit with a VDRL, ART, or FTA-ABS antibody reaction test. Those who have multiple sexual partners are typically tested again at about week 36 of pregnancy. In some institutions, women are screened again at the beginning of labor, and their newborns are screened for congenital syphilis by a cord blood sample. One injection of benzathine penicillin G is the drug of choice for the treatment of syphilis during pregnancy the same as for those who are not pregnant. If the woman has syphilis, her infant needs penicillin therapy at birth as well (Patel, Klinger, O'Toole, et al., 2012).

If a woman contracted syphilis during pregnancy but it was unrecognized and untreated, and so the newborn is untreated, a congenital form of the disease can occur in the newborn. Severely infected infants will be stillborn; others, less infected, are born with congenital anomalies. Wear gloves to handle such infants because moist lesions (the cord and nasal secretions) may be infectious.

Unlike adults, the infant does not develop a chancre but, about a week after birth, will develop a typical copper-colored rash most prominent over the face, soles of feet, and palms of hands. The infant's nose may show a severe rhinitis (stiffness). An X-ray of the long bones reveals changes of epiphyseal lines at about 1 to 3 months of age. By 5 to 6 months, these bone changes may no longer be visible and so may be missed.

When the child's permanent teeth erupt at 5 or 6 years of age, the tops may be pegged or notched (Hutchinson's teeth), tend to be of poor quality, and decay easily. If the disease remains untreated even with these symptoms, interstitial keratitis, an

inflammatory reaction of the cornea that can result in scarring and blindness, may develop by school age. As the disease progresses further, it may become tertiary or lead to severe neurologic symptoms.

## GROUP B STREPTOCOCCAL INFECTION

Although streptococcus B infection is a less publicized disease than STIs such as HSV-2 or gonorrhea, it may actually occur at a higher incidence than those diseases (Page-Ramsey, Johnstone, Kim, et al., 2013). If contracted during pregnancy, consequences can include UTIs, intra-amniotic infections, perhaps preterm birth, and postpartum endometritis.

Pregnant women are generally screened for streptococcus B at 35 to 38 weeks of pregnancy to prevent their newborn from becoming infected from placental transfer or from direct contact with vaginal secretions at birth. If they become infected, neonates can develop severe pneumonia, sepsis, respiratory distress syndrome, or meningitis (see Chapter 26).

A broad-spectrum penicillin such as ampicillin is the treatment of choice. Women who experience rupture of membranes at less than 37 weeks of pregnancy and so have not yet been screened may be treated with intravenous ampicillin during labor to reduce the risk of spreading the infection to the newborn.

## HIV

HIV is carried by semen as well as other body fluids, so, although not officially listed as such, is an STI. Invasion of the virus is discussed with other immune system disorders in Chapter 42.

### *What If . . . 47.4*

**A nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to reproductive disorders in children (see Box 47.1). What would be a possible research topic pertinent to this goal that would be applicable to Navi's family and would also advance evidence-based practice?**

## KEY POINTS FOR REVIEW

- Children who are born with a reproductive tract disorder frequently adjust well when young. They may need counseling at puberty or when they become aware of the impact of their disorder on sexual functioning or their ability to reproduce.
- The cause of ambiguous genitalia is unknown but may be related to the level of testosterone produced in utero. The true gender of children is established by a karyotype of chromosomes.
- The development of breast or pubic hair before age 8 years is considered precocious sexual development. Children may be treated with a synthetic analog of GnRH to

reduce development. Without effective support, such children are at high risk for disturbed body image.

- Delayed puberty is the failure to develop secondary sex characteristics by the age of 17 years. Girls may be administered estrogen to promote development; boys may be administered testosterone.
- Balanoposthitis (inflammation of the glans and prepuce of the penis) and phimosis (constricted foreskin) occur in boys. Phimosis can be treated with circumcision.
- Cryptorchidism is failure of one or both testes to descend during intrauterine life. The condition is surgically corrected to prevent subfertility and to make it possible to detect testicular cancer later in life.
- Testicular cancer is rare but tends to occur in young men. Boys need to be taught testicular self-examination for early detection.
- Dysmenorrhea, or painful menstruation, occurs frequently in adolescent girls. Therapy is the use of a prostaglandin inhibitor such as ibuprofen.
- Untreated endometriosis (the abnormal growth of extrauterine endometrial tissue) can lead to subfertility later in life. Therapy is the administration of a synthetic androgen or GnRH receptor inhibitor or surgery to reduce the size of the abnormal tissue.
- Vulvovaginitis (inflammation of the vulva and vagina) and PID are infections that can occur in adolescents. Therapy to prevent fallopian tube scarring and subfertility later in life is essential. In addition, girls need to be taught ways to avoid TSS from the use of menstrual tampons. Vulvovaginitis in young girls needs to be investigated for the possibility of sexual maltreatment.
- Conditions such as fibrocystic breast disease can occur in adolescents. Teaching to reduce the intake of caffeine and sodium can minimize symptoms and also help in planning nursing care that not only meets QSEN competencies but also best meets an adolescent's total needs.
- STIs such as candidiasis, trichomoniasis, *C. trachomatis* infection, genital warts, herpes genitalis, gonorrhea, and syphilis are increasing in incidence in the adolescent population. An important health-teaching area for adolescents is the need to follow safer sex practices.
- When teaching about STIs, it is important to stress that they do not confer immunity and therefore can be contracted more than once. If an STI occurs in a young child, the potential for child maltreatment should be investigated.

### CRITICAL THINKING CARE STUDY

Melinda is a 16-year-old teenager you meet at an adolescent clinic. Her parents are divorced and she lives with her father.

1. Melinda is concerned because she has little breast development as of yet and only began having menstrual periods last week. She asks you if she is going to be underdeveloped.

2. Melinda’s boyfriend wants to have sex with her. Because he has an unrepaired hypospadias, he has assured her she can’t get pregnant. Should she believe him?
3. Melinda tells you she learned everything she knows about sexual relations and contraception from the Internet because her father has difficulty discussing such things with her. Is this a good source of information for her?

# Nursing Care of a Family When a Child Has an Endocrine or a Metabolic Disorder

*Rob Tebecco is a 16-year-old boy with type 1 diabetes whom you meet in the emergency department, where he was taken after he became comatose while ice skating. His diabetes was diagnosed when he was 7 years old. His records indicate that his disease has generally been under good control over the past years, but in the last 6 months, he has “forgotten” to take his insulin at least once a week. During your assessment, he tells you that ice skating practice every morning and a new girlfriend have occupied his time and interrupted what used to be a strict schedule of home-cooked meals and a rigid routine.*

*Previous chapters described the growth and development of well children. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur when children develop an endocrine or metabolic disorder. This is important information because it builds a base for care and health teaching.*

**Is Rob’s history unusual for an adolescent? What health teaching do you think will most help him reestablish control?**

## KEY TERMS

**carpopedal spasm**

**exophthalmos**

**glycosuria**

**hormones**

**hyperglycemia**

**hypoglycemia**

**hypothalamus**

**ketoacidosis**

**latent tetany**

**manifest tetany**

**pedal spasm**

**polydipsia**  
**polyuria**  
**sella turcica**  
**Somogyi phenomenon**

## OBJECTIVES

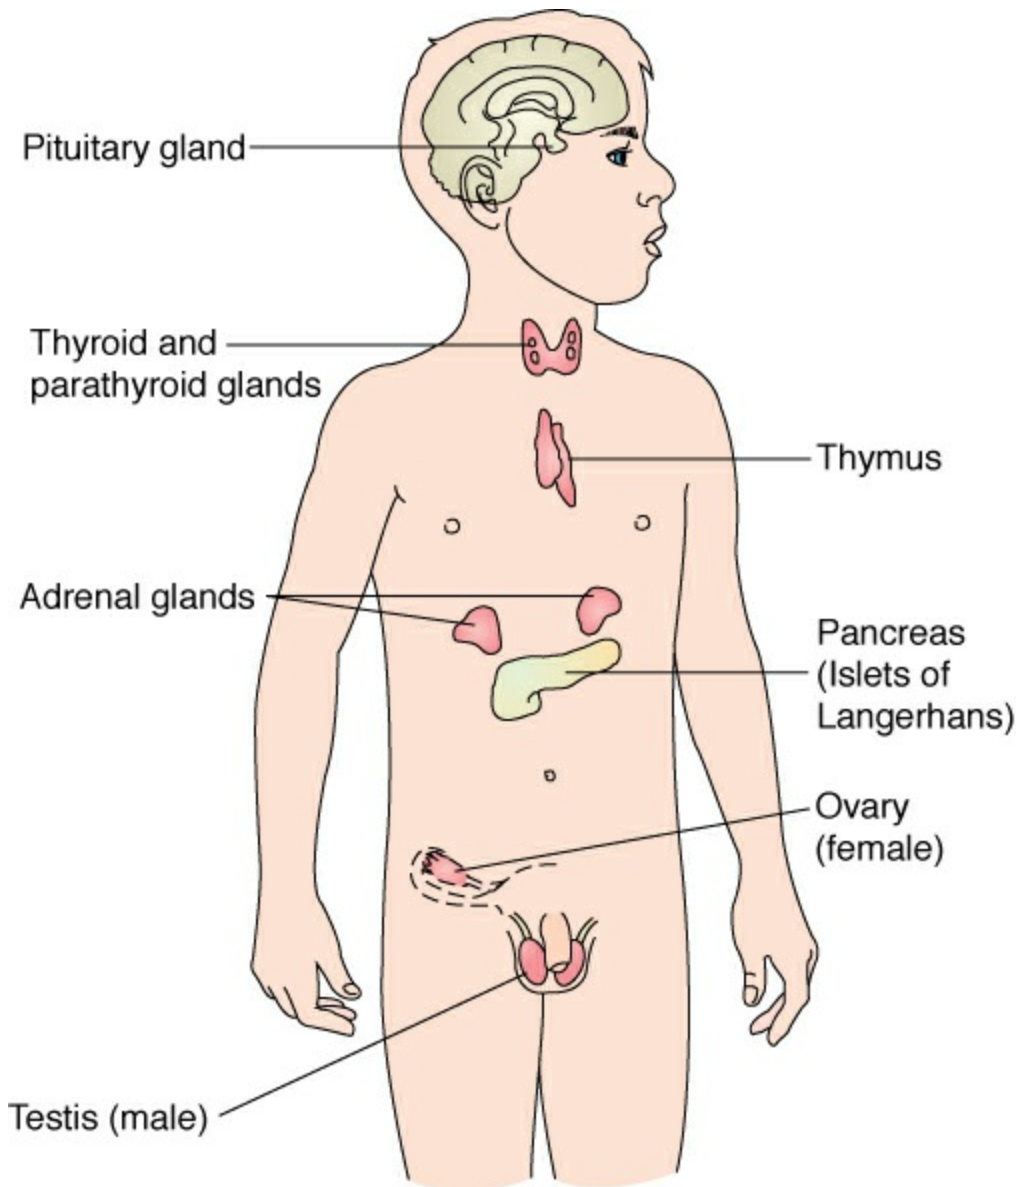

**After mastering the contents of this chapter, you should be able to:**

1. Describe the structure and function of the endocrine glands and why metabolic illnesses occur.
2. Identify 2020 National Health Goals that nurses can help the nation achieve related to childhood endocrine or metabolic disorders.
3. Assess a child with a disorder of endocrine or metabolic dysfunction.
4. Formulate nursing diagnoses for a child with altered endocrine or metabolic dysfunction.
5. Establish expected outcomes for a child with endocrine or metabolic dysfunction.
6. Help parents to manage seamless transitions across healthcare settings.
7. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
8. Implement nursing care such as teaching long-term medicine administration to a child with an endocrine or metabolic disorder.
9. Evaluate expected outcomes for achievement and effectiveness of care.
10. Integrate knowledge of endocrine and metabolic disorders with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to ensure quality maternal and child health nursing care.

---

The endocrine system is composed of a small group of ductless glands that work together with the neurologic system to regulate and coordinate all body systems (Fig. 48.1). The glands produce **hormones**, which are secreted into surrounding tissue and picked up by the bloodstream, where their action is to turn on or turn off various organ functions. (The word *hormone* is from the Greek *hormaein*, which means “to set in motion.”) Each gland of the endocrine system acts on a specific target (or designated) organ or has specific duties that are necessary for regulating body processes (van Karnebeek & Stockler, 2012).

**Figure 48.1** The location of the endocrine glands.

The inadequate secretion of hormones or dysfunction of the glands results in a variety of disorders, most of which have long-term implications. Parents and children, as soon as they are old enough, need to understand the causes and symptoms of these diseases so they can participate in their long-term plan of care. [Box 48.1](#) shows 2020 National Health Goals related to endocrine and metabolic disorders in children.

#### BOX 48.1

#### Nursing Care Planning Based on 2020 National Health Goals

Endocrine disorders tend to be long term and so cause lifetime consequences. Reducing the incidence of these or improving care has long-term implications. A sample of 2020 National Health Goals related to these include:

- Reduce the diabetes-related death rate from a baseline of 77 per 100,000 to no

more than 46 per 100,000 people.

- Increase the proportion of persons with diabetes who receive formal diabetes education from a baseline of 56.8% to a target of 62.5%.
- Reduce the proportion of children aged 3 to 10 years diagnosed with a disorder through newborn blood spot screening who experience developmental delay requiring special education services from 15.1% to a target level of 13.5%.
- Increase the proportion of children with long-term illnesses who have access to a medical home from 57.5% of children under 18 years to 63.3% ([U.S. Department of Health and Human Services, 2010](#); see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by educating children with diabetes about their care and being certain newborns receive blood spot testing so children with these disorders not only can be identified as early in life as possible but also can receive continuing care in a “medical home.” As the number of home births increases, it’s important to evaluate at well-child healthcare visits if a child did receive routine blood spot testing at birth or whether this should be obtained at a later date.

### *Nursing Process Overview*

## FOR CARE OF A CHILD WITH AN ENDOCRINE OR METABOLIC DISORDER

### **ASSESSMENT**

Endocrine and metabolic disorders, as a group, commonly cause changes in growth and a child’s social and physical development and may impair their cognitive development. These disorders are often manifested in growth and development delays, especially during puberty or adolescence. If not identified at birth, the disorder is usually detected when a child’s height and weight are measured at a healthcare visit and found to be above or below a typical measurement for that age. An acute loss in weight is often the first symptom of type 1 diabetes mellitus in children. Thyroid deficiencies or type 2 diabetes mellitus (T2D) may be revealed by being overweight. Pituitary difficulties may be revealed by unusually short or tall stature.

To obtain information on activity in the child, take a day history by asking a parent or child to describe all of the child’s actions on a typical day because this type of information yields clues that are helpful in distinguishing between a child with a more introverted nature (a “quiet” child) and one who is experiencing inactivity and chronic fatigue as a result of decreased endocrine function. For example, the quiet child lies down after school and reads, whereas the ill child lies down and sleeps. The healthy child appears to “go constantly” but can sit through a favorite television program or a meal. The child with increased thyroid hormone production may be unable to sit quietly at all.

Also assess dietary and elimination habits. Extreme thirst or appetite may occur with an endocrine disorder such as diabetes insipidus or type 1 diabetes mellitus. Frequent voiding in children most often reflects a urinary tract infection, but it may be evidence of excessive urine excretion (**polyuria**), possibly from pituitary dysfunction or diabetes mellitus. A child's general appearance may reveal early or late puberty changes, scaling or dry or darkening skin, drooping eyelids, protrusion of the eyeballs (**exophthalmos**), or poor muscle tone, all indications of endocrine disorders.

### **NURSING DIAGNOSIS**

Because endocrine glands control vital body functions, nursing diagnoses relevant to children with endocrine or metabolic disorders include both physiologic functions and the child's response to those changes. Some examples of such nursing diagnoses include:

- Deficient fluid volume related to constant excessive loss of fluid through urination
- Risk for imbalanced nutrition, less than body requirements, related to an inability to use glucose because of diabetes mellitus
- Disturbed body image related to abnormal height
- Health-seeking behaviors related to the self-administration of insulin
- Deficient knowledge related to long-term treatment needs
- Fear related to the potential and unknown illness outcome
- Anticipatory grieving related to presumed losses associated with diagnosis of long-term illness
- Interrupted family processes related to the child's chronic illness
- Anxiety related to financial resources required to maintain optimum family health

### **OUTCOME IDENTIFICATION AND PLANNING**

Although most endocrine and metabolic disorders have long-term implications, parents and children may find it easier to work with outcomes that are initially short term—particularly if they are having difficulty accepting the diagnosis and the long-term nature of the disorder. Because symptoms usually are not acute, children may easily forget to take (or parents may forget to give) necessary medications. Helping parents create reminder charts or set alerts on their smartphones are effective measures to increase compliance.

Evaluate both the school and home situation for any child with a chronic illness. You may need to help teachers better understand the child's health problem (with the parents' permission) so that they do not make excessive or inappropriate demands such as insisting that a child with hyperthyroidism submit neat handwriting assignments when the child cannot do so.

Selected organizations that are helpful for referral to parents include the American Diabetes Association ([www.diabetes.org](http://www.diabetes.org)), the Congenital Adrenal

Hyperplasia Support Group ([www.cah.org.uk](http://www.cah.org.uk)), Little People of America ([www.lpaonline.org](http://www.lpaonline.org)), and the National Tay-Sachs and Allied Diseases ([www.ntsad.org](http://www.ntsad.org)).

### **IMPLEMENTATION**

Interventions for children with endocrine or metabolic disorders must always be carried out with long-term aspects of care in mind. Bribing children to take medicine, for example, is never good practice with any child. It has no place with children who must continue to take a medication for the rest of their lives (bribery quickly becomes ineffective). Instead, offer the family referrals to age-appropriate support groups within their communities that will serve to build lifelong bonding and relationships. Sharing effective treatment plans and medication administration techniques can facilitate successful interventions in long-term care (Bell, Bayliss, Glauert, et al., 2016). As children reach maturity and can better understand their disorder, compliance increases as they begin to understand the way in which their daily medication is necessary to replace a missing endocrine component.

### **OUTCOME EVALUATION**

Children with disorders of endocrine or metabolic function need periodic evaluations throughout childhood because growth and changing activities necessitate changes in medication dosages or schedules. These checkups provide good opportunities for health teaching to equip children to meet new situations that arise as they mature. For example, body appearance such as being like, not unlike, their peers becomes increasingly important as children enter adolescence. Because of this, seemingly well-adjusted school-age children may develop extreme difficulty continuing to accept their illness as they get older. Adherence to a medication program may become erratic. Only by periodic reevaluation can these problems be identified so that healthcare plans can be modified and adapted to the child's needs, enabling the child and family to continue coping with a long-term illness.

The following examples suggest desired outcomes have been achieved:

- The child brings to clinic a written record showing that she took her medication as recommended.
- Parents list developmentally appropriate, not size-appropriate, activities for their child with a short stature.
- The child's blood pressure and pulse remain within normal limits for age, specific gravity of urine is between 1.003 and 1.030, skin turgor is good, and the child states thirst is not excessive.
- Parents demonstrate correct insulin injection technique and state they are comfortable administering an injection to their child.

## **Health Promotion and Risk Management**

Many endocrine and metabolic disorders are inherited; therefore, education and genetic

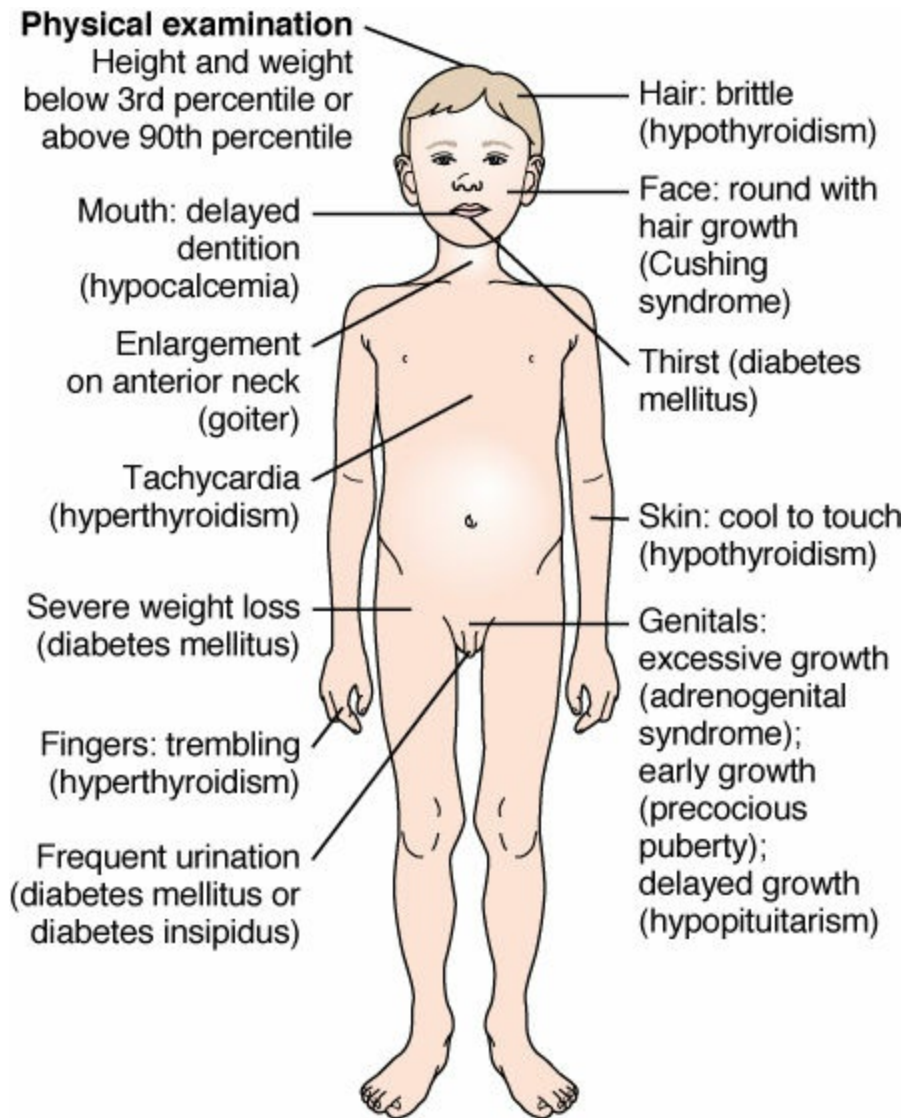

counseling are important preventive measures (Box 48.2).

BOX 48.2

## Nursing Care Planning Using Assessment

### ASSESSING A CHILD WITH AN ENDOCRINE DISORDER

T2D is strongly associated with obesity so is at an epidemic incidence because obesity in school-age children is also at epidemic proportions (Sherr & Weinzimer, 2012). School nurses can be instrumental not only in counseling and helping students manage this disorder during school hours but also in helping prevent T2D by serving as an advisor to what foods and snacks ought to be available in school settings.

## The Pituitary Gland

The work of the pituitary gland is directed by the **hypothalamus**, an organ located in the center of the brain and which serves as the regulator of the autonomic nervous system. About 1 cm long, 1.0 to 1.5 cm wide, and 0.5 cm thick, the pituitary gland rests in the **sella turcica**, a depression of the sphenoid bone.

The gland is divided into several distinct regions: the anterior lobe, or *adenohypophysis*; the posterior lobe, or *neurohypophysis*; and the intermediate lobe, or *pars intermedia*, which lies between the anterior and posterior lobes. Altogether, these divisions store and release eight different hormones. Four of these—the antidiuretic hormone (ADH), thyrotropin, corticotropin, and somatotropin—are prominently involved in childhood illnesses (Table 48.1).

**TABLE 48.1 Common Pituitary Hormones and Their Purposes**

<b>Pituitary Hormone</b>	<b>Source and Target Organs</b>	<b>Actions and Effects</b>
Antidiuretic hormone (ADH)	Secreted by the neurohypophysis <i>Target organ:</i> kidney	ADH helps regulate fluid volume by regulating urine output. By decreasing urine output, it increases the volume of extracellular fluid volume; when secretion of ADH is low, urinary output increases. Factors such as trauma, pain, anxiety, and exposure to high temperatures all increase ADH release.
Corticotropin (ACTH)	Secreted by the adenohypophysis <i>Target organ:</i> adrenal glands	ACTH stimulates the adrenal gland to produce glucocorticoid and mineralocorticoid hormones. Increased production of adrenal gland secretions decreases ACTH production and vice versa.
Somatotropin (growth hormone [GH])	Secreted by the adenohypophysis <i>Target organ:</i> none; acts on all body cells	GH increases bone and cartilage growth by increasing the gastrointestinal absorption of calcium. If GH production is inhibited, undergrowth will occur; if GH production is excessive, overgrowth will occur.
Thyrotropin (TSH)	Secreted by the adenohypophysis <i>Target organ:</i> thyroid gland	TSH stimulates the thyroid gland to produce thyroid hormones (thyroxine and triiodothyronine). Too little TSH leads to atrophy and inactivity of the thyroid gland; too much TSH causes hypertrophy (increase in size) and hyperplasia (increase in the number of cells) of the gland.

ACTH, adrenocorticotropin hormone; TSH, thyroid-stimulating hormone.

## Pituitary Gland Disorders

Illnesses caused by pituitary dysfunction can result from a tumor growing in either the pituitary gland or the hypothalamus, interference with circulation to the gland, trauma, inflammation, structural abnormalities, erratic or nonfunctional feedback mechanisms, and, possibly, autoimmune responses. Interference due to these reasons can result in hypopituitarism (lack of growth hormone), hyperpituitarism (excess secretion of growth hormone), or diabetes insipidus (undersecretion of ADH).

### GROWTH HORMONE DEFICIENCY

If production of human growth hormone (GH, or somatotropin) is deficient, children are not able to grow to full size (Dörr, Boguszewski, Dahlgren, et al., 2015). As a result, children may appear well proportioned but measure well below the average on a standard growth chart. Deficient production of GH may result from a nonmalignant cystic tumor of embryonic origin that places pressure on the pituitary gland or from increased intracranial pressure as a result of trauma. In most children with hypopituitarism, however, the cause of the defect is unknown; it may have a genetic origin.

If hypopituitarism is not treated, predicting exactly what height a child will reach is difficult because height varies with each individual. Without treatment, however, most children will not reach more than 3 or 4 ft in height.

### Assessment

The child with deficient production of GH is usually normal in size and weight at birth. Within the first few years of life, however, the child begins to fall below the third percentile of height and weight on growth charts. The face appears infantile because the mandible is recessed and immature, and the nose is usually small. The child's teeth may be crowded in a small jaw (and may erupt late). The child's voice may be high pitched, and the onset of pubic, facial, and axillary hair and genital growth will be delayed. The history, physical findings, and a decreased level of circulating GH contribute to the diagnosis.

A pituitary tumor must be ruled out as the cause of decreased GH production. Sudden halted growth suggests a tumor; gradual failure suggests an idiopathic involvement. A history of vision loss, headache, an increase in head circumference, nausea, and vomiting (signs of increased intracranial pressure) also suggest a pituitary tumor. Growth failure may be so marked in some children that the parents may be suspected of child neglect.

As part of the history taking, evaluate the family history for traits of short stature or constitutional delay (familial late development). If at all possible, obtain estimates of the parents' height and siblings' height and weight during their periods of growth. Assess the child's prenatal and birth history for any suggestion of intrauterine growth restriction. Assess also for any severe head trauma that could have injured the pituitary

gland or chronic illness, such as a heart, kidney, or intestinal disorder that could have contributed to the decreased level of growth. Take a 24-hour nutrition history to see if “picky eating habits” are extensive enough to halt growth. Be certain to assess not only the child’s actual height but also his or her feelings about being short.

A physical assessment, including a funduscopic examination, neurologic testing, and blood analysis for hypothyroidism, hypoadrenalism, hypoaldosteronism, and growth factor–binding proteins are also helpful in ruling out a lesion or tumor. Bone age is established by a wrist X-ray (epiphyseal closure of long bones is delayed with GH deficiency but is proportional to the height delay). A skull series, computed tomography (CT) scanning, magnetic resonance imaging (MRI), or ultrasound will be prescribed to detect possible enlargement of the sella turcica, which would suggest a pituitary tumor.

## Therapeutic Management

GH deficiency is treated by the administration of intramuscular recombinant human growth hormone (rhGH) usually given daily at bedtime, the time of day at which GH normally peaks (Graber & Rapaport, 2012) (Box 48.3). In addition, some children may need suppression of luteinizing hormone–releasing hormone (LHRH, or gonadotropin-releasing hormone [GnRH]) to delay epiphyseal closure. Other children may need supplements of gonadotropin or other pituitary hormones if these are determined to be deficient as well (Box 48.4 shows tips for the long-term administration of medicine to children).

### BOX 48.3

#### Nursing Care Planning Based on Responsibility for Pharmacology

#### SOMATROPIN (NUTROPIN, HUMATROPE)

**Classification:** Somatropin is an example of a recombinant human growth hormone (rhGH).

**Action:** used for the long-term treatment of children who have growth failure from inadequate production of pituitary hormone, renal failure, or Turner syndrome (Baronio, Mazzanti, Girtler, et al., 2017)

**Pregnancy Risk Category:** C

**Dosage:** Somatropin dosage is individualized. The drug is administered by injection either SC or intramuscularly.

**Possible Adverse Effects:** injection site pain, glucose intolerance, hypothyroidism, bone problems (particularly the hip), blood abnormalities, rare intracranial hypertension in first 8 weeks of therapy

#### Nursing Implications

- Advise parents that X-rays of the wrist or hip will be performed before therapy begins. Thereafter, parents should be alert for limping or knee or hip pain, which

should be reported to their primary healthcare provider because slipped capital epiphysis is associated with rhGH supplementation.

- Reinforce the need for periodic thyroid function tests and fundoscopic examination to detect rare intracranial hypertension.
- Alert parents that rhGH may interact with glucocorticoid therapy such as prednisone, causing a decrease in the effectiveness of the rhGH. Urge parents to inform all healthcare providers that the child is receiving rhGH to avoid this type of interaction.

#### BOX 48.4

### Nursing Care Planning to Empower a Family

#### GUIDELINES FOR SUCCESSFUL LONG-TERM MEDICINE ADMINISTRATION

**Q.** Rob's father asks you, "What are good rules for long-term medicine administration?"

**A.** To be successful giving medicine over a long period of time, build the administration of it into your family's general routine through such measures as:

- Begin involving your child as early as possible in medicine administration by explaining what it is and why the child needs to take it.
- Plan times for medication administration that allow for a normal lifestyle, such as not having to wake up at 2 AM or having to interrupt a meal for an injection.
- Be aware of the life span of the medicine so that medication does not expire.
- Be certain to anticipate the need to obtain prescriptions before vacations, summer camp, or holidays so medicine is always available.
- If an intramuscular, subcutaneous, or intravenous medication is prescribed, not only the child but also at least one parent should learn the injection technique to ensure adherence.

GH has been used irresponsibly by athletes in the hope that it will improve muscle growth and overall stamina. Caution children that the use of the drug when there is no medical reason for it is potentially dangerous and so they should not share the drug with friends or take excessive doses themselves (Baumann, 2012). Because they have delayed epiphyseal closure, if treatment is begun early, children can expect to reach a height individually targeted for them. Once epiphyseal lines of long bones close (with adolescence), GH will be tapered and stopped.

### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Situational low self-esteem related to short stature

**Outcome Evaluation:** Child speaks positively about self; identifies friends and activities enjoyed with peers.

If a child has been consistently behind in growth since early life, parents may simply assume in early childhood that the child is going to be short as an adult. The parents then may become concerned that something is wrong only after the child reaches puberty and fails to develop secondary sex characteristics. If an investigation at that time reveals the child's true problem is a lack of GH, parents may feel guilty that they did not become alarmed earlier. They may feel resentment toward healthcare personnel who did not alert them to the problem earlier. Encourage parents to discuss these feelings and provide support to help them accept their child in this new light as well as participate in making the new plan of care a success (Box 48.5). Children with short stature tend to report feelings of lower quality of life largely related to discrimination (Geisler, Lass, Reinsch, et al., 2012). You may need to remind parents to assign duties and responsibilities to children that match their chronologic age, not their physical size, in order to promote children's feelings of maturity and self-esteem. Because children different in any way from their peers may be the victims of bullying, alert parents to this possibility and assess for this at well-child visits to help protect the child's quality of life (Box 48.6).

#### BOX 48.5

#### Nursing Care Planning Tips for Effective Communication

Rob, a 16-year-old with diabetes, is short in stature. While observing him and his mother, you notice Rob is wearing clothes more suitable for a preteen than an adolescent.

*Tip:* Explore feelings around stature with both children and their parents. Help parents to understand all children grow older chronologically and need age-appropriate activities and interests even if they still appear young. Because many children with endocrine or metabolic disorders are short in stature, they are viewed as cute and petite by parents, and some parents express that they enjoy their child's short stature; it makes it seem as if the child will remain a child longer and not grow up and become independent. In the following scenario, the nurse gives Rob's mother the opportunity to discuss her feelings further.

**Nurse:** Mrs. Tebecco, do you have any questions about Rob's care?

**Mrs. Tebecco:** No. I'm worried, though, that he'll be wanting a driver's license soon. I'm lucky he's so short he can't really drive yet.

**Nurse:** Is he happy being so short?

**Mrs. Tebecco:** It made him better at gymnastics than the taller boys. Probably because he looks so much younger than he is.

**Nurse:** But how does he feel about his size? How do you think he'll feel in the future?

**Mrs. Tebecco:** I don't even think about that. I don't want to lose my baby.

**Nurse:** Let's talk a bit about how his growing up makes both of you feel before we review his insulin injection technique.

BOX 48.6

### Nursing Care Planning to Respect Cultural Diversity

The prevalence of endocrine disorders, such as type 2 diabetes, is correlated to nutrition and physical activity factors. The effects of nutrition impact a child's health from conception through adolescence. Nutrition and physical activity vary in families and are often a learned behavior.

Healthcare providers who seek to prevent diabetes and improve diabetes outcomes face challenges related to the disproportionate incidence and prevalence of both diabetes and diabetes-related complications among diverse populations, and each population has its own cultural influences. Culture can be defined by the way people look at the world, how they interact with others, and how they expect others to behave (Hagan, Shaw, & Duncan, 2017). Issues related to nutrition reflect the feeding environment, which includes foods selected, the environment within which food is offered, and the relationship between the caregiver and the child (Hagan et al., 2017). To provide effective patient education on nutrition, the nurse must understand attitudes about body weight and food insecurity. It is important for healthcare providers to respect and appreciate the variety of cultural traditions related to food and the variation in food practices among families, while promoting healthy nutrition and physical activity. Healthcare providers must also examine their own cultural influences and attitudes toward nutrition and physical activity when providing counseling (Hagan et al., 2017).

## GROWTH HORMONE EXCESS

An overproduction of GH usually is caused by a benign tumor of the anterior pituitary (an adenoma). If the overproduction occurs before the epiphyseal lines of the long bones have closed, excessive or overgrowth will result. Weight will become excessive also, but it is proportional to height. The skull circumference typically exceeds usual, and the fontanels may close late or not at all. After epiphyseal lines close, *acromegaly* (enlargement of the bones of the head and soft parts of the hands and feet) begins to be evident. The tongue can become so enlarged and thickened that it protrudes from the mouth, giving the child a dull, apathetic appearance and making it difficult to articulate words. If the condition remains untreated, a child may reach a height of more than 8 ft.

If X-rays or ultrasounds of the skull reveal that the sella turcica is enlarged or that a

tumor is present, laser surgery to remove the tumor or cryosurgery (freezing of tissue) is the primary treatment. If no tumor is present, a GH antagonist such as bromocriptine (Parlodel) taken orally or octreotide (Sandostatin) taken by injection can slow the production of GH. When GH secretion is halted in this way, other hormones may also be affected; therefore, the child may need to receive supplemental thyroid extract, cortisol, and gonadotropin hormones in later life. A more permanent therapy is irradiation or radioactive implants of the pituitary gland, again to halt GH production. It is difficult for a child always to be bigger and taller than playmates, and problems such as buying clothes or fitting into airline seats continue to be very real and distressing in adulthood. Counseling them about maintaining self-esteem and making the adjustments necessary to accommodate their larger-than-usual size is a nursing responsibility.

### ***QSEN Checkpoint Question 48.1***

#### **QUALITY IMPROVEMENT**

Sandy, Rob's 14-year-old girlfriend, often comes to the pediatric clinic with him. Sandy has hypopituitarism, and she and Rob first met at the endocrine clinic. Which of Sandy's statements would make the nurse believe she needs more education about her disorder? Select all that apply.

- a. "Taking growth hormone subcutaneously is a bother; I hope I'll be changed to pills soon."
- b. "I know I have to take growth hormone for life but it's okay; I'll be all right."
- c. "Growth hormone makes me pee a lot; I asked for a locker near the bathroom."
- d. "Growth hormone turned my cheeks red, but I cover it with makeup so it's okay."
- e. "I'm determined not to let this take away my quality of life."

*Look in Appendix A for the best answer and rationale.*

## **DIABETES INSIPIDUS**

Diabetes insipidus is a disease in which there is decreased release of ADH by the pituitary gland (Chamarthi, Morris, Kaiser, et al., 2013). This causes less reabsorption of fluid in the kidney tubules. Urine becomes extremely dilute, and a great deal of fluid is lost from the body. Diabetes insipidus may reflect an X-linked dominant trait, or it may be transmitted by an autosomal recessive gene. It may also result from a lesion, tumor, or injury to the posterior pituitary, or it may have an unknown cause. In a rare type of diabetes insipidus, pituitary function is adequate, but the kidneys' nephrons are not sensitive to ADH (a kidney-related etiology).

### **Assessment**

The child with diabetes insipidus experiences excessive thirst (**polydipsia**) that is

relieved only by drinking large amounts of water; there is accompanying polyuria. The specific gravity of the urine will be as low as 1.001 to 1.005 (normal values are more often 1.010 to 1.030). Urine output may reach 4 to 10 L in a 24-hour period (normal range, 1 to 2 L), depending on age.

Because so much fluid is lost, sodium becomes concentrated or hypernatremia occurs with symptoms of irritability, weakness, lethargy, fever, headache, and seizures. The signs and symptoms usually appear gradually. Parents may notice the polyuria first as bed-wetting in a toilet-trained child or weight loss because of the large loss of fluid. If the condition remains untreated, the child is in danger of losing such a large quantity of water that dehydration and death can result.

MRI, CT scanning, or an ultrasound study of the skull reveals whether a lesion or tumor is present. A further test is the administration of vasopressin (Pitressin) to rule out kidney disease. For this, after the child's urine output has been measured to establish a baseline, vasopressin is administered. The drug decreases the blood pressure, alerting the kidney to retain more fluid in order to maintain vascular pressure. If the fault that is causing the dilute urine is with the pituitary gland, not the kidneys, the child's urine output will decrease; if the fault is with the kidneys, urine will remain dilute and excessive in amount because the diseased kidneys cannot concentrate fluid.

### Therapeutic Management

Surgery is the treatment of choice if a tumor is present. If the cause is idiopathic, the condition can be controlled by the administration of desmopressin (DDAVP), an arginine vasopressin. In an emergency, this drug can be given intravenously (IV). For long-term use, it is given intranasally or orally (Burke, Vendrame, Pileggi, et al., 2016). If desmopressin is given as an intranasal spray, this may cause nasal irritation; the route will not be effective if the child develops an upper respiratory tract infection with swollen mucous membranes. Caution children that they will notice an increasing urine output just before the next dose is due so they can arrange their day according to where bathrooms are located.

### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for deficient fluid volume related to constant, excessive loss of fluid through urination

**Outcome Evaluation:** Child's blood pressure and pulse are within normal limits for age; specific gravity of urine is between 1.003 and 1.030; skin turgor is good; child states thirst is not excessive.

**Teach About Long-Term Therapy.** Be certain to explain the difference between diabetes insipidus and diabetes mellitus so the family is not confused about the

differences in therapy. Help the family establish a routine to ensure the child receives adequate fluid to discourage a feeling of thirst and has access to bathroom facilities possibly more frequently than others. Review suggestions for long-term medicine administration with them (see [Box 48.4](#)).

**Encourage Communication.** Caution parents that when seeking any type of health care, they should always notify healthcare providers that the child has diabetes insipidus. For example, surgery poses particular dangers because of the fluid restrictions that accompany most procedures. Encourage children to wear a medical alert tag identifying them as having diabetes insipidus. Urge parents to inform school personnel that the child may need to use the bathroom frequently and to plan on frequent bathroom stops and adequate fluid intake on long trips or activity-filled days.

### Concept Mastery Alert

Hyposecretion of antidiuretic hormone, as seen in diabetes insipidus, results in fluid loss. The symptoms—excessive thirst, frequent voiding, weakness, lethargy, and headache—are related to the loss of fluid.

## SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE

The syndrome of inappropriate antidiuretic hormone (SIADH) is a rare condition in which there is overproduction of ADH by the posterior pituitary gland. This results in a decrease in urine production, which leads to water intoxication. As sodium levels fall in proportion to water, the child develops hyponatremia or a lowered sodium plasma level. SIADH can be caused by central nervous system infections such as bacterial meningitis (see [Chapter 49](#)), long-term positive pressure ventilation, or pituitary compression such as could occur from edema or a tumor.

Mild symptoms of hyponatremia are weight gain, concentrated urine (increased specific gravity), nausea, and vomiting. As the hyponatremia grows more severe, coma or seizures occur from brain edema.

Therapy consists of restriction of fluid and supplementation of sodium by IV fluid if needed. Demeclocycline (Declomycin), a tetracycline antibiotic that has the side effect of blocking the action of ADH in renal tubules and reducing resorption of water, may be prescribed ([Miell, Dhanjal, & Jamookeah, 2015](#)).

## The Thyroid Gland

The thyroid gland, located at the front of the neck, is responsible for controlling the rate of metabolism in the body through the hormones thyroxine ( $T_4$ ) and triiodothyronine ( $T_3$ ), which are produced by its follicular cells.

## ASSESSMENT OF THYROID FUNCTION

Radioimmunoassay of  $T_4$  and  $T_3$  is a specific blood study to determine how much protein-bound iodine (PBI) is present in serum. Ask if a child has recently taken large amounts of cough medicine containing iodide or underwent a study using an iodine-based contrast medium (e.g., urography, bronchography) recently before the study or PBI levels may be abnormally elevated. The small amount of iodine ingested from iodized salt does not affect PBI levels.

Children who have low circulating albumin levels can have abnormally low PBI levels because iodine is carried bound to protein. Phenytoin (Dilantin), a common anticonvulsant medication prescribed for children with recurrent seizures, may displace  $T_4$  from binding globulin and further contribute to low PBI levels.

Another test of thyroid function is a radioactive iodine uptake test. The child is given an oral dose of a solution containing radioactive iodine ( $^{123}\text{I}$ ). The thyroid gland “traps” this iodine, and, 24 hours later, after the maximum amount has been trapped, the amount of radioactive iodine present can be determined. It is important in this type of test that the child swallows all the solution. In infants, the solution usually is given as a gavage feeding, so that accuracy of the dose can be ensured.

An uptake of less than 10% of the test dose suggests hypothyroidism. If the child vomits after ingesting the substance, this event should be recorded and called to the attention of the laboratory; it will obviously result in a lower uptake value because only a part of the actual dose will be available for uptake. Be certain that the child does not receive iodine or thyroid extract in any other form during the 24-hour test time because this would compete with uptake of the radioactive iodine and, again, produce a falsely low value.

## Thyroid Gland Disorders

### CONGENITAL HYPOTHYROIDISM

Thyroid hypofunction causes reduced production of both  $T_4$  and  $T_3$ . Congenital hypofunction (reduced or absent function) occurs as a result of an absent or nonfunctioning thyroid gland in a newborn. There has been a large increase in the incidence of congenital hypothyroidism in the United States in the last two decades (Kollati, Ambati, Reddy, et al., 2017). Researchers are attempting to determine if this increase reflects a true increase in the disorder possibly due to environmental factors, due to better screening methods, or results from an increase in transient hypothyroidism (lessened thyroid function caused by a low iodine level in the mother or autoimmune antibodies that crossed the placenta). The increased incidence is associated with Whites, is evident more in infant girls than boys, and in newborns of either low birth weight or a birth weight over 4,500 g (LaFranchi, 2014).

Congenital hypothyroidism or an indication that the infant’s thyroid is not functioning well may not be noticeable at birth because the mother’s thyroid hormones

(unless she ingested less than usual amounts of iodine) maintain adequate levels in the fetus during pregnancy. The symptoms of the disorder become apparent during the first 3 months of life in a formula-fed infant and at about 6 months in a breastfed infant. Because congenital hypothyroidism leads to both severe, progressive physical and cognitive challenges, early diagnosis is crucial.

### Assessment

A screening test for hypothyroidism is mandatory at birth in the United States in all 50 states (using the same few drops of blood obtained for a phenylketonuria [PKU] blood spot test) (Kollati et al., 2017). If an infant should miss this screening procedure, an early sign that parents report is that their child sleeps excessively, but because the tongue is enlarged, they notice respiratory difficulty, noisy respirations, or obstruction. The child may also suck poorly because of sluggishness or choking from the enlarged tongue. The skin of the extremities usually feels cold, dry, and perhaps scaly, and the child does not perspire. Pulse, respiratory rate, and body temperature all become subnormal. Prolonged jaundice may be present due to the immature liver's inability to conjugate bilirubin. Anemia may increase the child's lethargy and fatigue.

On a physical exam, the hair is brittle and dry, and the child's neck appears short and thick. The facial expression is dull and open mouthed because of the infant's attempts to breathe around the enlarged tongue. The extremities appear short and fat; as muscles become hypotonic, deep tendon reflexes decrease and the infant develops a floppy, rag-doll appearance. Generalized obesity usually occurs. Dentition will be delayed, or teeth may be defective when they do erupt.

The hypotonia affects the intestinal tract as well, so the infant develops chronic constipation; the abdomen enlarges because of intestinal distention and poor muscle tone (Fig. 48.2). Many infants have an umbilical hernia. Infants have low radioactive iodine uptake levels, low serum  $T_4$  and  $T_3$  levels, and elevated thyroid-stimulating factor. Blood lipids are increased. An X-ray may reveal delayed bone growth. An ultrasound reveals a small or absent thyroid gland. Untreated, the condition will result in severe irreversible cognitive deterioration or delay (Kollati et al., 2017).

**Figure 48.2** An infant with congenital hypothyroidism. Notice the short, thick neck and enlarged abdomen. (© David/NMSB/Custom Medical Stock Photograph.)

### Therapeutic Management

Transient hypothyroidism usually fades by 3 months' time. The treatment for true hypothyroidism is the oral administration of synthetic thyroid hormone (sodium levothyroxine). A small dose is given at first, and then the dose is gradually increased to therapeutic levels. The child needs to continue taking the synthetic thyroid hormone indefinitely to supplement that which the thyroid does not make. Supplemental vitamin D may also be given to prevent the development of rickets when, with the administration of thyroid hormone, rapid bone growth begins (Kim, 2016).

Further cognitive challenges can be prevented as soon as therapy is started, but any degree of impairment that was already present cannot be reversed, making the disorder one of the most preventable causes of mental development delay known (LaFranchi, 2014).

Be certain the parents know the rules for long-term medication administration with children, particularly the rule about not putting medicine in a large amount of food ( $T_4$  tablets must be crushed and added to food or a small amount of formula or breast milk) and being certain they have medicine during holidays or vacations. Periodic monitoring of  $T_4$  and  $T_3$  helps to ensure an appropriate medication dosage. If the dose of thyroid hormone is not adequate, the  $T_4$  level will remain low and there will be few signs of clinical improvement. If the dose is too high, the  $T_4$  level will rise and the child will show signs of hyperthyroidism: irritability; fever; rapid pulse; and perhaps vomiting, diarrhea, and weight loss.

## ACQUIRED HYPOTHYROIDISM (HASHIMOTO THYROIDITIS)

Hashimoto disease is the most common form of acquired hypothyroidism in childhood; the age at onset is most often 10 to 11 years. There may be a family history of thyroid disease and it occurs more often in girls than in boys. The decrease in thyroid secretion is caused by the development of an autoimmune phenomenon that interferes with thyroid production.

### Assessment

The excretion of thyroid-stimulating hormone (TSH) from the pituitary increases when thyroid hormone production decreases in an attempt by the pituitary gland to increase thyroid function. In response to the increased level of TSH, hypertrophy of the thyroid gland (goiter) can occur, and body growth is impaired by a lack of T<sub>4</sub>, with prominent symptoms of obesity, lethargy, and delayed sexual development.

Antithyroid antibodies will be present in serum if the illness was caused by an autoimmune process. If the thyroid enlarges, it may become nodular as well. Although in childhood, a nodular thyroid is usually benign, an investigation into the possibility this could be a thyroid malignancy must be considered. For diagnosis, children are administered radioactive iodine. If the nodes are benign, there is generally a rapid uptake of radioactive iodine (“hot nodes”). If there is no uptake (“cold nodes”), carcinoma is a much more likely diagnosis (which is rare at this age).

### Therapeutic Management

Treatment for acquired hypothyroidism is the administration of synthetic thyroid hormone (sodium levothyroxine), the same as for congenital hypothyroidism. With adequate dosage, the obesity diminishes and growth begins again. It is important that the disease be recognized as early as possible so there is time to stimulate growth before the epiphyseal lines close at puberty.

If acquired hypothyroidism exists in a woman during pregnancy, her infant can be born cognitively challenged because there was not enough iodine present for fetal growth. It is important, therefore, that girls with this syndrome be identified before they reach childbearing age.

#### *What If . . . 1.1*

Rob’s mother tells a nurse that her sister (Rob’s aunt) is 3 months pregnant and was prescribed levothyroxine (Synthroid) (synthetic thyroid hormone) but “forgets to take it most days and really cannot afford it.” What should the nurse do?

## HYPERTHYROIDISM (GRAVES DISEASE)

Hyperthyroidism is oversecretion of thyroid hormones by the thyroid gland. Neonatal

Graves disease develops in the newborns of 1% to 2% of pregnant women who have the disease. Like transient hypothyroidism, this usually resolves between 3 to 12 weeks of age with no long-term results as the maternal antibodies are cleared (Rivkees, 2014).

In older children, overactivity of the thyroid gland can occur from the glands being overstimulated by TSH from the pituitary gland due to a pituitary tumor. More frequently, however, hyperthyroidism in children is caused by an autoimmune reaction that results in overproduction of immunoglobulin G (IgG), which stimulates the thyroid gland to overproduce T<sub>4</sub>. An exophthalmos-producing pituitary substance causes the prominent-appearing eyes that accompany hyperthyroidism in some children.

### Assessment

Some children may have a genetic predisposition to development of the disorder, although Graves disease often follows a viral illness or a period of stress. With overproduction of T<sub>3</sub> and T<sub>4</sub>, children gradually experience nervousness, tremors, loss of muscle strength, and easy fatigue. Their basal metabolic rate, blood pressure, and pulse all increase. Their skin feels moist, and they perspire freely. They always feel hungry and, although they eat constantly, do not gain weight and may even lose weight because of the increased basal metabolic rate. On X-ray, bone age will appear advanced beyond the chronologic age of the child. Unless the condition is treated, the child is not likely to reach usual adult height because epiphyseal lines of long bones will close before full height can be attained.

The thyroid gland, which usually is not prominent in children, appears as a swelling on the anterior neck as goiter develops. In a few children, the eye globes become prominent (exophthalmia), giving the child a wide-eyed, staring appearance. Laboratory tests show elevated T<sub>4</sub> and T<sub>3</sub> levels and increased radioactive iodine uptake. TSH is low or absent because the thyroid is being stimulated by antibodies, not by the pituitary gland. Ultrasound will reveal the enlarged thyroid.

### Therapeutic Management

Therapy consists first of a course of a  $\beta$ -adrenergic blocking agent, such as propranolol, to decrease the antibody response. After this, the child is placed on an antithyroid drug, such as propylthiouracil (PTU) or methimazole (Tapazole), to suppress the formation of T<sub>4</sub>. While the child is taking these drugs, the blood is monitored for leukopenia (decreased white blood cell count) and thrombocytopenia (decreased platelet count)—side effects of these drugs. If either of these results, the drug is discontinued until the white blood cell or platelet count returns to normal, so the child does not develop an infection or experience spontaneous bleeding.

Because the thyroid stores considerable thyroid hormone that must be used up first before T<sub>4</sub> levels decline, it takes about 2 weeks for these drugs to have an effect. The child needs to continue to take the drug for 2 to 3 years before the condition “burns itself out.” The exophthalmos may not recede, but it will not become worse once

therapy is instituted.

If the child has a toxic reaction to medical management (severely lowered white blood cell count or platelet count) or is noncompliant about taking the medicine, radioiodine ablative therapy with  $^{131}\text{I}$  or thyroid surgery to reduce the size of the thyroid gland can be accomplished. This has long-term effects, however, because after both radioiodine ablative therapy and thyroidectomy, supplemental thyroid hormone therapy may need to be taken indefinitely because the gland is no longer able to produce an adequate amount (Léger & Carel, 2013). It is important that adolescent girls be carefully regulated before they consider childbearing because hyperthyroidism during pregnancy can lead to neonatal hyperthyroidism in a fetus.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Situational low self-esteem related to lack of coordination and presence of prominent goiter or exophthalmia

**Outcome Evaluation:** Child states positive traits about self and identifies friends and activities enjoyed; is not the victim of bullying because of unusual appearance.

Hyperthyroidism begins gradually and so may become fairly involved before it is detected. Suspect children at puberty of having hyperthyroidism if they are losing weight or have behavior problems in school, which occur because of the hand or tongue tremors that make it hard for them to write or speak and the nervousness that makes them unable to sit still during class.

Offer parents support to supervise medication administration so they can be certain the child takes the prescribed medicine every day. Caution children not to stop taking the medicine abruptly, or a thyroxine crisis (sudden onset of extreme symptoms of hyperthyroidism) can occur. Parents may ask if their child can have surgery as a cure so that long-term administration of medicine will not be required. Help them understand that surgery may not dispel the need for medication; if a large portion of the thyroid gland is removed, it may be necessary for their child to take medicine indefinitely to make up for the missing gland. In any event, it is preferable to try a course of medical management before resorting to surgery.

### *QSEN Checkpoint Question 48.2*

#### **PATIENT-CENTERED CARE**

Rob has a cousin who has developed hyperthyroidism with puberty. Which of the effects of this health problem might a school nurse need to support Rob's cousin in dealing with?

- a. Slow, lethargic movements

- b. Swollen, protuberant abdomen
- c. Jittery, nervous mannerisms
- d. Reduced intellectual processing

*Look in Appendix A for the best answer and rationale.*

## The Adrenal Gland

The two adrenal glands are located retroperitoneally, just above the kidneys. They are made up of two distinct divisions; together, these divisions protect the body against acute and chronic forms of stress. Three hormones—cortisol (a glucocorticoid responsible for glucose and protein metabolism and preventing inflammation), androgen (a steroid hormone responsible for muscle development), and aldosterone (a mineralocorticoid hormone necessary for sodium and fluid balance) are important in childhood illnesses.

## Adrenal Gland Disorders

Disorders of the adrenal glands cause either hypofunction, which can lead to acute or chronic production of necessary hormones, or hyperfunction (overactivity), which most often leads to overproduction of androgen or cortisol.

### ACUTE ADRENOCORTICAL INSUFFICIENCY

Insufficiency (hypofunction) of the adrenal gland can occur in either an acute or chronic form. In either type, the function of the entire gland suddenly becomes nonproductive. Usually, this occurs following a severe overwhelming body infection such as meningococemia. It also can occur when corticosteroid therapy such as prednisone, which has been maintained at high levels for a long period, is abruptly stopped and the gland does not return to usual function.

#### Assessment

With acute adrenocortical insufficiency, the child's blood pressure drops to extremely low levels, the child appears ashen gray, and the pulse will be weak. Temperature gradually becomes elevated; dehydration and **hypoglycemia** (an abnormally low concentration of blood glucose) become marked because cortisol is no longer present to regulate this. As sodium and chloride blood levels fall from a lack of aldosterone production, the potassium level becomes elevated due to the usual inverse relationship between sodium and potassium values. The child appears prostrate and seizures may occur. Without treatment, death can occur abruptly (Agarwal, Singh, Chowdhury, et al., 2017; Korzeniewski, Grigorescu, Kleyn, et al., 2012).

#### Therapeutic Management

Acute adrenocortical insufficiency is a medical emergency. Treatment involves the immediate replacement of cortisol (with IV hydrocortisone sodium succinate [Solu-Cortef]); the administration of deoxycorticosterone acetate (DOCA), the synthetic equivalent of aldosterone; and IV 5% glucose in normal saline solution to restore blood pressure, sodium, and blood glucose levels. A vasoconstrictor may be necessary to elevate the blood pressure.

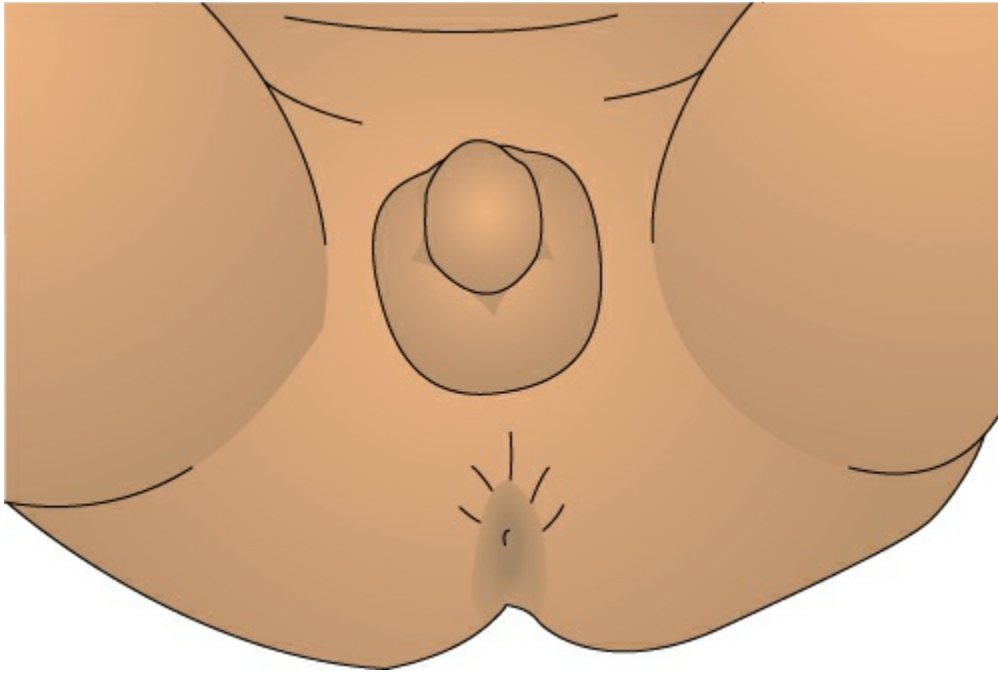

Although acute adrenal insufficiency is seen less often now than in the past because of the availability of antibiotics that quickly halt the course of infectious disease because more conditions are being treated with corticosteroids than ever before, the chance the syndrome will occur from sudden withdrawal of high-dose steroids is actually increasing.

## CONGENITAL ADRENAL HYPERPLASIA

Congenital adrenal hyperplasia is a syndrome that is inherited as an autosomal recessive trait and which causes the adrenal glands to not be able to synthesize cortisol. Because the adrenal gland is unable to produce cortisol, the level of adrenocorticotropic hormone (ACTH) secreted by the pituitary increases in an attempt to stimulate the gland to increase function. Although the adrenals enlarge (hyperplasia) under the effect of ACTH, they still cannot produce cortisol; instead, they overproduce androgen.

### Assessment

The excessive androgen production during intrauterine life causes the genital organs in a male fetus to “overgrow,” or increase in size; it masculinizes a female fetus (i.e., the clitoris is so enlarged that it appears to be a penis; if the labia are fused, she appears to be a boy with undescended testes and hypospadias (Fig. 48.3) (Graber & Rapaport, 2012). Other female organs appear normal, although a sinus between the urethra and vagina may be present (see the discussion of ambiguous genitalia in Chapter 47). If the condition is not recognized at birth and the child remains untreated, bone age will advance so the epiphyseal lines of the long bones close early, preventing the child from reaching a usual adult height; pubic and axillary hair, acne, and a deep masculine voice will appear precociously. At puberty, there will be no breast development or menstruation.

**Figure 48.3** A female infant with congenital adrenogenital hyperplasia. Note the fused labia and abnormally enlarged clitoris.

By 3 or 4 years of age, untreated boys develop acne and a deep, mature voice; pubic hair and still greater enlargement of the penis, scrotum, and prostate occur. In contrast, the testes do not enlarge and so appear small in relation to the size of the penis. Spermatogenesis does not occur with puberty, leaving the child infertile.

It is possible to identify the fetus with congenital adrenogenital hyperplasia as early as 6 to 8 weeks of pregnancy by means of maternal serum analysis and at 15 weeks by amniocentesis (see [Chapter 9](#)). Although controversial, treatment of a mother with dexamethasone (a corticosteroid), which crosses the placenta to the fetus, can prevent masculinization in the fetus for the remainder of the pregnancy. The newborn will then need hydrocortisone administration after birth for continuing therapy.

The condition is usually diagnosed not during pregnancy, however, but in infancy by serum analysis, which shows the increased level of androgen. By determining the levels of other adrenal hormones, the exact degree of the metabolic defect in production of cortisol can be measured.

### **Therapeutic Management**

The ultimate goal of therapy is to replace the cortisol that is missing, thereby suppressing ACTH concentrations and normalizing adrenal size and androgen production, a goal that seems quite simple but is actually very difficult to achieve ([Léger & Carel, 2013](#)). For therapy, both male and female infants are given a corticosteroid agent, such as oral hydrocortisone, to replace what they cannot produce naturally. When a corticosteroid is given to the child in this way, stimulation by ACTH decreases, the production of androgen returns to normal limits, and no further

masculinization occurs. Because corticosteroid therapy needs to continue indefinitely, the child needs periodic analysis of serum cortisol levels and growth measurements to estimate the effectiveness of the therapy. Children may need to have a routine dose increased when they are undergoing periods of stress, such as during surgery or infection. They may need support throughout life if their body image is distorted because of body changes at birth.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Situational low self-esteem related to genital formation at variance with true gender

**Outcome Evaluation:** Child identifies positive traits about self and describes activities enjoyed with peers; expresses satisfaction with gender identity; does not report bullying from peers.

All newborns need an extensive physical examination at birth so chromosomal girls with this syndrome are not wrongly identified as male. It is sometimes recommended to parents that a girl's enlarged clitoris be reduced by plastic surgery in infancy. This treatment is controversial, however, because even with finer surgical techniques, clitoral reduction can also result in reduced clitoral sensation. A girl should have the right to make this decision for herself, however, so, as a rule, surgery is delayed until the girl is old enough to understand what will be the implication of not having clitoral sensation on her sexual enjoyment (Michala, Liao, Wood, et al., 2014).

Parents of females with congenital adrenogenital hyperplasia may need a great deal of support during the first few days of their child's life because they may voice that their child is imperfect in an embarrassing, hard-to-explain way. When they are the results of the chromosome analysis, parents may react with grief for the loss of the son they first thought had been born to them. Parents need support from healthcare personnel who recognize that the child is simply lacking the ability to produce cortisol but is complete in every other way.

## SALT-LOSING FORM OF CONGENITAL ADRENOGENITAL HYPERPLASIA

If there is a complete blockage of cortisol formation, aldosterone production will also be deficient. Without adequate aldosterone, salt is not retained by the body, so fluid is not retained. Almost immediately after birth, affected infants begin to have vomiting, diarrhea, anorexia, loss of weight, and extreme dehydration (Mak, Lee, Chan, et al., 2013). If these symptoms remain untreated, the extreme loss of salt and fluid can lead to collapse and death as early as 48 to 72 hours after birth.

About one third of children with congenital adrenogenital hyperplasia are affected by this complete deficiency. Because boys with this syndrome appear normal at birth, the symptoms may be incorrectly diagnosed as infection or as failure to thrive. In girls, because of the ambiguous genitalia, the correct diagnosis can be made more easily.

### Assessment

The salt-losing form must be detected before an infant reaches an irreversible point of salt depletion. (The reason newborns are weighed at birth and again at 24 hours is to detect this condition.) Weighing infants at each well-child health checkup is also important because, in boys, the inability to gain back their birth weight may be the first sign of the syndrome.

### Therapeutic Management

Children with this form of congenital adrenogenital hyperplasia need to be supplemented with hydrocortisone, an increased salt intake, and DOCA, a synthetic aldosterone, in order to maintain a balance of fluid and electrolytes. A long-acting form of DOCA can be given once a month intramuscularly. Capsules of DOCA can also be implanted subcutaneously (SC) as another form of long-acting therapy. As the child grows older, fludrocortisone (Florinef), a mineralocorticoid, may be given orally to aid salt retention.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for deficient fluid volume related to loss of body fluid

**Outcome Evaluation:** Child's skin turgor remains good; specific gravity of urine is between 1.003 and 1.030.

Teach parents about the body's critical need to balance aldosterone, salt, and water, so they understand the drastic consequences if their child skips a dose of medication. Otherwise, they may underestimate that salt, although an "extra" in their own diet, is as vital to their child's intake as digitalis is in heart disease or insulin is in diabetes. Help them to set up a schedule as necessary for measuring their child's weight, giving medication, or measuring urine output.

## CUSHING SYNDROME

Cushing syndrome is caused by overproduction of the adrenal hormone cortisol; this usually results from increased ACTH production due to either a pituitary or adrenal cortex tumor. The peak age of occurrence is 6 or 7 years, but the syndrome can occur as early as infancy. The inappropriate use of high-potency steroid creams for diaper

dermatitis may be a possible cause (Smy, Shaw, Smith, et al., 2015). The overproduction of cortisol results in increased glucose production; this causes fat to accumulate on the cheeks, chin, and trunk, causing a moon-faced, stocky appearance. Cortisol is catabolic, so protein wasting also occurs. This leads to muscle wasting, making the extremities appear thin in contrast to the trunk, and loss of calcium in bones (osteoporosis). Cortisol also suppresses the immune system, so humoral immunity is decreased, leaving children susceptible to infections. Additionally, it causes vasoconstriction, so extreme hypertension may occur.

Yet, other effects are hyperpigmentation (the child's face appears unusually red, especially the cheeks), which occurs from the melanin-stimulating properties of ACTH; abnormal masculinization or feminization, which occurs from overproduction of androgen or estrogen; and poor wound healing, which results from reduced protein regulation. Purple striae resulting from collagen deficit appear on the child's hips, abdomen, and thighs, similar to those seen in pregnancy (Fig. 48.4).

**Figure 48.4** Signs and symptoms of Cushing syndrome.

Polyuria begins to develop as the body tries to excrete increased glucose levels. Growth ceases, and, if the condition is not reversed before the epiphyseal lines close, short stature will result.

Children who receive high doses of synthetic corticosteroids, such as prednisone, over a long period may develop the same symptoms as those observed in Cushing

syndrome (termed a *cushingoid appearance*). Children who are obese may have elevated levels of plasma corticosteroids and so be wrongly diagnosed as having Cushing syndrome. However, with this, the child's growth is not impaired, so these elevated levels of corticosteroids are secondary to the obesity, not the cause.

### Assessment

The serum of children with Cushing syndrome reveals an elevated plasma cortisol and increased urinary free-cortisol levels. A dexamethasone suppression test may be administered for diagnosis. For this test, a child is administered a dose of dexamethasone (a glucocorticoid); if the child has the syndrome, the plasma level of adrenal cortisol will fall. It will not fall in children with adrenocortical tumors because the tumor continues to stimulate the adrenal glands to oversecretion. If cosyntropin (Cortrosyn), a synthetic corticotropin, or ACTH is administered, plasma cortisol levels will normally rise. In children with an adrenal tumor, the gland is already functioning at full capacity, so no cortisol elevation occurs. A CT scan or ultrasound reveals the enlarged adrenal or pituitary gland, confirming the diagnosis.

### Therapeutic Management

Treatment of Cushing syndrome is the surgical removal of the causative tumor. The prognosis depends on whether the tumor is benign or malignant because a carcinoma of this type tends to metastasize rapidly. If a major part of the adrenal glands are surgically removed, the child will need replacement cortisol therapy indefinitely.

If a major portion of the pituitary gland is removed because the problem was overproduction of ACTH, the replacement of all pituitary hormones may be necessary. After adrenal surgery, observe the child carefully for signs of shock: Without epinephrine also produced by the gland, the body's ability to maintain blood pressure is severely compromised, and severe hypotension can result.

### QSEN Checkpoint Question 48.3

#### INFORMATICS

Rob has his adrenal gland function assessed through diagnostic testing. What is the effect on a child when sufficient aldosterone cannot be produced?

- Substantially fewer red blood cells are produced.
- There is an overall decreased urine output.
- An excessive amount of sodium is lost in urine.
- The child's growth rate increases abnormally.

Look in *Appendix A* for the best answer and rationale.

## The Pancreas

The pancreas is a unique organ in that it has both endocrine (ductless) and exocrine (with duct) types of tissue. The *islets of Langerhans* form the endocrine portion, alpha islet cells have the responsibility to secrete glucagon, and beta islet cells secrete insulin.

Insulin is essential for carbohydrate metabolism and is also important in the metabolism of both fats and protein. It is formed from amino acids at a rate between 35 and 50 units per day in adults and proportionately less in children. When serum glucose that passes through the pancreas exceeds 100 mg/dl, beta cells immediately begin insulin production. When serum glucose levels are low, production decreases.

Insulin production is also stimulated by gastrin, a gastrointestinal hormone that rises when the stomach is full as well as the levels of glucagon, cortisol, GH, progesterone, and estrogen. Increasing levels of epinephrine or norepinephrine inhibit the secretion of insulin in order to preserve glucose for “flight or fight.”

The principal childhood disorders associated with pancreatic dysfunction are type 1 and type 2 diabetes mellitus and cystic fibrosis. Because the nursing care for children with cystic fibrosis includes many respiratory care procedures, it is discussed in [Chapter 40](#).

## TYPE 1 DIABETES MELLITUS

Type 1 diabetes mellitus is a disorder that involves an absolute or relative deficiency of insulin, which is in contrast to type 2, where insulin production is only reduced ([Table 48.2](#)). Type 1 diabetes is equal in incidence in boys and girls and affects approximately 1 of every 500 children and adolescents in the United States ([Sherr & Weinzimer, 2012](#)).

**TABLE 48.2** Comparison of Type 1 and Type 2 Diabetes

Assessment	Type 1	Type 2
Age at onset	5–7 years or at puberty	40–65 years (may occur in adolescents as maturity-onset diabetes of youth [MODY])
Type of onset	Abrupt	Gradual
Weight changes	Marked weight loss often initial sign	Associated with obesity
Other symptoms	Polydipsia and polyphagia	Polydipsia
	Polyuria (often begins as bed-wetting)	Polyuria
	Fatigue (marks fall in school)	Fatigue
	Blurred vision (marks fall in school)	Blurred vision
	Mood changes (may cause behavior	Mood changes

	problems in school)	
Therapy	Hypoglycemia agents never effective; insulin required	Diet, oral hypoglycemic agents, or insulin
	No dietary foods used; should count carbohydrates plus evaluate blood glucose levels to help determine insulin dosage.	Nutrition concentrates on no excess weight gain and balanced intake of carbohydrates, protein, and fat
	Commonsense foot care for growing children	Meticulous skin and foot care necessary
Period of remission	Period of remission for 1–12 months (“honeymoon period”) generally after initial diagnosis	Not demonstrable

## Etiology

The disease apparently results from immunologic damage to islet cells in susceptible individuals. Why autoimmune destruction of islet cells occurs is unknown, but children with the disorder have a high frequency of certain human leukocyte antigens (HLAs), particularly HLA-DR3 and HLA-DR4, located on chromosome 6, that may lead to susceptibility. If one child in a family has diabetes, the chance that a sibling will also develop the illness is higher than in other families because siblings also tend to have one of the specific HLA that are associated with the disease.

## Disease Process

Insulin can be thought of as a compound that opens the doors to body cells, allowing them to admit glucose, which is needed for functioning. It does not play a major role in glucose transport into the brain, erythrocytes, leukocytes, intestinal mucosa, or kidney epithelium. These cells, therefore, can survive insulin deficiency but not glucose deficiency.

If glucose is unable to enter body cells because of a lack of insulin, it builds up in the bloodstream (**hyperglycemia**). As soon as the kidneys detect hyperglycemia (greater than the renal threshold of about 160 mg/dl), the kidneys attempt to lower it to normal levels by excreting excess glucose into the urine, causing **glycosuria**, accompanied by a large loss of body fluid (polyuria). Excess fluid loss, in turn, triggers the thirst response (polydipsia), producing the three cardinal symptoms of diabetes: polyuria, polydipsia, and hyperglycemia.

Because body cells are unable to use glucose but still need a source of energy, the body begins to break down protein and fat. If large amounts of fat are metabolized this way, weight loss occurs and ketone bodies, the acid end product of fat breakdown, begin to accumulate in the bloodstream (creating high serum cholesterol levels and ketoacidosis) and spill into the urine as ketones. Potassium and phosphate, attempting to

serve as buffers, pass from body cells into the bloodstream. From there, they are evacuated, causing a loss of these important electrolytes.

Untreated diabetic children, therefore, lose weight, are acidotic due to the buildup of ketone bodies in their blood, are dehydrated because of the loss of water, and experience an electrolyte imbalance because of the loss of potassium and phosphate in urine. Because large amounts of protein and fat are being used for energy instead of glucose, children lack the necessary components for growth; they therefore remain short in stature and underweight.

## Assessment

Although children may be prediabetic for some time, the onset of symptoms in childhood is usually abrupt. Parents notice increased thirst and increased urination (which may be recognized first as bed-wetting [enuresis] in a previously toilet-trained child). The dehydration may cause constipation.

## Laboratory Studies

In some children, diabetes is detected at a routine health screening. For others, although the disease has been progressing internally for some time, outward symptoms have such an abrupt onset that the child is in a coma from acidosis and hyperglycemia by the time it is detected. Laboratory studies usually show a random plasma glucose level greater than 200 mg/dl (normal range, 70 to 110 mg/dl fasting; 90 to 180 mg/dl not fasting) and significant glycosuria (Table 48.3).

**TABLE 48.3** Acceptable Blood Glucose Ranges for Children With Type 1 Diabetes

Timing	Value (mg/dl)
Before a meal	70–110
1 hr after a meal	90–180
2 hr after a meal	80–150
Between 2 am and 4 am	70–120

Two diagnostic tests, the fasting blood glucose test and the random blood glucose test, are used to confirm diabetes. A diagnosis of diabetes is established if one of the following three criteria is present on two separate occasions:

- Symptoms of diabetes plus a random blood glucose level greater than 200 mg/dl
- A fasting blood glucose level greater than 126 mg/dl
- A 2-hour plasma glucose level greater than 200 mg/dl during a 75-g oral glucose tolerance test (GTT)

Typically, a GTT involves the oral ingestion of a concentrated glucose solution followed by blood glucose levels drawn at fasting (baseline), after 1 hour, and after 2 hours. The test is difficult for children to undergo because it requires them to fast for 8

hours, drink an overly sweet solution, and submit to painful, intrusive procedures (routine application of lidocaine/prilocaine [EMLA] cream to finger stick or venipuncture sites and use of intermittent infusion devices greatly reduces this problem). Do not take blood for glucose analysis from functioning IV tubing to try to help with pain because the glucose in the IV solution will cause the serum reading to be abnormally high.

### Other Diagnostic Tests

If diabetes is detected, the diagnostic workup also usually includes an analysis of blood samples for pH, partial pressure of carbon dioxide (PCO<sub>2</sub>), sodium, and potassium levels; a white blood cell count; and a glycosylated hemoglobin (HbA1c) evaluation. Normally, the hemoglobin in red blood cells carry only a trace of glucose. If serum glucose is excessive, however, excess glucose attaches itself to hemoglobin molecules, creating HbA1c. In nondiabetic children, the usual HbA1c value is 1.8 to 4.0. A value greater than 6.0 reflects an excessive level of serum glucose. Measuring HbA1c has advantages because it not only provides information on what is the child's present serum glucose level but what the serum glucose levels have been during the preceding 3 to 4 months (red blood cells have a life span of 120 days).

If the potassium level of the blood is low, a child may need an electrocardiogram to observe for T-wave abnormalities, the mark of potassium deficiency. The white blood cell count of a child with diabetes may be elevated even though no infection is present, apparently as a response to the ketoacidosis. The presence of infection must always be suspected, however, because it is often a precipitant to a diabetic crisis. For this reason, nose and throat cultures may be obtained as well.

### Therapeutic Management

Therapy for children with type 1 diabetes involves five measures: insulin administration, regulation of nutrition and exercise, stress management, and blood glucose and urine ketone monitoring. The standard of care in the United States regarding a child with newly diagnosed diabetes involves a hospital admission of approximately 3 days, which includes extensive education involving caretakers and the child (Schmidt, Bernaix, Chiappetta, et al., 2012).

### The Initial Regulation of Insulin

When children are first diagnosed with diabetes, they are usually hyperglycemic and perhaps ketoacidotic. To correct the metabolic imbalance, they are given insulin administered IV at a dose of 0.1 to 0.2 units per kilogram of body weight per hour. This initial IV infusion of insulin is then gradually reduced once the blood glucose level is lower than 200 mg/dl. Ideally, within 12 hours, the acidosis is considerably less than when a child was admitted to the hospital, and the serum glucose level is near the normal range. The insulin given for emergency replacement this way is regular (short-

acting) insulin such as Humulin-R because this is the form that takes effect most quickly.

It may seem that in a child with diabetes in a state of acidosis, the administration of glucose would not be warranted. Because the child is being given insulin, however, body cells soon become ready to use glucose, so they require, incorporate, and use available glucose quickly. If more glucose is not provided, cells are forced to continue to break down fats and protein, and the acidosis can increase, not decrease. Glucose, therefore, may be added to the infusion.

After 24 hours, as the child's serum glucose returns to normal, oral feedings may replace the IV route. Further management in the days after this first crucial 24-hour period is based on serum glucose determinations. A child may remain on regular insulin given SC alone (given three or four times a day) for the first 1 or 2 days. Typically, intermediate-acting insulin is then added as soon as oral fluids are taken, usually on the second day of therapy.

### Insulin Administration

Types of insulin vary as to their time of onset, peak action, and duration of action (Table 48.4). Children can be regulated on a variety of insulin programs, but typically receive a combined insulin dose of 0.4 to 0.7 units per kilogram of body weight daily in two divided doses (one before breakfast and one before dinner); adolescents may need as much as 1.2 units per kilogram daily divided into the two doses. The most common mixture of insulin used with children is a combination of an intermediate-acting insulin and a regular insulin, usually in a 2:1 ratio or 0.75 units of the intermediate-acting insulin to 0.33 units regular insulin, and given in the same syringe, although this prescription varies for individual children. The morning dose is two thirds of the total daily dose; the evening dose is the remaining one third.

**TABLE 48.4 Common Types of Human Insulin**

Preparation	Onset	Peak Effect	Duration of Effect (hr)
Lispro (Humalog)	Immediate	30 min–1 hr	3–4
Aspart	15 min	30–40 min	3–5
Regular (Humulin-R)	0.5–1.0 hr	2–4 hr	5–7
Lantus	1 hr	5 hr	24
Humulin-N	1–2 hr	4–12 hr	24+
Humulin-L	1–3 hr	6–14 hr	24+
Humulin-U	6 hr	16–18 hr	36+

From Karch, A. M. (2013). *2013 Lippincott's nursing drug guide*. Philadelphia, PA: Lippincott Williams & Wilkins.

The advantage of using two different types of insulin is that the peak effects occur at

different times. Because the peak time of short-acting insulins is 3 to 4 hours, the child who takes insulin before breakfast will notice a maximum effect between 10 AM and 12 noon. The peak effect period of the intermediate-acting insulin is 8 to 14 hours, or late afternoon, just before dinner. These are important times to remember because these are the times when a child is most apt to experience symptoms of hypoglycemia.

Some children require a program of insulin therapy that includes three or even four injections daily in order to prevent hyperglycemia. Although these regimens are not popular with children, multiple injections allow for greater variation in activity and calorie consumption.

Part of the education of parents is to allow them to vary their child's insulin doses based on an insulin algorithm or protocol influenced by the child's level of activity and the size of meals consumed for that day (referred to as "thinking scales"). The time between the insulin injection and a meal is known as "lag time." If a child's premeal blood glucose level is above a target range, parents learn that increasing the lag time or delaying the meal will help prevent hyperglycemia. If the blood glucose is low at a premeal test, decreasing the lag time could help prevent hypoglycemia. If it is anticipated that the child will eat an unusually large meal such as at a special birthday dinner, parents can increase the size of the premeal regular insulin injection. If the child is to participate in a strenuous sport in the afternoon that will use glucose, the regular insulin injection can be decreased. Insulin glargine injection (Lantus) is a new long-acting insulin that is supplied in an injectable pen and lasts 24 hours. A disadvantage of this insulin is its pH, which is so low it cannot be mixed in a syringe with other insulins. In some children, glucose levels can be regulated on insulin glargine injection (Lantus) plus three doses of regular insulin before meals.

### *Injection Technique*

Teach parents that when insulins are mixed in one syringe, the regular or short-acting insulin should be drawn into the syringe first. Then, if mixing accidentally occurs in the bottle, the time of effectiveness of the short-acting insulin (which needs to be kept short-acting for emergency treatment) will not be lengthened by the addition of the intermediate-acting insulin.

Insulin is always injected SC except in emergencies, when half the required dose may be given IV. Subcutaneous tissue injection sites used most frequently in children include those of the upper outer arms and the outer aspects of the thighs (Fig. 48.5). The abdominal subcutaneous tissue injection sites commonly used in adults can be adequate sites, but most children dislike this site because abdominal skin is tender. Encourage children or parents to rotate sites in a pattern based on their planned activity. Absorption, for example, is increased if the muscles under the injection site are exercised, so it is best to choose sites that will not be exercised soon after the injection. If a child will be jogging after an injection, for example, the thigh probably should not be used. Similarly, if the child will be playing tennis, the injection probably should not be given in the dominant arm.

**Figure 48.5** According to the American Diabetes Association, insulin injection sites in children and adults are the upper outer portions of the arms; the thighs, 4 in. below the hip and 4 in. above the knee (adjusted proportionally for children); and the abdominal area just above and just below the waist. The navel and a circular area just around it are excluded as injection sites. In some children, the abdominal area may not be an appropriate injection site.

Work out a plan of rotation with children so that everyone who will be giving injections knows what injection site should be used next. In the hospital, record the injection site in the child's record or nursing plan, so each nurse can check it before an injection and not repeat an injection site. This is less of a problem now that synthetic human insulin is used, but if the same injection site is used repeatedly, a great deal of subcutaneous atrophy (lipodystrophy) can occur, causing deep pockmarks.

Children quickly learn that if they continuously give injections in the same site, scar tissue (lipohypertrophy) forms there, and no pain will be felt on injection (a situation sometimes called subcutaneous insulin resistance syndrome [SIRS]). This is a dangerous practice, however, because as lipohypertrophy occurs, insulin no longer absorbs well from the site. To be effective, the dose has to be increased beyond what the

child actually needs for glucose metabolism because a portion of each dose is “locked” in the tissue. Should the child then inject this larger dose of insulin into a new site, there is a potential for overdose (which would cause hypoglycemia).

Although parents should keep additional bottles of insulin in the refrigerator to increase the insulin’s shelf life, insulin should be administered at room temperature because this diminishes subcutaneous atrophy and ensures peak effectiveness.

Because a short needle (less than 0.4 in.) is used, insulin can be injected at a 90-degree angle (Fig. 48.6). Although this is not a usual subcutaneous injection technique, because the needle is so short, the insulin will be deposited into the subcutaneous tissue. This technique is easier for children to learn because it takes less coordination to administer an injection at a 90-degree angle than at a 45-degree subcutaneous angle. Automatic injection devices are available, such as pens and jet injectors, which are easy for children to use, come with prepared doses, promote early independence, and can be given with the 90-degree technique (Fig. 48.7).

**Figure 48.6** Insulin is usually injected at a 90-degree angle with a

short needle. This angle places the insulin in the subcutaneous space.  
(© Lesha Photography.)

**Figure 48.7** The injection of insulin by an automatic device. (© Lesha Photography.)

### *Insulin Pumps*

An insulin pump is an automatic device approximately the size of an iPhone. It delivers insulin at a constant rate, so it regulates serum glucose levels better than periodic injections (Buchko, Artz, Dayhoff, et al., 2012). To use a pump, a syringe of regular insulin is placed in the pump chamber; a length of thin polyethylene tubing leads to the child's abdomen, where it is implanted into the subcutaneous tissue of the abdomen by a small-gauge needle. Women who develop gestational diabetes also use insulin pumps; therefore, these are illustrated and the care is described in Chapter 20. Most children adjust well to pump therapy and prefer it to daily injections.

## *Inhalation Insulin*

Inhalation insulin is not available as yet but may be in the future; production of it is in experimental trials. Difficulties with development are constructing an accurate delivery system and determining how the development of a cold or allergies that cause edema of the nasal membrane will affect drug absorption (Boss, Petrucci, & Lorber, 2012).

## Nutrition

In order to know how much insulin to give before a meal, parents need to learn to count the total carbohydrate amount in food by carefully reading food labels. An insulin-to-carbohydrate ratio is then calculated individually for each child depending on age and activity to guide insulin administration. For example, if a child is prescribed an insulin-to-carbohydrate ratio of 1 unit of insulin to each 10 g of carbohydrates and the meal the child will be served contains 50 g carbohydrates, the parent would administer 5 units of regular insulin before the meal.

An overall meal pattern should include three spaced meals that are high in fiber plus a snack in the midmorning, midafternoon, and evening to keep carbohydrate amounts as level as possible during the day. Most parents need to meet with a nutritionist to discuss what a “meal high in fiber” means, how to become adept at carbohydrate counting, and what meals are best to serve to their age child. General rules are shown in [Box 48.7](#).

### BOX 48.7

#### Nursing Care Planning Based on Family Teaching

#### **NUTRITIONAL GUIDELINES FOR CHILDREN WITH TYPE 1 DIABETES**

**Q.** Rob’s mother is concerned that Rob, as an adolescent, doesn’t eat well. She asks you, “How can we make sure our child, who has diabetes, gets adequate nutrition?”

**A.** Here are some nutritional guidelines to help you:

- Be certain you understand your child’s insulin-to-carbohydrate ratio and how to use this to plan meals. As a rule, foods high in carbohydrates are fruit and vegetables, “starchy foods” such as bread or pasta, milk and yogurt, and “sugary” foods such as candy bars or cake.
- Be aware of food portions. The total carbohydrate on a package of pasta refers to what one serving of pasta will contain, not the whole box of pasta.
- Provide three meals throughout the day, plus three snacks. A total daily caloric intake divided to provide 20% as breakfast, 20% as lunch, 30% as dinner, and 10% as morning, afternoon, and evening snacks help distribute carbohydrates throughout the day.
- Do not use dietetic food. This food is expensive and not necessary.
- Urge your child not to omit meals. Getting him to eat at every meal calls for creative planning so he likes the foods served and eats readily.

- Maintain a positive outlook by stressing the foods your child is allowed to eat, not those he should avoid.
- Steer clear of concentrated carbohydrate sources, such as candy bars, and be sure to include foods with adequate fiber, such as broccoli, because fiber helps prevent hyperglycemia.
- Keep complex carbohydrates available to be eaten before exercise, such as swimming or a softball game, to provide a sustained carbohydrate energy source to prevent hypoglycemia.
- Teach children about carbohydrate counting as early as possible so they can wisely select what to eat at school or at a friend's home and can begin independent self-care.

### Self-Monitoring of Blood Glucose

Children as young as early school age can learn the techniques of finger puncture and reading a computerized monitor. Using a spring-loaded injection pen helps minimize pain; an automatic readout monitor simplifies the procedure (Fig. 48.8). Children are adolescents, however, before they can be counted on to independently monitor their serum glucose levels on a daily basis.

**Figure 48.8** A child uses an automatic lancet for blood sampling (*left*). Blood glucose level will be determined by the glucometer (*right*). (© Lesha Photography.)

### Urine Testing

Urine testing is not used routinely but is used to test for ketonuria if the child develops a gastrointestinal “flu” and is not able to eat. Acetone revealed by a test strip is a sign of fat

is being used for energy or that the child is becoming acidotic.

### The “Honeymoon” Period

After a child’s diagnosis has been confirmed and the blood glucose level has been initially regulated by insulin, a honeymoon period may follow, during which only a minimal amount of insulin, or none at all, is needed for glucose regulation. This apparently occurs because the exogenous insulin stimulates the islet cells to produce a small amount of natural insulin, as if they are being reminded of their function. After a month or even up to a year, however, the islet cells will begin to fail once again, and diabetic symptoms will recur. This can be upsetting to parents if they began to believe their child was wrongly diagnosed or that a cure had taken place. Caution both the parents and the child that symptoms will inevitably recur.

### Stress Adjustment

Whenever children with diabetes undergo a stressful situation, either emotionally or physically, they may need increased insulin to maintain glucose homeostasis. When children are seen at healthcare facilities for periodic checkups, ask them whether they are having any difficulty with blood testing or insulin injection and how things are at home and at school to detect their stress level.

Try to interview children separately from their parents, so they can feel free to talk about anything that may be happening or going wrong. If a child is experiencing stress because of school, parents may have to meet with school officials to help them view the child as well, not ill, so that they will allow participation in all activities, including sports. Sometimes, children are embarrassed to have to do blood glucose testing in school, especially in a public lavatory. It may be easier for them if they can go to the nurse’s office for privacy when testing.

### Complications

If an infection occurs and the child’s temperature rises, insulin resistance increases, causing a need for additional insulin. Teach parents to notify their primary healthcare provider if their child appears to be ill (particularly if the child is nauseated or vomiting) for careful observation and a change in insulin dosage if necessary. If a child with diabetes is scheduled for surgery, careful regulation on the day of surgery and in the immediate postoperative period is essential, especially if oral fluids will be restricted.

Many long-term body changes such as arteriosclerosis (hardening of artery walls), which can lead to general poor circulation and kidney disease, and thickening of retinal capillaries and cataract formation, which ultimately can result in blindness, occurring because of chronic hyperglycemia, are not a major part of disease management in childhood because their onset does not begin until adulthood. It is not too early, however, when discussing hyperglycemia to mention that it does have long-term effects if not regulated beginning in childhood.

## Pancreas Transplantation

For children who develop severe kidney disease or arteriosclerosis, pancreas transplantation may be considered to prevent further damage. In contrast to other organ transplantation procedures, the child's pancreas is not removed entirely prior to transplant. This is because the portion that supplies digestive enzymes is still functioning and so is left in place. The digestive enzymes of the new pancreas are diverted into the intestine or bladder, or the pancreatic ducts can be sclerosed, so the digestive enzymes do not leave the transplanted organ. Grafts may be taken from cadavers or from live donors, who can donate up to 45% of their pancreas and still maintain a functioning organ for themselves.

To reduce the child's immune response and protect against graft rejection, drugs such as antilymphocyte globulin, cyclosporine, prednisone, or azathioprine (Imuran) are administered after surgery. If rejection does start to occur, the patient is given monoclonal T-cell antibodies (OKT3) to try to reverse this process.

Pancreatic transplantation is a last resort solution for children because it involves major surgery, the outcome is guarded (about 50% of transplanted organs are rejected), and the result—continuous immunosuppressive medication for life—may not be regarded as a major improvement over the original illness, which requires continuous daily insulin for life. In addition, some pancreatic transplant recipients have a recurrence of diabetes (Burke, Vendrame, Viridi, et al., 2015).

### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis** Health-seeking behaviors related to self-administration of insulin, balanced exercise, and nutrition

**Outcome Evaluation** Child demonstrates insulin injection technique to nurse, describes steps correctly, and discusses plans for an exercise and nutrition program.

**Self-Administration of Insulin.** From about 8 years of age, children can be taught to administer their own insulin (Fig. 48.9). Many children younger than this do not have the dexterity to handle a syringe or an understanding of the importance of sterile technique and proper dosage. They may skip injections if they are tired or busy.

**Figure 48.9** A school-age child practices insulin administration using a teaching doll for practice.

Do not underestimate how difficult it is for children to learn to give injections to themselves. Although it may seem like a two-step process (draw up the medication and then inject it), in actuality, more than 25 steps are involved.

If the child has to mix insulins, the number of steps increases. Besides lacking dexterity and adult-level fine motor skills, children have to face injecting themselves. There is no such thing as getting used to injections. Children grow used to the *idea* of self-injection, not to the injections themselves.

Even if children are taught to give their own insulin from the beginning, at least one adult in the family should be taught to give it as well. There will be days when the child refuses to administer his or her own insulin or is not feeling well and needs to have or appreciates having someone administer it. Parents may have a hard time giving their child a painful injection; teaching them to view it as a helping action helps to alleviate their distress.

**Exercise.** Exercise is an important component of care because it uses up carbohydrates and helps reduce hyperglycemia. No type of exercise is restricted for children with diabetes. A problem that arises with vigorous exercise, however, is the development of hypoglycemia due to increased absorption of insulin from the injection site and use of glucose by active body cells. One way to minimize this effect is to choose the injection site that is least likely to be exercised. Another method is to eat additional carbohydrates or decrease the regular insulin injection according to an established protocol before exercise.

Teach children to design a consistent daily exercise program such as briskly walking the dog or 10 minutes of aerobics every day before school. Once a daily

program is established, the child needs to continue this type of exercise every day (including weekends) to avoid becoming hyperglycemic on days of no exercise. If this process is not explained, parents may attempt to keep the child relatively quiet, unaware that exercise is actually healthful.

**Hygiene.** Skin care, particularly foot care, is extremely important for adults with diabetes because arteriosclerosis causes loss of circulation to the feet, and decreased circulation leads to poor healing ability. This is not as important a concern with children, but they (and all children) should be taught to cut their toenails straight across, to prevent ingrown toenails, and to tend to cuts and scrapes promptly so that healing can begin right away. Properly fitted shoes are essential. Girls may need to be reminded of good perineal care to prevent vaginal infections.

**Nursing Diagnosis:** Parental anxiety related to newly diagnosed diabetes mellitus in their child

**Outcome Evaluation:** Parents accurately describe their child's illness and treatment and ways in which the disease will affect their lifestyle. They state a specific plan for daily routine child care and identify potential problems in the schedule and ways they can be managed.

Parents whose child is newly diagnosed with diabetes mellitus have a great deal of new responsibility. Be certain they have the telephone number of the healthcare facility, liaison, or home care person to call during the first days of home management so they have someone to consult before they give insulin the first several times.

**Encourage the Expression of Feelings.** Although parents may be aware that other family members have the disease, they may be surprised that diabetes has occurred in their child. Both the parents and the child need time to describe their perception of diabetes. If there are other family members with the illness, children may have heard many false stories about the disorder and may have been told how difficult it was in the past to achieve insulin control. These misconceptions need to be corrected so children can begin to accept their diagnosis and view themselves as basically well except for faulty insulin release.

### *What If . . . 48.2*

**Rob wants to try out for the soccer team at his school, but the soccer coach thinks children with diabetes should be excluded from sports. Because Rob doesn't always take his insulin reliably, would you agree with the coach?**

**Establish a Mode of Supervision and Support.** Children with diabetes need frequent health supervision visits, approximately every 3 months. Those who appear to accept their diagnosis initially may have difficulty later, when their true feelings about their

disorder surface. When they reach adolescence and are rebelling against a multitude of things, they may choose to rebel against blood glucose testing and insulin administration. Assess that children with diabetes have supportive friends to help them through “bad days.” Make sure the parents can identify support people and others to contact if they have problems or questions. Sometimes what is needed most from healthcare personnel is understanding and appreciation of the difficulties encountered by children living with diabetes.

**Teach Hypoglycemic Management.** An episode of hypoglycemia is an extremely serious condition and must be prevented, if possible, because if it is not recognized and treated, it can lead to coma and seizures. Severe glucose depletion can lead to permanent brain damage with mental and motor impairment because brain cells need glucose for metabolism.

Symptoms of hypoglycemia occur when the blood glucose level falls to about 60 mg/dl. At this point, there is no glycosuria. It results from the administration of too much insulin, excessive exercise (because exercise uses up glucose), or failure to eat enough food. Typically, beginning symptoms include nervousness, weakness, dizziness, sweating, or tremors. In many children, the first signs of hypoglycemia are behavior problems: temper tantrums, stubbornness, silliness, irritability, or simply “not acting like usual self.” A few children become insensitive to the symptoms of hypoglycemia (termed *hypoglycemia unawareness*) and are then unable to recognize that it is occurring. Such children need more blood glucose determinations built into their routine.

When the signs of hypoglycemia are recognized, a child needs an immediate source of carbohydrates. Fifteen grams of a fast-acting carbohydrate such as that contained in a half glass of orange juice or regular soda is recommended. It is easy for children always to carry glucose tablets or hard candy such as Life Savers with them to have them available for these times. If there is no improvement in symptoms and the blood glucose level has not risen by 15 mg/dl after 15 minutes, more carbohydrates (perhaps juice) should be given.

If the child is comatose when first discovered or is too upset or uncooperative to take oral sugar, parents can inject a specified dose of glucagon hydrochloride intramuscularly. This converts the glycogen that is stored in the liver into glucose. Usually, enough glycogen is converted after the drug injection to bring the child out of the coma, after which an oral form of glucose can be given. The drug will not be effective, however, if the child’s supply of glycogen is depleted.

If parents cannot give their child an injection and oral sugar cannot be given, honey, corn syrup, cake icing gel, or glucose can be rubbed onto the gums or inside the cheek (of course, parents should be taught how to prevent aspiration) or corn syrup can be given as an enema. As soon as children are out of the coma or are cooperative, they should take a source of complex carbohydrates, such as crackers or whole wheat toast, to prevent further hypoglycemia. The primary healthcare provider

needs to be notified of the incident so that its cause can be determined and steps can be taken to prevent hypoglycemia from occurring again.

Urge parents to anticipate occasions when hypoglycemia is likely to occur and to take preventive measures if possible. Hypoglycemia is most likely to occur, for example, at the peak effective time of the insulins being given, such as just before lunch or just before dinner. This means that many children who are attending school need to be scheduled for the first lunch period, not the second, or need a snack before lunch. Encourage the child and parents to discuss lunch times with the school nurse so appropriate meal planning is coordinated with the child's insulin schedule. Follow-ups at 6-month intervals are important so adjustments to account for changes in growth and school schedules can be made.

If children are going to engage in an active sport, such as swimming, tennis, or basketball, they should ingest a source of sugar before participation. This precaution is extremely important before swimming because a child who suddenly becomes weak in the middle of a pool may be unable to reach the side safely. Although eating before swimming is something that children typically are taught not to do, the child with diabetes must be taught to break this rule. This should be done sensibly, of course—before swimming, the child should eat a complex carbohydrate, such as crackers, not a full meal. Day and residential camps are available to help children learn more about diabetes and common measures other athletic children use to prevent hypoglycemia.

Occasionally, insulin overuse and persistent hypoglycemia cause a rebound hyperglycemic response; this is referred to as the **Somogyi phenomenon**. This phenomenon is suspected when children have nighttime (2 AM or 3 AM) hypoglycemia followed by high early-morning hyperglycemia. These children need to be referred to their healthcare provider because they actually need less insulin rather than more to correct the problem.

***Teach Signs of Ketoacidosis.*** Because hyperglycemia leads to diabetic **ketoacidosis** (DKA), it is a metabolic emergency (Donahy & Folse, 2012). DKA is a serious complication of diabetes that occurs when the body produces high levels of blood acids called ketones. The condition develops when the body can't produce enough insulin and begins to break down fat as fuel. It may be difficult for parents to distinguish between hypoglycemia (occurring from too much insulin) and hyperglycemia (occurring from too little insulin for the level of glucose present in the bloodstream) because hyperglycemia presents with almost the same symptoms as hypoglycemia: irritability, vomiting and abdominal pain, and behavior changes such as temper tantrums.

If a parent does not know whether the problem is hypoglycemia or hyperglycemia, the child should be offered a carbohydrate, as if the problem were hypoglycemia. This is because the added carbohydrate will do no harm if the problem is already hyperglycemia, whereas giving insulin is harmful if the cause is

hypoglycemia. An inability to void is a good clue that the problem is hypoglycemia because with hyperglycemia, urine output is copious—one of the primary signs of diabetes. The real key to differentiating ketoacidosis from hypoglycemia, however, is the blood glucose level. Assessing the blood glucose concentration by finger stick solves the problem of whether symptoms relate to hypoglycemia or hyperglycemia. For quick reference, a comparison of hypoglycemia and hyperglycemia is shown in [Table 48.5](#).

**TABLE 48.5 Comparison of Hypoglycemia and Hyperglycemia**

<b>Comparison Factor</b>	<b>Hypoglycemia</b>	<b>Hyperglycemia</b>
Cause	Excessive insulin injection	Inadequate insulin injection
	Limited food intake	Excessive food intake
	Excessive exercise	Stress from infection, surgery, etc.
Symptoms	Hunger	Glycosuria and ketonuria
	Lethargy and sensorial changes	Polyuria, polydipsia; vomiting
	Sweating	Kussmaul respirations
	Pallor	Flushing and dehydration
	Seizures	Sweet (acetone) breath
	Coma	Lowered sodium, potassium, bicarbonate, chloride, and phosphate levels; decreased CO <sub>2</sub> combining power
		Coma
Danger	Brain cells need glucose for function and survival	Fatty acids used and ketoacidosis develops
Major nursing interventions	Administration of source of glucose by oral or intravenous route Education to prevent recurrences	Reestablishment of electrolyte balance and hydration Education to prevent recurrences

If ketoacidosis is not relieved when it first begins, it becomes severe with deep and rapid respirations (Kussmaul breathing) as the body attempts to “blow off” carbon dioxide and lessen the acidotic state. The child’s breath smells sweet because of the presence of ketone bodies, and the pulse rate may be rapid. Signs of

dehydration, including dry mucous membranes and skin, sunken eyeballs, and no tears, may be present. This is typically the picture when children are first diagnosed as having diabetes. It is also seen in children with diabetes who develop gastroenteritis and so eat poorly for several meals. Because the child is not eating well, parents may omit giving insulin. In actuality, because of an increased metabolic rate due to fever, parents need to consult with their primary care provider because the child may need more insulin and glucose than usual during these times. [Box 48.8](#) shows an interprofessional care map for a child with diabetes type 1 to show how aspects of care need coordination.

## BOX 48.8

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR AN ADOLESCENT WITH TYPE 1 DIABETES MELLITUS

Rob Tebecco is a 16-year-old boy with type 1 diabetes whom you meet in the emergency department, where he was taken after he became comatose while ice skating. He has had diabetes since he was 7 years of age; he was managing his insulin administration well up until 6 months ago when he began to “forget” to take his insulin at least once a week. When you ask him about this, he tells you ice skating practice every morning and a new girlfriend have occupied his time and interrupted what used to be a strict schedule of home-cooked meals and a rigid routine.

**Family Assessment:** Adolescent lives with one younger sister and parents. Father works as Zamboni operator at a professional hockey arena. Mother works part-time at the local post office. Family rates finances as “We have everything we need.”

**Patient Assessment:** Child was skating at local ice rink when he suddenly collapsed. Was brought to the emergency department by the emergency medical technician service, unconscious and breathing deeply. Breath smelled sweet. Blood glucose was 700 mg/dl. Received regular insulin intravenously (IV). As soon as blood glucose returned to normal, he regained consciousness. Arterial blood gases: pH, 7.20; PCO<sub>2</sub>, 10 mmHg; HCO<sub>3</sub>, 10 mEq/ml. Right heel has red and inflamed ulcer.

Currently takes short-acting and intermediate-acting insulin every morning before breakfast and again before dinner with self-injection device. Child performs finger-stick blood glucose levels four times a day. Blood glucose levels normally range between 105 and 115 mg/dl. Dietary history reveals three meals per day with midmorning, afternoon, and bedtime snack. Rob states, “Okay. I’m ready to do better. That was scary to black out.”

**Nursing Diagnosis:** Health-seeking behaviors related to need to follow a more conscientious diabetes regimen.

**Outcome Evaluation:** Child and parents voice intention to be more conscientious

about insulin administration and serum glucose testing. Child voices willingness to try insulin pump therapy.

<b>Team Member Responsible</b>	<b>Assessment</b>	<b>Intervention</b>	<b>Rationale</b>	<b>Expected Outcome</b>
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Explore with child and parents their understanding of the interrelationship of nutrition, exercise, and diabetes.	Review and reinforce the importance of insulin administration, blood glucose monitoring, and exercise.	Explore and provide baseline information for identifying teaching needs and developing possible strategies.	Adolescent and parent state they understand new regimen; glucose levels do not fluctuate higher than 126 mg/dl.
<i>Teamwork and Collaboration</i>				
Nurse/primary care provider	Assess whether adolescent would be a good candidate for insulin pump therapy to increase adherence.	Consult with diabetic service team to present the new method of insulin administration.	Use of an insulin pump offers a continuous supply of insulin; can be advantageous for busy adolescent.	Diabetic service team meets with adolescent and parent to present possibility of using insulin pump.
<i>Procedures/Medications for Quality Improvement</i>				
Nurse	Assess adolescent's level of understanding about the action of insulin with pump therapy.	Demonstrate and observe the adolescent draw up and refill the insulin syringe and begin insulin pump infusion.	Adolescent's return demonstration best reveals whether he understands how to maintain the insulin pump.	Adolescent demonstrates proper preparation and administration of the insulin pump.
<i>Nutrition</i>				
Nurse/nutritionist	Assess adolescent's usual meal	Review importance of regular meals	Irregular meal patterns can cause	Parents and adolescent state they will try to

pattern; determine who prepares food and whether adolescent counts carbohydrates.	plus a bedtime snack to keep glucose within consistent levels with the insulin pump.	hypoglycemia with pump therapy.	estimate carbohydrate count better; adolescent will test blood glucose according to set schedule.
---	---	---------------------------------------	--

---

*Patient-Centered Care*

---

Nurse/diabetic service team member	Assess whether adolescent and parents are aware of actions to take if hypoglycemic symptoms should occur with pump therapy.	Review signs and symptoms of hypoglycemia; review need to always carry a source of carbohydrate.	Having a readily available source of carbohydrate helps raise blood glucose levels quickly should hypoglycemia occur.	Adolescent and parents describe signs of hypoglycemia and action of carbohydrates to prevent this.
--	---	---	---	--

Nurse/diabetic service team member	Assess whether adolescent and parents are aware of necessity to safeguard feet against trauma.	Review necessity to wear properly fitting shoes and skates and to clean any cuts or scrapes promptly.	Diabetes can result in decreased circulation to the feet and slowed healing, increasing the possibility for infection, which can ultimately affect glucose control.	Adolescent states he will be more conscientious about foot care; acknowledges foot infection may have contributed to his ketoacidosis episode.
--	--	--	--	--

---

*Psychosocial/Spiritual/Emotional Needs*

---

Nurse/nurse practitioner	Assess whether child's busy schedule allows for adequate diabetic control.	Encourage parents to discuss adolescent's needs with him	Poor medicine adherence may be a way adolescents express their	Parents and child plot out a weekly schedule that allows both
-----------------------------	--	--	--	---

and ways he identity. freedom for  
 could modify his new activities  
 schedule to and for  
 better conscientious  
 accommodate diabetic care.  
 his diabetic  
 routine.

---

*Informatics for Seamless Healthcare Planning*

---

Nurse	Assess whether child has experience with keeping a diabetic care journal.	Suggest the adolescent keeps a written diary of blood glucose levels, dietary intake (including snacks), and any symptoms of hypo- or hyperglycemia.	A written diary provides objective evidence for evaluating the new regimen and can indicate the need for possible changes or adjustments.	Adolescent agrees to keep a detailed journal until returning to clinic for a follow-up visit.
Nurse	Assess whether the adolescent or parents have any additional questions.	Arrange for a follow-up appointment in 1 week; encourage adolescent and parents to call with any questions or concerns.	Follow-up visit provides a means for evaluating the effectiveness of the new regimen and child's adaptation.	Adolescent and parents state they understand importance of follow-up visit for regulation of insulin pump therapy.

---

***QSEN Checkpoint Question 48.4***

**TEAMWORK & COLLABORATION**

Rob tells the nurse that he experienced a “honeymoon” period when he was first diagnosed with diabetes mellitus. The nurse recognizes that this would be demonstrated by which of the following signs?

- a. He developed an unnatural craving for sweets.
- b. His metabolism increased because of glucose stimulation.
- c. He became light-headed or “giddy” every afternoon.

d. His need for injected insulin was drastically reduced.

Look in *Appendix A* for the best answer and rationale.

## TYPE 2 DIABETES MELLITUS

T2D, characterized by diminished insulin secretion, is a separate disease from type 1 diabetes because it is not caused by autoimmune factors (Sherr & Weinzimer, 2012). Usually, children with T2D do not need daily insulin because their disease can be managed with diet alone or with diet and an oral hypoglycemic agent. Once thought to occur only in older adults, T2D is now seen as early as in overweight school-aged children (Caprio, 2012). Other influencing factors are a strong family history of diabetes; children from African, Hispanic, Asian, or Native Indian descent; those who eat a diet high in fats and carbohydrates; and those who do not exercise regularly. Development of polycystic ovary syndrome (PCOS) (see Chapter 8) is also strongly associated with the disorder. At the time of diagnosis, it may not be possible for the classification to be correctly determined because symptoms and findings are so similar.

Symptoms often become apparent for the first time at puberty because increasing sex hormones naturally increase insulin resistance, creating a need for more insulin production. Children's urine will show glucose but few ketones. Children experience lessened amounts of thirst or increased urination. About 90% of children with T2D have dark shiny patches on the skin (*acanthosis nigricans*), which are most often found between the fingers and between the toes, on the back of the neck ("dirty neck"), and in axillary creases (Stephen, Gungor, & Douty, 2012). Children whose family has a history of T2D, are from susceptible genetic groups, or have symptoms such as *acanthosis nigricans* or high blood pressure should be screened by a fasting blood sugar test at puberty and again every 2 years.

With this type of diabetes, because the pancreatic islet cells are still able to minimally function, the pancreas continues to secrete at least small amounts of insulin. Therapy, therefore, consists of nutrition and exercise, the same as for type 1 diabetes, combined with an oral antiglycemic agent such as a biguanide (metformin), which decreases the amount of glucose produced by the liver and increases insulin sensitivity in both the liver and muscle cells.

T2D is a chronic condition that will extend into adulthood and be present for life. Eventually, it leads to atherosclerosis with thickening of arteries and capillaries, kidney disease, poor healing ability, and blindness because of poor circulation to body organs. In order to prevent these complications, children who develop T2D need good instruction in how to manage their illness so, whether they are home with their parents supervising their care or away from home at camp or college, they can prevent hyperglycemia and the irritation to blood vessels which that causes.

### *QSEN Checkpoint Question 48.5*

## SAFETY

Rob needs to adjust his regular insulin dose to the amount of carbohydrates he eats in order to prevent dangerous complications of his disease. If his insulin-to-carbohydrate ratio is 1:10, how many units of insulin should he inject if his lunch will consist of a hotdog on a bun (24 g), 1 cup chicken noodle soup (7 g), an apple (19 g), and a glass of milk (25 g)?

- a. 3 units
- b. 7.5 units
- c. 9 units
- d. 12 units

Look in [Appendix A](#) for the best answer and rationale.

## The Parathyroid Glands

The four parathyroid glands, located posterior and adjacent to the thyroid gland, regulate serum levels of calcium in the body by controlling the rate of bone metabolism through the secretion of parathyroid hormone. This hormone is unique in that it is not under the control of the pituitary gland but rather is controlled by a negative feedback from the circulating serum levels of calcium and how much vitamin D is present to allow absorption of calcium from the gastrointestinal tract into the bloodstream.

### HYPOCALCEMIA

Hypocalcemia is a lowered blood calcium level that occurs to some extent in all newborns before they begin sucking well. It occurs because phosphorus and calcium levels are always maintained in an inverse proportion to each other in the bloodstream (if phosphorus levels rise, calcium levels decrease, and vice versa). Hypocalcemia may be caused, therefore, by a change in either calcium or phosphorus metabolism (Thomas, Smith, White, et al., 2012).

### Assessment

Hypocalcemia tends to occur in infants who experienced birth anoxia (phosphorus is released with anoxia), in immature infants (the parathyroid glands are immature), and in infants of women with diabetes (it tends to accompany the hypoglycemia that occurs in these infants shortly after birth).

The chief sign of hypocalcemia is neuromuscular irritability, referred to as **latent tetany**. This occurs if the blood calcium level falls below 7.5 mg/dl. The newborn will demonstrate jitteriness when handled or if the infant has been crying for an extended period.

Four methods are used to produce the clinical manifestations of tetany for diagnosis, as shown in [Table 48.6](#). Any of these tests are helpful in determining whether a newborn's jitteriness is a result of hypocalcemia or a central nervous system concern.

**TABLE 48.6 Tests for Detection of Hypocalcemia**

Sign	Description
Chvostek	When skin anterior to external ear (just over sixth cranial nerve) is tapped, facial muscles surrounding eye, nose, and mouth contract unilaterally.
Trousseau	When upper arm is constricted by tourniquet for 2–3 min and area becomes blanched, carpal spasm is elicited (hand abducts, wrist flexes, thumb is positioned across cupped palm).
Peroneal	When fibular side of leg over peroneal nerve is tapped, foot abducts and dorsiflexes.

If the blood calcium level falls well below 7 mg/dl, **manifest tetany** may result, which is commonly observed as muscular twitching and a **carpopedal spasm** (abduction of the hand and flexion of the wrist with the thumb positioned across the palm). In **pedal spasm** (foot spasm), the foot is extended, the toes flex, and the sole of the foot cups. Without therapy at this point, generalized seizures or spasm of the larynx, with the infant emitting a high-pitched, crowing sound on inspiration, can occur. If the spasm is prolonged, respirations may cease.

### Therapeutic Management

Treatment is aimed at increasing the calcium level in the blood above the point of latent tetany. This can be administered orally as 10% calcium chloride if the infant can and will suck. Otherwise, it will be given IV as a 10% solution of calcium gluconate. Newborns who are having generalized seizures may require anticonvulsant therapy in addition to the calcium gluconate to halt the seizures. Emergency equipment for intubation to relieve laryngospasm should be available.

After immediate therapy to increase the low blood calcium levels, infants are given oral calcium therapy until their calcium level stabilizes at greater than 7.5 mg/dl. Because vitamin D is necessary for the absorption of calcium from the gastrointestinal tract, the infant also may be given a vitamin D supplement such as calcitriol.

### Metabolic Disorders (Inborn Errors of Metabolism)

Many causes of hormonal deficiency or excess in children are not related to the endocrine glands and the highly complex system of feedback and communication between these glands and the pituitary but rather are due to inherited biochemical disorders that disrupt the metabolism of amino acids, proteins, carbohydrates, or lipids. Many of these disorders are evident at or soon after birth and can cause irreversible cognitive challenge and early death, making early detection and treatment crucial. Gene therapy is expected to be available in the future to reverse symptoms of these disorders ([van Karnebeek & Stockler, 2012](#)).

## PHENYLKETONURIA

PKU is a disease of metabolism, which is inherited as an autosomal recessive trait. The infant lacks the liver enzyme phenylalanine hydroxylase, which is necessary to convert phenylalanine, an essential amino acid, into tyrosine (a precursor of epinephrine, T<sub>4</sub>, and melanin). As a result, excessive phenylalanine levels build up in the bloodstream and tissues, causing permanent damage to brain tissue and leaving children severely cognitively challenged.

The metabolite phenylpyruvic acid (a breakdown product of phenylalanine) spills into the urine to give the disorder its name. It causes urine to have a typical musty or “mousy” odor that is so strong that it often pervades not only the urine but the entire child.

As the disease progresses, because tyrosine is necessary for building body pigment and T<sub>4</sub>, the child becomes blue-eyed with very fair skin and light blonde hair. Without adequate T<sub>4</sub>, the child fails to meet average growth standards. Many children develop an accompanying seizure disorder. The skin is prone to eczema (atopic dermatitis). There is such a strong association between these two disorders that all infants with atopic dermatitis need to be rescreened for PKU at a well-child visit (Cunningham, Bausell, Brown, et al., 2012).

PKU is found in 1 of every 10,000 births in the United States; it occurs rarely in people of African or Jewish ancestry. If the condition remains untreated, the child will be left with an IQ below 20, muscular hypertonicity and spasticity, and possible recurrent seizures. PKU cannot be detected by amniocentesis as a routine screening measure because the phenylalanine level does not rise in utero while the infant is still under the control of the mother’s enzyme system. Recombinant DNA techniques can be used for carrier detection and prenatal diagnosis from maternal serum.

### Assessment

Early identification of the disorder is essential to prevent the child from becoming severely cognitively challenged. Because of this, all infants in the United States are screened at birth by blood spot analysis after receiving 2 full days of breast or formula feedings. If an infant is born at home or is discharged from a hospital or birthing center before the second day of life, remind the parents to have the test performed on the second or third day after birth. If a newborn did not suck well, so there is a question as to whether the baby received adequate milk for the test to be effective, the test can be repeated at the second week of life during a healthcare visit.

### Therapeutic Management

Dietary restriction has been the main treatment of PKU for over 50 years and still remains the main therapy. In addition to this, large neutral amino acids have been suggested as an alternative treatment to improve outcomes (Miell et al., 2015). The drug sapropterin (Kuvan), which works by increasing tolerance to phenylalanine, has been

approved by the U.S. Food and Drug Administration (FDA) for treatment (Cunningham et al., 2012).

To begin dietary regulation, infants in whom this disease is detected during the first few days of life are placed on a formula that is extremely low in phenylalanine, such as Lofenalac. A dietitian may recommend a mother who wants to breastfeed do so on a limited basis so the child does receive some phenylalanine (this essential amino acid is necessary for growth and repair of body cells). Unfortunately, a low amino acid formula can cause stools to be loose and has a rather disagreeable taste; therefore, some infants may resist drinking the formula after tasting breast milk.

Providing nutrition for a child with PKU becomes a difficult task as the child grows older because there is no natural protein with both a low phenylalanine concentration and normal levels of other essential amino acids. This means dietary management of PKU must consist of a balancing act between the child consuming enough nutrition to support growth and development and not consuming enough protein to increase the blood phenylalanine level (MacDonald, Rocha, van Rijn, et al., 2011).

Foods highest in phenylalanine are those that are rich in protein, such as meats, eggs, and milk. Foods low in phenylalanine include orange juice, bananas, potatoes, lettuce, spinach, and peas. A formula such as Lofenalac can be used to prepare treat foods, such as ice cream, milk shakes, birthday cakes, and puddings (foods that would otherwise be forbidden because they are made with milk). Children need their blood and urine monitored frequently for phenylalanine levels (which should be below 8 mg/dl). Hemoglobin levels should also be closely monitored to ensure the child is not becoming anemic because iron is found primarily in protein-rich foods, which the child must avoid. Because the diet tends to be high in carbohydrates to replace protein, children need to be screened for obesity at healthcare visits as well.

Be certain to offer parents the opportunity to express their feelings about the difficulty of maintaining a young child on such a restricted diet. Also assess the child's ability to cope with the illness because by the time they reach adolescence, they tend to grow very tired of the constant testing and restrictive diet.

### *What If . . . 48.3*

**A nurse is helping at a preschool and notices a teacher's assistant urging Rob's cousin Mike, who has PKU, to drink his milk. When the nurse suggests that milk might not be good for him, the assistant says, "Of course it is. Milk is nature's perfect food." How should the nurse respond?**

At one time, it was thought children could discontinue the diet when they reached adolescence to solve the problem of compliance. The current advice is for children to follow the diet indefinitely, therefore, because discontinuing the diet may lead to some detrimental consequences, such as a lack of muscle strength. A woman who has PKU must anticipate when she wants to have children as an adult; if she has not been

following her diet conscientiously, she needs to return to a strict low-phenylalanine diet for about 3 months before conception and must remain on the diet for the duration of pregnancy (see [Chapter 13](#)). Otherwise, her fetus will be exposed to high levels of phenylalanine during pregnancy and will be born cognitively challenged.

## MAPLE SYRUP URINE DISEASE

Maple syrup urine disease is a rare disorder, inherited as an autosomal recessive trait, in which there is a defect in metabolism of the amino acids leucine, isoleucine, and valine, which leads to cerebral degeneration similar to that observed in children with PKU.

Infants who have the disorder appear well at birth but quickly begin to show signs of feeding difficulty, loss of the Moro reflex, and irregular respirations. The symptoms progress rapidly to *opisthotonos*, generalized muscular rigidity, and seizures. If the condition remains untreated, an infant may die of the disease as early as 2 to 4 weeks of age. Fortunately, prenatal detection is possible by analyzing cells obtained by amniocentesis or from maternal serum ([Cunningham et al., 2012](#)). Also, like PKU, all infants in the United States are screened at birth for the disorder ([Chen, Mei, Kalman, et al., 2012](#)).

Although the disorder is rare, it is mentioned here because nurses are the healthcare personnel who are often the first ones to detect the disorder because on the first or second day of life, the urine of the child develops the characteristic odor of maple syrup (hence the name of the disease) due to the presence of ketoacids. Being aware of the disorder prevents discounting the pleasant urine odor not as an innocent finding but as the mark of a severe metabolic disorder.

### Therapeutic Management

If maple syrup urine disease is diagnosed during the first day or two of life and the child is placed on a well-controlled diet that is high in thiamine and low in the amino acids leucine, isoleucine, and valine, cerebral degeneration can be prevented, just as it can be prevented in PKU. Such a diet is extremely difficult to maintain, however, because of its low protein content. Parents need intensive nutritional counseling. Hemodialysis or peritoneal dialysis may be necessary to temporarily reduce abnormal serum levels at birth or during a childhood infection, when catabolism of cells releases increased amino acids into the bloodstream.

## GALACTOSEMIA

Galactosemia is a disorder of carbohydrate metabolism that is characterized by abnormal amounts of galactose in the blood (*galactosemia*) and in the urine (*galactosuria*). It occurs in about 1 in every 60,000 births, most often as an inborn error of metabolism, which is transmitted as an autosomal recessive trait. The child is deficient in the liver enzyme galactose-1-phosphate uridylyltransferase ([Chen et al., 2012](#)).

Lactose (the sugar found in milk) normally is broken down into galactose and glucose; galactose is then further broken down into additional glucose. Without the galactose 1-phosphate uridyltransferase enzyme, this second step, the conversion of galactose into glucose, cannot take place, and galactose builds up in the bloodstream and spills out into the urine. When it reaches toxic levels in the bloodstream, it destroys body cells.

### Assessment

Symptoms appear as soon as the child begins formula or breastfeeding and include lethargy, hypotonia, and perhaps diarrhea and vomiting. The liver enlarges as cirrhosis develops. Jaundice is often present and persistent, and bilateral cataracts develop. If the condition remains untreated, symptoms can worsen so rapidly, a child may die by 3 days of age. Untreated children who survive beyond this time may be cognitively challenged and have bilateral cataracts.

Diagnosis is made by measuring the level of the affected enzyme in the red blood cells. A screening test (the Beutler test) can be used to analyze cord blood if a child is known to be at risk for the disorder.

### Therapeutic Management

The treatment of galactosemia consists of placing the infant on a diet free of galactose or giving the child formula made with milk substitutes such as casein hydrolysates (Nutramigen). Once the child's condition is regulated on this diet, symptoms of the disease do not progress; however, any neurologic or cataract damage that is already present will persist. The duration of the restricted diet is controversial but probably should be followed for life.

### *QSEN Checkpoint Question 48.6*

#### **EVIDENCE-BASED PRACTICE**

Because parents have so much influence on how children adjust to having a long-term illness, researchers administered a questionnaire to a total of 185 parents with children 1 to 19 years of age divided into three groups: one where the children had either PKU or galactosemia; one where the children were healthy; and a third group where the children had a chronic illness, which was likely to interfere with longevity. Results of the study revealed that the parents of children with PKU or galactosemia rated their quality of life equal with that of parents of healthy children and far above that of parents whose child could have a short life span. Factors that influenced the children's quality of life most were the presence of support people (a positive effect) and loss of friends (a negative effect) (Fidika, Salewski, & Goldbeck, et al., 2013).

Based on this study, which comment by LaRoya, a 12-year-old girl who comes to the clinic because she has galactosemia, would make the nurse believe LaRoya's family's quality life is not ideal?

- a. “My mother still loves to cook, although no one comes over anymore.”
- b. “We go to church every Sunday; my dad helps teach church school.”
- c. “We’ve lived in the same house for 10 years; the carpet is getting old.”
- d. “My grandmother is hard of hearing, so we have to shout so she hears us.”

---

*Look in [Appendix A](#) for the best answer and rationale.*

---

## GLYCOGEN STORAGE DISEASE

Glycogen storage disease refers to a group of genetically transmitted disorders that involve altered production and use of glycogen in the body. Twelve of the 13 described types are inherited as autosomal recessive traits; the other is a sex-linked disorder.

Glycogen is normally stored in the liver to provide a reserve supply of glucose. When the body needs glucose for energy, this glycogen is transformed back to glucose. In children with glycogen storage disease, glycogen is deposited normally, but an enzyme deficiency prevents retransformation of the glycogen back to glucose.

In one form of this disorder (type II, or Pompe disease), children deposit large stores of glycogen not only in the liver but also in the muscle and heart ([Rajan & Abdel-Hamid, 2012](#)). The muscles begin to feel hard on palpation due to the deposits of glycogen. The heart becomes enlarged, and often, an arrhythmia will be present. Without therapy, children with this form usually die of heart failure before they reach adulthood.

### Assessment

Because the liver must store such a large supply of glycogen, it increases so much in size that the abdomen protrudes. Over a long period, the child’s growth will be stunted because there is only glucose available for energy, not for growth. If hypoglycemic episodes have been severe, brain damage may result. Many children have a tendency toward epistaxis or hemorrhage and are at risk when having surgery performed because of an impaired clotting ability due to decreased platelet adhesiveness. They are susceptible to periods of hypoglycemia because their only source of ready glucose is their oral intake. The development of gout from deposition of uric acid crystals in joints may also occur ([Kuwahara, Yoshitaka, Tomonori, et al., 2017](#)).

### Therapeutic Management

Children with glycogen storage disease need to eat a high-carbohydrate diet with snacks between meals to prevent hypoglycemia. In addition, a continuous glucose nasogastric or gastrostomy feeding during the night may be necessary to prevent hypoglycemia while sleeping. Therapy with diazoxide (Proglycem), an antihypoglycemic drug that inhibits insulin release, may help regulate the glucose level to provide additional growth. Liver transplantation may be a possibility, but it will not cure the basic enzyme deficiency.

## TAY-SACHS DISEASE (INFANTILE GM2 GANGLIOSIDOSIS)

Tay-Sachs disease is an autosomal recessively inherited disease in which the infant lacks hexosaminidase A, an enzyme necessary for lipid metabolism. Without this enzyme, lipid deposits accumulate on nerve cells, leading to severe cognitive challenge, due to deposits on brain cells, and blindness, due to deposits on optic nerve cells (Chen et al., 2012).

Tay-Sachs disease is found primarily in the Ashkenazi Jewish population (Eastern European Jewish ancestry). Children generally appear well in the first few months of life except for an extreme Moro reflex and mild hypotonia. If left untreated, at about 6 months of age, they begin to lose head control and are unable to sit up or roll over without support. On an ophthalmoscopic examination, a characteristic cherry-red macula is noticeable (caused by lipid deposits). By 1 year of age, children will have developed symptoms of spasticity and are unable to perform even simple motor tasks. By 2 years of age, generalized seizures and blindness will have occurred. Most children die of cachexia (malnutrition) and pneumonia by 3 to 5 years of age. There is no cure for Tay-Sachs disease. The disorder may be detected in utero by amniocentesis. Carriers for the disease trait may be identified by hexosaminidase. For more information about Tay-Sachs disease and updates on health and family stories, please visit <http://curetay-sachs.org/>.

### *What If . . . 48.4*

A nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to endocrine or metabolic disorders in children (see Box 48.1). A total of 16.9% of children and adolescents aged 2 to 19 years were considered obese in 2009 to 2012 ([www.healthypeople.gov](http://www.healthypeople.gov)). According to the Healthy People 2020 Leading Indicators, a 14.2% decrease in obesity in children and adolescents is needed by the year 2020. What would be a research topic pertinent to this goal that would be applicable to Rob's family and would also advance evidence-based practice?

## KEY POINTS FOR REVIEW

- Endocrine disorders are almost all long-term disorders. Helping parents and children remember to take medicine on a long-term basis is an important nursing responsibility that not only meets QSEN competencies but that also best meets the family's total needs.
- Children with endocrine or metabolic disorders often develop height or weight discrepancies. Help children continue to maintain high self-esteem by concentrating on the things they are able to do despite a growth lag.
- GH deficiency, a pituitary disorder, results in extremely short stature if left untreated. Therapy for children consists of the injection of synthetic GH. Children

can experience situational low self-esteem if they do not receive adequate emotional support from significant others.

- Other pituitary disorders include GH excess and diabetes insipidus. With GH excess, there is an overgrowth of body tissues. With diabetes insipidus, there is a decreased release of ADH, which leads to polyuria. Therapy is the administration of desmopressin, an arginine vasopressin.
- Congenital hypothyroidism occurs as a result of an absent or nonfunctioning thyroid gland. The condition is discovered by a blood spot test at birth. Therapy is the oral administration of synthetic thyroid hormone.
- Acquired hypothyroidism (Hashimoto disease) is an autoimmune phenomenon that interferes with thyroid gland function. Therapy is the administration of synthetic thyroid hormone.
- Hyperthyroidism is caused by overproduction of thyroid hormones. It leads to jitteriness and tachycardia. It is treated by medication to suppress thyroxine release.
- Acute adrenocortical insufficiency is an emergency situation in which there is abrupt nonfunction of the adrenal glands. Congenital adrenogenital hyperplasia is an inherited disorder in which girls are born masculinized. Both girls and boys may be unable to retain sodium, resulting in rapid fluid loss. Therapy is the administration of hydrocortisone and also aldosterone if sodium loss is present.
- Cushing syndrome is caused by the overproduction of cortisol by the adrenal gland, which is usually caused by a tumor in the gland. Children appear abnormally obese. Therapy is the surgical removal of the tumor.
- The most frequently occurring pancreatic disorder is type 1 diabetes mellitus, an autoimmune process that destroys insulin-producing islet cells. Therapy is a combination of insulin, diet, and exercise. Type 2 diabetes is now occurring in children, especially those who are obese. Therapy is diet, exercise, and an oral antiglycemic agent.
- Hypocalcemia, a parathyroid gland disorder, results in a lowered blood calcium level, causing tetany to develop. Therapy is the administration of calcium.
- Various disorders of metabolism that interfere with carbohydrate, amino acid, or fat metabolism occur in children. Representative of these are PKU, galactosemia, and Tay-Sachs disease.

### CRITICAL THINKING CARE STUDY

Cassie is a 4-year-old child who has hypocalcemia because of inadequate parathyroid function caused by being struck in the neck by a baseball when she was 2 years of age. She takes a daily supplement of both vitamin D and calcium, and she is urged to eat a diet high in calcium. She has begun to be increasingly uncooperative about taking her medication. Her mother worries that, as Cassie grows older, she will refuse her medication completely.

1. Cassie's mother is worried her daughter will gain weight drinking whole milk and

so serves her nonfat milk. She adds chocolate syrup to it to change the taste. This morning, she realized Cassie gave her 10-year-old brother her glass of milk to drink. Does serving nonfat milk or adding chocolate to it change the calcium content of milk? What actions could you take to help Cassie’s mother increase Cassie’s cooperation with drinking more milk?

2. Cassie’s mother tells you she is at “the end of her rope” with trying to get Cassie to take her medicine. She’s so frustrated that she’s stopped trying to give her vitamin D because “it’s only a vitamin.” What suggestions could you make to help the mother increase Cassie’s medicine compliance?
3. The teacher at the preschool Cassie attends has told her mother that Cassie refuses to hold a pencil when it’s time to practice alphabet letters. She “acts out” by holding her hands together, “pretending they hurt” instead. She’s asked the mother to reinforce with Cassie the importance of learning letters to be ready for kindergarten. How would you suggest the mother handle this?

## Nursing Care of a Family When a Child Has a Neurologic Disorder

*Tasha is a 3-year-old girl you meet in an emergency department because she's had a seizure. Her mother grabs your arm, visibly upset. "Her sister has cerebral palsy and seizures. Does this mean Tasha has cerebral palsy too?" she asks you.*

*Previous chapters described normal growth and development in children and nursing care of children with disorders of other systems. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur when a child is born with or develops a neurologic disorder. Such information builds a base for care and health teaching for children with these disorders.*

**What education does this parent need about cerebral palsy or recurrent seizures?**

### KEY TERMS

**astereognosis**

**kinesthesia**

**paraplegia**

**pulse pressure**

**quadriplegia**

**status epilepticus**

**stereognosis**

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe common neurologic disorders in children.
2. Identify 2020 National Health Goals related to neurologic disorders in children that nurses can help the nation achieve.
3. Assess a child with a neurologic disorder.
4. Formulate nursing diagnoses for a child with a neurologic disorder.
5. Establish expected outcomes for a child with a neurologic disorder to help the family manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care, such as monitoring medicine effectiveness, for a child with a neurologic disorder.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of neurologic disorders and the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

Neurologic disorders encompass a wide array of problems resulting from congenital disorders, infection, or trauma. Many of these disorders severely alter the child's life; some result in life-threatening complications. Whenever possible, prevention must be the highest priority for keeping the nervous system healthy because, in the future, stem cell research may offer a cure for neurologic disorders, but for now, because neural tissue does not regenerate like other body tissue, any nervous system degeneration is likely to be permanent. Therefore, nursing care focuses on prevention or measures to help the child and family develop strategies for dealing with the associated loss in mental or physical functioning, making the child comfortable, and providing an environment conducive to the child's development and self-esteem (Parachuri & Inglese, 2013). The 2020 National Health Goals related to neurologic disorders in children are shown in [Box 49.1](#).

**BOX 49.1**

**Nursing Care Planning Based on 2020 National Health Goals**

Neurologic disorders are major causes of long-term disability in children. The 2020

National Health Goals that address these disorders are:

- Increase the proportion of children or youth with disabilities who spend at least 80% of their time in regular education programs from a baseline of 56.8% to a target level of 73.8%.
- Reduce the number of people 21 years of age and younger with disabilities who are in congregate care facilities from a baseline of 28,890 to 26,001.
- Increase the proportion of people with epilepsy or uncontrolled seizures who receive appropriate medical care.
- Reduce emergency department visits for nonfatal traumatic brain injuries from 407.2/100,000 population to 366.3/100,000 (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals through helping to prevent neurologic injury by educating children and parents about the use of helmets for bicycle and motorcycle safety, by administering and teaching paramedical personnel to administer safe care at accident scenes so children's heads and necks are protected, and by decreasing the possible spread of bacterial meningitis through good hand washing and infection control precautions in hospitals.

### *Nursing Process Overview*

## FOR CARE OF A CHILD WITH A NEUROLOGIC SYSTEM DISORDER

### **ASSESSMENT**

Neurologic disorders often begin with vague symptoms. Parents may report that their child seems to be “walking strangely” or is “just not herself,” making a thorough history and neurologic examination imperative for isolating the cause of the concern.

The neurologic examination covers six areas of neurologic functioning as well as motor and sensory functioning. If more information is needed following an exam, additional diagnostic tests will be prescribed. The parents and child need considerable support throughout the assessment process because, although the neurologic examination can be made “fun” for a child, other procedures such as a computed tomography (CT) scan or lumbar puncture can be frightening. Additionally, the anxiety of not knowing what is wrong and fearing the worst can make the waiting period for test results especially difficult for the child's parents.

### **NURSING DIAGNOSIS**

Nursing diagnoses for children with neurologic disorders vary according to the child's needs and level of functioning. Initially, a child may need emergency care and constant observation; later on, maintenance care to retain function is the priority. If the child has surgery, nursing diagnoses need to address not only immediate preoperative and postoperative care but also long-term care such as rehabilitation and home care. Three common nursing diagnoses that apply to almost all neurologic disorders are:

- Risk for disuse syndrome related to neurologic deficit affecting one area of functioning
- Interrupted family processes related to stress associated with the long-term effects of neurologic involvement
- Health-seeking behaviors related to care of a child with neurologic involvement

Other nursing diagnoses are specific for disorders and thus are described along with specific disorders.

## **OUTCOME IDENTIFICATION AND PLANNING**

Be realistic when establishing expected outcomes because children who have permanent limitations will not be able to achieve progress in all areas. When neurologic disorders are first diagnosed, parents may be so stressed that they may be able to focus only on short-term aspects of care, such as whether the child will survive meningitis or whether the child has stopped convulsing. Later, they'll be able to concentrate on the long-term picture: What type of education setting will be best for their child? What type of exercise program will be required?

Before a diagnosis is confirmed, parents may attribute their child's functional deficits to immaturity (she is not walking yet because she is simply too young). This can make them unable to make plans because they have not fully acknowledged their child's neurologic deficits. Only when parents begin to adjust to the new reality are they ready to participate in planning and problem solving.

Numerous organizations are available for assistance and support, such as the Epilepsy Foundation of America ([www.epilepsyfoundation.org](http://www.epilepsyfoundation.org)), the National Dissemination Center for Children With Disabilities ([www.parentcenterhub.org](http://www.parentcenterhub.org)), the Children's Tumor Foundation ([www.ctf.org](http://www.ctf.org)), the United Spinal Association ([www.spinalcord.org](http://www.spinalcord.org)), and the United Cerebral Palsy Association ([www.ucp.org](http://www.ucp.org)).

## **IMPLEMENTATION**

Nursing interventions for a child with a neurologic problem must address both short- and long-term needs. A lot of nursing care involves modeling care, such as how to gently handle an infant with increased intracranial pressure (ICP) and how to turn an infant on the side during a seizure to prevent choking, and reviewing needed medications with parents—actions that give parents confidence to be able to care for their child at home.

## **OUTCOME EVALUATION**

Evaluation of a child with a neurologic disorder should address not only the child's progress in regaining physical function but also the child's level of self-esteem. Some examples indicating achievement of possible outcomes are:

- The child states he or she is aware of potential for injury related to recurrent seizures.
- The parent/caregiver states understanding of potential for injury related to recurrent seizures.
- Family members state they are able to maintain family cohesiveness yet sustain

contact with hospitalized child.

- The child practices exercises daily to reduce possibility of contracture from disuse syndrome.

## Anatomy and Physiology of the Nervous System

Nerve cells (*neurons*) are unique among body cells in that, instead of being compact, they consist of a cell nucleus and extensions: one axon and several dendrites. The *dendrite* transmits impulses to the cell nucleus; the *axon* transmits impulses away from the cell nucleus to body organs. These cells vary in size, ranging from a few inches to several feet long, reaching from distant body sites such as the feet, through the spinal cord, and to the brain. Although their great length is vital to motor and sensory function, it also makes nerve cells more susceptible than other body cells to injury.

The nervous system is not fully functioning at birth; it continues to mature through the first 12 years of life. Two separate systems are involved: the *peripheral nervous system* (PNS) and the *central nervous system* (CNS). The PNS consists of the cranial nerves, the spinal nerves, and the somatic and visceral divisions. The CNS includes the brain and the spinal cord (Fig. 49.1) surrounded by the cerebrospinal fluid (CSF), the skull, and three membranes or meninges (the *dura mater*, a fibrous, connective tissue containing many blood vessels; the *arachnoid membrane*, a delicate serous membrane; and the *pia mater*, a vascular membrane) that protect the brain and spinal cord from trauma.

**Figure 49.1** Meninges of the (A) brain and (B) spinal cord.

The properties of CSF are shown in Table 49.1. Basically, it is a colorless, alkaline fluid with a specific gravity of approximately 1.004 to 1.008, containing traces of protein, glucose, lymphocytes, and body salts.

**TABLE 49.1** NORMAL PROPERTIES OF CEREBROSPINAL FLUID

Parameter	Normal	Abnormal Finding: Possible Significance
-----------	--------	---

Finding		
Opening pressure	Newborns: 8–10 cm H <sub>2</sub> O; children: 10–18 cm H <sub>2</sub> O	Lowered pressure usually indicates there is subarachnoid obstruction in the spinal column above the puncture site. Elevated pressure suggests intracranial compression, hemorrhage, or infection. Pressure increases if a child coughs or pressure is applied to the external jugular vein (Valsalva maneuver).
Appearance	Clear and colorless	If cloudy, indicates possible infection with an increased number of white blood cells (WBCs). If reddened, color is probably because of red blood cells (RBCs).
Cell count	0–8/mm <sup>3</sup>	Granulocytes suggest cerebrospinal fluid (CSF) infection. Lymphocytes suggest meningeal irritation and inflammation. A few RBCs and WBCs are normally present in the newborn CSF due to the trauma of birth.
Protein	15–45 mg/100 ml	Elevated count (>45/100 ml) occurs if RBCs are present. If both protein content and RBC count are elevated, meningitis or subarachnoid hemorrhage is suggested. If protein content alone is elevated, it more likely suggests a degenerative process such as multiple sclerosis.
Glucose	60%–80% of serum glucose level	Bacterial meningitis causes a marked decrease in CSF glucose; invasion of fungi, yeast, tuberculosis, or protozoans into the CSF results in some decrease in glucose level. Viral infections do not cause a decrease in CSF glucose and may occasionally cause a slight increase.
Albumin/globulin (A/G) ratio	8:1	Increased level suggests infection or an A/G ratio neurologic disorder.

## Assessing the Child With a Neurologic Disorder

Because neurologic symptoms, such as headache, unsteady gait, or lethargy, are often insidious, both a thorough history and a neurologic examination are needed to reveal the cause and extent of such symptoms (Box 49.2).

## BOX 49.2

### Nursing Care Planning Using Assessment

#### ASSESSING A CHILD FOR SIGNS AND SYMPTOMS OF A NEUROLOGIC DISORDER

##### History

*Chief concern:* Seizure, loss of consciousness, delay in developmental tasks, headache, clumsiness at motor tasks.

*Past medical history:* Infection during pregnancy; difficult birth; difficulty with initiating respirations at birth; head injury from fall or unintentional injury.

*Family medical history:* History of seizures or headaches in other family members.

##### Physical examination

Increased head circumference; bulging fontanelles, bulging forehead

Unequal size and response of pupils; unequal eye globe movements

Projectile vomiting

Widening systolic and diastolic blood pressure

Decreased pulse rate

Headache

Increased temperature

Pain on neck flexion

Ineffective sucking

Decreased respiratory rate

Spasticity of muscles

## HEALTH HISTORY

A child's history may first reveal symptoms of a neurologic disorder. Because many neurologic problems that are evidenced in infants and young children result from injury that occurred in utero, it is important to obtain the mother's pregnancy history as well.

At primary care visits, always ask parents about their child's developmental milestones and ability to perform age-appropriate tasks successfully. A screening test can be used to indicate whether a parent's concern about a preschool child is well founded. The ability to perform well in school is important documentation for an older child.

## NEUROLOGIC EXAMINATION

A complete neurologic examination takes at least 20 minutes and requires both patience and skill to keep a child's attention while observing for possible indications of neurologic disease. For a full examination, six areas are assessed: cerebral, cranial nerve, cerebellar, motor, sensory, and reflex function.

### Cerebral Function

Both general and specific cerebral functions need to be evaluated by assessing level of consciousness, orientation, intelligence, performance, mood, and general behavior (Rust, 2011). Children do best when these types of tests are presented as a game. Be certain to convey that there are no right or wrong answers because children who believe that they have failed these tests may not respond well to further testing.

The best way to evaluate a child's level of *consciousness* is through conversation. Note any drowsiness or lethargy. Allow the child to answer questions without prompting and listen carefully to be certain the answer is appropriate to the question.

*Orientation* refers to whether children are aware of who they are, where they are, and what day it is (person, place, and time). Be certain to take into account a child's age, making questions age-appropriate to the child's developmental abilities. Children younger than 4 years of age, for example, may not know both their first and last names. Children may be of school age before they know their address. Children younger than 7 or 8 years of age may have difficulty with the days of the week, confusing "yesterday" with "today" or "tomorrow." Intellectual performance (IQ) can be determined by the child's score on a standard intelligence test. Estimates of intellectual function can be made by asking the child questions on common topics.

*Immediate recall* is the ability to retain a concept for a short time, such as being able to remember a series of numbers and repeat them (a child of 4 years can usually repeat three digits; a child older than 6 years can repeat five digits). *Recent memory* covers a slightly longer period of time. To measure this, show the preschool child an object such as a key and ask the child to remember it because later you will ask him or her to tell you what it was. After about 5 minutes, ask whether the child remembers what object you showed him or her. Ask older children what they ate for breakfast to test recent memory.

*Remote memory* is long-term recall. Ask preschoolers what they ate for breakfast that morning or for dinner the night before because, for them, that was a long time ago; ask older children what was the name of their first-grade teacher because most people

remember this information their whole life.

Specific cerebral function can be measured by assessing language, sensory interpretation, and motor integration. When assessing language, listen to the child's ability to articulate. Remember, when listening to speech, many preschoolers substitute "w" for "r," saying "west time" instead of "rest time"; be aware that pronunciation is altered if English is not the child's primary language.

**Stereognosis** refers to the ability of a child to recognize an object by touch; it is a test of sensory interpretation. For this, ask a child to close his or her eyes and then place a familiar object, such as a key, a penny, or a bottle cap, in her hand and ask her to identify it. This is a skill even preschoolers are able to do successfully.

**Graphesthesia** is the ability to recognize a shape that has been traced on the skin. Ask a child to close his or her eyes; trace first a circle and then a square on the back of his or her hand and then ask him or her whether the shapes are the same or different. Be sure the child understands the concept of "different" by first showing him or her objects such as two keys and a bottle cap and documenting that he or she is able to identify the keys as being the same and the bottle cap as being different. For older children, trace numbers (8, 3, 0, and 1 work well) and ask the child to identify each one.

**Kinesthesia** is the ability to distinguish movement. Have a child close her eyes and extend her hands in front of her. Raise one of her fingers and ask her whether it is up or down. Hold the finger by its sides so that your other fingers do not brush against the child's palm or the back of her hand and reveal the finger position. Repeat the same movement with a toe on each foot. For preschoolers, be certain to first determine whether the child understands the concept of up and down.

To measure motor integration, ask a child to perform a complex motor skill, such as folding a piece of paper and putting it into an envelope. A child of 4 years or older should be able to do this neatly.

Remember, children do best when these tests are presented as a game. Be certain to convey that there are no right or wrong answers. A child who believes that he or she has failed these tests may not respond well to further testing.

## Cranial Nerve Function

Testing for cranial nerve function consists of assessing each pair of cranial nerves separately. Cranial nerves and methods of cranial nerve testing are described in [Table 49.2](#). Methods to test pupil constriction and ability to follow into fields of gaze are described in [Chapter 34](#).

**TABLE 49.2 CRANIAL NERVE FUNCTION**

Cranial Nerve	Function	Assessment
I (olfactory)	Sense of smell	Assess child's ability to recognize common odors such as peanut butter or an orange while eyes are closed.

II (optic)	Vision	Assess vision fields and visual acuity; examine retinas.
III (oculomotor)	Motor control and sensation for eye muscles and upper eyelid	Assess pupillary size, equality, reaction to light, and ability to follow an object in all directions. Note any nystagmus (an abnormal jerking motion).
IV (trochlear)	Movement of major eye globe muscles	As for nerve III
V (trigeminal)	Mastication muscles and some facial sensations	Assess ability to discern light touch to test sensory component; assess symmetry and strength of bite to test motor component.
VI (abducens)	Movement and muscle sense of eye globe	As for nerves III and IV
VII (facial)	Impulses for facial muscles, salivation, and taste	Assess motor strength by asking child to close eyes while you attempt to open them. Note symmetry of facial expression (such as smile) and movement (such as wrinkling forehead). Assess taste by asking child to identify salt or sugar.
VIII (acoustic)	Equilibrium and hearing	Assess hearing by the response to a whispered word or a Weber or Rinne test. Equilibrium is not tested routinely.
IX (glossopharyngeal)	Motor impulses to heart; sensation from pharynx, thorax, and abdominal organs	Assess gag reflex by pressing on back of tongue with tongue blade. Note midline uvula (tested together with nerve X).
X (vagus)	Swallowing and gag reflexes	Assess ability to swallow; elicit gag reflex by pressing a tongue blade on posterior tongue.

XI (accessory)	Impulses to striated muscles of pharynx and shoulders	Ask child to turn head to the side; try to turn it to center. Ask the child to elevate shoulders while you press down on them.
XII (hypoglossal)	Motor impulses to tongue and skeletal muscles; sensation from skin and viscera	Ask child to protrude tongue. Assess for tremors. Ask child to press on side of cheek with tongue; assess tongue strength.

### Cerebellar Function

Tests for cerebellar function are tests for balance and coordination. To test these, observe the child walk to assess whether the walk is natural (most children walk at least a little self-consciously when they know they are being observed, so watch them also as they enter the exam room and move around for other activities). Ask the child to stand on one foot; a child as young as 4 years should be able to do this for as long as 5 seconds. Ask the child to attempt a tandem walk (walk a straight line, one foot directly in front of the other, heel touching toe) (Fig. 49.2A). A child older than 4 years of age should be able to do this for about four consecutive steps. Ask the child to touch his or her nose with his or her finger and then to reach and touch your finger with the same hand (held about 1½ feet in front of the child) (see Fig. 49.2B). Tell the child to repeat this action and move your finger to a new position each time. The average child rarely reaches past your finger or stops before touching it.

**Figure 49.2** Cerebellar function tests. **(A)** A child attempting a tandem walk. **(B)** Nose-to-finger test. (© Lesha Photography.)

Ask the child to pat one knee with the palm of the hand and then quickly turn the hand over and pat the knee with the back of the hand; repeat over and over, one hand at a time. The majority of children are able to do this rapid, coordinated motion without much difficulty. Preschoolers will “mirror” the movement of the actively moving hand by moving the inactive hand as well. Older children should not demonstrate this (or should show only a small amount of movement).

Other tests are to ask the child to touch each finger on one hand with the thumb of that hand in rapid succession or ask the child to run the heel of one foot down the front of his or her other leg while he or she is lying supine (children should be able to do this without “running off” the leg). With the child lying on the examining table, ask the child to close his or her eyes and draw a circle or figure 8 in the air with his or her foot (children should also be able to do this without difficulty).

Tests of cerebellar function such as these are fun for children to do as long as they know that there are no passes or failures. Show approval for effort even if they are having difficulty with a task so that they have confidence to try another one.

### **Motor Function**

Motor function is measured by evaluating muscle size, strength, and tone. Begin by comparing the size and symmetry of extremities. If in doubt about either of these, measure the circumference of the calves and thighs or upper and lower arms with a tape measure. Palpate muscles for tone. Move the extremities through passive range of motion to evaluate symmetry, spasticity, and flaccidity bilaterally. To test for strength, ask the child to extend her arms in front of her and then resist your action as you push

down or up on her hands or push them out to the side. Do the same with the lower extremities.

## Sensory Function

If children's sensory systems are intact, they should be able to distinguish light touch, pain, vibration, hot, and cold. Have a child close his or her eyes and then ask the child to point to the spot where you touch him or her with an object. Light touch is tested by using a wisp of cotton, deep pressure by pressure of your finger, pain by a safety pin, and temperature by water bottles filled with hot or cold water. Vibration is tested by touching the child's bony prominences (iliac crest, elbows, knees) with a vibrating tuning fork. Warn the child that on pin testing, he or she will feel a momentary prick. Otherwise, the child may be unwilling to close his or her eyes again for further testing.

## Reflex Testing

Deep tendon reflex testing, which is part of a primary physical assessment (see [Chapter 34](#)), is also a basic part of a neurologic assessment. In newborns, reflex testing is especially important because the infant cannot perform tasks on command to demonstrate the full range of neurologic function (see [Chapter 18](#)).

### *QSEN Checkpoint Question 49.1*

#### **PATIENT-CENTERED CARE**

Tasha, 3 years old, is scheduled for a full neurologic examination. What explanation would best prepare her for this?

- “You’ll need to answer questions carefully so you can pass this test.”
- “I’ll be asking you to move in different ways, almost like a game.”
- “I need to find out how healthy or unhealthy your brain seems to be.”
- “Seizures can be caused by a brain tumor, so that needs to be ruled out.”

*Look in [Appendix A](#) for the best answer and rationale.*

## DIAGNOSTIC TESTING

A variety of diagnostic tests may be prescribed to provide additional information should any abnormalities be detected in the health history, physical examination, or neurologic examination. Many of these tests are invasive, so if you are scheduling these, be certain both the child and family are well prepared for these procedures; try to schedule the least invasive procedures first to better elicit the child's cooperation. So explanations will be well understood, take into account not only the child's chronologic age but also the child's level of cognitive functioning. Provide an explanation that includes not only physically what will happen but also a description of any sensory experiences the child might undergo such as anything he or she might feel, hear, smell, or taste.

## Lumbar Puncture

Lumbar puncture, the introduction of a needle into the subarachnoid space (under the arachnoid membrane) at the level of L4 or L5 to withdraw CSF for analysis, is used most frequently with children to diagnose hemorrhage or infection in the CNS or to diagnose an obstruction of CSF flow. The procedure is contraindicated if the skin over the needle insertion site is infected (to avoid introducing pathogens into the CSF) or if there is a suspected elevation of CSF pressure (if intracranial pressure [ICP] is elevated, the higher pressure in the intracranial space could cause the brainstem to be drawn down into the spinal cord space, compressing the medulla and compromising the action of the cardiac and respiratory centers). To limit pain, EMLA or lidocaine cream should be applied to the puncture site 1 hour before the procedure. Alternatively, the child may be administered conscious sedation for the procedure (see [Chapter 39](#)).

For a lumbar puncture, a newborn is seated upright with the head bent forward ([Fig. 49.3A](#)). The older infant or child is placed on one side on the examining table. Help the child flex the head forward, flex the knees against the abdomen, and arch the back as much as possible; this position opens the space between the lumbar vertebrae, facilitating needle insertion (see [Fig. 49.3B](#)). You might describe the position as “rolling into a ball” or “folding up like an astronaut in a small spaceship” to associate it with something the child knows about. Children younger than school age need to be held in this position because they may be so frightened by someone working on their back unseen that they are unable to hold this arched position (they try to turn over or turn their head to see what is happening). It helps a school-age child or adolescent if you stand by the table facing him or her and gently rest your hand on the back of the head, as a reminder to keep it bent forward. Talking quietly with the child not only assists in calming the child but also helps assess the child’s respiratory status as the child is “curled up.” Closely observe an infant for any respiratory distress.

**Figure 49.3** (A) Positioning an infant for a lumbar puncture. (© Barbara Proud.) (B) Positioning an older child for a lumbar puncture.

Children need good preparation for a lumbar puncture because they cannot see what is happening. Be certain they know the healthcare provider performing the procedure will wash their back with a solution that feels cold and then inject a local anesthetic that might sting for a moment (if an analgesic cream was not applied before the procedure).

Caution children they will feel pressure but not pain as the lumbar puncture needle is inserted. Occasionally, the needle will press against a dorsal nerve root and the child will experience a shooting pain down one leg. If this happens, reassure the child this feeling passes quickly and does not indicate an injury.

When the insertion stylette is removed and CSF drips from the end of the needle, the procedure has been successful. An initial pressure reading is made. To confirm the subarachnoid space in the cord is patent with that in the skull, the examiner may ask a child who is older than 3 years of age to cough; for an infant, the examiner may ask you to press on the child's external jugular vein. If either of these measures causes an increase of CSF pressure, it indicates that fluid is flowing freely through the subarachnoid space. Typically, three tubes of CSF, containing 2 to 3 ml each, are collected; a closing pressure reading is taken; and the needle is withdrawn. Samples are usually sent for culture, sensitivity, glucose level, and presence of red blood cells. The first sample obtained may contain blood or skin pathogens from the puncture, so it should not be the sample sent for determination of red blood cell content or culture. Additional evaluations requested might be albumin/globulin ratio or gamma-globulin level (an increased level of gamma-globulin is suggestive of multiple sclerosis or meningitis).

Lumbar puncture involves at least momentary pain, so children need to be comforted afterward. A few children may develop a headache after a lumbar puncture as a result of the reduction in CSF volume or invasion of a small air pocket during the puncture, although this is rare because of the small-sized needle used. Encourage the child to lie flat for at least 30 minutes and to drink a glass of fluid afterward to help prevent cerebral irritation caused by air rising in the subarachnoid space and to help increase the amount of CSF quickly. Encourage parents to hold an infant in a flat position across their knees. If the child develops a headache despite the precautions taken, an analgesic can be given for pain relief.

If a child had minimally increased CSF pressure at the time of the puncture, closely observe the child after the procedure to detect respiratory and cardiac difficulty from medulla pressure. An increase in blood pressure or a decrease in pulse and respiration rates, a change in consciousness, pupillary changes, or a decrease in motor ability are all important signs of increased intracranial compression.

### ***QSEN Checkpoint Question 49.2***

#### **TEAMWORK & COLLABORATION**

Tasha's diagnostic workup will include a lumbar puncture. When collaborating with the physician to perform this procedure, what nursing action should the nurse prioritize?

- a. Explain to Tasha that her back will be washed with a cold liquid.
- b. Apply EMLA cream to Tasha's lumbar region 5 to 10 minutes before the procedure.

- c. Reassure Tasha that the procedure will not hurt.
- d. Help Tasha into a prone position on the procedure table.

*Look in [Appendix A](#) for the best answer and rationale.*

## Ventricular Tap

In infants, CSF may be obtained by a subdural tap into a ventricle through the anterior fontanelle. A small space on the scalp over the insertion site is shaved or clipped, and the area is prepared with an antiseptic. The infant's head must be held firmly in a supine position to prevent movement during the procedure so the needle does not strike and lacerate meningeal tissue.

Fluid must always be removed from this site slowly, rather than suddenly, to prevent a sudden shift in pressure that could cause intracranial hemorrhage. After the procedure, a pressure dressing is applied to the site, and the infant is placed in a semi-Fowler's position to prevent additional drainage from the puncture site. After the procedure, comfort the infant or allow the parents to do so to both reduce the stress of a painful procedure and prevent the infant from crying excessively, an action that could increase ICP and loss of additional CSF.

## X-Ray Techniques

A flat-plate skull X-ray film may be used to obtain information about increased ICP or skull defects such as fracture or craniosynostosis (premature knitting of cranial sutures). Increased ICP is suggested if skull sutures appear separated on the X-ray. If the ICP is chronic, other subtle changes, such as a flattening of the sella turcica or an increase in the convolutions of the inner table of the skull, may be present.

## Cerebral Angiography

Cerebral angiography is an X-ray study of cerebral blood vessels that involves the injection of a contrast material into the femoral or carotid artery. Serial X-rays are then taken as the dye flows through the blood vessels of the cerebrum, and any vessel defects or space-occupying lesions occluding cranial blood vessels are revealed.

## Myelography

Myelography is the X-ray study of the spinal cord following the introduction of a contrast material into the CSF by lumbar puncture to reveal the presence of space-occupying lesions of the spinal cord. After the procedure, keep the head of the child's bed elevated to prevent contrast medium from reaching the meninges surrounding the brain and causing irritation.

## Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) involves the use of X-rays to reveal densities at multiple

levels or layers of brain tissue and is helpful to confirm the presence of a brain tumor or other encroaching lesions. Single-photon emission computed tomography (SPECT) is a similar procedure used mainly for blood flow evaluation. Magnetic resonance imaging (MRI) uses magnetic fields to show differences in tissue composition, revealing normal versus abnormal brain tissue. Both CT and MRI are discussed in greater detail in [Chapter 37](#).

## **Nuclear Medicine Studies (Brain Scan and Positron Emission Tomography)**

### **Brain Scan**

For a brain scan, a radioactive material is injected intravenously, and after a fixed time during which the injected material is deposited in cerebral tissue, radioactivity levels over the skull are measured. If the blood–brain barrier is not functioning, the radioactive material will accumulate in specific areas, suggesting possible tumor, subdural hematoma, abscess, or encephalitis.

### **Positron Emission Tomography**

The diagnostic technique of positron emission tomography (PET) involves imaging after injection of positron-emitting radiopharmaceuticals into a vein. These radioactive substances accumulate at diseased areas of the brain or spinal cord. PET is extremely accurate in identifying seizure foci.

## **Echoencephalography (Ultrasound of Head or Spinal Cord)**

Echoencephalography involves the projection of ultrasound (high-frequency sound waves above the audible range) toward the child’s head or spinal cord (a type of ultrasound). The technique may be used to outline the ventricles of the brain. Because this technique of scanning is noninvasive, produces no discomfort, and has no known complications, it may be repeated frequently to monitor changes in the size of ventricles or an invading lesion and is particularly effective in infants with open fontanelles. This noninvasive technique is often used in neonatal intensive care units to monitor intraventricular hemorrhages and other problems frequently encountered by preterm infants.

## **Electroencephalography**

The electroencephalogram (EEG) reflects the electrical patterns of the brain summarizing the physical and chemical interactions within the brain at the time of the test ([Rapin, 2011](#)). An EEG tracing typically indicates four types of waves: delta (1 to 3 waves per second), theta (4 to 7 waves per second), alpha (8 to 12 waves per second), and beta (13 to 20 waves per second).

To reduce extraneous movements of the eyes, head, or muscles that would affect the

tracing, the child must be cooperative and quiet during the procedure. Traditionally, therefore, parents are asked to keep their child up later than usual the night before the exam so the child will fall asleep during the test. Educate children and their families that the room will be darkened to help them rest. Use terminology to describe the procedure in terms that the child can understand depending on age and development. Reassure them that attaching the small suction cups or leads is not painful. Use of terminology that is age appropriate will help to keep the patient and family at ease during the procedure.

Sedation or conscious sedation may be necessary for children who are unable to lie still during the procedure. The goals of sedation are to (a) assure the patient's safety and welfare, (b) assure minimal pain and discomfort during the procedure, (c) control the patient's anxiety with minimal psychological trauma, and (d) modify behavior and movements during the procedure (Coté & Wilson, 2016). For example, chloral hydrate, a frequently used sedative for this procedure, may increase the fast activity of brain waves; chlorpromazine (Thorazine) is known to increase slow activity. Because some seizure medications also cause changes in brain waves, be certain to note on the child's electronic record what medications the child is currently receiving. Parents should receive specific instructions whether antiseizure medication should be given on the morning of testing.

Although EEGs can show important information about brain activity, they are not helpful in all circumstances because about 15% of children who have no cranial trauma or seizure activity demonstrate some abnormality on an EEG. They may not reveal a brain tumor because most brain tumors in children are in the posterior fossa, which is not revealed on an EEG. On inspection of the symmetry of brain waves in different hemispheres, local lesions such as a hematoma may be suggested. An EEG is most beneficial in diagnosing absence seizures. The typical pattern with this disorder is discussed later in this chapter.

Visual stimulation, such as having a child look at a whirling disk, may be used in connection with an EEG because various types of electrical discharges increase with rapid eye movements. In a child who is sensitive to this type of stimulation, the testing may produce a seizure; therefore, it is up to the prescriber to decide if the benefits outweigh the possible effects. Following an EEG, children will be sleepy if they have been sedated or had an EEG while sleep-deprived. Allow them to sleep as long as needed.

## Health Promotion and Risk Management

Health promotion for the nervous system begins prenatally with measures to ensure optimal fetal growth and development and prevention of problems associated with anoxia. It continues throughout childhood with routine health maintenance visits, screening for possible neurologic or developmental problems, and timely immunizations to prevent sequelae of childhood infections such as measles or

chickenpox. Nurses play a key role in providing education to parents about the importance of prenatal care, obtaining immunizations, and completing medication therapy to ensure complete resolution of an infection.

Nurses are able to provide parents with anticipatory guidance about safety measures to prevent injury, specifically, head and spinal cord injury by the use of seat belts or child restraints while riding in automobiles and protective gear when playing contact sports. Remind parents and children to wear helmets when riding or using anything that can move faster than the child can run such as scooters, roller skates/rollerblades, ice skates, horses, skis, skateboards or snowboards, bicycles, or motorcycles (Riesch, Kedrowski, Brown, et al., 2012). For a child with a long-term neurologic disorder, rehabilitation and early intervention play a major role in reducing the risk of complications and in promoting the child's and family's optimal level of functioning.

## Increased Intracranial Pressure

Increased ICP is not a single disorder but a group of signs and symptoms that occur with many neurologic disorders (Table 49.3). It is important to assess for signs and symptoms when caring for a child with a potential neurologic disorder (Sigurtà, Zanaboni, Canavesi, et al., 2013). Increased ICP occurs because of an increase in the CSF volume, blood entering the CSF, cerebral edema, head trauma or infection, space-occupying lesions such as brain tumors, or the development of hydrocephalus or Guillain-Barré syndrome.

**TABLE 49.3 SIGNS AND SYMPTOMS OF INCREASED INTRACRANIAL PRESSURE**

Sign or Symptom	Indication of Increased Intracranial Pressure
Increased head circumference	An increase >2 cm per month in first 3 months of life, >1 cm per month in the second 3 months, and >0.5 cm per month for the next 6 months
Fontanelle changes	Anterior fontanelle tense and bulging; closing late
Vomiting	Occurring in the absence of nausea, on awakening in morning or after nap; possibly projectile
Eye changes	Diplopia (double vision) from pressure on abducens nerves; white of sclera evident over pupil (setting sun sign); limited visual fields, papilledema
Vital sign changes	Elevated temperature and blood pressure; decreased pulse and respiration rates
Pain	Headache, often present on awakening and standing; increasing with

	straining at stool (Valsalva maneuver) or holding breath
Mentation	Irritability, altered consciousness such as sleepiness

The rate at which symptoms develop depends on the cause and the ability of the child’s skull to expand to accommodate the increased pressure. Children with open fontanelles, for example, can withstand more pressure without brain damage than older children, whose suture lines and fontanelles have closed.

## ASSESSMENT

Assessment of ICP may involve only a few quick procedures, such as obtaining vital signs, evaluating pupil response, and determining levels of consciousness, motor, and sensory function, or it may include more elaborate electronic monitoring.

Because symptoms are subtle at first, the initial signs children may show are headache, irritability, or restlessness. Growing pressure on the brainstem, which controls respiration and cardiac activity, soon causes pulse and respiration rates to slow. Compression of cranial vessels leads to a compensatory increase in blood pressure (or **pulse pressure**, the gap between the systolic and diastolic blood pressures). Pressure on the hypothalamus, the temperature-regulating center of the body, causes an increase in body temperature. An older child may be able to report symptoms such as diplopia (double vision). On funduscopic examination, papilledema may be detected. Compare a new assessment against all recordings taken in the last 24 hours so a progressive change can be detected.

If ocular changes such as a dilated pupil occur, this indicates pressure is increasing posterior to the eye globe, causing compression of the second cranial nerve. Record any tendency toward strabismus, nystagmus (constant eye movement), or “sunset eyes” (white sclera showing over the top of the cornea) or inability to follow the light into any quadrant. Be sure to be specific about what you document. “Inability to follow light,” for example, is not as informative as “Inability to follow light into left superior field; vertical nystagmus noted as child follows light into other fields.”

An additional test for ICP is a “doll’s eye” reflex. If a child lies supine and you turn his or her head gently but rapidly to the right, the eyes will normally turn toward the left, and vice versa. If a child has increased ICP, this phenomenon will be absent (a test useful in assessing a comatose child who is unable to cooperate by following a light).

Assess the child’s level of consciousness because if the child is alert but unable to comprehend surroundings, time, or place, this may be the first indication of increased ICP. As pressure continues to increase, a pseudo-awake state will occur, in which the child is awake but unable to follow light or locate a noise. Finally, the child becomes fully comatose, unable to be roused by any stimuli. Levels of coma are rated by the Glasgow Coma Scale, discussed in [Chapter 52](#) in connection with assessment for head trauma.

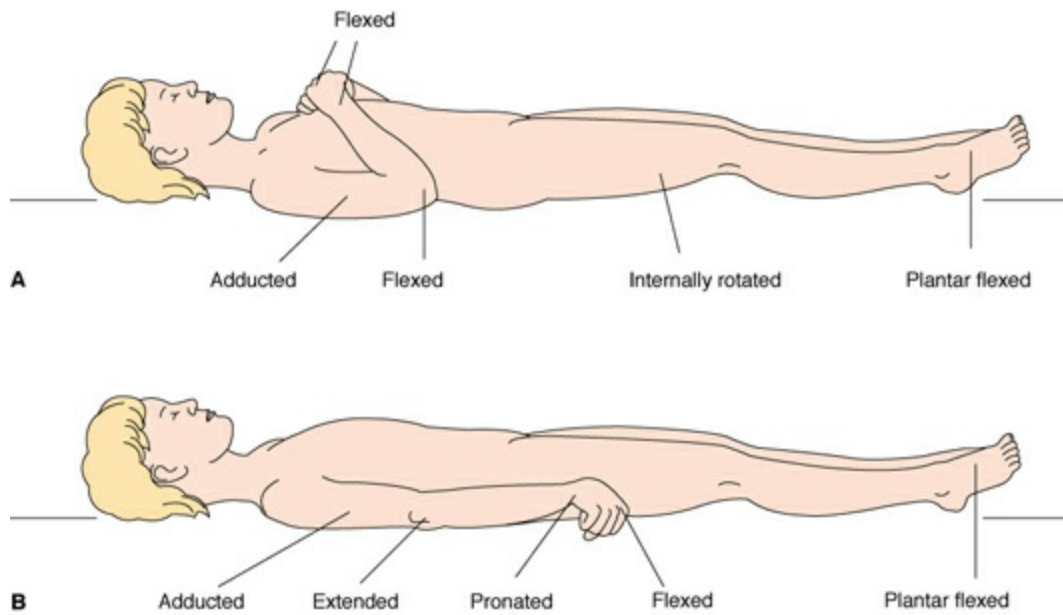

Children, like adults, generally become disoriented about time first, then place, and

then self. Explain to the parent and child that you will be periodically asking seemingly simple questions, such as asking the child for his or her name or to identify the day of the week. Let them know that it is important for the child to answer the questions if the child is able in order to understand the child's level of consciousness.

Be aware that many children, even when healthy, are groggy when they first awaken, especially if they have been dreaming. Make sure children are fully awake, therefore, before attempting to determine level of consciousness. Ask questions appropriate to the child's age. Preschoolers, for example, do not usually know their whole name or the day of the week and may not know concepts such as *morning* or *night*. To assess consciousness in children this age, it is often more productive, every hour, to show them a colored block, a piece of fruit, or a cartoon character known to the child and ask them to name it.

A good way to test an infant's level of consciousness is to determine whether the child responds to sounds, such as a familiar music box or voices, or reaches for an attractive object you offer. Motor ability can be assessed by asking a child to perform some simple motor tasks, such as squeezing your hands, pushing against your hands with both feet, or performing rapid, alternating hand movements, such as turning a hand over and back several times. Evaluate cranial nerves grossly by having the child make a face, close the eyes tightly, or smile. Evaluate whether the facial responses are equal and symmetric bilaterally. Test deep tendon reflexes because these decrease in intensity with decreased level of consciousness.

As a final assessment, carefully observe the child's resting posture because when motor control grows weaker because of loss of cell function, characteristic posturing (primitive reflexes) occurs. Cerebral loss is shown mainly by **decorticate posturing**: the child's arms are adducted and flexed on the chest with wrists flexed, hands fisted; the lower extremities are extended and internally rotated; the feet are plantar flexed (Fig. 49.4A). **Decerebrate posturing**, which occurs when the midbrain is not functional, is characterized by rigid extension and adduction of the arms and pronation of the wrists with the fingers flexed; the legs are held extended with the feet plantar flexed (see Fig. 49.4B).

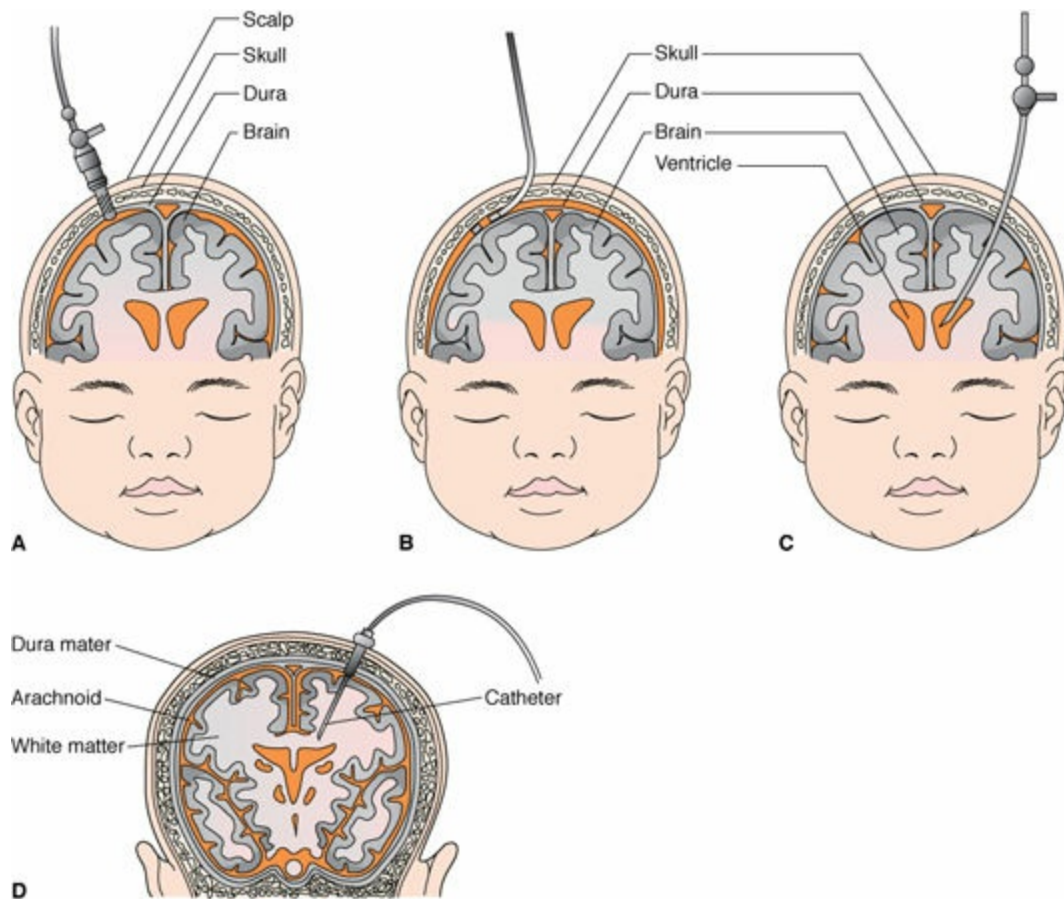

**Figure 49.4** (A) Decorticate posturing. (B) Decerebrate posturing.

Seizures are a sign of increased ICP, so if these occur, the child's ICP is becoming greatly compromised.

## INTRACRANIAL PRESSURE MONITORING

ICP can be measured by several additional methods:

- An intraventricular catheter inserted through the anterior fontanelle
- A subdural screw or bolt inserted through a burr hole in the skull
- A fiberoptic sensor implanted into the epidural space (or the anterior fontanelle in an infant) (Fig. 49.5)

**Figure 49.5** Devices used to monitor intracranial pressure. **(A)** Subarachnoid screw. **(B)** Epidural sensor. **(C)** Intraventricular catheter. **(D)** Intraparenchymal monitoring.

Intraventricular catheters (see Fig. 49.5C) are threaded into the lateral ventricle, filled with normal saline, and then connected to an external pressure monitor (Bailey, Liesemer, Statler, et al., 2012). As pressure in the ventricle fluctuates, it registers through the filled catheter onto an oscilloscope screen plus a written printout. This method is advantageous over simple scanning because it also enables CSF drainage and administration of medication through the catheter.

ICP in children normally ranges from 1 to 10 mmHg; a level greater than 15 mmHg needs further assessment. As blood pressure rises and falls with the influx of blood through vessels, so does ICP. On a monitor, this appears as A waves (plateau waves), B waves (short-duration waves), or C waves (small, rhythmic bursts). If brain ischemia is present, wave patterns change even before there is a deviation in blood pressure or pulse rate (Fig. 49.6). Because A waves appear to reflect brain ischemia, they can be used to signal when a child needs more oxygen.

**Figure 49.6** Normal intracranial pressure (ICP) waveform and generalized shapes of the three types of ICP waves: A waves or plateau waves, B waves, and C waves.

ICP monitoring also supplies information on cerebral perfusion pressure (CPP) or the amount of cerebral blood flow available to the brain ([Box 49.3](#)) because, if ICP ever exceeds arterial blood pressure (arises above about 50 mmHg), cerebral vessels can become obstructed ([Budohoski, Zweifel, Kasprowicz, et al., 2012](#)).

### BOX 49.3

#### Calculating Cerebral Perfusion Pressure

Cerebral perfusion pressure (CPP) ranges from about 60 to 150 mmHg. If it is too low, it suggests blood is having difficulty circulating to brain cells; if it rises too high, it can also result in brain ischemia from the increased intracranial pressure (ICP).

CPP is calculated by subtracting the mean ICP from the mean arterial pressure (MAP) or:

$$\text{MAP} - \text{ICP} = \text{CPP}$$

MAP is determined by subtracting the diastolic blood pressure (DBP) level from the systolic blood pressure (SBP) level, then dividing the result by 3, and adding that sum to 80 or:

$$\text{MAP} = \frac{(\text{SBP} - \text{DBP})}{3} + 80$$

To calculate CPP in a child with a blood pressure of 100/70 mmHg and an ICP of 10 mmHg, for example, first calculate the MAP:

$$\frac{(100 - 70)}{3} + 80 = 90 \text{ mmHg}$$

Next, calculate the CPP:

$$90 - 10 = 80 \text{ mmHg (the child's CPP or a normal value)}$$

Parents can have difficulty accepting procedures such as the insertion of intraventricular catheters or screws. Explaining the brain's anatomy can help them understand that the catheter or screw is inserted into a hollow space and thus does not puncture or tear brain tissue. Be sure to explain that this type of monitoring is advantageous not only because it enables early detection should problems arise but also because it helps to reduce the risk of further injury or complications.

## THERAPEUTIC MANAGEMENT

The cause of ICP must be identified and remedied as quickly as possible to prevent brain injury or compression to the brainstem, which can lead to both cardiac and respiratory failure. Actions such as coughing, vomiting, and sneezing and rapid administration of intravenous (IV) fluid increase ICP. When a parent is burping an infant after a feeding, caution them to be careful not to put pressure on the jugular veins because this is another action that increases ICP. Placing a child in a semi-Fowler's position (use an infant seat for babies) or administering a corticosteroid such as dexamethasone (Decadron) can effectively reduce cerebral edema and its accompanying pressure. An osmotic diuretic, such as mannitol, given IV, causes a shift of fluid from extravascular compartments into the vascular stream (from brain tissue into blood vessels), so it also reduces pressure. Children usually have an indwelling urinary catheter inserted before beginning an osmotic diuretic to ensure that the child's kidneys are able to successfully excrete the intravessel fluid and prevent back pressure on the heart. If the ICP is caused by excessive fluid accumulating in the brain's ventricles, a ventricular tap may be necessary for immediate reduction of pressure.

Because increased ICP is a sign of an underlying disorder, after the pressure is reduced, the underlying cause must then be identified and rectified or the pressure will rise again from the original disorder.

## Neural Tube Disorders

The neural tube is the embryonic structure that matures to form the CNS. Because this structure first forms in utero as a flat plate and then molds to form the brain and cord, it is susceptible to malformation. The disorders that occur as a result, such as spina bifida, are present at birth and are discussed in [Chapter 27](#).

## Neurocutaneous Syndromes

Neurocutaneous syndromes are characterized by the presence of skin or pigment disorders with CNS dysfunction.

### STURGE-WEBER SYNDROME

A child with Sturge-Weber syndrome (encephalofacial angiomas) has a congenital port-wine birthmark on the skin of the upper part of the face that follows the distribution of the first division of the fifth cranial nerve (trigeminal nerve). Because the lesion is usually unilateral, the port-wine stain ends abruptly at the midline, although it may extend inward at that point to the meninges and choroid plexus. If the disorder is limited to the ophthalmic branch of the fifth nerve, the lesion is usually confined to the upper aspect of the face.

Because of involvement of the meningeal blood vessels, blood flow can be sluggish, and anoxia may develop in some portions of the cerebral cortex. The child will develop symptoms of hemiparesis (numbness) on the side opposite the lesion from destruction of motor neurons. Intractable seizures, a cognitive challenge, or blindness caused by glaucoma may also be present. A CT scan or an MRI of the skull usually demonstrates calcification of the involved cerebral cortex, which appears as a “railroad track” or double-groove pattern on the CT or MRI screen. An EEG usually shows decreased voltage in the affected areas.

When this syndrome is first diagnosed, parents may ask to have the skin lesion surgically removed in the belief that this will correct their child’s condition. Unfortunately, because the lesion is not just a surface phenomenon, it’s important that parents understand the need for long-term follow-up, particularly if the child has accompanying seizures that require long-term antiseizure therapy ([Lo, Marchuk, Ball, et al., 2012](#)).

### NEUROFIBROMATOSIS (VON RECKLINGHAUSEN DISEASE)

*Neurofibromatosis* is the unexplained development of subcutaneous tumors. The disorder can occur as a mutation or it can be inherited as an autosomal dominant trait carried on the long arm of chromosome 17. It occurs in approximately 1 of every 4,000 live births and may be diagnosed prenatally ([Ardern-Holmes & North, 2011](#)). As an infant, the child typically shows irregular but excessive skin pigmentation. Later in childhood, pigmented nevi or café-au-lait (“coffee with cream”) spots appear that tend

to follow the paths of cutaneous nerves (six or more spots larger than 1 cm in diameter are diagnostic). By puberty, multiple soft cutaneous tumors begin to form in the child's skin along nerve pathways, and the child may develop seizures. Subcutaneous tumors develop by young adulthood. The acoustic nerve (cranial nerve VIII) is frequently involved, leading to hearing impairment. Involvement of the optic nerve can lead to vision loss. Approximately 8% of patients become cognitively challenged as a result of cerebral tumor formation or deterioration. Girls especially need to be aware of the disorder not only because of its inheritance pattern but also because tumor formation can increase with pregnancy ([Chetty, Shaffer, & Norton, 2011](#)). Little therapy is available to halt the tumor growth. If lesions are causing acoustic or optic degeneration, surgical removal of the tumors may be attempted to preserve hearing or sight. Be certain that both the parents and child have a source of emotional support through the disease's slow but invariably fatal course.

## Cerebral Palsy

Cerebral palsy (CP) is a group of nonprogressive disorders of upper motor neuron impairment that result in motor dysfunction. Affected children also may have speech or ocular difficulties, seizures, cognitive challenges, or hyperactivity. Muscle spasticity can lead to orthopedic or gait difficulties ([Crosbie, Alhusaini, Dean, et al., 2012](#)).

CP is caused by abnormal brain development or damage to the developing brain, leading to cell destruction of the motor tracts. Nutritional deficiencies, drug use, and maternal infections such as cytomegalovirus or toxoplasmosis, as well as direct birth injury, may also contribute to the cause.

CP occurs in approximately 2 of every 1,000 births, most frequently in very-low-birth-weight infants and those who are small for gestational age; it is increasing in incidence because of the number of very-low-birth-weight infants who survive today. Head injury such as from child maltreatment or automobile accidents also may lead to CP symptoms. Infections such as meningitis or encephalitis can result in CP symptoms as well.

### TYPES OF CEREBRAL PALSY

There are four main types of CP: a pyramidal or spastic type (approximately 40% of affected children), an extrapyramidal (dyskinetic) type, ataxic, and mixed ([Centers for Disease Control and Prevention, 2017](#)).

#### Spastic Type

Spasticity is excessive tone in the voluntary muscles that results from loss of upper motor neurons. A child with spastic CP has hypertonic muscles, abnormal clonus, exaggeration of deep tendon reflexes, abnormal reflexes such as a positive Babinski reflex, and continuation of neonatal reflexes, such as the tonic neck reflex, well past the

age at which these usually disappear. If infants with CP are held in a ventral suspension position, they arch their backs and extend their arms and legs abnormally. They fail to demonstrate a parachute reflex if lowered suddenly and tend to assume a “scissors gait” because tight adductor thigh muscles cause their legs to cross when held upright. This involvement may be so severe that it leads to a subluxated hip. By school age, tightening of the heel cord can become so severe that children walk on their toes, unable to stretch their heel to touch the ground (Fig. 49.7).

**Figure 49.7** Physical therapy can help a child with cerebral palsy to lengthen the heel cords. (© Tina Manley/Alamy.)

Spastic involvement may affect both extremities on one side (**hemiplegia**), all four extremities (**quadriplegia**), or primarily the lower extremities (**diplegia** or **paraplegia**). Children with hemiplegia usually have greater involvement in the arm than the leg. The involved arm may be shorter and may have a smaller muscle circumference than the other arm. Most children with hemiplegia have difficulty identifying objects placed in

their involved hand when their eyes are closed (**astereognosis**).

In older children, leg involvement may be detected most easily by examining the child's shoes as, because the child does not put the heel all the way down on the involved side, one shoe heel will be much more worn than the other. On physical examination, it may be difficult to abduct the involved hip fully, extend the knee, or dorsiflex the foot.

A child with quadriplegia invariably has impaired speech (pseudobulbar palsy) but may or may not be cognitively challenged. Swallowing saliva may be so difficult that the child drools and has difficulty swallowing food (Lewis, 2011).

### **Dyskinetic or Athetoid Type**

The athetoid type of CP involves abnormal involuntary movement (*athetoid* means "wormlike"). Early in life, the child appears limp and flaccid. Later, in place of voluntary movement, children make slow, writhing motions. This can involve all four extremities plus the face, neck, and tongue. Because of the poor tongue and swallowing movements, the child drools and speech is difficult to understand. Under emotional stress, the involuntary movements may become irregular and jerking (**choreoid**) with disordered muscle tone (**dyskinetic**).

### **Ataxic Type**

Children with ataxic involvement have an awkward, wide-based gait. On neurologic examination, they are unable to perform fine coordinated motions, the finger-to-nose test, or rapid, repetitive movements (tests of cerebellar function).

### **Mixed Type**

Some children show symptoms of both spasticity and athetoid or ataxic and athetoid movements. This combination obviously results in a severe degree of physical impairment.

## **ASSESSMENT**

The diagnosis of CP is based on history and physical assessment. Any episode of possible anoxia during prenatal life or at birth should be documented. Determining the extent of involvement in an infant is difficult, so the full extent of the disorder may not be recognized until the child attempts complex motor skills, such as walking or coloring.

Children with all forms of CP may have sensory alterations such as strabismus, refractive disorders, visual perception problems, visual field defects, and speech disorders such as abnormal rhythm or articulation. They may show an attention deficit disorder or autism spectrum syndrome. Cognitive challenge and recurrent seizures also frequently accompany all types of the disorder. A skull X-ray or ultrasound may show cerebral asymmetry. An EEG may be abnormal, although the pattern is highly variable.

## Nursing Diagnoses and Related Interventions

Parents who are reacting to the news that their child has multiple physical disabilities often find it difficult to make long-range plans. Therefore, try to focus expected outcomes on short-term concerns to assist with family functioning.

**Nursing Diagnosis:** Deficient knowledge related to understanding of complex disease condition

**Outcome Evaluation:** Parents state that they understand the cause of the disease is unknown but it is not progressive.

It's important for parents to understand that CP is nonprogressive and that the brain damage that occurred during pregnancy or at birth will not extend. The child's condition may seem to grow more apparent with age, however, as the child is expected to complete fine motor tasks. Without follow-up care, contractures from spasticity can result, further reducing existing motor function.

Caution parents also that CP is a single name for a wide variety of disorders of varying consequence. Although another child they know may have such severe CP that he has no useful function in his extremities, this does not mean their own child will be affected to the same extent. Conversely, although they know someone with CP who is able to hold a full-time job, their child may not be able to do so as well. Each child needs individual assessment so the child's maximum potential can be evaluated.

**Nursing Diagnosis:** Risk for disuse syndrome related to spasticity of muscle groups

**Outcome Evaluation:** Child walks with a minimum of support or equipment; skin and tissue remain intact.

Children with CP need promotion of any function that is not already impaired to prevent further loss of function and allow them to master the highest level of self-care, communication, ambulation, education, nutrition, and establishment of self-esteem they can achieve.

Learning to be ambulatory is an important part of self-care because it plays a large role in determining how independent the child can become. Walking can be difficult for the child to master because of lack of muscle coordination. Following surgery to lengthen heel tendons, assisted ambulation devices such as wheeled walkers may be necessary (Fig. 49.8). There are no drugs that cure CP, but a number can help relieve spasticity. Dopaminergic drugs, such as carbidopa/levodopa (Sinemet), widely used in Parkinson disease, increase the level of dopamine and, therefore, reduce rigidity. Muscle relaxants such as baclofen (Lioresal), given either

orally or administered continuously by an infusion pump, and benzodiazepines such as diazepam (Valium) can also help with smoother muscle movement (Gray, Morton, Brimlow, et al., 2012). Administration of botulinum toxin (Botox) has been successful in some children to relieve spasticity and aid in walking (Placzek, Siebold, & Funk, 2010). Cerebellar pacemakers and vagal stimulation are future therapy options.

**Figure 49.8** Wheeled walkers give a child added stability for walking and keep heel cords from shortening. (© [fotosearch.com](http://fotosearch.com).)

Preventing contractures is vitally important to maintain motor function. To help avoid these, teach parents that the passive exercises and games their child has been prescribed are an important part of their child's therapy and must be done consistently each day. To further prevent contractures, partial lightweight leg braces may be prescribed to encourage children to bring their heels down and to keep heel cords from tightening. If leg braces are prescribed, parents may need some encouragement and support to insist a child wears them because it is the constant

stretching that offers best results.

**Nursing Diagnosis:** Risk for self-care deficit related to impaired mobility

**Outcome Evaluation:** Child feeds and dresses self and manages elimination independently.

Children need to learn self-care measures such as dressing, tooth brushing, bathing, and toileting, so they can not only gain self-esteem by accomplishing these tasks but also achieve optimal independence. Modifications such as straps attached to their toothbrush or feeding utensils may be necessary so they can hold them more securely. Advise parents to always supervise children during bathing because lack of coordination could cause them to slip under water and drown. Toileting is often difficult because the child does not have the muscle group coordination necessary to achieve successful bowel evacuation. A high-fiber diet helps prevent constipation and aids bowel evacuation. Voiding may be equally difficult because the child may lack sufficient voluntary muscle control.

Parents may need considerable support and guidance to allow a child to complete self-care tasks independently because doing so often requires extreme patience. Letting a child perform these activities, however, helps to instill confidence and self-esteem in the child and helps allow the child to reach his or her maximum potential.

**Nursing Diagnosis:** Risk for delayed growth and development related to activity restriction secondary to CP

**Outcome Evaluation:** Child receives environmental stimulation; expresses interest in people and activities around him or her; attends school setting that is as free of restrictions as possible.

Children with CP may be unable to pursue stimulating activities and surroundings because they are not fully mobile. Therefore, encourage parents to bring these things to them as well as be certain that toys and activities are appropriate to the child's intellectual, developmental, and motor levels, not the child's chronologic age. Some children need more stimulating activities than others because they have difficulty concentrating on one activity for any length of time.

A preschool program is important to provide exposure to the outside world. If at all possible, school-age children with CP should be mainstreamed so that they can learn alongside other children. You may need to advocate that a child be placed in a school setting that is consistent with intellectual abilities.

**Nursing Diagnosis:** Risk for imbalanced nutrition, less than body requirements, related to difficulty sucking in infancy or difficulty feeding self in an older child

**Outcome Evaluation:** Child's weight remains within 5th to 95th percentile on height-weight chart; skin turgor remains good; specific gravity of urine is 1.003 to 1.030.

Providing adequate nutrition to children with CP can be difficult because they often have difficulty sucking because uncoordinated movements of the tongue, lips, and jaw and tongue thrusting make this difficult. They may tend to push food out of their mouth (a retained primitive reflex) rather than swallow smoothly. Older children may have difficulty holding and controlling a spoon to bring food to their mouths. Parents may need guidance in finding a feeding pattern that works for their child. Manually controlling the jaw may help control the head, correct neck and trunk hyperextension, and stabilize the jaw to assist with feeding. If a child cannot chew or swallow well, a liquid or soft diet may be necessary. A hyperactive gag reflex or symptoms of gastroesophageal reflux may cause children to vomit after feeding. Positioning infants upright after feeding helps to prevent aspiration if vomiting occurs.

**Nursing Diagnosis:** Impaired verbal communication related to neurologic impairment

**Outcome Evaluation:** Child can verbally make needs known to strangers and family members.

Most children with CP benefit from speech therapy, which helps them learn to speak slowly and to coordinate their lips and tongue to form speech sounds. Be patient when talking to them so they feel comfortable taking their time to form words deliberately. For the child who cannot speak clearly, provide an alternative form of communication, such as flash cards, a picture board, or a touch-screen computer, to aid communication.

## LONG-TERM CARE

Because CP is not always diagnosed early in infancy, parents may not learn their child has a chronic disorder until 2 to 4 years later. Listen to parents during healthcare visits and encourage them to discuss the difficulties of daily living, such as feeding problems. Offer them support as needed if they grieve because their child is not able to accomplish all of the major things they had wished for during pregnancy or feel defeated by the day-to-day strain of caring for their child's multiple special needs. Care of a child with a chronic illness is discussed further in [Chapter 56](#).

### *QSEN Checkpoint Question 49.3*

#### INFORMATICS

Tasha's sister Wanda was diagnosed with CP as an infant. What information would the nurse want her parents to know about her prognosis?

- Symptoms of CP typically begin to wane just after puberty.
- The severity of cognitive deficits parallels the severity of physical deficits.
- CP may occasionally be caused by a childhood vaccine reaction.
- Symptoms may seem to grow worse as fine motor skill is needed.

## Infection

Infection of the nervous system is always potentially serious. It typically occurs from illnesses such as meningitis, encephalitis, Guillain-Barré syndrome, Reye syndrome, and botulism.

### BACTERIAL MENINGITIS

Meningitis is, as the name implies, infection of the cerebral meninges. It tends to occur most frequently in children younger than 24 months of age and most often in winter. The organisms most frequently seen are *Streptococcus pneumoniae* or group B *Streptococcus*. In children younger than 2 months of age, *Escherichia coli* is a common cause. If children with myelomeningocele develop meningitis, *Pseudomonas* infection may be the causative agent. Children who have had a splenectomy are particularly susceptible to pneumococcal meningitis unless they have received a pneumococcal vaccine. *Haemophilus influenzae*, once a major cause of meningitis, is now rarely seen because of routine immunization against this organism ([Greenberg-Kushnir, Haskin, Yarden-Bilavsky, et al., 2012](#)).

Pathologic organisms usually spread to the meninges from upper respiratory tract infections by lymphatic drainage possibly through the mastoid or frontal sinuses or by direct introduction through a lumbar puncture or skull fracture. Once organisms enter the meningeal space, they multiply rapidly and then spread throughout the CSF to invade brain tissue through the meningeal folds, which extend down into the brain itself. Brain abscess or invasion of the infection into cranial nerves can result in blindness, hearing impairment, or facial paralysis. If a thick exudate accumulates in the narrow aqueduct of Sylvius, it can cause obstruction leading to hydrocephalus. Brain tissue edema can put pressure on the pituitary gland, causing increased production of antidiuretic hormone, resulting in the syndrome of inappropriate antidiuretic hormone secretion (SIADH), causing hyponatremia.

### Assessment

Children usually have had 2 or 3 days of upper respiratory tract infection prior to the development of meningitis. They then grow increasingly irritable because of an intense headache. They experience sharp pain when they bend their head forward. In the newborn, symptoms such as poor sucking, weak cry, or lethargy develop. As the disease progresses, signs of meningeal irritability then occur, as evidenced by positive Brudzinski and Kernig signs.

Children may hold their back arched and their neck hyperextended (opisthotonos). If third and sixth cranial nerve paralysis occurs, a child will not be able to follow a light through full visual fields. If the fontanelles are open, they bulge upward and feel tense;

if they are closed, papilledema may develop. If the meningitis is caused by *H. influenzae*, the child may develop septic arthritis. If it is caused by *Neisseria meningitidis*, a papular or purple petechial skin rash may occur (Pace & Pollard, 2012).

After this beginning of a myriad of general symptoms, sudden cardiovascular shock, seizures, nuchal rigidity, or apnea can occur. Because the infant has open fontanelles, nuchal rigidity appears late and is not as useful a sign for diagnosis as in the older child. As a rule, a child with a high temperature who then has a seizure is assumed to have meningitis until CSF findings prove otherwise.

CSF analysis obtained by lumbar puncture confirms the diagnosis. CSF results indicative of meningitis include increased white blood cell and protein levels, increased ICP, and a glucose level less than 60% of blood glucose (because bacteria have fed on the glucose). In addition to supplying blood for glucose level, blood is cultured and examined for increased WBC count. If the child has had close association with someone with tuberculosis, a tuberculin skin test to rule out tuberculosis meningitis will be done. A CT scan, MRI, or ultrasound study will be prescribed to examine for brain abscess.

## Therapeutic Management

Antibiotic therapy as indicated by sensitivity studies is the primary therapy. Intrathecal injections (directly into the CSF) may also be necessary, especially because the blood–brain barrier may prevent the chosen antibiotic from passing freely into the CSF. In some children, it takes a month before the CSF cell count returns to normal. A corticosteroid such as dexamethasone or the osmotic diuretic mannitol may be administered to reduce ICP and help prevent hearing loss.

In addition to standard precautions, children with meningitis are placed on respiratory precautions for 24 hours after the start of antibiotic therapy to prevent transmission of the infection to other family members or healthcare providers. In addition, an antibiotic may be prescribed prophylactically for the child’s immediate family members or for playmates who have been in close contact with the child.

Meningitis is always a serious disorder because it can run a rapid, fulminating, and possibly fatal course. If symptoms are recognized early and treatment is effective, however, a child will recover with no sequelae. Neurologic sequelae, such as learning problems, seizures, hearing and cognitive challenges, and inability to concentrate urine from lessened antidiuretic hormone secretion, must be assessed in the weeks to come because these can be long-term consequences.

### What If . . . 49.1

**The cause of Tasha’s seizure is found to be bacterial meningitis. Because she has severe neck pain whenever she is moved, her mother asks the nurse not to be so concerned about measuring intake and output, so her daughter can rest. How should the nurse respond? The nurse calls Tasha’s name and she does not answer. Why is this a particular cause of concern in a child with meningitis?**

## Nursing Diagnoses and Related Interventions

If a child has meningitis, the parents may feel responsible for the illness because they knew the child had an upper respiratory infection. They may ask if they could have prevented meningitis if only they had taken the child to their primary care provider as soon as the respiratory symptoms began. You can assure them the symptoms of meningitis occur so insidiously that no one can appreciate what disease process is at work from the first generalized signs.

Be certain to orient parents to infection control techniques if the child is isolated so they can feel comfortable caring for their child.

**Nursing Diagnosis:** Pain related to meningeal irritation

**Outcome Evaluation:** Child states pain is tolerable and shows no facial grimacing or other signs of discomfort.

For a child with meningitis, dealing with the number of invasive procedures, such as lumbar puncture, venipuncture, and IV therapy, necessary can make a hospital stay difficult. Remember that children feel pain when their head is flexed forward, so they usually are more comfortable without a pillow. Be careful not to flex their neck forward when turning or positioning them.

Although children would probably benefit from puppet play or coloring, activities that could help them express how they feel about so many intrusive procedures, frequently, they are too uncomfortable to play and thus are not able to be comforted by these measures. Be certain that children receive a good explanation of everything that is happening and extra attention from healthcare personnel not just when they perform painful procedures but so children can feel secure. Help parents understand that their child's acute irritableness is caused by the disease process and not by anything they did or are doing so they can continue to interact with the child. You can assure them that, as their child recovers, irritability will lessen and the child will begin to show more interest in communicating feelings. Promote rest by keeping stimulation in the room to a minimum.

**Nursing Diagnosis:** Risk for ineffective tissue perfusion (cerebral), related to increased ICP

**Outcome Evaluation:** Child's vital signs return to normal; child is alert and oriented; motor, cognitive, and sensory functions are within acceptable parameters for the child's age; specific gravity of urine is 1.003 to 1.030.

Observe the child carefully for signs of increased ICP such as increased blood pressure or slowed pulse rate. Carefully monitor the rate of all IV infusions to prevent overhydration and increased ICP. Measure urine specific gravity to detect

oversecretion or undersecretion of antidiuretic hormone because of pituitary pressure. Measure the child's head circumference and weigh the child daily. Monitor hearing acuity (reduced if there is compression of the eighth cranial nerve) by asking an older child a question or observing whether an infant listens to a music box or to your voice.

## GROUP B STREPTOCOCCAL INFECTION

A major cause of meningitis in newborns is group B streptococci. The organism is contracted either in utero or from secretions in the birth canal. It can spread to other newborns in a hospital nursery if good hand washing technique is not used.

Colonization can result in either an early-onset or a late-onset illness. With the early-onset form, symptoms of pneumonia become apparent in the first few hours of life. The late-onset type leads to meningitis instead of pneumonia.

With meningitis, at approximately 2 weeks of age, the infant gradually becomes lethargic and develops a fever and upper respiratory tract symptoms. The fontanelles bulge from increased ICP. The disease is extremely serious as mortality from the infection is approximately 25%; surviving infants may develop neurologic consequences such as hydrocephalus or seizures (Libster, Edwards, Levent, et al., 2012). Treatment is with antibiotics that are effective against the group B *Streptococcus*, such as ampicillin and cephalosporins. Because it can be difficult for parents to understand how their infant suddenly became so ill, they may need considerable support in immediately caring for the infant or if the infant is left neurologically challenged.

### QSEN Checkpoint Question 49.4

#### QUALITY IMPROVEMENT

Tasha is diagnosed as having bacterial meningitis, and her plan of care is being amended in light of this diagnostic finding. How long should the care team maintain respiratory precautions for this condition after Tasha begins an antibiotic?

- 4 hours
- 24 hours
- Until her core body temperature returns to normal
- Until her arterial blood gases return to normal

Look in [Appendix A](#) for the best answer and rationale.

## ENCEPHALITIS

Encephalitis is an inflammation of brain tissue and, possibly, the meninges as well (Kneen, Michael, Menson, et al., 2012). It can arise from protozoan, bacterial, fungal, or viral invasions. Enteroviruses are the most frequent cause, followed by arboviruses. Several encephalitis viruses, such as those that cause St. Louis encephalitis, West Nile

encephalitis, and Eastern equine encephalitis, are borne by mosquitoes and thus are seen most often during the summer months. Encephalitis also can result from direct invasion of the CSF during lumbar puncture. Yet, another cause is as a complication of childhood diseases such as measles, mumps, or chickenpox. In order to prevent the disease, therefore, it is crucial children receive immunization against childhood diseases and use mosquito repellents when in mosquito-infested areas.

### Assessment

Symptoms of encephalitis begin either gradually or suddenly and include symptoms such as headache, high temperature, ataxia (loss of usual muscle movements), muscle weakness or paralysis, diplopia, confusion, and irritability; if meninges are also involved, signs of meningeal irritation, such as nuchal rigidity and a positive Brudzinski or Kernig sign, may also be present. A child becomes increasingly lethargic and eventually comatose.

The diagnosis is made by the history and physical assessment. CSF evaluation will reveal an elevated leukocyte count and an elevated protein level. An EEG will demonstrate widespread cerebral involvement. A brain biopsy, usually taken from the temporal lobe or infected CSF, identifies the virus.

### Therapeutic Management

Treatment for a child with encephalitis is primarily supportive. An antipyretic is prescribed to control fever. Mechanical ventilation may be required to maintain the child's respirations during the acute phase. A variety of medications, such as acyclovir (Zovirax), an antiviral agent, and carbamazepine (Tegretol), an anticonvulsant, may be prescribed. A steroid such as dexamethasone or an osmotic diuretic such as mannitol may be needed to decrease brain edema and ICP.

Encephalitis is always a serious diagnosis because although a child may recover from the initial attack without further symptoms, there can be residual neurologic damage, such as seizures or learning disabilities. Parents may find it hard to believe their child is so seriously ill at first because in the beginning of the illness, their child only seemed tired and had a slight headache. They can find it even harder to accept that permanent impairment, such as a learning disability, could result. This makes follow-up care after hospitalization important both for the child's rehabilitation and to help parents deal with their grief, shock, and possible anger over this devastating turn of events in their life.

## REYE SYNDROME

Reye syndrome is acute encephalopathy with accompanying fatty infiltration of the liver, heart, lungs, pancreas, and skeletal muscle. It occurs in children from 1 to 18 years of age regardless of gender (Ninove, Daniel, Gallou, et al., 2011).

The cause is unknown, but symptoms such as lethargy, vomiting, confusion, and

combativeness usually occur after a viral infection such as varicella (chickenpox) or influenza that was treated with acetylsalicylic acid (aspirin). Treatment is supportive. Untreated, the condition leads to coma and death. Anticipatory guidance to parents and children about avoiding the use of aspirin during viral infections has almost prevented the syndrome (Bennett, Starko, Thomsen, et al., 2012).

## **GUILLAIN-BARRÉ SYNDROME**

*Guillain-Barré syndrome* (inflammatory polyradiculoneuropathy) is a perplexing syndrome that occurs in about 1 in every 100,000 children. Both motor and sensory portions of peripheral nerves are affected. Boys develop it more often than girls (Yuki & Hartung, 2012). With successful widespread polio eradication efforts, Guillain-Barré syndrome is now the most common cause of acute and subacute flaccid paralysis in childhood (Rosen, 2012).

The cause of the condition is unknown, but it is suspected that the reaction is immune mediated, occurring after upper respiratory tract or gastrointestinal illnesses or, rarely, immunizations. Inflammation of the nerve fibers apparently causes temporary demyelization of the nerve sheaths.

### **Assessment**

Children experience peripheral neuritis several days after the primary infection. Tendon reflexes begin to decrease and then become absent. Muscle paralysis and paresthesia (loss of sensation) begin first in the legs and then spread to involve the arms, trunk, and head. The symmetric nature of the disorder helps to differentiate it from other types of paraplegia. Cranial nerve involvement leads to facial weakness and difficulty in swallowing. As the respiratory muscles become involved, spontaneous respirations are no longer possible, leading to respiratory involvement severe enough to warrant mechanical ventilation.

A significant laboratory finding is an elevated CSF protein level. An EEG may show denervation and decreased nerve conduction velocity.

### **Therapeutic Management**

Treatment of Guillain-Barré syndrome is supportive until the paralysis peaks at 3 weeks and then is followed by gradual recovery. A course of prednisone to halt the autoimmune response may be tried, but its use is controversial. Plasmapheresis or transfusion of immune serum globulin may shorten the course of the illness. Cardiac and respiratory function must be closely monitored. All patients should be given subcutaneous fractionated or unfractionated heparin and support stockings until they are able to walk independently to prevent deep vein thrombosis.

Other necessary measures include prevention of the effects of extreme immobility while guarding respiratory function. An indwelling urinary catheter is usually inserted to monitor urine output. Enteral or total parenteral nutrition may be used to support

protein and carbohydrate needs. If the child has discomfort from neuritis, adequate analgesia is necessary.

To prevent muscle contractures and effects of immobility, turning and repositioning every 2 hours is important in addition to passive range-of-motion exercises about every 4 hours. Be certain to provide adequate stimulation for the long weeks when the child is unable to perform any care independently. Fortunately, despite the long period of mandatory ventilation therapy, most children recover completely, without any residual effects of the syndrome, although some may continue to have minor problems such as residual weakness.

## **BOTULISM**

Botulism occurs when spores of *Clostridium botulinum* colonize and produce toxins in the intestine. Infant botulism is not transmitted from person to person and occurs predominantly in infants younger than 6 months of age ([American Academy of Pediatrics, 2015](#)). Honey has been identified as a common source for infant botulism and should not be given prior to 12 months of age ([American Academy of Pediatrics, 2015](#)).

Symptoms occur within a few hours after ingestion of the contaminated food. Almost immediately, there is generalized weakness, hypotonia, listlessness, a weak cry, and a diminished gag reflex, followed by a flaccid paralysis of the bulbar muscles that leads to diminished respiratory function. The organism can be cultured from stools or serum. Electromyography may be helpful to support the diagnosis. Treatment is supportive care. Human-derived botulinum immune globulin may stop the progress of the disease.

## **Inflammatory Disorders**

Two neurologic inflammatory disorders are found frequently in adolescents.

### **CARPAL TUNNEL SYNDROME**

*Carpal tunnel syndrome* is nerve compression of the median nerve that passes through the carpal tunnel at the wrist ([Luckhaupt, Dalhamer, Ward, et al., 2013](#)). Compression of the nerve causes numbness and sharp pain and burning in the thumb and the second, third, and fourth fingers of the hand. Word processing, texting, and video games have turned this previously adult disorder into a disorder that occurs in children as well. Pain usually occurs at night and is enough to keep a child awake. The usual therapy is application of a splint to the wrist, which holds the wrist in a neutral (not flexed and not extended) position. An oral anti-inflammatory medication and perhaps a corticosteroid injection into the inflamed wrist both help to relieve pain. If these therapies are not successful, the stricture at the carpal canal can be relieved surgically.

## FACIAL PALSY (BELL PALSY)

Facial palsy is facial paralysis of the seventh (facial) cranial nerve, the nerve that innervates the muscles of facial expression. The syndrome occurs abruptly and may be associated with herpes or Lyme disease infection or occur as a result of cold air from skiing or from riding in a convertible. Therapy in adults consists of prednisone to reduce inflammation and acyclovir if the syndrome is herpes related. In children, prednisone use is variable. If the child is unable to close the eye on the affected side, eye drops three or four times daily will be needed. Although recovery is slow, usually takes about 4 months, most children recover without any permanent disability (McNamara, Doyle, McKay, et al., 2013).

## Paroxysmal Disorders

A paroxysmal disorder is one that occurs suddenly and recurrently. Seizures, headaches, and breath-holding spells are the most frequent types seen in childhood.

## EPILEPSY (RECURRENT SEIZURES)

A *seizure* is an involuntary contraction of muscle caused by abnormal electrical brain discharges. Approximately 5% of children will have at least one seizure by the time they reach adulthood (Sidhu, Velayudam, & Barnes, 2013). These episodes are always frightening to parents and other children because of the intensity. Although about 50% of seizures are idiopathic (unknown cause), they also can be attributed to infection, trauma, or tumor growth. Familial or polygenic inheritance may be responsible. Because they are not so much a disease as a symptom of an underlying disorder, all seizures need to be investigated.

The term *epilepsy* comes from a Greek word meaning “to take hold of.” Because the word has stigmas of cognitive challenge, behavioral disorders, institutionalization, or unexplainable strangeness attached to it, a preferred term is *recurrent seizures* because this term explains the disease process without the effect of discrimination (Box 49.4).

### BOX 49.4

#### Nursing Care Planning to Respect Cultural Diversity

The degree of understanding about the cause of disorders such as recurrent seizures varies in different cultures. The often unknown cause of recurrent (idiopathic) seizures has led to them being attributed to an invasion by evil spirits or the effect of curses. Many people today still fear that recurrent seizures will lead to cognitive impairment. Many parents worry that their child will be refused admission to a school or refused a job as an adult because their child is viewed as so unpredictable. Being aware of these common misconceptions can help you appreciate parents' anxiety about the diagnosis of recurrent seizures, an anxiety that can accentuate the need for

parent education and careful planning to maintain self-esteem in their child.

The types and causes of seizures vary with age and are classified into two major categories: partial and generalized seizures. As the name implies, with partial seizures, only one area of the brain is involved; with generalized seizures, the disturbance appears to involve the entire brain; loss of consciousness usually occurs. It's important that seizures be differentiated by their degree of severity and type so that parents can know any special precautions they need to take for their child and appropriate management and drug therapy can be instituted.

### Seizures in the Newborn Period

Seizure activity in the newborn period may be difficult to recognize because it may consist only of twitching of the head, arms, or eyes; smacking of the lips; slight cyanosis; and perhaps respiratory difficulty or apnea. Afterward, the infant may appear limp and flaccid. Whereas seizures in older children are often of unknown cause, 75% of seizures in neonates have a known cause such as trauma and anoxia from intrauterine life or birth; metabolic disorders, such as hypoglycemia, hypocalcemia, or lack of pyridoxine (vitamin B<sub>6</sub>); neonatal infection; or acute bilirubin encephalopathy caused by a blood incompatibility.

Because of the nervous system's immaturity, EEGs in the newborn may be normal despite extensive disease. A noticeably abnormal EEG in the newborn period, therefore, generally means a poor prognosis, indicating that involvement this early in life must be severe. Because almost 20% of all newborns have abnormal CSF values compared with adult standards (protein is increased, and there may be a few red blood cells from rupture of subarachnoid capillaries from the pressure of birth), lumbar puncture also is not conclusive.

High doses of antiseizure medication may be needed to control seizures in newborns because they metabolize drugs more rapidly than older children. In adults, for example, phenobarbital may be administered in the range of 1.5 mg/kg body weight per day. In newborns, the dose might be as high as 3 to 10 mg/kg/day.

### Seizures in the Infant and Toddler Periods

Seizures commonly seen in this age group are **infantile spasms**, a form of generalized seizure often called "salaam" or "jackknife" seizures, or infantile myoclonic seizures. These are characterized by very rapid movements of the trunk with sudden strong contractions of most of the body, including flexion and adduction of the limbs, or the infant suddenly slumps forward from a sitting position or falls from a standing position. The episode may occur singly or in clusters as frequently as 100 times a day.

In approximately 50% of affected children, there is an identifiable cause such as trauma, a metabolic disease such as phenylketonuria, or a viral invasion such as herpes or cytomegalovirus. In other children, the spasms apparently result from a failure of

normal organized electrical activity in the brain. Approximately 90% of infants with this type of involvement will be developmentally delayed as intellectual development appears to halt and even regress after the pattern of seizures begins. Most children with infantile spasms show high-amplitude slow waves and spikes, a chaotic discharge called *hypsarrhythmia* on an EEG tracing.

These seizures occur slightly more often in males than females, occur in 2 to 3 per 10,000 live births, have a family history in 3% to 6% of cases, and only spontaneously stop in 30% of children (Go, Mackay, Weiss, et al., 2012). Because the response to treatment with antiseizure therapy tends to be poor, parenteral adrenocorticotrophic hormone (ACTH) therapy, prednisone, or high-dose vigabatrin, an amino acid, are used in its place. High-dose valproate or a newer antiseizure agent such as topiramate (Topamax) may be used in children who do not respond to usual therapy, as well as pyridoxine (vitamin B<sub>6</sub>) or a ketogenic diet (see following discussion), but research shows none to be as effective as ACTH, especially for preserving neurodevelopmental outcomes (Go et al., 2012). In most children, the seizure phenomenon seems to “burn itself out” by 2 years of age. Any associated cognitive or developmental delay remains, however, so children need good follow-up planning and care.

### Seizures Caused by Poisoning or Drugs

The possibility of poisoning has to be considered in any child who has a first seizure. Although this is most likely to occur between 6 months and 3 years of age, it must be considered again in adolescence, when drugs may be intentionally self-administered. Seizures also can be a late symptom of encephalopathy caused by lead poisoning (see Chapter 52).

## Seizures in Children Older Than 3 Years of Age

### Febrile Seizures

Seizures associated with high fever (102° to 104°F [38.9° to 40.0°C]) are the most common type seen in preschool children, although these can occur as late as 7 years of age. They are most serious if they occur under 6 months of age. Such seizures may occur after immunization with live vaccines because these most commonly produce fevers. The seizure is usually a generalized tonic–clonic pattern, which lasts for 15 to 20 seconds. An EEG tracing afterward is usually normal. There also is usually a history of other family members having had similar seizures.

The seizure is due to a sudden spike of temperature, not a gradual incline. The seizure only lasts 1 to 2 minutes or less. Further evaluation is necessary after a febrile seizure to exclude underlying conditions or infections (Sidhu et al., 2013).

### *Prevention of Febrile Seizures*

Because these seizures arise with high fever, they are largely preventable. If ibuprofen or acetaminophen is given to keep a developing fever below 101°F (38.4°C), the

seizures rarely occur. They happen most often when a child develops a fever at night, when a parent is not aware of it, or when a parent is reluctant to give ibuprofen or acetaminophen in large enough doses to be therapeutic. Because the recommended doses of these medicines vary with the type (liquid or pills), caution parents to read the bottle label carefully before administration to be certain they are administering the correct dosage. Family history and younger age at onset of first seizure are risk factors for reoccurrence of a febrile seizure.

Teach parents that every child who has a febrile seizure must be seen by a healthcare provider to rule out meningitis and to be aware that it will be assumed by emergency room personnel that the child has meningitis until it is ruled out by a complete neurologic workup.

### *Therapeutic Management*

After a febrile seizure subsides, parents should sponge the child with tepid water to reduce the fever quickly. Advise them not to put the child in a bathtub of water to do this because it would be easy for the child to slip under water should a second seizure occur. Caution parents not to apply alcohol or cold water because extreme cooling causes shock to an immature nervous system; in addition, alcohol can be absorbed by the skin or the fumes can be inhaled in toxic amounts, compounding the child's problems. Parents should not attempt to give oral medications such as acetaminophen because the child will be in a drowsy, or *postictal*, state after the seizure and might aspirate the medicine. Suppositories may be given at the appropriate dose. If attempts to reduce the child's temperature by sponging are unsuccessful, advise parents to put cool washcloths on the child's forehead, axillary, and groin areas and transport the child, lightly clothed, to a healthcare facility for immediate evaluation.

At the healthcare facility, a lumbar puncture will be performed to rule out meningitis. If warranted, antipyretic drugs to reduce the fever below seizure levels will be administered. Appropriate antibiotic therapy will be prescribed if an infection is documented.

Many parents need to be reassured that febrile seizures do not lead to brain damage and that the child is almost always completely well afterward.

#### *What If... 49.2*

**Tasha's mother refuses to allow her to play with other children because she's worried Tasha will contract an upper respiratory infection from one of them and then have a febrile seizure. Is the mother taking a safe precaution or overreacting to the possibility of a seizure?**

### Complex Partial (Psychomotor or Temporal Lobe) Seizures

More than half of children who develop recurrent seizures during school age have an

idiopathic type or the cause of the seizures cannot be discovered. Despite this, medication can effectively control these seizures in almost all affected children. Some seizures in this age group occur because of organic causes such as laceration of brain tissue from an automobile accident or fall, an enlarging brain tumor, hemorrhage due to a blood dyscrasia, infection (meningitis or encephalitis), anoxia, or toxic conditions such as lead poisoning that have left residual damage. The possibility that brain trauma could have been caused by child maltreatment is always another possibility to consider.

Complex partial (psychomotor) seizures vary greatly in extent and symptoms and tend to be a difficult type to control. The child may notice a slight *aura*, or sensation a seizure is about to occur, but this is rarely as definite as that seen with tonic-clonic seizures. Results of a CT or MRI scan and EEG will invariably be normal.

This type of seizure often begins with a sudden change in posture, such as an arm dropping suddenly to the side. Other motor, sensory, and behavioral signs might include **automatisms** (complex purposeless movements, such as lip smacking, fumbling hand movements, intense running, or screaming). A few children may then slump to the ground, unconscious. Circumoral pallor develops due to a halt in respirations. The child begins breathing again almost immediately and usually regains consciousness in less than 5 minutes. He or she may feel slightly drowsy afterward but does not have an actual postictal stage or a period of sustained unconsciousness as seen with tonic-clonic seizures.

Common drugs used to treat this type of seizure include carbamazepine (Tegretol) (Box 49.5) or valproate (Depakene). Carbamazepine can lead to neutropenia, so white blood cell counts need to be monitored during therapy. If these drugs are not effective, surgery to remove the epileptogenic focus or the implantation of a vagus nerve stimulator can be used to significantly reduce seizure frequency. If seizures cannot be controlled fully, parents need to anticipate potentially hazardous situations during their child's day, such as having to cross a busy street on the way to school or riding a bicycle. State regulations vary, but the majority of adolescents are not eligible to secure a permit to drive until they are cleared by their primary care provider (after about a year free of seizures) to protect their own safety and that of others.

#### BOX 49.5

### Nursing Care Planning Based on Responsibility for Pharmacology

#### **CARBAMAZEPINE (TEGRETOL)**

**Classification:** Carbamazepine is an antiseizure medication.

**Action:** Exact mechanism of action is unknown, but it is believed to inhibit polysynaptic responses and block post-tetanic potentiation (Karch, 2013).

**Pregnancy Risk Category:** C

**Dosage:** Initially in children 6 to 12 years of age, 10 mg/kg/24 hr orally twice a day on the first day (maximum dose 100 mg), increased gradually in 100-mg increments

at 1-week intervals until best response is achieved, or 10 to 30 mg/kg/day in divided doses three or four times a day. Not to exceed 1,000 mg/day.

**Possible Adverse Effects:** Dizziness, drowsiness, behavioral changes, nausea, vomiting, abnormal liver function tests, bone marrow depression, rash, photosensitivity

### **Nursing Implications**

- Advise parents to administer the drug with food to minimize gastrointestinal upset.
- Remind parents to obtain serum drug levels as prescribed to monitor for effectiveness and to prevent possible toxicity; also, obtain liver function studies and blood cell counts to detect marrow depression.
- Suggest that parents obtain a medical alert bracelet and have the child wear it in case of a seizure.
- Instruct parents to not give sleep-inducing or over-the-counter drugs because these can interact with antiseizure medication to cause dangerous synergistic effects. Caution adolescents to avoid alcohol.
- Caution parents not to discontinue the drug abruptly or change the dose unless ordered by the healthcare provider.
- Instruct parents to notify their healthcare provider if the child develops bruising, bleeding, or signs of infection because these could be signs of bone marrow depression.

## Partial (Focal) Seizures

Partial seizures originate from a specific brain area. A typical partial seizure with motor signs begins in the fingers and spreads to the wrist, arm, and face in a clonic contraction. If the movement remains localized, there will be no loss of consciousness. If the spread is extensive, the seizure can cross the midline and become generalized and, at that point, is impossible to differentiate from a full generalized tonic–clonic seizure. This makes it important, therefore, to observe children carefully as a seizure begins to distinguish whether it began with local signs such as numbness, tingling, paresthesia, or pain all associated with one brain area. Documenting the spread can help localize the spot in the brain that first initiated the abnormal electrical discharge or be instrumental in detecting the location of a rapidly growing brain tumor.

## Absence Seizures

Absence seizures are one form of generalized seizures, formerly known as petit mal seizures (Sidhu et al., 2013). They occur more often in girls than boys, usually occur in school-age children between 4 and 12 years, and consist of a staring spell that lasts for a few seconds. A child might be reciting in class, for example, when he or she pauses and stares for 1 to 5 seconds and then continues the recitation as if he or she is unaware time

has passed. Rhythmic blinking and twitching of the mouth or an extremity may accompany the staring. As many as 100 seizures can occur during a day.

Children with absence episodes usually have normal intelligence but may have failing school marks, be accused of daydreaming in school, or be referred to the school nurse for behavior problems because they miss so many of a teacher's instructions.

On a neurologic exam, the presence of absence seizures can usually be demonstrated by asking a child to hyperventilate while the child counts out loud. If the child is susceptible to such seizures, he or she typically breathes in and out deeply, possibly 10 times, stops and stares for 3 seconds, and then continues to hyperventilate and count, unaware that he or she paused.

No first aid measures are necessary for absence seizures, and downplaying the importance of these episodes helps children maintain a positive self-image. They can be controlled by ethosuximide (Zarontin), valproate, or "off-label" lamotrigine (Robotham, 2011). If seizures are fully controlled by medication, children can participate in normal school activities and ride a bicycle or motorcycle. If seizures cannot be controlled fully, parents need to anticipate potentially hazardous situations during the child's day to prevent risky activities such as swimming alone.

Approximately one third to one half of all children with absence seizures "outgrow" them by adulthood. This does not mean that treatment is not necessary during childhood, however, in order to keep the child safe and maintain self-esteem. Follow-up health supervision is necessary during adolescence because some children's seizure pattern changes from absence involvement to tonic-clonic involvement as they approach adulthood.

### Tonic-Clonic Seizures

Typical tonic-clonic seizures (formerly termed grand mal seizures) are generalized seizures usually consisting of three stages: a prodromal period of hours or days or an aura, or warning, immediately before the seizure that a seizure is about to occur; a tonic-clonic stage; and, finally, a postictal stage.

The prodromal period may consist of drowsiness, dizziness, malaise, lack of coordination, or tension. As a child reaches school age, the child may be able to predict from these vague preliminary feelings when a seizure is about to occur.

An aura reflects the portion of the brain in which the seizure originates. Smelling unpleasant odors (often reported as feces) denotes activity in the medial portion of the temporal lobe. Seeing flashing lights suggests the occipital area, repeated hallucinations arise from the temporal lobe, numbness of an extremity relates to the opposite parietal lobe, and a "Cheshire-cat grin" relates to the frontal lobe. Young children, unable to describe or understand an aura, may scream in fright or run to their parent at its onset. Noting exactly what symptoms the child experiences during this time helps to localize the involved brain portion.

The next phase is the tonic stage. All muscles of the body contract, extremities stiffen, the face distorts, air is pushed through the glottis from contraction of the chest

muscles to produce a guttural cry, and the child falls to the ground. Although this phase lasts only about 20 seconds because the respiratory muscles remain contracted during this time, the child may experience hypoxia and begin to appear cyanotic. Contraction of the throat prevents swallowing, so saliva collects in the mouth. A few children bite their tongue when the jaws contract and thus have bleeding from their mouth.

The seizure then enters a clonic stage, in which muscles of the body rapidly contract and relax, producing quick, jerky motions. The child may blow bubbles from foamy or bloody saliva and will be incontinent of stool and urine. This phase usually lasts 20 to 30 seconds.

Following this tonic–clonic period, the child falls into a sound sleep, the *postictal period*. He or she will sleep soundly for 1 to 4 hours rousing only to painful stimuli. When children awake, they often experience a severe headache. They have no memory of the seizure.

In some children, seizures occur only at night. The child wakes in the morning with a sore tongue, blood on the pillow, or a bed wet with urine. In a child with persistent bed-wetting, the possibility this may be occurring from nocturnal seizures should be considered.

Children with this type of seizure may or may not have an abnormal EEG pattern. If an abnormal pattern is found, other family members may be found to have similarly abnormal EEG patterns, although they do not have symptoms.

Therapy includes the daily administration of an antiseizure medication such as valproate (Depakene) and carbamazepine (Tegretol). Phenobarbital may be administered to young children.

Medications are usually continued until the child has been seizure free for 2 to 3 years. No antiseizure medication should be stopped suddenly (it should be tapered) because rapid withdrawal may precipitate a seizure. In addition to medication, some children may be prescribed a ketogenic diet or a diet high in fat and low in protein and carbohydrate. This diet is proven to be highly effective in 40% to 50% of children who are started on it. This diet is difficult for parents to adhere to and to incorporate into the family's lifestyle and may need to be "fine-tuned" to improve seizure control ([Selter, Turner, Doerrer, et al., 2014](#)).

## Status Epilepticus

**Status epilepticus** refers to a seizure that lasts continuously for longer than 30 minutes or a series of seizures from which the child does not return to the previous level of consciousness. This is an emergency situation requiring immediate treatment before exhaustion, respiratory failure, permanent brain injury, or death occurs. An IV benzodiazepine drug such as diazepam (Valium) or lorazepam (Ativan) halts seizures dramatically. Diazepam must be administered with extreme caution, however, based on the child's drug history because the drug is incompatible with many other medications, and any accidental infiltration into subcutaneous tissue causes extensive tissue sloughing. Parents can be instructed on how to administer diazepam by enema at home.

Lorazepam (Ativan), a long-acting benzodiazepine used for children older than 2 years of age, provides a longer duration of action and also less respiratory depression (Karch, 2013). Both oxygen to relieve cyanosis and administering a medication to halt the seizure may be necessary; obtaining blood to monitor for glucose may reveal that hypoglycemia needs to be corrected.

### QSEN Checkpoint Question 49.5

#### EVIDENCE-BASED PRACTICE

Recurrent seizures can be depressing for children and parents if the seizures are difficult to eliminate with therapy. A 2015 study looked at parents' coping behaviors and stressors, and their ability to care for their child with chronic disease. The parents were given the *Coping Inventory for Parents* (CHIP) survey along with the *Pediatric Inventory for Parents* (PIP). Significant correlations were found in the study showing the need for early identification by nurses of disease-related challenges, stressors, and parental coping methods to improve the outcomes of the children (Senger, Ward, Barbosa-Leiker, et al., 2015).

Based on this study, if Tasha is found to have recurrent seizures, which statement by her mother at a healthcare visit would concern a nurse the most?

- "I forgot to give Tasha her medicine twice last week; I have to try harder."
- "I feel really sad when children call Tasha names because of her seizures."
- "I don't like having to miss work due to Tasha's clinic visits."
- "I think Tasha's medicine is giving her headaches; maybe she needs glasses."

Look in [Appendix A](#) for the best answer and rationale.

## Unfolding Patient Stories: Jackson Webber • Part 2

Think back to [Chapter 31](#) where you met **Jackson Webber**. Jackson was diagnosed with generalized seizures 2 years ago at age 3 years. He had another seizure and his mother brought him to the hospital. How would the nurse differentiate tonic-clonic seizures from other types of seizures? Compare and contrast the characteristics of each type of seizure.

Care for Jackson and other patients in a realistic virtual environment: **vSim for Nursing** ([thepoint.lww.com/vSimMaternityPed](http://thepoint.lww.com/vSimMaternityPed)). Practice documenting these patients' care in DocuCare ([thepoint.lww.com/DocuCareEHR](http://thepoint.lww.com/DocuCareEHR)).

### Assessment of the Child With Seizures

It's important that a thorough pregnancy history be obtained on any child with seizures. Events that occurred immediately before the seizure and an accurate description of the seizure itself also should be recorded. Investigate the child's overall behavior in the last few weeks such as bed-wetting or failing marks in school because these might be signs

of absence or nocturnal seizures that have occurred but gone unnoticed.

A complete physical and neurologic examination and blood studies are necessary to rule out metabolic or infectious processes. Prepare a child for a lumbar puncture to rule out meningitis or bleeding into the CSF. A CT scan, MRI, skull radiograph, or EEG may be obtained as indicated. Caution children during the EEG that they may be stimulated with rhythm patterns or flashing lights or asked to hyperventilate to see whether a seizure can be provoked.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for injury related to recurrent seizures

**Outcome Evaluation:** Child exhibits no signs of aspiration or traumatic injury.

Help a child having a partial seizure to a sitting position to protect against falling. Turn a child who has fallen to the floor onto the side so fluid will drain from the mouth and not be aspirated. Protecting a child from being hurt during a tonic–clonic seizure is crucial, but restraining the child’s thrashing extremities is not advisable because it is difficult for an adult to do so and could result in injury to the parent or child because of the amount of force needed to keep the child still (Box 49.6). Do not insert anything between the child’s teeth to stop tongue biting because this is rarely necessary and can result in broken and aspirated teeth.

### BOX 49.6

#### Nursing Care Planning Based on Family Teaching

##### SAFETY DURING SEIZURES

**Q.** Tasha’s mother asks you, “What can we do to be certain she doesn’t get hurt during a seizure?”

**A.** Here are the usual actions to help keep her safe:

- Remain calm.
- Move away furniture or any sharp objects.
- Turn your child gently on her side, or on her abdomen with her head turned to the side, to prevent aspiration of unswallowed mouth secretions.
- Do not restrain her other than to keep her head turned to the side. Restraining a child could result in injury because of the amount of force necessary.
- Do not attempt to place an object between the child’s teeth to prevent tongue biting. Trying to force an object into the mouth could break or loosen teeth.
- Be aware that a child having this type of seizure may have some slight cyanosis during the tonic and clonic stages, but these stages are so short that administering

oxygen is not needed.

- After any seizure, telephone your primary care provider about the seizure so arrangements for any necessary follow-up care can be initiated.
- If your child should pass rapidly from one seizure into another (status epilepticus), she may need supplemental oxygen or medicine to stop the seizure. If this happens, telephone your emergency medical service number (911).

Remaining calm is an important responsibility because it is reassuring for parents to see someone calm and in control of a situation that seems to be very out of control. If the child passes rapidly from one seizure into another (status epilepticus), be prepared to provide supplemental oxygen and administer antiseizure therapy as needed.

**Nursing Diagnosis:** Interrupted family processes related to diagnosis of long-term illness in child

**Outcome Evaluation:** Child, parents, and other family members express fears and questions about disease to healthcare team; parents discuss ways to accommodate the illness in their daily life, such as medication schedules, school accommodations, sports activities, plans for vacation, and discipline.

As soon as the diagnosis of a seizure disorder is made, parents and children need to be told that it is likely to signify a long-term disorder because although seizures can be controlled with medication, these do not change or cure the underlying cause of the seizures. [Box 49.7](#) shows an interprofessional care map illustrating both nursing and team planning for a child with recurrent seizures. Most children are given tablets rather than liquid medication because the latter tends to settle at the bottom of the bottle, resulting in over diluted or over concentrated doses that can allow seizures to break through at the end of the prescription period. To avoid this happening, caution parents to shake liquid medication thoroughly before every dose. Parents need to establish ways to remember to buy medicine so they always have an adequate supply, especially if they are taking a trip away from home or need to provide enough for holidays.

## BOX 49.7

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR A CHILD WITH RECURRENT SEIZURES

Tasha is a 3-year-old girl who was brought to the emergency department by her mother because she had a seizure. Her mother grabs your arm, visibly upset. “Her sister has cerebral palsy and seizures. Does this mean Tasha has cerebral palsy too?” she asks you.

**Family Assessment:** Parents are divorced. Child lives in a two-bedroom apartment with mother and a 6-year-old sibling; attends child care daily from 9 AM to 3 PM. Neighbor watches her from 3 to 6 PM, when mother returns from work as a research librarian.

**Patient Assessment:** Well-proportioned preschooler sleeping soundly on left side since admission. Had first seizure 2 hours ago; a second one 30 minutes ago. Temperature at 103.4°F. Other vital signs within age-appropriate parameters. Reacts to painful stimuli only. Deep tendon reflexes depressed. Mother reports, “I kept her home from child care because she has a cold. Suddenly, she fell to the floor and started shaking. I called 911, and they brought her here.” Apparent pain on forward flexion of the neck. Lumbar puncture performed; pressures within normal limits; specimens sent for cell count, glucose, and culture.

**Nursing Diagnosis:** Risk for injury related to diminished level of consciousness resulting from seizure episode

**Outcome Criteria:** Child is conscious within the hour. Exhibits no signs of aspiration or traumatic injury.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess whether mother was aware child’s temperature was elevated. Assess whether child has continued pain on dorsiflexion of neck.	Keep child on side to help ensure an open airway until alert and responsive. Ask if mother has a thermometer to take any future fevers.	Side-lying position reduces risk for aspiration. Pain on dorsiflexion of neck and irritability are symptoms of meningitis.	Mother states she understands importance of taking temperature in the future; difficult to evaluate pain as child is unconscious.
<i>Teamwork and Collaboration</i>				
Nurse/primary care provider	Assess in light of this second seizure and spinal tap results whether	Consult with neurologic service, if indicated, about management	A second seizure suggests this may be more than a simple response to elevated fever.	Neurologic service meets with mother and child as appropriate based on

	neurologic service should be consulted.	of child.		findings.
<i>Procedures/Medications for Quality Improvement</i>				
Nurse	Assess whether child has had a lumbar puncture or intravenous (IV) fluid administration before.	Assist with lumbar puncture and specimen collection. Begin IV fluid administration as prescribed.	Lumbar puncture is a frightening procedure for both child and parent. IV line supplies an emergency medicine route if needed for seizure control or infection therapy.	Mother states she understands reason for procedure and gives consent. IV line is established and safeguarded with board for unresponsive child.
Nurse	Assess whether mother understands why respiratory precautions are necessary.	Obtain equipment for respiratory precautions as needed.	Diagnosis could be meningitis, which is contagious by contact with nasal secretions.	Mother states she understands the importance of precautions. Respiratory precautions are readied.
<i>Nutrition</i>				
Nurse	Assess child's level of consciousness using a Glasgow Coma Scale.	Do not give anything by mouth until the child is fully awake, alert, and oriented and the gag reflex is intact.	Giving oral fluids too early increases risk for aspiration.	Child receives no oral fluid until she is awake and aware.
<i>Patient-Centered Care</i>				
Nurse/nurse practitioner	Assess what mother knows about febrile seizures and meningitis.	Teach that a febrile seizure is more of a symptom of fever than a	Understanding the basis for febrile seizures and meningitis can help the parent	Mother states she understands child's current status and possible future

		long-term condition. A meningial infection could be very serious.	understand the basis for emergency care.	implications.
--	--	---	--	---------------

*Psychosocial/Spiritual/Emotional Needs*

Nurse	Assess whether mother needs to contact a support person if her child's diagnosis is found to be serious.	Help mother contact a support person if she feels this would be helpful.	A support person can be vital to help a parent withstand an ominous diagnosis.	Mother contacts support person as needed.
-------	--	--	--	---

*Informatics for Seamless Healthcare Planning*

Nurse	Assess whether parent has any further questions about child's condition before transfer to pediatric intensive care unit.	Answer any remaining questions to make transfer as comfortable for parent and child as possible.	A parent gains confidence in emergency department staff and may find it difficult to change to new healthcare providers.	Mother states she understands that if meningitis or recurrent seizures are diagnosed, her child needs ongoing care.
-------	---	--	--	---

Be certain the child receives health maintenance care during childhood to be certain that the medication dosage remains adequate with continued growth. To document that serum levels of drugs are adequate, children need periodic blood sampling.

Provide parents with as much information as possible about the cause of their child's seizures because it's almost always easier to deal with a known disease, not an unexplainable and unpredictable one. Although the cause of the seizures is unknown, you can assure them that treatment is known; new antiseizure medications are being introduced yearly into therapy.

General guidelines for safe administration of antiseizure medications to stress with parents include:

- Caution children to be careful around motor vehicles and electrical equipment because many antiseizure medications cause drowsiness.
- Advise the child and parents to observe for easy bruising because some antiseizure medicines may suppress bone marrow function.
- Caution the adolescent to avoid alcohol while taking antiseizure medications because alcohol can potentiate the CNS effects of these medications.
- Use caution when administering antiseizure medications to children with liver disease. Because many of these drugs are metabolized by the liver, they may not be fully effective in such children.
- Caution the child and parents not to discontinue antiseizure therapy abruptly because this may lead to uncontrolled seizures.
- Remind parents about the need for follow-up blood tests to evaluate the drug level. Maintaining a therapeutic blood level enhances the drug's effectiveness and minimizes the risk for toxicity.

Discuss with parents the need to treat children with seizures the same as other family members. Scolding children, asking them to do household chores, or insisting they do their homework will not cause seizures. A few children with absence seizures can initiate them by hyperventilating and may try to manipulate those around them by doing this to gain sympathy. The few children who use this extreme form of manipulation may need to be referred for counseling.

Assure parents also that occasional seizures in children are not harmful. Unless status epilepticus occurs and the child becomes anoxic, the chance their child will be injured during a seizure is remote. Knowing this helps parents not to worry about the child becoming cognitively challenged or about other misconceptions regarding seizures. Although some children who have seizures are cognitively challenged, this impairment and the seizures were caused by the same event; the seizures did not cause the impairment. At every healthcare visit, be certain parents have time to ask questions about their child's care and to express concerns. There are so many "scare stories" about seizures that every parent is likely to believe some of these stories unless counseled otherwise (Box 49.8).

#### BOX 49.8

#### Nursing Care Planning Tips for Effective Communication

Tasha, 3 years old, had a febrile seizure and was diagnosed as having meningitis. You talk to her mother about the seizure.

*Tip:* Be sure to identify the parent's concern and attempt to clarify it, providing an opportunity for patient teaching. In the following scenario, the nurse responds with a therapeutic statement ("That must have been frightening.") and identifies a misconception verbalized by the mother.

**Nurse:** Mrs. Jarman, can you describe what happened?

**Mrs. Jarman:** She started shaking all over. It was really frightening.

**Nurse:** Did she voice any symptoms before the seizure?

**Mrs. Jarman:** No, just started shaking.

**Nurse:** That must have been frightening.

**Mrs. Jarman:** Thinking about what it did to her is scarier.

**Nurse:** Did to her?

**Mrs. Jarman:** I know seizures cause mental retardation. Our neighbor's son has them, and he's severely retarded.

**Nurse:** Let's talk about this a little more.

As a rule, children with seizures should attend regular school and participate in physical education classes and active sports (with possible exceptions such as scuba or sky diving or rock climbing). Many teachers are concerned about the responsibility of having a child with seizures assigned to their class. Contact the school nurse (with the parents' permission) to help them learn about the success of modern seizure control.

In many children, seizures increase or intensify at puberty, probably as the result of glandular changes or the need for an increased medicine dosage because of preadolescent growth. All antiseizure medications are potentially teratogenic to a fetus, so be certain adolescent girls are aware of this so they can choose to delay childbearing until later in life, when their medication can be reduced or even discontinued.

### ***QSEN Checkpoint Question 49.6***

#### **SAFETY**

Suppose Tasha has a tonic-clonic seizure while in the hospital. Which of the following items should the nurse keep available at the bedside for a child known to have generalized seizures? (Select all that apply.)

- a. Suction
- b. Tracheostomy tube
- c. Oxygen
- d. Call bell
- e. Padded tongue blade

*Look in Appendix A for the best answer and rationale.*

#### **BREATH HOLDING**

Breath holding is a phenomenon that occurs in young children when they are stressed or angry. The child breathes in and, because of anger or stress, does not breathe out again or else breathes out and then does not inhale again. As brain cells become anoxic, the child appears cyanotic and slumps to the floor, momentarily unconscious. With loss of consciousness, the child begins breathing again, color returns, and the child awakens. Breath holding this way is frightening to parents but results from the immaturity of the

child's neurologic control. This differs from a temper tantrum, in which a child deliberately attempts to hold his or her breath and then passes out (see [Chapter 30](#)). The child needs no immediate therapy except reassurance the episode is over. Breath holding may be associated with iron-deficiency anemia; if this is discovered, iron supplementation may be prescribed to decrease the breath-holding episodes.

## **HEADACHE**

Headaches in children younger than school age used to be considered rare, but young children can report “hair hurt” or have fussiness from allergies and viral inflammation of the upper respiratory tract that cause headaches. A toddler who has both vomiting and a headache should be evaluated because these are common signs of brain tumor, one of the most common tumors of childhood ([Cleves & Rothner, 2011](#)). Headache may also occur with a fever because of increased ICP caused by increased cerebral blood flow. As children reach school age, headaches may occur as a result of conditions as simple as eyestrain and sinusitis or, again, as serious as a brain tumor.

Headache pain results because of meningeal or vascular irritation, not from the brain itself because brain tissue is insensitive to pain. Because of this insensitivity, a cerebral tumor can be present for a lengthy time before meningeal irritation is enough that pain symptoms become apparent. With a brain tumor, pain becomes intense on changing body position, so a young child who reports a headache shortly after getting up in the morning should be carefully evaluated. Pain from a brain tumor is also usually occipital, so asking the child to indicate where it hurts helps determine whether a tumor could be the cause.

### **Tension or Stress Headache**

When children are studying intently or taking a test, contraction of their neck muscles from tension can cause temporary ischemia to the head. This type of headache is usually experienced as a dull, steady pain across the forehead, the temporal area, or the back of the neck. Children with these symptoms should have their vision tested because poor eyesight may be the reason they hunch over their books. Stress headaches are relieved by simple analgesics, such as acetaminophen or ibuprofen, or by sleep or application of a cool compress. Advising children to take frequent “stretches” while studying can help avoid muscle tension and stress and reduce the number of headaches experienced.

### **Sinus Headache**

Sinus headache usually accompanies sinusitis or is associated with inflammation and possible obstruction of the sinuses and is discussed in [Chapter 40](#).

### **Migraine Headache**

*Migraine headache* refers to a specific type of headache that may or may not begin with an aura or visual disturbance such as diplopia or a zigzag pattern across the visual field.

The pain that follows is usually unilateral and extremely intense, with throbbing that is moderate to severe. The headache is aggravated by routine physical activity or menstrual periods; it may be compounded by nausea and vomiting and intolerance to bright lights and noise (Cleves & Rothner, 2011).

The cause of migraine headache is not well understood but probably results from abnormal constriction of intracranial arteries that temporarily reduces cerebral blood supply. The reduction in blood flow is then followed by compensating over distention of cranial blood vessels. The aura accompanying such headaches results from the temporary ischemia that occurs in between those two processes. Some children who have migraine headaches have an abnormal EEG, but a normal EEG does not rule out the reality of the headaches.

Most children with migraine headache have a positive family history, or someone else in the family also has the same type of headache. A migraine syndrome may be inherited as a dominant trait.

## Assessment

To help assess the cause of a headache, obtain a thorough history, including:

- When the headache usually occurs
- The events preceding it (to detect an aura)
- Its usual duration, frequency, intensity, description, and associated symptoms
- Any actions taken to treat the headache

The child needs a thorough physical examination, including funduscopic examination, to rule out papilledema. Blood pressure must be measured to rule out hypertension. If an aura is documented, an EEG will be prescribed to investigate a seizure as the basis of the headache.

## Therapeutic Management

At the time of the headache, sleep or lying down may be necessary to relieve the pain and vomiting. Acetaminophen and nonsteroidal anti-inflammatory drugs are the first-line medical treatment for headaches in children, including migraines. Ergotamine tartrate (Cafergot), a vasoconstrictor, may be prescribed in addition for some children. Almotriptan, a member of the triptan family of drugs, is approved by the U.S. Food and Drug Administration for migraine in adolescents and may also be helpful. Frequent headaches interfere with a child's ability to achieve in school. Children may need to be reassured that even though their headaches are intense and even incapacitating, migraine headaches are benign and will not lead to any other condition so they can keep their headaches in perspective. Follow-up visits are necessary to confirm that they are not growing worse so treatment is remaining adequate (El-Chammas, Keyes, Thompson, et al., 2013).

If other family members have migraine headaches, counsel them that their reactions to their headaches influence their child's reaction to a headache. If the mother goes to

bed for the day when she has a migraine headache, for example, she cannot expect her child to go to school when the child has a headache.

## Spinal Cord Injury

Because of the resilience of their vertebrae, children have fewer spinal cord injuries than adults. However, the incidence among adolescents is increasing, especially among male adolescents, because more teenagers are involved in motor vehicle accidents, particularly motorcycle or off-road vehicle accidents, than previously (Martin-Herz, Zatzick, & McMahon, 2012). Another frequent cause of spinal cord injury is diving into too shallow water at beaches or backyard pools. Spinal cord injury without radiologic abnormality (SCIWORA) syndrome may occur, so any child with a multiple traumatic injury needs to be assessed for spinal cord damage. Stabilizing the neck at the accident scene is the best protection against further injury in these children (Hazinski, 2012).

### RECOVERY PHASES

Spinal injuries result when the spinal cord becomes compressed or severed by the vertebrae; further cord damage can result from hemorrhage, edema, or inflammation at the injury site as the blood supply becomes impeded. Table 49.4 summarizes functional ability that will probably be present after spinal cord injury at different vertebral levels. Predictions such as these of useful body function cannot be made accurately at the time of the injury, however. Three phases of recovery must first take place.

**TABLE 49.4 FUNCTIONAL ABILITY AFTER SPINAL CORD INJURY**

Injury Site	Highest Key Functions Still Present	Effects and Possible Interventions
C1–C3	Head and neck muscles intact	Respiratory paralysis from loss of phrenic nerve innervation; will need ventilatory assistance No voluntary motion below chin; possibly able to learn to use mouth to control pen for writing and mouth stick to reach objects
C4	Diaphragm intact	Loss of motor function of upper and lower extremities and trunk; able to learn to use abdominal muscles to breathe independently
C5	Shoulder control; biceps, deltoid function	Able to feed self and operate wheelchair if fitted with self-care aids
C6	Forearm pronation; wrist extension	Use of upper extremities for self-care; can transfer to wheelchair and so have increased independence
C7	Triceps function	Able to transfer to wheelchair readily; increasing

		independence
C8	Thumb and finger function	Able to do fine motor tasks; increases self-care ability
T1–T7	Intercostal muscles (able to breathe with chest, not abdominal, muscles)	Full use of upper extremities but is still dependent on wheelchair Possibly able to drive car with hand controls Possibly able to have high leg braces fitted for standing
T10–12	Abdominal muscles	Use of long leg braces and four-point crutch to ambulate
L2–L4	Hip flexion Leg extension	Use of long or short leg braces to ambulate
L5–S1	Gluteus maximus muscle function	Able to walk without aids
S4	Bladder and anal sphincter control	Able to control bladder and bowel function Penile erection and ejaculation possible

### First Recovery Phase

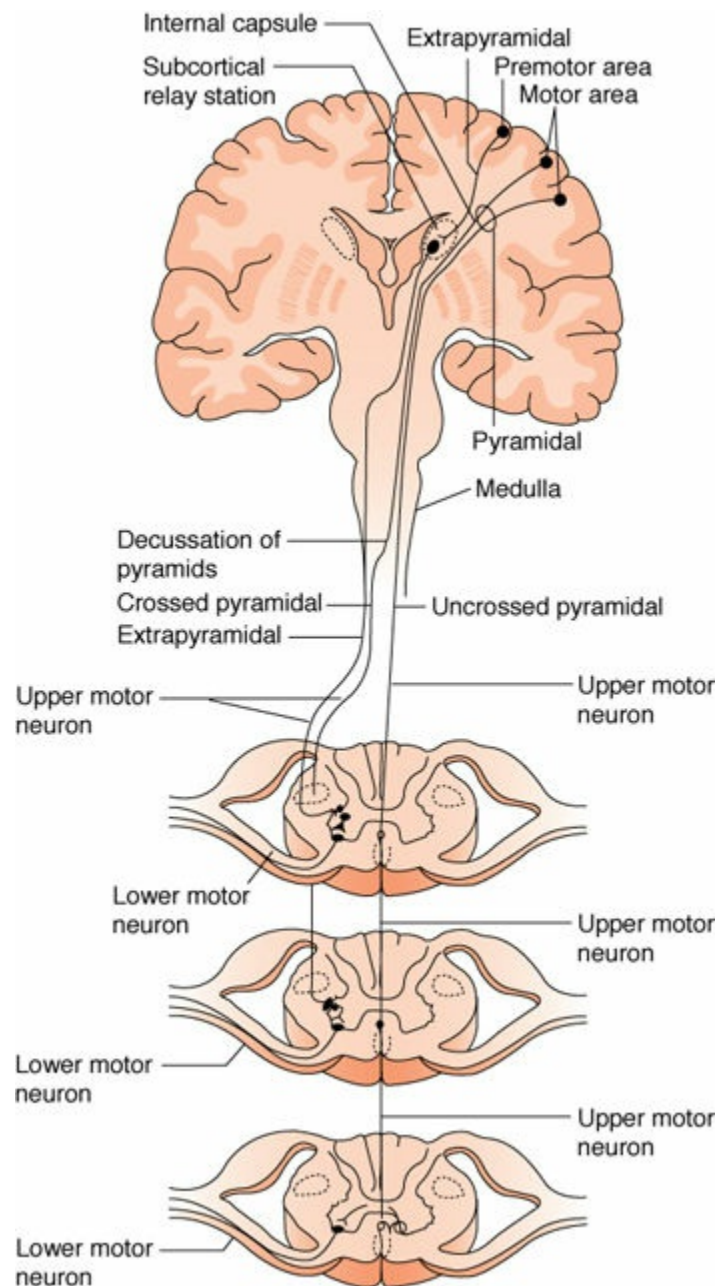

Immediately after the injury, the child experiences a *spinal shock syndrome* or loss of autonomic nervous system function (loss of nerve fibers traveling through the anterior horn of the spinal canal), leading to loss of motor function, sensation, reflex activity, and the presence of flaccid paralysis in body areas below the level of the injury. If a cervical or high thoracic injury is present, there will be loss of or decreased respiratory function because of flaccidity of the diaphragm or loss of the accessory muscles of the chest. At all levels, the child has no ability to sweat or shiver to change body temperature below the level of the lesion because of loss of autonomic nerve control; therefore, hypothermia or hyperthermia always becomes a threat. Blood vessels below the level of the injury are no longer able to constrict, so blood tends to pool in the lower body, leading to yet another concern—upper body hypotension, especially if the upper body is elevated. Loss of bladder control occurs if the bladder is left flaccid (it expands and continually overflows). Loss of control in the bowel allows it to become equally distended; bowel sounds will be absent. This phase of spinal cord injury lasts from 1 to 6 weeks. As a rule, the shorter the phase of spinal shock, the better is the final outcome.

Administration of a corticosteroid can help reduce edema and possibly protect function of the spinal cord during this phase. A vasopressor agent such as dopamine may be prescribed to maintain blood pressure and perfusion to the cord.

### Second Recovery Phase

During the second phase of recovery, the flaccid paralysis of the shock phase is replaced by spastic paralysis. Normally, motor impulses begin in the brain cortex and are

transmitted to the medulla, where they cross to the opposite side of the cord; they then travel down the descending motor tracts of the spinal cord. They synapse in the anterior horn of the spinal cord and travel by way of the spinal and peripheral nerves to the designated muscle group, which they set in motion. The nerve pathways of the brain and the descending tracts are termed *upper motor neurons*. Those in the anterior horn cells and the spinal and peripheral nerves are termed *lower motor neurons*. Whether a motor neuron has upper or lower function, therefore, does not depend on its height in the spinal tract but rather on its position in relation to an anterior horn: Between the brain and the anterior horn, it is an upper motor neuron; between the anterior horn and the point of innervation, it is a lower motor neuron (Fig. 49.9).

**Figure 49.9** Diagram of motor pathways between the cerebral cortex, one of the subcortical relay stations, and lower motor neurons in the

spinal cord. Decussation (crossing of fibers) means that each side of the brain controls skeletal muscles on the opposite side of the body.

Spasticity in the second phase is caused by the loss of upper level control or transmission of meaningful innervation to the anterior horn. Lacking upper motor neuron function because of a severed cord, the lower motor neurons or reflex arcs cause the muscles to contract and remain that way. Parents and children are quick to interpret the sudden spastic movement of a lower extremity as meaningful activity. This is particularly easy to believe with infants, who cannot tell you they have no control or cannot stop their legs from contracting. Differences between upper and lower neuron damage are listed in [Table 49.5](#). If the injury is very low in the spinal tract, affecting mostly lower motor neurons, the muscles will remain flaccid because the lower motor neurons cannot send impulses for contraction.

**TABLE 49.5 CHARACTERISTICS OF UPPER AND LOWER MOTOR NERVE INJURY AFTER SPINAL SHOCK PHASE**

Finding	Upper Motor Lesion	Lower Motor Lesion
Spasticity	Present	Absent (flaccidity present)
Clonus	Present, increased	Absent
Tendon reflexes	Increased	Absent
Babinski reflex	Present	Absent
Reflexes below level of lesion	Present	Absent
Reflex at level of lesion	Absent	Absent
Atrophy of muscles	Absent or present only to slight degree	Present (muscle fasciculations may be present)

During this phase, if the child’s bladder is allowed to fill, the resultant sensory stimulation relayed to the damaged cord can initiate a powerful sympathetic reflex reaction (**autonomic dysreflexia**). The child will experience extreme hypertension, tachycardia, flushed face, and severe occipital headache. This is an emergency situation because if the severe hypertension is not relieved, cerebrovascular accident can result ([Pellatt, 2010](#)). Assess that the child’s urinary catheter is not obstructed, so urine can flow freely and reduce the sensory stimulation. Also, frequently assess for signs of urinary tract infection such as elevated temperature or cloudy urine because urinary complications remain the leading cause of morbidity and the most common infection for individuals with spinal cord injury ([Eves & Rivera, 2010](#)).

*Concept Mastery Alert*

Respiratory function is of great concern in the first stage of recovery. By the second stage, respiratory function should have stabilized and become predictable. Contractures can occur during this stage as the flaccid paralysis of the first stage passes and the spastic paralysis of the second stage begins.

### Third Recovery Phase

The third phase of recovery from spinal cord injury is learning to live with the final outcome or permanent limitation of motor and sensory function. If the compression of the spinal cord was only caused by edema that is then relieved, no permanent motor and sensory disability will occur.

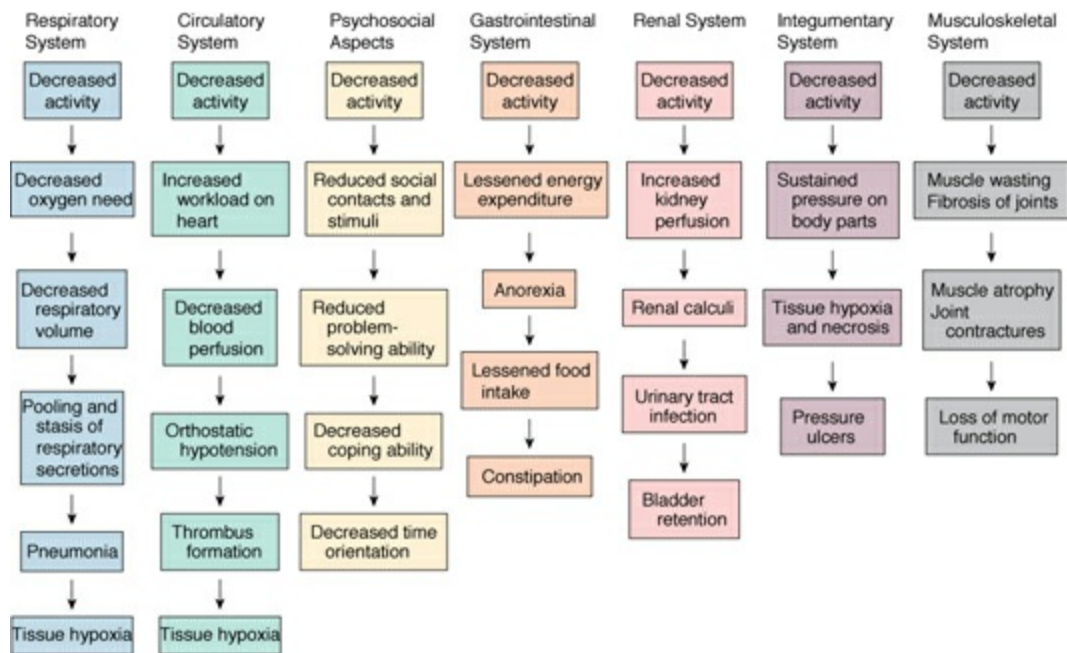

### ASSESSMENT OF SPINAL CORD INJURY

Cervical and thoracolumbar areas of the spine are the ones most likely to sustain injury, but spinal cord injury should be suspected whenever a child has sustained a forceful trauma of any kind. Do not move a child with suspected spinal cord injury at the scene of the injury until the back and head can be supported in a straight line to prevent further injury to the spinal column from twisting or bending. In the emergency department, as a general rule, do not attempt to move the child from a stretcher to an examining table until spinal X-ray films have been obtained; if helping move the child onto the X-ray table, use a gentle log-rolling technique to avoid additional movement or injury. If resuscitation is necessary, be certain to maintain the child's head in a neutral position, not hyperextended. To keep the neck immobilized, if a child is wearing a football, bicycle, or motorcycle helmet or a neck brace, do not remove these (Nayduch, 2010). Help maintain spinal immobilization during such procedures as obtaining blood samples or a neurologic assessment.

### Nursing Diagnoses and Related Interventions

During the first phase of recovery, a child's major problems are those that result from almost complete immobility: pressure ulcers on bony prominences, loss of appetite and subsequent poor nutrition from depression or being kept in a supine position, urinary calculi caused by excessive calcium loss from bones, atrophy of flaccid muscle groups, and urinary retention and bladder infection. These effects of immobility are presented in [Figure 49.10](#).

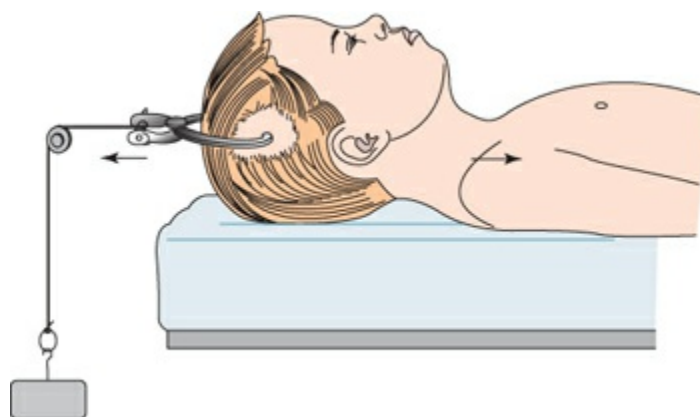

**Figure 49.10** Effects of immobilization.

**Nursing Diagnosis:** Impaired physical mobility related to effects of spinal cord injury

**Outcome Evaluation:** Child ambulates with a minimum of artificial support and equipment; participates in exercise program within limitations.

To relieve edema at the injury site and prevent further injury, IV corticosteroids will be administered. Children may be placed in cervical traction with Crutchfield tongs and a traction belt (Fig. 49.11) or with halo traction (see Chapter 51). Having tongs inserted into the skull is a very frightening procedure for children because they worry the tongs will burrow into their skull and strike their brain. Encourage parents to stay with children during the procedure both for psychological support and to help them lie still during the procedure.

**Figure 49.11** Crutchfield tongs used to create spinal traction.

To promote circulation and prevent loss of calcium that results from inactivity, full range-of-motion exercises must be scheduled approximately three times per day. Assist with these as necessary as they are time-consuming but important to maintain joint function.

During the second phase of recovery, when spasticity of muscle groups occurs, preventing contractures becomes the chief concern. Specialized splints, boots, or even high-top sneakers may be used to prevent foot drop (Fig. 49.12). If children have upper extremity mobility but will be left with lower extremity paralysis, exercises to strengthen the upper extremity muscle groups are needed so children will be strong enough to lift themselves from a bed to a wheelchair or raise themselves with a trapeze over the bed when changing positions. Holding legs and arms at the joints while moving is a good technique to help reduce muscle spasms.

**Figure 49.12** Specialized splints are used for a child with a low spinal cord injury to prevent contractures and foot drop. Here, the physical therapist prepares to apply the splint to the child's leg. (Photograph courtesy of Sue Moses.)

One major problem of ambulation after spinal cord injury is helping a child's body readjust to a vertical position after being maintained in the supine position for so long. In the new upright position, blood tends to pool in dilated blood vessels below the level of the spinal injury, resulting in a pseudohypovolemia and hypotension. The first time a child sits up or stands may occur to such an extent that the child faints. Gradually increasing the angle of the bed helps the child become

acclimated to the upright position without experiencing so much vascular pooling.

**Nursing Diagnosis:** Self-care deficit related to spinal cord injury

**Outcome Evaluation:** Child states intention of taking over self-care; practices using equipment for eating, bathing, and toileting; participates in one new aspect of self-care each week.

As soon as possible, children should be introduced to self-help methods for activities of daily living. You may need to encourage parents to allow a child to become as self-sufficient as possible or not to take over complete care. The child may well outlive them and will someday need to be able to function as independently as possible without them.

Remember, without autonomic nervous system function, a child is unable to sweat and becomes hyperthermic if covered too warmly; if not covered warmly enough, the capillaries dilate, and the child loses considerable heat into the environment. If the room temperature cools at night, be careful to dress the child appropriately for sleeping.

Specific measures for bowel evacuation may be necessary, depending on the level of the injury. A bowel program incorporating the use of stool softeners, suppositories, and bowel retraining may be required. The child and parents need support and instructions in accomplishing this task and gaining independence as it may take weeks or months to accomplish.

For some children and parents, the first day of using a wheelchair is exciting (proof that the child can be partially ambulatory). For others, it is the day on which they are forced to face the reality that they cannot undo the results of the injury and that their child has a permanent lifelong disability. If parents have almost overcome their grief and accepted their child's disability, the introduction of a symbol of disability such as a wheelchair or long leg braces may bring new grieving and a sense of loss.

When the child reaches sexual maturity, limitations in this area may become a child's chief concern. If a male has had an upper motor neuron injury, he will not be able to achieve spontaneous erection or ejaculation. However, with manual stimulation of the penis (stimulation of lower motor neuron function), he may be able to achieve an erection and engage in coitus even though ejaculation and fertility remain limited. With most spinal cord injuries, a female is not able to experience orgasm but is able to conceive and bear children.

The limitations caused by a spinal cord injury become especially evident to the child (and the parents) when choosing a vocation and selecting an appropriate school program (remember children cannot be denied regular schooling by federal law in the United States, even with a severe physical disability). Counseling and rehabilitation are crucial aspects to achieve an optimal level of functioning and independence.

**Nursing Diagnosis:** Risk for impaired gas exchange related to spinal cord injury

**Outcome Evaluation:** Respiratory rate is within acceptable parameters; lungs are clear; airway is patent.

If the cervical level of the cord is involved, a child will need ventilatory assistance. The child may be intubated at first, but orotracheal or nasotracheal intubation is only a temporary measure to maintain a patent airway. At a later date, a tracheostomy will be done for long-term airway management and to prevent sloughing of pharyngeal tissue from the constant pressure of the intubation tube. If a tracheostomy tube is required, be certain parents receive thorough instructions on caring for the tracheostomy and, if necessary, working with a mechanical ventilator. A phrenic nerve pacemaker may be used to stimulate the diaphragm to contract and initiate respirations. If the child has a thoracic-level injury (which is rare because the rib cage gives extra strength to thoracic vertebrae), the child will be able to breathe independently but will have reduced vital capacity. Periodic positive-pressure breathing treatments may be necessary to encourage increased lung filling. Be careful when positioning a child not to compromise chest movement with equipment or other restricting objects. Other respiratory care measures, such as suctioning and chest physiotherapy, also help maintain chest function.

**Nursing Diagnosis:** Risk for impaired skin integrity related to immobility

**Outcome Evaluation:** Child's skin remains clean, dry, and intact without signs of erythema or ulceration.

To prevent skin breakdown, turn children about every 2 hours (always being certain to logroll or maintain immobilization with a striker frame or a continuously moving, automatically controlled bed). The use of an alternating-pressure mattress may also be helpful. With loss of sensation in body parts, the child is unable to report skin irritation from a wrinkled sheet or wet clothing. If the child is incontinent, change the linen immediately to prevent skin breakdown. Once children are ambulatory by wheelchair, check their legs and buttocks regularly to prevent pressure ulcers caused by sitting or using leg braces (McCaskey, Kirk, & Gerdes, 2011).

**Nursing Diagnosis:** Risk for impaired urinary elimination related to spinal cord injury

**Outcome Evaluation:** Child's urine output is adequate for intake; child identifies measures to assist with voiding; child demonstrates procedure for self-catheterization.

To prevent urinary retention during the first phase of recovery, a Foley catheter is usually inserted, or the bladder can be emptied by periodic suprapubic aspiration or intermittent catheterization. Second-stage spasticity causes periodic reflex emptying. The bladder rarely empties completely, however, so problems of stasis and infection continue. To live independently, the child needs to learn self-catheterization to empty the bladder (see Chapter 46).

**Nursing Diagnosis:** Anticipatory grieving related to loss of function secondary to

spinal cord injury

**Outcome Evaluation:** Child and parents openly discuss their feelings about the injury and its effect on their lives.

The second recovery phase is the time for parents and children to begin thinking about what this degree of disability will mean to them as a family and to face what adjustments they will need to make. Children and parents typically react to the initial diagnosis with grief. They may still be in denial or shock when the second phase begins. With no sudden miracle cure in sight, they may begin to move through stages of anger, bargaining, depression, and then acceptance (the injury happened; we must go on from this point). They need assistance and support to work through all of these feeling, however. Both the parents and the child may need counseling to reach acceptance (Fig. 49.13).

**Figure 49.13** A 6-year-old girl with a cervical spine injury adapts to her disability by using her mouth to hold a paintbrush and participate in age-appropriate activities. (© Elisa Peterson/Stock Boston.)

### *What If... 49.3*

**Tasha's father, a high school science teacher, asks the nurse to help him design a program to teach teenagers how to prevent spinal cord injury. What topics would be best to include?**

## **Ataxic Disorders**

Ataxia is failure of muscular coordination or irregularity of muscle action. Ataxic disorders are often manifested by an awkward gait or lack of coordination. Causes of ataxia differ, but degeneration of cerebellar or vestibular function is always involved.

## ATAXIA-TELANGIECTASIA

Ataxia-telangiectasia, transmitted as an autosomal recessive trait attributable to a defect of chromosome 11, is a primary immunodeficiency disorder that results in progressive cerebellar degeneration. This is a multisystem disease with neurologic and immunologic aspects. In addition, endocrine abnormalities may occur, and there is an increased risk of cancer, particularly brain tumor. Telangiectasias (red vascular markings) appear on the conjunctiva and skin at the flexor creases ([American Academy of Pediatrics, 2012](#)).

Both immunologic and neurologic symptoms of this disorder vary in severity and onset. Serum immunoglobulin A (IgA) and immunoglobulin E (IgE) levels may be low, and there is often evidence of reduced T-cell function. Children develop frequent infections (primarily sinopulmonary) because of the immunologic deficits. Tonsillar tissue in the pharynx appears scant.

Neurologic symptoms caused by the degeneration process can usually be detected in early infancy when developmental milestones are not met. Children develop an awkward gait when they begin to walk. **Choreoathetosis** (rapid, purposeless movements), nystagmus, an intention tremor, or scoliosis may develop. Children may be unable to move their eyes or follow movement through visual fields. Eye changes (conjunctival telangiectasia) develop by 5 years of age. Unfortunately, there is no effective treatment. Children with this disorder often die in late adolescence of infection, respiratory failure, or a malignant brain tumor.

## FRIEDREICH ATAXIA

Friedreich ataxia, which is carried on the short arm of chromosome 9 as an autosomal recessive trait, involves a variety of degenerative symptoms ([Koeppen, 2011](#)).

Symptoms such as progressive cerebellar and spinal cord dysfunction occur in late adolescence. Teenagers develop a progressive gait disturbance, a lack of coordinated arm movements, a high-arched foot (pes cavus), hammer toes, and scoliosis. The combined symptoms of a positive Babinski reflex, absence of deep tendon reflexes in the ankle, and ataxia are strongly diagnostic. Neurologic examination shows difficulty in recognizing foot position (whether the foot is moved up or down). If the ataxia remains untreated, death occurs in young adulthood from myocardial failure. Antioxidant therapy may help to delay this outcome by reducing ventricular hypertrophy ([Lynch, Regner, Schadt, et al., 2012](#)).

### *What If . . . 49.4*

**A nurse is interested in exploring one of the 2020 National Health Goals related to children with neurologic disorders (see [Box 49.1](#)). Most government-sponsored funding for nursing research is allotted based on these goals. What would be a possible research topic pertinent to these goals that would be applicable to Tasha's family and also advance evidence-based practice?**

## KEY POINTS FOR REVIEW

- Nerve cells are unique in that they do not regenerate if damaged, tending to make neurologic diseases long-term illnesses. Parents and children alike need support from healthcare providers to cope with problems that continue to occur over a long period. Planning nursing care to achieve this not only meets Quality & Safety Education for Nurses (QSEN) competencies but hopefully also meets the family's total needs.
- Increased ICP arises from an increase in the volume of CSF or from blood accumulation, cerebral edema, or space-occupying lesions. Vital sign changes such as increased temperature and blood pressure and decreased pulse and respirations begin as subtle changes. Always compare assessments with previous levels to detect that a consistent, although minor, change is occurring.
- CP is a nonprogressive disorder of upper motor neurons. The exact cause is usually unknown, but the condition is caused by abnormal brain development or damage to the developing brain. Four major types are identified: spastic (excessive tone in the voluntary muscles), dyskinetic or athetoid (abnormal involuntary movement), atonic (decreased muscle tone), and mixed (symptoms of both spasticity and athetoid movements).
- Meningitis is infection of the cerebral meninges, caused most frequently by bacterial invasion. Children need follow-up afterward to monitor for hearing acuity and impaired secretion of antidiuretic hormone.
- Encephalitis is inflammation of brain tissue. This is always a serious diagnosis because the child may be left with residual neurologic damage, such as seizures or learning disabilities.
- Reye syndrome is acute encephalitis with accompanying fatty infiltration of the liver, heart, and lungs; it most frequently occurs if a child with a viral infection is administered acetylsalicylic acid (aspirin) and is the reason children should not be administered aspirin for fever.
- Guillain-Barré syndrome is inflammation of motor and sensory nerves. The reaction may be immune mediated, occurring after an upper respiratory tract illness. Temporary demyelization of the nerve sheaths causes loss of function.
- Botulism occurs when spores of *C. botulinum* produce toxins in the intestine. Because honey can be a source of the organism, it should not be given to infants.
- Recurrent seizures are involuntary contractions of muscles caused by abnormal electrical brain discharges. Common types seen in children include febrile seizures, infantile spasms, partial (focal) seizures, absence seizures, and tonic-clonic seizures. Therapy is administration of antiseizure drugs.
- Spinal cord injury is occurring at increased rates in children involved in sports and motor vehicle accidents. Children pass through a first, second, and third recovery phase after the injury until they reach a final outcome.

Darien Fisher is a 12-year-old boy you see in the emergency room because he was brought to the hospital by ambulance after having a tonic–clonic seizure at basketball practice. His parents are divorced, so Darien lives with his mother and two younger brothers in a trailer park during weekdays. On the weekend, he lives with his father on a houseboat.

1. The emergency room physician asked Mrs. Fisher for permission to do a lumbar puncture on Darien but she refused because she remembered what a terrible headache she had after receiving spinal anesthesia for Darien’s birth. Would you agree that lumbar punctures often lead to severe headaches? What are some things you could do to help prevent a headache in Darien?
2. Darien is prescribed carbamazepine (Tegretol) for recurrent seizures. His mother is concerned he won’t take it on weekends because his father is “all fun—nothing serious.” Would you agree with her that she’s right in refusing to allow Darien to visit his father on weekends?
3. Darien is concerned that he won’t be allowed to play on his school basketball team if he has another seizure. Are recurrent seizures aggravated by strenuous activity? Would preventing him from playing be good advice?

# Nursing Care of a Family When a Child Has a Vision or Hearing Disorder

*Carla Vander, a 6-year-old child, is brought to your pediatric clinic for evaluation. Her mother states, “She was born deaf and with a cataract. Today, she has pain in her ear and her left eye is red. How could a bad eye or an ear without a functioning nerve get infected?”*

*Previous chapters discussed the growth and development of well children. This chapter adds information about the changes, both physical and psychosocial, that occur when a child develops a disorder of the eyes (vision) or ears (hearing). This is important information because it builds a base for care and health teaching.*

**How would you answer Ms. Vander? What additional information does she need to know about eye and ear disorders?**

## KEY TERMS

**accommodation**  
**amblyopia**  
**astigmatism**  
**diplopia**  
**enucleation**  
**fovea centralis**  
**goniotomy**  
**hyperopia**  
**light refraction**  
**myopia**  
**nystagmus**  
**orthoptics**  
**photophobia**  
**ptosis**  
**stereopsis**

strabismus  
tympanocentesis

## OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe the structure and function of the eyes and ears and disorders of these organs as they affect children.
2. Identify nursing contribution in achieving 2020 National Health Goals related to vision and hearing disorders of children.
3. Assess a child who has a disorder of vision or hearing.
4. Formulate nursing diagnoses related to a child with a disorder of vision or hearing.
5. Establish expected outcomes for a child with a disorder of vision or hearing to help parents manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care to meet the specific needs of a child who has a disorder of the eyes or ears, including patient and parent education.
8. Evaluate effectiveness and achievement of expected outcomes for a child with a vision and/or hearing disorder.
9. Integrate knowledge of childhood disorders of the eyes or ears with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

Any interference with vision or hearing poses a threat to normal growth and development because so much of what and how a child learns about the world are achieved through these sensory organs. Infants first learn how to interact with others by watching their parents' faces, for example. They learn to speak by listening to words spoken to them. They continue to depend on sensory input for stimulation and to protect their safety throughout life (LaRoche, 2013).

Eye and ear disorders may be transitory. However, they always have the potential for becoming long-term illnesses if they permanently affect vision and hearing. This is an area, therefore, in which health promotion, illness prevention, and health rehabilitation are all vital aspects of nursing care. Because of the importance of vision and hearing, the 2020 National Health Goals have been established in relation to them (Box 50.1).

BOX 50.1

Adequate vision and hearing ability are necessary for normal growth and development; therefore, several 2020 National Health Goals focus on prevention, early detection, treatment, and rehabilitation of eye and hearing health. These include:

- Increase the proportion of preschool children aged 5 years and younger who receive vision screening from a baseline of 40.1% to 44.1%.
- Reduce blindness and visual impairment in children and adolescents aged 17 years and younger from 28.2 per 1,000 children to 25.4 per 1,000.
- Reduce visual impairment in children aged 12 years and older from 136.1 per 1,000 population to 122.5 per 1,000.
- Increase the use of personal protective eyewear in recreational activities and hazardous situations around the home from 16.5% to 18.2% of children and adolescents aged 6 to 17 years.
- Reduce otitis media in children and adolescents from 246.1 persons per 1,000 persons younger than age 18 years to 221.5 per 1,000.
- Increase the proportion of persons with hearing impairments who have ever used a hearing aid or assistive listening devices or who have cochlear implants (developmental).
- Increase the proportion of persons who have had a hearing examination on schedule from 79.3% to 87.2% of adolescents aged 12 to 19 years (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by screening for vision and hearing at all well-child assessments, paying particular attention to those children who had low birth weight, were cared for in neonatal intensive care units, or who were excessively exposed to loud noises such as loud music.

### *Nursing Process Overview*

#### FOR CARE OF A CHILD WITH A VISION OR HEARING DISORDER

##### **ASSESSMENT**

All newborns should be assessed for their ability to focus on or see an examiner's face and to follow an object from the periphery to the midline. Observe the infant closely to ensure that this response is evoked by sight, not by the sound of your voice. If it's unclear whether a newborn can see, vision can be further tested by optokinetic nystagmus testing.

Assessing newborn infants for hearing loss is an equally important part of newborn care. This can be done by assessing if newborns quiet to the sound of a soothing voice. Most hospitals further routinely test newborns' hearing with otoacoustic emissions and auditory brain stem response (Akinpelu, Peleva, Funnell, et al., 2014).

Throughout childhood, children should be assessed by history for both vision and

hearing disorders. In addition, children also should be assessed for their ability to speak clearly and appropriately for their age because language development is influenced by hearing. Because hearing and vision assessment are part of routine physical exams, the techniques of these are discussed in [Chapter 34](#).

### **NURSING DIAGNOSIS**

Teaching health promotion measures to safeguard vision and hearing is one of the most important roles in nursing. Examples of nursing diagnoses in this area include:

- Health-seeking behaviors related to the prevention of trauma to the eyes or ears
- Deficient knowledge related to the importance of early diagnosis and treatment of eye or ear infections
- Self-care deficit related to impaired visual acuity
- Risk for injury related to hearing loss
- Risk for situational low self-esteem related to long-term vision deficit
- Impaired verbal communication related to congenital hearing deficit
- Social isolation related to effects of hearing loss
- Risk for complicated grieving related to child's loss of sight
- Risk for parental role strain related to responsibilities of caring for a sensory impaired child
- Readiness for enhanced family coping related to child's traumatic injury and subsequent loss of vision in one eye

### **OUTCOME IDENTIFICATION AND PLANNING**

Be certain that expected outcomes established are realistic and address areas in which treatment can have some impact. By listening attentively to the concerns of parents and those of the child and by providing useful anticipatory guidance, you can help to increase a child's ability to function effectively. Because many eye and ear disorders cause pain, helping parents reduce pain in their child is a major nursing responsibility. Be certain that expected outcomes address preventive aspects of care in all areas of daily living.

When parents learn a child will have a vision or hearing disorder, they usually need help in planning for schooling and activities such as toilet training and self-care. Discuss with them the importance of talking to and touching their infant, so the infant learns how to communicate and learn about the world through his or her functioning senses. Most children with sensory disorders benefit from very early preschool education programs because this exposes them to interesting and stimulating tasks while their initiative is strongest.

Many parents whose infant screens positive for hearing loss in the hospital do not follow up with additional hearing screening as recommended probably because of inadequate communication about the concern or a lack of health insurance ([Alam, Gaffney, & Eichwald, 2014](#)). Internet resources that can be helpful to parents are the Alexander Graham Bell Association for the Deaf and Hard of Hearing ([www.agbell.org](http://www.agbell.org)), the American Foundation for the Blind ([www.afb.org](http://www.afb.org)), the

American Speech-Language-Hearing Association ([www.asha.org](http://www.asha.org)), Lighthouse Guild ([www.lighthouseguild.org](http://www.lighthouseguild.org)), the National Federation of the Blind ([www.nfb.org](http://www.nfb.org)), Learning Ally ([www.learningally.org](http://www.learningally.org)), and the National Association of the Deaf ([www.nad.org](http://www.nad.org)).

### IMPLEMENTATION

A disorder of the eyes or ears can range from an acute, onetime illness to a chronic and developmentally debilitating condition if steps are not taken to treat the initial problem quickly and completely. However, even the most rigorous preventive care and attention cannot avert the occurrence of some serious disorders affecting vision and hearing. Nursing care must then focus on helping the child and parents adjust to the condition, ensuring that the child receives the stimulation needed to grow and develop on a usual continuum.

Nursing interventions for a child with a disorder of the eyes or ears range from providing anticipatory guidance and teaching children and parents measures to promote eye and ear health to preparing a child for surgery. Nursing interventions also include helping a child and parents adjust to aids that are used to improve hearing, speech, or sight.

### OUTCOME EVALUATION

Continuing follow-ups with hearing and vision concerns is essential so self-esteem can be evaluated. Do children think of themselves as well or ill? As people able to do things or as disabled? Some parents may require help with their own feelings of worth (feeling inferior to other parents is common among parents of children with vision and hearing impairment or challenge) before they can help their children. Be certain to evaluate if they're able to "let go" so their child can attend school.

Examples of expected outcomes include:

- Parent states she understands that antibiotics are no longer prescribed for simple otitis media.
- Parents state concrete plans for enrolling child in a hearing-impaired preschool program.
- The child wears corrective lenses for a major portion of each day.
- The child with a hearing disorder communicates effectively with healthcare providers by lip reading or writing out her needs.

## Health Promotion and Risk Management

Vision can be assessed shortly after birth by eliciting a blink reflex and the ability to follow a moving object. All babies should be screened by a formal method for hearing loss before leaving the hospital or no later than 1 month of age (Kemper, Crews, Strickland, et al., 2014). Such tests give reassurance to worried parents that their child's vision and hearing is adequate or set the stage for early interventions if their child is visually or hearing challenged. School nurses play a vital role in the continuing

assessment and formal screening of vision and hearing as well as being instrumental in laying a foundation for steps that parents and children need to take to maintain vision and hearing health (Box 50.2).

## BOX 50.2

### Nursing Care Planning Using Assessment

#### ASSESSING A CHILD FOR VISION OR HEARING DISORDERS

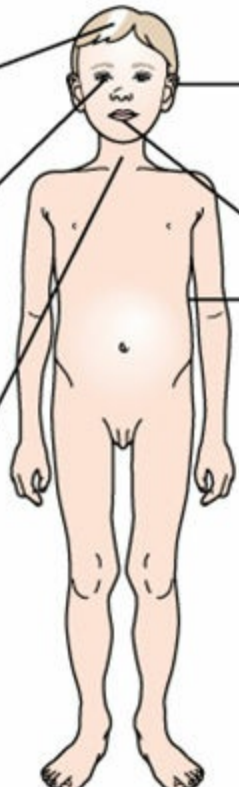

##### History

*Chief concern:* Are symptoms of vision or hearing difficulty present—blurriness of vision, squinting, turning head, leaning toward speaker, ignoring instructions?

*Past health history:* Has child had any exposure to loud noises? Eye trauma? Ear infection?

*Family medical history:* Do any family members have a hearing disorder? What is the vision level of parents?

##### Physical assessment

Hair: white forelock (associated with congenital deafness)

Eyes: tearing, crusting of eyelids, uneven size of pupils, improperly formed pupils, squinting, white pupils

Neck: "cocking neck"

Ears: incompletely formed pinna

Speech: unclear

Posture: leaning forward

A history and physical examination performed at each health maintenance visit can provide important clues to possible problems or the need for further evaluation. General guidelines for evaluation are listed in Table 50.1. During these visits, be certain to offer parents opportunities to ask questions and voice any concerns they may have regarding their child.

**TABLE 50.1 ASSESSMENT PARAMETERS FOR VISION AND HEARING SCREENING**

<b>Age</b>	<b>Vision Assessment Parameters</b>	<b>Hearing Assessment Parameters</b>
Infant	Ability to follow objects Corneal (blink) reflex Ability to turn to light stimuli	Startle reflex at hearing sound (at birth) Ability to track sounds (3–6 months) Ability to recognize sounds (6–8 months) Ability to locate sounds (8–12 months)
Toddler	Corneal light reflex Cover test Smooth ocular movements Hand–eye coordination	Ability to react to soft sounds (whispers) Ability to form a noun–verb sentence by 2 years Ability to follow simple directions Awareness of pitch and tone
Preschooler	Corneal light reflex Cover test Snellen E chart, Allen figures (or modification)	Pure tone audiometry (starting at age 4 years) Understandable language with increasing vocabulary
School age	Visual acuity testing every 1–2 years	Pure tone audiometry at ages 6, 8, and 11 years
Adolescent	Visual acuity testing every 1–2 years	Pure tone audiometry at ages 14 and 18 years

Children with vision or hearing disorders need to attend regular classrooms in school, if possible, so that they can have contact with seeing and hearing children to promote growth and development. If a child has a vision or hearing impairment, assist the parents with measures to adapt the child’s environment to meet safety needs while promoting growth, development, and independence as much as possible. Help them to supplement verbal explanations with tactile and visual aids as appropriate as well as allow the child to use drawings, writing, gestures, a talking picture board, text messaging, and/or e-mail to respond and communicate. Assess whether parents are interested in investigating a cochlear implant for a child with hearing impairment. Be certain parents are familiar with measures to prevent eye and ear infections so that these do not lead to long-term problems. Assess that children receive adequate vitamin A because, although not common in the United States, a deficiency of vitamin A may cause diminished night vision or even blindness (Bruins & Kraemer, 2013).

Caution children that exposure to high levels of sound over a period of time can permanently lower the level at which they hear. Music heard through earbuds, for

example, is at about 110 dB (compared to 50 to 60 dB, the level of usual conversation). Rock concerts expose listeners to decibels as high as 120 to 140 dB. To lessen the danger of such exposure, urge students to invest in quality earplugs, don't listen through them for long time intervals, and listen to music at the lowest level possible. At music concerts, they should not sit near loud speakers and should wear foam earplugs to decrease the sound level (Box 50.3).

### BOX 50.3

## Nursing Care Planning Based on Family Teaching

### PROTECTING VISION AND HEARING

**Q.** Carla's mother says to you, "What can we do to protect our children from having problems with their eyes and ears?"

**A.** Here are some helpful tips to protect children's vision and hearing:

#### To protect vision

- Place infants and small children in a car seat (for older children, use a seat belt). Follow National Highway and Traffic Safety Administration (NHTSA) guidelines when in a car to keep them from hitting the dashboard or front seat in the event of an accident.
- Do not allow infants to hold sharp objects because the object could strike the eye as the infant brings the hand to the mouth to suck his or her thumb.
- Do not allow children to carry sharp objects such as lollipop sticks in their hands while walking. If they fall, the object could puncture their eye.
- Caution older children to use eye-protection measures, such as goggles, when working with projects, such as soldering metal, in school or at home.
- Encourage the use of proper athletic facial protective gear when playing sports.
- Teach children not to place any medication in their eyes that is not prescribed by a healthcare provider; do not use outdated eye medication because it may become contaminated with bacteria or may change in composition with time.
- Wear a hat or ultraviolet (UV) coated lenses when outdoors, especially for children with light-colored eyes.
- Caution children that chemicals can cause burns to the eye; alert them to the emergency shower installations in science rooms that are used to wash away any spilled chemical from their eyes. Chemical burns may be worse in children who have contact lenses in place because chemicals can flow under the lens and remain in contact with the cornea longer.
- Teach children not to wear contact lenses for longer intervals than recommended by the manufacturer to prevent drying and a lack of oxygen supply to the cornea.

#### To prevent hearing loss

- Keep children away from high noise levels, such as loud toys or electronic games.

While in loud environments, protect ears with earplugs or earmuffs.

- Teach children to avoid chronic exposure to loud noises, such as can occur with radios and earbuds/earphones.
- Secure prompt treatment for pharyngitis (fever and sore throat) because this condition can lead to otitis media (middle ear infection).
- Caution children not to put anything in their ear canals because they could puncture their eardrums.
- Be certain children's immunizations are kept up to date because illnesses such as parotitis (mumps) or bacterial meningitis can lead to hearing loss.

## Vision

Vision occurs because light rays reflect from an object through the corneas, aqueous humors, lenses, and vitreous humors to the retinas (Fig. 50.1). If any of these structures have defects, light rays may not be able to reach the retinas or focus correctly there, resulting in a vision disorder. Both retinas are studded with *rods*, which are instrumental for night vision and for detecting movement in the visual field, and *cones*, which register daylight and color vision. The **fovea centralis** (the center of the macula) is an area of closely packed cones on the retinas where color is best perceived.

**Figure 50.1** The anatomy of the eye.

Each eye globe must not only develop good central and peripheral vision but also learn to work with the other eye to fuse or interpret a dual image as one (*single binocular vision*). Infants with poor eye alignment cannot establish single binocular vision but have **diplopia**, or double vision, instead.

## STEREOPSIS

**Stereopsis** is depth perception, or the ability to see objects as three-dimensional. Children with vision loss in one eye do not develop stereopsis and, consequently, tend to reach farther or closer than the actual distance of an object when attempting to grasp it. They have difficulty learning to ride a bicycle and have great difficulty driving a car safely. Lack of stereopsis can be detected by a depth perception test such as the *Stereo Fly* dot test, a test where the image of a fly is constructed from a series of colored dots. When asked to touch the fly's wings, a child with good depth perception touches them accurately. A child with poor depth perception touches a spot 2 or 3 in. above the

pattern.

## ACCOMMODATION

**Accommodation** is the adjustment the eye makes to focus on a close image. To do this, the eyes converge (look medially) and the pupils constrict. To test for accommodation, ask a child to follow a penlight as you move it in toward the nose, if developmentally appropriate. Children who cannot accommodate are unable to fuse their vision to follow a penlight toward their nose this way; instead, they demonstrate double vision (diplopia). Poor accommodation is important to recognize because it can lead to headaches, poor reading ability, and difficulty achieving in school.

## Disorders That Interfere With Vision

Eye disorders in children are always potentially serious because, if permanent vision impairment occurs, a child's functioning at many everyday tasks can be severely compromised.

## REFRACTIVE ERRORS

Refractive errors that cause visual impairment are one of the most common visual deficits in school-age children (Qiu, Wang, Singh, et al., 2014; Wojciechowski, 2011). **Light refraction** refers to the manner in which light is bent as it passes through the lens. Normally, this bending causes a ray of light to fall directly on the retina (Fig. 50.2A). Because the depth of the eye globe in infants and children increases with age, the light rays do not always focus onto the retina accurately as the child grows older, but at a point behind the retina. This results in **hyperopia** (farsightedness), in which vision is blurry at a close range and clear at a far range. It is important to remember that this normal hyperopia of preschoolers needs no correction when performing vision screening with children of this age because at about 5 years of age, as a result of developmental changes, hyperopia will begin to diminish. Some children, however, remain hyperopic. Focusing on close objects requires such strong accommodation that these children often develop headaches or dizziness while doing schoolwork. A finding of hyperopia in a school-age child is cause for referral so that the child can get a prescription for glasses with a convex lens (see Fig. 50.2B).

**Figure 50.2** Corrective lenses for refractive errors of vision. **(A)** Normal vision. **(B)** Convex lens for hyperopia (farsightedness). **(C)** Concave lens for myopia (nearsightedness).

**Myopia** (nearsightedness) occurs when light rays focus anterior to the retina, causing objects that are far away to be unfocused. Typically, this develops around age 8 years and then progresses (Belden, DeFriez, & Huether, 2013). These children can read a book or a computer screen immediately in front of them but are unable to read the blackboard clearly from a distance. They have difficulty reading signs across the street or playing baseball. Myopia tends to plateau as the child reaches adolescence. Children with myopia need corrective (concave) lenses to enable them to see at a distance (see Fig. 50.2C).

Myopia has a familial tendency, so if both parents are myopic, their children should be screened yearly during the early school years. Because children with myopia try to focus on objects by squinting or rubbing their eyes, any child who reports difficulty seeing or who shows mannerisms suggestive of refraction errors—rubbing the eyes, tearing, blinking, squinting, or pressing on the eyes—should be screened for visual difficulty.

It is possible for contact lenses to be fitted for even young infants. Children as young as 5 years of age are capable of putting them in and taking them out if taught

properly. Contact lenses are a big responsibility, however; they require conscientious cleaning or changing to prevent eye irritation or infection. Children are usually about 12 years of age before they can be relied on to take appropriate care of contact lenses independently.

Young children may resist wearing glasses because they're worried they'll be bullied if they wear them. If glasses are needed, however, encourage children to give them a fair try. In most instances, glasses improve vision to such an extent that after trying them, children will appreciate the difference they make and continue to wear them. Some children may need continued encouragement to keep wearing glasses, however, until they are old enough for contact lenses or surgical correction. Advise parents to choose frames fitted with safety glass (shatterproof) lenses so that if the lenses accidentally break, the child's eyes will not be injured.

By late adolescence, children can have laser surgery (known as laser in situ keratomileusis [LASIK] or photorefractive keratectomy [PRK]) to permanently change the contour of the cornea and correct refractive vision errors.

### **Laser In Situ Keratomileusis and Photorefractive Keratectomy**

LASIK and PRK are both laser surgery correction procedures for either myopia or hyperopia (Stahl, 2014). These involve an incision under the cornea to change the contour of the eye globe so that light rays fall more accurately on the retina.

Postoperatively, children may have disturbed tear functioning for 1 or more months and so need to instill artificial tears or ointments to prevent surface damage. Because having the procedure carried out before the child's eye globe has reached its adult size would require the surgery to be repeated with maturity, the youngest age at which LASIK therapy is appropriate is controversial; most authorities recommend this not be done before 21 years of age to allow for natural eye contour changes to occur. The exception to this is children who have amblyopia or strabismus (see later in the chapter) (Birch, 2013; Stahl, 2014).

### **ASTIGMATISM**

**Astigmatism** is an irregular curvature of the cornea, causing light to focus incorrectly on the retina, resulting in an uneven quality of vision. When children with astigmatism look at the letter T, for example, they may see the crossbar but not the letter stem. If they focus on the stem, they cannot see the crossbar. On any given page of print, therefore, they may see only half the letters or can have great difficulty reading or following written instructions. They may report headache and vertigo after doing close work. Even though their vision appears deceptively normal on vision screening tests (they are able to see all of the numbers on a chart by tilting their head), these children need to be referred to an ophthalmologist on the basis of their other problems such as vertigo, headaches, and difficulty with reading. Corrective lenses for close work relieve the symptoms and restore functional vision. Contact lenses may be even more helpful

because they actually smooth out the curvature of the cornea. A form of LASIK surgery may be appropriate to correct astigmatism (Ivarsen, Næser, & Hjortdal, 2013).

## NYSTAGMUS

**Nystagmus** is rapid, irregular eye movement, either vertically or horizontally. It is not a disease in itself but rather a symptom of an underlying disease condition. It is seen in children with vision-impairing lesions such as congenital cataracts. It also occurs as a neurologic sign if there is a lesion of the cerebellum or brain stem. Children with nystagmus should be referred to their primary care provider initially so the underlying cause of the symptom can be determined (Penix, Swanson, & DeCarlo, 2015). A referral to an ophthalmologist may be indicated.

## AMBLYOPIA

**Amblyopia** is “lazy eye” or subnormal vision in one eye that causes a child to use only one eye for vision while “resting” the other eye (DeSantis, 2014). If this process continues for too long time, central vision fails to develop (or the central vision that had developed fades in the poorer eye), and the child becomes functionally blind in that eye. This can occur in children who have a refractive error in one eye that is significantly different from that of the other eye or in children with astigmatism.

Amblyopia can also develop from strabismus (crossed eyes). With strabismus, one eye looks straight ahead while the other eye “wanders,” causing suppression of one visual image or a loss of central vision in that eye (amblyopia). The same phenomenon can occur if the vision in one eye is obscured by a lid that does not open fully (ptosis).

### Assessment

It is recommended that all children between the ages of 3 and 5 years have at least one vision screening to detect amblyopia (Kemper et al., 2014). If a child has amblyopia, a screening exam such as a preschool E chart (see Chapter 34) typically demonstrates 20/50 vision (which is normal for preschool age) in one eye, but the other eye shows lessened vision (perhaps as different as 20/100).

### Therapeutic Management

Treatment for amblyopia is most successful among children younger than the age of 7 years, but there is evidence to show a response to treatment for children between 7 and 13 years of age (DeSantis, 2014). Treatment can consist of wearing correcting lenses (glasses), covering the good eye with a patch, or a combination of the two (Holmes, 2014). Wearing a patch over the good eye forces the child to use the poor eye, thus developing vision in that eye. Usually, children have some difficulty initially adjusting to a patch because they are unable to see well from the unpatched eye. They may report headaches or dizziness and notice poor depth perception. Only constant attempts to see with the weaker eye, however, will improve binocular vision, so parents have to enforce

patching if prescribed (DeSantis, 2014; Pediatric Eye Disease Investigator Group, 2014).

The patch should be removed for 1 hour each day to prevent amblyopia from developing in the nonamblyopic eye. If patching does not produce the anticipated result, LASIK surgery to improve the refractive error may be indicated. Yet, a further option is the administration of levodopa in addition to occlusion therapy because this almost immediately improves vision in both eyes (Pediatric Eye Disease Investigator Group, 2014).

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Deficient knowledge related to the need for consistent wearing of eye patch

**Outcome Evaluation:** Parents state the reason their child must wear a patch over the functioning eye is to improve vision in the poorly functioning eye. Child wears patch over functioning eye for all but 1 hour per day.

Children with an eye patch in place may have more difficulty with motor coordination due to the decreased field of vision and so need careful supervision with activities such as bicycle riding or crossing a street safely. A child may beg to remove the patch for special occasions, such as a birthday party or a family wedding, or just for an hour. If this is allowed, the “special occasions” may soon become so frequent that the child is wearing the patch for only half the time. Remind parents how important it is to adhere to occlusion therapy so that their child will achieve good vision. Safety may also be a concern due to child’s decreased field of vision. If amblyopia occurs secondary to another disorder such as strabismus or ptosis, the primary problem also needs to be corrected. Otherwise, the amblyopia will recur after the patching is completed.

### *QSEN Checkpoint Question 50.1*

#### **PATIENT-CENTERED CARE**

Carla, who is 6 years old, has developed amblyopia. Which statement by her mother would assure the nurse that her learning needs are being met?

- “I place the patch over her weak eye to enhance the vision in her stronger eye.”
- “I place the patch over her good eye to allow the weaker eye to strengthen.”
- “I alternate the patch between eyes every other day so both eyes strengthen.”
- “I can take off the patch while Carla eats to make it easier for her.”

## COLOR VISION DEFICIT (COLOR BLINDNESS)

Color deficit is, as the name implies, the inability to perceive color correctly. It occurs in 4% to 8% of boys because one of the sets of cones of the retina that perceive red, green, or blue is absent. It is inherited as a sex-linked disorder, although there is also a high incidence in children with hemophilia (which is also sex linked), congenital nystagmus, or glucose-6-phosphate dehydrogenase deficiency (Rajavi, Sabbaghi, Baghini, et al., 2015).

The vision problem may involve the inability to distinguish red from green or blue from yellow. A small proportion of children are unable to see any colors. It can be detected by the use of color plates or discs for children as young as preschool age. Children with normal vision see numbers or patterns on these plates, whereas children with a color vision deficit see only a jumble of dots or unclear images.

There is currently no therapy for color vision deficit because the condition is caused by a genetic mutation. The deficit is categorized based on severity. It's important that the loss of color perception is detected early so the child is not asked to complete color identification assignments in preschool and can learn to appreciate color changes in traffic signals or other color-dependent signs necessary for safety.

Some children associate color blindness with total "blindness" and fear they will eventually lose their eyesight. Reassure them that although color blindness means they have a loss of color discrimination, their loss is limited to that one area.

## Structural Problems of the Eye

Structural problems of the eye tend to be congenital or already present at birth.

### COLOBOMA

A *coloboma* is an example of an incomplete closure of the facial cleft. The incomplete closure may involve only the lower eyelid (there is a notch in the lid). It may involve the iris, giving it the shape of a keyhole rather than a circle (Fig. 50.3). It may involve the ciliary body, the lens, the choroid, the retina, and the optic nerve. Children with any degree of coloboma should be referred to an ophthalmologist for further investigation to determine the extent of the condition. Children with only iris involvement have no decline in vision; those with retina and optic nerve coloboma will have some vision impairment in the affected eye (Braverman, 2012).

**Figure 50.3** Coloboma involving the iris, showing a “keyhole” appearance. (From Tasman, W., & Jaeger, E. A. [1996]. *The Wills Eye Hospital atlas of clinical ophthalmology*. Philadelphia, PA: Lippincott-Raven Publishers.)

## **HYPERTELORISM**

*Hypertelorism* is congenital, abnormally wide-spaced eyes. Children with wide epicanthal folds by the inner canthus may appear to have wide-spaced eyes, but, when the distance between the pupils is measured and compared with standards for the child’s age, the true condition is revealed. Detecting true hypertelorism in children is important because this condition is associated with chromosomal abnormalities, most notably Waardenburg syndrome, which also involves congenital hearing impairment. Children with this syndrome also have a white forelock of hair, different-colored irises, and eyebrows that tend to grow together in the center line, all signs not necessarily noticeable in newborns. Therefore, wide-spaced eyes, because of a broad-bridged nose, are the chief clue in a newborn that the child can hear no sound and will need close follow-up to determine whether cochlear implants or hearing aids can provide their ability to hear.

## **PTOSIS**

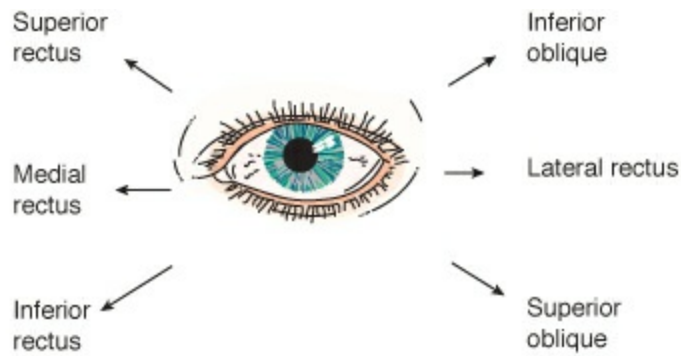

**Ptosis** is the inability to raise the upper eyelid the usual distance, so the eyelid always remains slightly closed. With this, children tend to wrinkle their forehead and raise their eyebrows more than usual in an attempt to lift the eyelid further or cock their heads back to see under the lowered lid. The condition may be congenital (frequently hereditary and bilateral) or acquired (usually unilateral) (Marenco, Macchi, Galassi, et al., 2017). It may be a result of injury to the lid or levator muscle, injury to the third cranial nerve, or from the development of myasthenia gravis (see Chapter 51). If the third cranial nerve has been injured, paralysis of one or more of the other muscles supplied by that nerve will also be affected and a child will exhibit:

- A dilated pupil
- An inability to rotate the eye globe upward, medially, or downward
- Weakness of accommodation (looking at near objects)

After a careful investigation of the cause has been completed, ptosis is corrected surgically. The correction is usually important to the child from a cosmetic standpoint, but if the ptosis is unilateral, and more importantly, if the lid obstructs vision, early surgery is necessary to prevent the development of amblyopia (from a lack of use of the closed eye) (Stein, Kelly, & Weiss, 2014). Be certain that parents understand it's important that ptosis be corrected during the preschool period because although the ptosis can be corrected when the child is older, the amblyopia cannot.

## STRABISMUS

**Strabismus** is unequally aligned eyes (cross-eyes) caused by an imbalance of the extraocular muscles that control the movement of the eye globes, similar to the handling of reins of a horse (Fig. 50.4). Approximately 1% to 2% of children demonstrate some degree of strabismus. The condition does not favor either gender, social status, or geographic area; about 30% of children have a history of a similar strabismus in the family.

Eye muscle	Action	Innervation
Superior rectus	Turns eye up and medially	Oculomotor (third cranial) nerve
Medial rectus	Turns eye inward	Oculomotor (third cranial) nerve
Inferior rectus	Turns eye down and medially	Oculomotor (third cranial) nerve
Lateral rectus	Turns eye out	Abducens (sixth cranial) nerve
Superior oblique	Turns eye down and laterally	Trochlear (fourth cranial) nerve
Inferior oblique	Turns eye up and laterally	Oculomotor (third cranial) nerve

**Figure 50.4** The extraocular eye muscles.

With strabismus, the resting position of one eye, instead of facing forward, will be *divergent* (turned out) or *convergent* (turned in). One pupil may appear higher than the other (vertical strabismus). The strabismus may be monocular, in which the same eye deviates constantly, or it may be an alternating strabismus, in which one eye and then the other deviates.

### Assessment

Infants' eyes may cross occasionally until 6 weeks of age. If infants demonstrate a constant strabismus, refer them to their primary care provider at any time; if they still demonstrate occasional strabismus past 6 months, refer them at that point.

Definite deviations are obvious at a physical exam (Fig. 50.5). Note if the deviation is *exotropia* (an eye turns out), *esotropia* (an eye turns in), or *hypertropia* (an eye turns up). If the deviation is not so obvious or occurs only when the child is fatigued or ill and, therefore, less able to maintain fixation, the terms used are *exophoria*, *esophoria*, and *hyperphoria*. If the parents report that the deviation occurs only when the child is tired or sick, attempt to assess the strabismus at such a time because then the deviation

will be most striking.

**Figure 50.5** Strabismus (esotropia) in an infant.

Strabismus may be detected best when children are asked to examine a nearby object because to do this, they must turn both eyes medially, or *converge*, to focus at the short distance. If they are farsighted in one eye, they will have to turn the affected eye in more than the other, causing esotropia. If one eye is nearsighted, they will not need to turn that eye in as far as the other one; this results in divergence or exotropia.

Some children have a latent strabismus or appear to have straight vision. Because they are only able to maintain fusion at the expense of eyestrain; however, they develop symptoms such as headache; tired, irritated eyes; and perhaps even nausea and vomiting.

Children who have flat, broad-bridged noses, a narrow interpupillary distance, an epicanthal fold, or oval-shaped palpebral fissures may appear to have strabismus (pseudostabismus) because less white sclera is visible in the inner margin of the eye than usual. A cover test reveals the true condition. If pseudostabismus is present, the covered eye will not move after being uncovered because it only appears to be turned medially due to the obscured sclera at the inner canthus. The Hirschberg test is another method of detecting true strabismus (see [Chapter 34](#)).

Once strabismus is detected, it is important to attempt to discern whether it is concomitant (measures the same in all directions of gaze) or nonconcomitant (greater in one direction than in another, often called *paralytic strabismus*). Concomitant (nonparalytic) strabismus is the most usual type found in children. All the muscles of the eye are capable of functioning, but they do not function together. The deviation is equally apparent in all directions of gaze.

Paralytic strabismus is caused by paralysis of a muscle or nerve, perhaps from an injury (such as a birth injury), or an invading lesion. The eyes appear straight except when they are moved in the direction of the paralyzed muscle. Then, double vision occurs, and the crossed eye is evident. Such children often close one eye or tilt their head to decrease the double vision. They may tilt their head so much that they appear to have a torticollis or “wry neck”—an orthopedic rather than an eye problem. They may

appear clumsy because of the diplopia. Because they are too young to describe double vision and how nauseated this makes them feel, they may express this by fussiness or whining.

## Therapeutic Management

The therapy for strabismus depends on the cause of the problem. If the fusion mechanism is weak, eye exercises (**orthoptics**) can strengthen the weak muscle. If eyes are diverging because of farsightedness or nearsightedness, the child needs glasses or contact lenses to correct the basic visual defect. Surgical treatment can be used to permanently align the extraocular muscles if the cause is due to muscle strength.

A side effect of strabismus can be amblyopia because, to avoid double vision, the child suppresses the vision in one eye. For this reason, eye correction for strabismus must be done early in life, before 7 years of age. Some children, because of an accommodation problem caused by hyperopia in one eye, outgrow the condition as the normal hyperopia of the preschooler lessens. This does not always occur, however. Even if the child's eyes appear to be straighter later, an amblyopia may be present that could have been prevented by earlier treatment.

After strabismus surgery, eye patches are not usually required. Postoperatively, antibiotic ointment is applied to the eye for 2 or 3 days. The child may experience some pain on eye movement for the first day as well as nausea and vomiting. Further nursing care for the child having eye surgery is discussed later in this chapter.

Follow-up visits after surgery are necessary to determine the success of the surgery. Retest children who have had this surgery periodically at health maintenance visits to be certain their vision remains equal and eye alignment remains straight.

## Infection or Inflammation of the Eye

Many different types of eye infections or inflammatory conditions can occur in children (Table 50.2). Newborns are at risk for contracting an eye infection from exposure to a variety of organisms while passing through the birth canal (see Chapter 26). Although it is a controversial practice, in most hospitals, antibiotic ointment is placed in each newborn's eye after birth to prevent serious eye infections (Cotter, Cyert, Miller, et al., 2015). Small children contract infections by rubbing their eyes with unclean hands. School-age children are exposed to many infectious agents from other children in school classrooms or by participating in sports activities. Regardless of how the infection was contracted, be certain parents have specific instructions about instilling eye drops or applying ointment, preventing the transmission of infection, applying compresses, and completing systemic antibiotic therapy. Having eye medication applied can be frightening for children because they worry a healthcare provider's or a parent's hand will slip and cut their eye. If they have pain, they may be especially reluctant to let anyone touch their eye.

**TABLE 50.2 INFECTIOUS AND INFLAMMATORY EYE DISORDERS**

<b>Disorder</b>	<b>Description/Cause</b>	<b>Signs and Symptoms</b>	<b>Treatment</b>
Stye	Infection of a ciliary gland (a modified sweat gland) that enters into the hair follicle at the lid margin; most commonly caused by <i>Staphylococcus</i>	Pain and redness at a localized point on the lid margin with possible edema of the lid out of proportion to the severity of the disease; preauricular lymph node swelling and tenderness	Hot, moist compresses for 15–20 minutes four times daily; antibiotic ointment application after the compresses (possible); incision and drainage (when the stye points [develops a head]); nose and throat cultures for <i>Staphylococcus</i> Follow-up evaluation for repeated episodes to rule out other debilitating diseases such as diabetes mellitus or anemia Visual acuity assessment (although styes are not associated with refraction error, they occur when children rub their eyes excessively possibly because of problems with visual acuity)
Chalazion	Low-grade granulation tissue tumor of the <i>meibomian</i> , or tarsal, gland on the eyelid; cause unknown but may be a result of a low-grade infection produced by retained secretion	Small, slow-growing, hard, but painless nodule on the lid; skin freely movable over it; absence of inflammation or edema	Nodule may resolve spontaneously, evacuating itself onto the conjunctival surface of the lid; incision and drainage if no spontaneous remission, followed by antibiotic ointment application to prevent secondary gland infection

	in the gland		If ptosis is present in a child younger than 7–8 years of age, surgical removal is performed to prevent possible subsequent amblyopia.
Blepharitis marginalis	Inflammation of the eyelid margin; usually a local infection caused by <i>Staphylococcus</i> ; possibly an extension of seborrheic dermatitis (cradle cap)	Eyelid margin reddened, possibly covered by hard, dirty-yellow crusts that stick tenaciously to the lid margin and lashes; styes possibly present secondary to the presence of <i>Staphylococcus</i>	Application of an antibiotic ointment six to eight times a day to the lower conjunctival rim; removal of crusts with a moistened cotton applicator after the lid margins have been covered by wet compresses for 10–15 minutes If condition persists, systemic antibiotic therapy is used to reduce the presence of <i>Staphylococcus</i> on the skin surface.
Conjunctivitis	Inflammation of the conjunctiva; causes are numerous, including ophthalmia neonatorum (exposure to gonococcus bacillus; see <a href="#">Chapter 26</a> ) and bacterial, viral, and fungal organisms	Eyes watery with reddened conjunctiva and sensitivity to light; sticking of eyelids with pustular drainage	Application of an antibiotic ointment applied from inner to outer canthus to prevent spread of infection to other eye; follow-up visit is mandatory to be certain infection clears.
Inclusion blennorrhoea	<i>Chlamydia</i> organism	Acute inflammation usually occurring on the 5th–14th day after birth;	Systemic antibiotic such as erythromycin

		conjunctiva reddened with tearing; eye discharge	
Acute catarrhal conjunctivitis	Commonly called “pinkeye,” usually caused by a virus or irritation from a foreign body; most frequently caused by <i>Haemophilus influenzae</i> and <i>Streptococcus pneumoniae</i>	Conjunctiva fiery red with tearing; mucopurulent or purulent discharge	Antibiotic ointment or drops three to four times daily for 7 days (redness usually disappears within 48 hours); avoid rubbing and transmitting infection to unaffected eye. Cool, moist compresses to affected eye
Herpetic conjunctivitis	Herpes simplex viral infection (may occur along with development of facial herpes lesion)	Series of pinpoint vesicles on the conjunctiva; on fluorescein stain, vesicles stain bright green and are readily evident	Referral to ophthalmologist (can spread easily and become a corneal infection with resultant opacity and permanent scarring) Antibiotics are ineffective; steroids are avoided. Idoxuridine (Herplex), specific for herpesvirus, is possibly effective in limiting corneal involvement.
Allergic conjunctivitis	Hypersensitivity to specific allergen; usually seasonal	Eyelid edema; profuse tearing and severe itching	Treatment of underlying allergy; cool, moist compresses
Keratitis	Inflammation and infection of the superficial layers of the cornea; may accompany or be a complication of conjunctivitis;	Acute pain, tearing, photophobia (sensitivity to light), and redness	Referral to ophthalmologist for therapy (infection could lead to corneal scarring, resulting in vision impairment [light rays unable to

	may result when a foreign body strikes the cornea		enter the eye normally])
Periorbital cellulitis	Cellulitis (infection of subcutaneous tissue) most often caused by extension of a superficial infection after an open break in the skin, such as a mosquito bite or scratch near the eye	Swelling around and in the eye with possible damage to eye globe or optic nerve	Intravenous antibiotic therapy
Dacryostenosis	Blockage of the nasolacrimal duct; primarily in newborns because of a membrane obscuring distal end of duct or plugging by epithelial debris	Painless lump in the inner canthus; tearing; usually unilateral	Gentle pressure to inner aspect of each eye at each feeding in attempt to “milk” secretions down into duct; ophthalmologic probing of gland duct if condition not corrected spontaneously after age 6 months
Dacryocystitis	Inflammation of nasolacrimal duct; possibly secondary to dacryostenosis (from fluid stasis) or from nasal mucosal swelling and infected mucus being forced back into duct	Acute pain in inner canthus (from presence of infected sac); complaints of pain in back of eye or possibly in the eye itself	Local and systemic antibiotics; possible probing of duct to free obstruction and allow for free drainage; antihistamines for children with chronic allergies or sinusitis to reduce nasal congestion

**QSEN Checkpoint Question 50.2**

**QUALITY IMPROVEMENT**

Carla is diagnosed as having a bacterial conjunctivitis of her right eye, and the unit has a standardized care plan and educational materials that address this common diagnosis. What instruction should the nurse check in these clinical resources?

- a. Keep the infected eye tightly closed by covering it with clean gauze.
- b. Do not apply the eye drops for more than 3 days in order to prevent a rebound.
- c. Clean the eye discharge away from the inner to the outer canthus.
- d. Caution Carla not to blow her nose for the next 24 hours.

---

*Look in [Appendix A](#) for the best answer and rationale.*

---

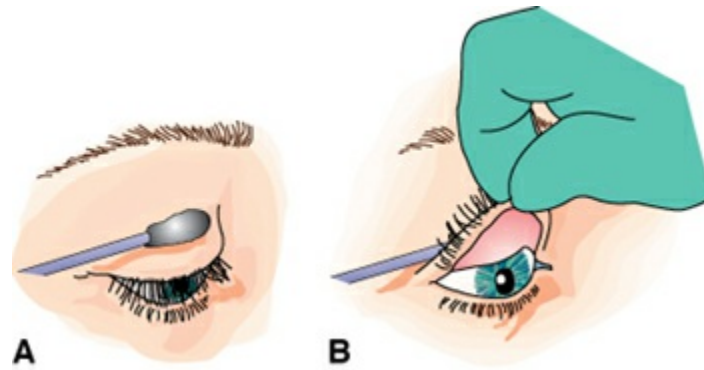

## Traumatic Injury to the Eye

Children account for 35% of ocular injury in the United States (Li, Zarbin, & Bhagat, 2015). These injuries may be caused by a variety of situations, such as improper use of fireworks, sports injuries, dirt, pieces off toys, fighting with others, and even fingernail scratches (Li et al., 2015).

### ASSESSMENT

Children who have eye injuries are usually in acute pain immediately after the injury. Their eyes tear and are sensitive to light, and they blink rapidly. Vision may be blurred or lost in the affected eye. Because of the pain and the fear of not being able to see clearly, most children are very reluctant to let anyone examine or touch their injured eye. A few drops of a topical anesthetic instilled into the eye may be necessary to relieve the pain and allow the eye to be opened for examination. Even after the anesthetic is applied, the child needs a thorough explanation that an examiner is “just looking” (provided this is true). Even after an anesthetic application, a child may not be able to open the eye readily for inspection because the acute pain of the injury can cause either the eyelid to close by reflex spasm or eyelid edema to form so quickly that these interfere with the eye’s ability to open. Do not confuse these physical problems with an unwillingness to open the eye.

To visualize the inner surface of the lower lid and the bottom half of the eye globe, press firmly on the lower lid with your fingertip until it turns out. The inner surface of the upper lid and the upper portion of the eye globe can best be visualized if the upper eyelid is everted. Ask the child to look downward. Grasp the eyelashes and gently stretch the upper eyelid downward. Place the stick of a cotton-tipped applicator horizontally against the center of the upper lid. While still grasping the eyelashes, pull the eyelid upward and over the applicator until it is everted (Fig. 50.6). Gently press the everted eyelid against the eyebrow to maintain the everted position. Be careful not to exert pressure on the eye globe during the procedure in case a penetrating injury from a foreign body is present to prevent further embedding the object into the eye globe.

**Figure 50.6** The technique for everting the upper eyelid for examination and foreign body removal. **(A)** Place a cotton applicator across the upper eyelid. **(B)** Pull the eyelid outward and upward over the applicator.

A foreign body, such as a speck of dirt or a fragment of glass, often clings inside of the upper lid and can be readily removed by touching it with a moistened, sterile, cotton-tipped applicator while the lid is everted. Keep an eyelid everted no longer than is necessary while you remove the object because the eye globe begins drying as soon as it is exposed. Magnetic resonance imaging (MRI) and ultrasound are excellent methods for documenting internal eye damage or corneal scarring from an injury (Sung, Nadqir, Fujita, et al., 2014).

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Parental role conflict related to feelings of guilt about unintentional injury affecting child's vision

**Outcome Evaluation:** Parents accurately state child's treatment plan and expected outcome; child and parents talk openly about the injury and ways to prevent future injuries; parents participate actively in child's care and in decision making with healthcare providers regarding follow-up care.

Eye injuries are almost always serious in children because of the pain and the potential threat to vision. Both parents and children are apt to feel guilty that an injury occurred. Parents may have difficulty handling this emergency because they are angry at their child and even angrier at themselves for not supervising the child or teaching the child more about eye safety. Children may need help understanding that although this injury might have been prevented, unintentional injuries do happen. Doing so can help them maintain a sense of self-esteem. Parents also may need counseling to reestablish their feelings of worth as parents (Box 50.4).

After eye trauma, the degree of vision in the child's affected eye as well as the

status of the parent–child relationship needs to be evaluated because guilt about the injury, in either the parent or the child, can interfere with this relationship.

#### BOX 50.4

### Nursing Care Planning Tips for Effective Communication

Carla’s older brother, Jon, a 7-year-old, is brought to the emergency department by his mother after his right eye was hit by a baseball.

*Tip:* Avoid focusing on assessing the events surrounding the injury so much that you fail to identify the parent’s feelings. In the following scenario, the nurse actively listens to the mother and so elicits information not just about the injury but also about her feelings.

**Nurse:** Hello, Mrs. Vander. How did this injury happen?

**Ms. Vander:** He was playing catch with his cousin in the backyard.

**Nurse:** Is he hurt anywhere else?

**Ms. Vander:** No. I should have been watching him more closely.

**Nurse:** Watching him more closely?

**Ms. Vander:** I should have been outside supervising them. What kind of a mother am I?

**Nurse:** Let’s talk a little more about this.

## FOREIGN BODIES

Foreign bodies such as sand or dirt that are loose on the conjunctiva can be removed by irrigation with a sterile normal saline solution or by gentle wiping with a well-moistened, sterile, cotton-tipped applicator after the eyelid is everted. After the removal, if the conjunctiva is touched with a strip of filter paper impregnated with fluorescein stain, any corneal ulceration or abrasion from the foreign body will stain green and be readily apparent. If the foreign body is easily removed and no corneal ulceration or injury is present, no further treatment is necessary. The child will blink a few times after the upper lid is returned to its place, but, in a matter of minutes, the child will report feeling “fine” again. If the fluorescein stain shows any corneal ulceration, refer the child to an ophthalmologist for follow-up care.

If a foreign body adheres to the cornea, it needs to be removed by an ophthalmologist because if the foreign body is metallic and has been in contact with the cornea for a period of hours, a rust ring can form around the particle. This rust ring must be removed as well as the object, or it will continue to act as a foreign body. After corneal injury, corneal tissue begins to regenerate. To aid this, the eye is washed with an antibiotic solution and then closed and patched. Assess that the patch is secure enough to keep the eyelid closed yet does not put undue pressure on the eye. Caution the child that the patch must be left in place until it is well healed and secure once more.

This prevents the delicate regenerating corneal epithelium from being rubbed off. If a foreign object is relatively large, such as a BB bullet, lollipop stick, or piece of broken glass, the fact that it has punctured the eye globe is usually apparent on first inspection. In these instances, the child also needs to be examined by an ophthalmologist. Surgery may be necessary to explore the depth of the puncture and to save the child's sight in that eye. Iron or copper fragments must be removed to prevent rust formation and continued irritation.

An extremely serious (although rare) complication called *sympathetic ophthalmia*, or inflammation of the opposite eye, may result if the uveal tract was involved in a penetrating injury. As a result, an autoimmune inflammatory response occurs in the noninjured eye, possibly leading to blindness in that eye. This complication can be prevented by the administration of a corticosteroid and antibiotics to reduce inflammation in the injured eye. If this is unsuccessful, removal (**enucleation**) of the injured eye may be necessary to prevent the other eye from being affected. In either case, the decision is a difficult one for the parents to make because this is a loss for them and their child. Allow the parents to verbalize their feelings and provide support to the parents. Fortunately, immediate treatment with corticosteroids and antibiotics has significantly reduced the incidence of this complication; if these are prescribed, be certain parents understand the importance of giving the full course of these medications (Edelson, 2013).

## CONTUSION INJURIES

Many eye injuries happen not from a sharp object striking the eye but from blunt trauma such as being hit in the eye by a baseball, a fist, a soccer ball, or an automobile dashboard. With this type of injury, the eyelid and the surrounding tissue, including the intraorbital tissue, hemorrhage and become edematous (Armstrong, Kim, Linakis, et al., 2013).

The simplest form of contusion injury is a "black eye." When this occurs, the eye globe (including a fundoscopic examination) must be assessed. If a vision chart is not available, vision can be assessed by having children tell you how many fingers they can count at a distance of about 6 ft (assuming they are old enough to count accurately) or by having them read a printed page at reading distance (assuming they are old enough to read). Evaluate extraocular eye movements by asking the child to follow a light into all six cardinal positions of gaze (see Chapter 34). Children should be able to look up and down, left and right, upward obliquely, and downward obliquely (LaRoche, 2013).

If there is no apparent eye injury, ocular movement is good, and vision is normal (for that child), the only treatment necessary is an ice pack applied to the eye to minimize swelling (20 minutes on, 20 minutes off, and repeat). The reabsorption of hemorrhage in the tissue surrounding the eye will take place over the next 1 to 3 weeks. Often, tissue hemorrhage extends across the nose and surrounds the other eye the day after the injury. You can assure both the parents and the child that this is not a worsening of the condition but rather mainly evidence of the severity of the initial blow.

Limited eye movement or reports of diplopia (double vision) are strong evidence a “blowout” fracture of the floor of the orbit (the maxillary bone) has occurred, and the fracture line is trapping intraorbital tissue and preventing the eye globe from moving freely. Refer these children to an ophthalmologist because surgery is needed to free the entrapped tissue, prevent interference with vascular flow, and restore normal eye movements.

After a blunt contusion to the eye globe, findings such as a dilated, fixed, or cloudy pupil; a cloudy lens or cornea; a loss of vision in the eye; or visible blood in the anterior chamber (hyphema) indicate that dislocation of the lens or retinal detachment may have occurred. Again, immediate evaluation by an ophthalmologist is necessary.

## EYELID INJURIES

Eyelid injuries may accompany eye globe injuries, or they may be the only finding present after a foreign body has struck the eye. Although such injuries appear to be trivial, don’t dismiss them lightly. Refer the child to a primary care provider for care because a deep laceration of the eyelid can cause a permanent ptosis. A laceration to the inner canthal area can disrupt the lacrimal drainage system (dacryostenosis).

### *What If... 50.1*

**A nurse is asked to teach Carla Vander’s first-grade class on ways to prevent eye injuries. What suggestions should the nurse include? How would the nurse’s teaching plan be different if the class was for 16-year-old students?**

## Inner Eye Conditions

Inner eye conditions are those that affect the lens, the retina, or the aqueous humor.

### CATARACTS

A *cataract* is marked opacity of the lens. This may be present at birth, or it may become apparent in early childhood. Some children have cataracts as a dominantly inherited condition, whereas in others, it may be as a result of another disease process such as galactosemia or scarring from an injury. A few children develop cataracts as a result of steroid use or radiation exposure. If the opacity occurs on the anterior surface of the lens, the cause is thought to be a birth injury or possibly contact between the lens and the cornea during intrauterine life. If the opacity is located at the edge of the lens, it may be a result of nutritional deficiency during intrauterine life, such as hypocalcemia. A quarter of infants born to women who were exposed to or contracted rubella may develop cataracts (Medsinge & Nischal, 2015).

### Assessment

When you inspect the pupil of a child with a cataract, the red reflex elicited by shining a light into the pupil appears white. Older children may report blurred vision because of cataract formation. In the infant, this can be detected by lack of response to a smile or an inability to reach and grasp a nearby object. The infant may also demonstrate nystagmus from being unable to focus the eye on objects. A few other conditions, such as retinoblastoma, retinopathy of prematurity, congenital glaucoma, or an abscess of the posterior chamber, simulate this appearance.

## Therapeutic Management

Treatment of childhood cataract is the surgical removal of the cloudy lens, followed by insertion of an internal intraocular lens. If the total lens is involved, this may be done as early as 3 months of age. If this is not done before 6 years of age, amblyopia may result.

With modern surgical techniques, the incision is so small that eye patching is not necessary. Infants may be given a sedative to help them rest for 24 hours to keep them from rubbing their eyes. Introduce fluids cautiously after eye surgery so nausea and vomiting do not occur because vomiting increases intraocular pressure (IOP), which could injure the suture line. Encourage parents to stay with their infant and to help with care so the infant does not cry because crying also increases IOP. Infants can be expected to have some discomfort, but in general, they should not have acute pain after surgery. If they are unusually restless, fussy, or cry as if in pain, report this. Use an appropriate pain assessment scale, such as CRIES or FLACC, to assess pain. Although this could be unrelated to the surgery, it may be a sign of increased IOP from hemorrhage or from occlusion of the canal of Schlemm, causing a developing glaucoma. The child may need to be medicated for pain.

As a rule, children will be given a mydriatic agent to dilate the pupil and steroids to prevent postoperative development of pupillary adhesions. If the eye that had the cataract is now amblyopic, patching the better eye (as with usual amblyopia correction) may be necessary to improve vision. Holding, rocking, and stimulating the child's senses in other ways will help to decrease their fear and anxiety.

Parents of children with congenital cataracts need support to carry out the procedures necessary and to give the long-term medication and corrective measures needed. Outcome evaluations should include children's current vision status and also how they view themselves in light of this early vision problem (Rajavi & Sabbaghi, 2016).

### *QSEN Checkpoint Question 50.3*

#### **SAFETY**

If Carla, the 6-year-old who has strabismus, has to have corrective eye surgery, why would the prevention of vomiting from anesthetic be a high priority?

- a. Vomitus could be splashed into the eye.
- b. Loss of sodium threatens the integrity of the new lens.

- c. Vomiting increases IOP.
- d. Loss of fluid causes the globe diameter to shrink.

Look in [Appendix A](#) for the best answer and rationale.

## CONGENITAL GLAUCOMA

Childhood glaucoma is a condition of the eye characterized by increased IOP, potential damage to the optic nerve, and possible vision loss ([Giangiacomo & Beck, 2017](#)).

Normally, aqueous humor, produced by the ciliary body, flows from the posterior chamber through the pupil to the anterior chamber; it is excreted through the canal of Schlemm at the lateral angle into the venous circulation ([Fig. 50.7](#)). In congenital glaucoma, a developmental anomaly in the angle of the anterior chamber prevents proper drainage into the canal. Later in life, glaucoma can occur when the canal becomes blocked, usually as a result of eye trauma. The increased fluid content that accumulates in the eye causes the globe to increase in size. After it has increased in size to the extent that it can, pressure in the eye globe continues to rise, compressing and ultimately destroying the optic nerve ([Yeung & Walton, 2012](#)). Glaucoma (meaning “gray”) gets its name from the color of the retina or red reflex (which appears gray to green) in the eye after sight has been lost.

**Figure 50.7** (A) The circulation of aqueous humor. (B) The blockage of the canal of Schlemm in congenital glaucoma.

## Assessment

Although congenital glaucoma is a rare disorder, all infants should be assessed for it because the disease accounts for vision disorders in 5% to 13% of children in schools for those with visual impairment. In most infants, the condition is bilateral and is caused by the inheritance of a recessive gene. Symptoms may be noticeable as soon as shortly after birth, and they are readily noticeable at 1 year of age. The condition occurs in about 1 in every 10,000 live births and more often in girls than in boys (Papadopoulos, Brookes, & Khaw, 2013).

The cornea, which appears enlarged, may also be edematous and hazy; it feels tense to finger palpation. There may be accompanying tearing, pain, and **photophobia** (sensitivity to light)—all difficult signs to identify in a newborn.

Eye pressure is measured by means of a *tonometer*, a pressure-sensitive device that is placed against the anterior eye globe and measures eye pressure by a beam of light directed toward the eye. Tension greater than the normal range of 12 to 20 mmHg is suggestive that glaucoma has developed. If local anesthesia is needed for tonometry, caution parents that children should not rub their eyes after the procedure (an infant's arms may need to be gently restrained to prevent eye rubbing for about 4 hours after such an examination). Otherwise, corneal abrasions could occur because of the cornea's temporary lack of sensitivity.

## Therapeutic Management

Surgery, such as trabeculotomy and **goniotomy**, laser procedures that create shunts to allow fluid to drain from the eye, as well as medical treatment are used to lower IOP (El Sayed & Gawdat, 2017).

A drug such as acetazolamide (Diamox), a carbonic anhydrase inhibitor that suppresses the formation of aqueous humor, may be used temporarily to reduce eye pressure before surgery can be scheduled.

Before surgery, the infant should not receive any drug, such as atropine sulfate, that dilates the pupil because this will further occlude the canal of Schlemm. After surgery, rough play activities should be restricted for 1 week.

Surgery may need to be repeated before the new opening for the drainage of fluid is adequate to keep eye globe tension at a usual level. Inform parents of this possibility when surgery is first proposed so that they will not think the additional surgery is needed because the first operation was inadequate or was done incorrectly.

Children who have eye injuries are usually scheduled for a follow-up appointment in 1 month for eye pressure assessment. Stress the importance of this visit in order to assess eye pressure and to prevent complications (Lin, Xu, Huang, et al., 2016).

### QSEN Checkpoint Question 50.4

#### TEAMWORK & COLLABORATION

Glaucoma can occur in children following surgery for cataracts. Because Carla had

surgery for congenital cataracts as an infant, she is being followed by a pediatric ophthalmologist. What assessment finding from the ophthalmologist's documentation would best reveal that Carla is developing glaucoma?

- a. Assessment for migraine headaches
- b. Carla's ability to identify colors
- c. Results of eye pressure assessment
- d. Results of temporal palpation

*Look in Appendix A for the best answer and rationale.*

## The Child Scheduled for Eye Surgery

Inform the parents that surgery for cataracts or glaucoma in childhood is usually performed during the infant period. The preparation for surgery, therefore, primarily consists of helping a baby to adjust to a strange environment and encouraging parents or a primary caregiver to room-in with the infant if possible to decrease anxiety and provide auditory and tactile stimulation. This is particularly important if the eyes will be patched after surgery. Surgery for strabismus is often done during the preschool period. Explaining why the operation is needed can be done by the use of puppets or dolls so that it feels nonthreatening. Manipulation of equipment is also a way children cope with unfamiliar situations. As with all surgical procedures, talk about the child's affected parts (in this case, the eyes) being "fixed" or "made better" but never "cut." Be sure that the language and descriptions are concrete and developmentally appropriate.

### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Anxiety related to lack of knowledge about eye surgery and postoperative experience

**Outcome Evaluation:** Child asks questions and expresses fears about surgery; child states plans for postoperative period and practices putting on eye patches if these will be used.

Most eye surgery is completed as ambulatory surgery. A major nursing role is preparing the parents to support the child through the procedure.

If the child's eyes are going to be patched after surgery, introduce these preoperatively so the child can become accustomed to the feeling of the patches beforehand. Even when only one eye is going to be operated on, it is not unusual for both eyes to be patched because the eyes move conjugately—that is, when the right eye looks to the right, so does the left. The repaired eye, therefore, will stay immobile under a bandage only if both eyes are patched.

You could show the child a doll with eye patches and let the child practice wearing them. You could play a game such as “pin the tail on the donkey” or “blind man’s bluff” to adjust to the sensation of the eyes being covered. Another helpful game is to have the child pull out familiar objects from a paper bag—a key, an orange, a spoon, and a penny—and, with the eyes covered, try to guess what they are.

Postoperatively, check that the young child’s favorite toy is within reach if eyes are patched. If a child will require arm restraints to prevent pressing on the eyes or removing patches, introduce these preoperatively as well. Children who awaken from conscious sedation and find their arms tied down can be extremely frightened. Encourage the parents to room-in if possible.

### *What If . . . 50.2*

**Carla, a 6-year-old, is scheduled for surgery under conscious sedation to remove a chalazion from her eyelid. Her mother tells the nurse, “She’s always good so I’m sure she’ll cooperate. If not, we’ll just wait until she’s older to have it removed.” Why might the nurse not be surprised if Carla was not as cooperative as her mother predicts? Is the mother’s “plan B” to delay surgery a best plan?**

## The Hospitalized Child With a Visual Impairment

The National Dissemination Center for Children With Disabilities (NDCCD, 2012) defines *vision impairment* as “vision that, even with correction, adversely affects a child’s educational performance.” Vision losses of this extent can occur for a multitude of reasons, including congenital cataracts, glaucoma, vitamin A deficiency, inadequately treated eye infections, or corneal scarring (Solebo & Rahi, 2014). Children may be hospitalized because of their primary vision disorder or, like other children, be hospitalized for a disorder such as appendicitis or pneumonia. Severe vision impairment or blindness can make it exceptionally difficult for a child to adjust to a hospital environment.

### **Nursing Diagnoses and Related Interventions**

**Nursing Diagnosis:** Powerlessness related to difficulty adjusting to strange environment, secondary to vision impairment

**Outcome Evaluation:** Child identifies specific fears and concerns; child is able to make age-appropriate decisions regarding self-care.

Vision impairments can range from severe disorders to total blindness. Assess children carefully for the degree of their vision impairment to better gauge their abilities so you help them neither too much nor too little. Keep in mind that severe vision impairment can lead to chronic depression as children grow older and begin to realize more and more the many ways their reduction or lack of vision affects their life. To help avoid this, be sure to thoroughly orient them to the hospital experience and their surroundings. Remind them as necessary that their parents are nearby because they may become extremely frightened if they think a parent has left them when the parent has only moved a few feet away or behind a curtain.

Before you approach children who are blind, always speak first to avoid startling them. Children can usually sense another person's presence in the room, so don't attempt to slip into their room quietly to straighten their bed or pick up some equipment without speaking to them.

Common hospital sounds such as beeping infusion pumps, call lights, etc., can be frightening to a child with a visual impairment. Stand by the child's bed and explain the sounds you both hear together because sound is a major way that children with visual impairment experience their environment.

Children who are blind learn self-care the same as other children; they bathe themselves, brush their teeth, and put on clothes the same as other children their age. Toilet training may come later than usual because they cannot see the excretions that parents are asking them to dispose of in a special place.

Children who are blind often want to be told what is on their food tray when it is first presented to them. Name the foods so they can identify tastes with names as well as the location of the foods on the plate. Do not hesitate to use food colors: "Those are green beans; this is an orange; those are red beets" because these words are names as well as colors. Preschoolers with visual impairment enjoy the same finger foods as sighted children. Children with severe vision disorders have difficulty getting food from spoons or forks to their mouths neatly. However, they should not be spoon-fed just because it is neater and faster; eating is an important self-care skill a blind child must learn in order to be independent as an adult.

Be certain to offer frequent descriptions of what is happening or planned for children with visual impairments. They cannot see their surgical dressing, for example, so encourage them to feel it. They cannot see the intravenous infusion, but they can feel the tubing and the arm board that is holding their arm in place.

Parents of a child with severe visual impairment usually plan to room-in with their child during a hospitalization experience. Review with the parents their routine at mealtime and bedtime, their child's favorite toy, what word is used for voiding, and so on, and post it conspicuously or pass this information on to the entire nursing staff. Only when parents have confidence in you and the other staff members will they be able to leave their child in your care to meet their own needs, such as going to a coffee shop for a meal.

## Structure and Function of the Ears

Ear anatomy is shown in [Figure 50.8](#). Most diseases of the ear in children involve the external and middle portions.

**Figure 50.8** The structures of the ear.

### THE PHYSIOLOGY OF HEARING LOSS

Hearing loss is termed a *conduction loss* if there is interference with sound reaching the inner ear (difficulty with the external canal, the tympanic membrane, or the ossicles). It is termed *nerve* or *sensorineural loss* if the inner ear or the eighth cranial nerve is affected. Conduction loss occurs in children if the external canal is obstructed with cerumen (wax) or a foreign object, if the tympanic membrane is damaged or immobile, or if the middle ear is filled with fluid, as occurs in *serous otitis media*. Sensorineural loss results from diseases that affect the transmission of sound sensation to the cerebral cortex or because of a pathologic condition of the cochlea. In children, nerve damage is usually congenital, although it can occur after drug therapy, an infection such as meningitis or rubella, or exposure to loud sound ([Prosser, Cohen, & Greinwald, 2015](#)).

Because diseases such as Treacher Collins syndrome, otosclerosis, osteogenesis imperfecta, and Waardenburg syndrome that lead to inherited hearing challenges tend to be autosomal dominant, there is a strong chance they will occur in future siblings of the child with hearing impairment. Genetic counseling can aid in increasing parental awareness of this possibility.

### HEARING IMPAIRMENT

Approximately 12,000 infants, or 2 to 3 out of 1,000 children born in the United States

are hard of hearing or deaf. Without newborn screening, these children may not be diagnosed with hearing loss until 2.5 to 3 years of age when development delays such as a lack of speech are identified (Alford, Arnos, Fox, et al., 2014).

Hearing impairment occurs in many different degrees and is rated by level of severity (Table 50.3). Causes of slight hearing impairment include serous otitis media, trauma from such things as inflating automobile airbags, and untreated acute otitis media with rupture of the tympanic membrane.

**TABLE 50.3 LEVELS OF HEARING IMPAIRMENT**

<b>Decibel Level (dB)</b>	<b>Hearing Level Present</b>
Slight (<30)	Unable to hear whispered words or faint speech No speech impairment present May not be aware of hearing difficulty Achieves well in school and home by compensating (such as leaning forward, speaking loudly)
Mild (30–50)	Beginning speech impairment may be present Difficulty hearing if not facing speaker; some difficulty with normal conversation
Moderate (55–70)	Speech impairment present; may require speech therapy Difficulty with normal conversation
Severe (70–90)	Difficulty with any sounds but nearby loud voice Hears vowels more easily than consonants Requires speech therapy for clear speech May still hear loud sounds, such as jets or train whistles
Profound (>90)	Hears almost no sound

The discovery that a child is hearing challenged is almost always a shock to parents because 9 out of 10 children born deaf are born to hearing parents (Poon & Zaidman-Zait, 2014). Children with hearing deficits should be exposed to language programs for children with hearing impairment as soon as possible so they have an optimum chance for language development and effective communication (Fig. 50.9).

**Figure 50.9** A young girl with hearing impairment learning to use the computer with the aid of a speech therapist. (© Bob Daemmrich/Stock Boston.)

For children who have conductive losses, an improvement in hearing usually can be achieved by use of a hearing aid (which intensifies the level of sound waves). Children who have inner ear or nerve deafness, however, cannot expect this kind of improvement. Parents of children with neural deafness need an explanation of the difference so they do not continue to search for a “cure” for their child or spend a great deal of money for hearing aids or alternative therapies, hoping a different brand, model, or technique will help their child.

### **Hearing Aids and Cochlear Implants**

Hearing aids pick up sound through a microphone, convert the sound waves into electrical impulses, and amplify them across the tympanic membrane. They are powered by batteries that must be changed periodically.

Hearing aids are designed to be as inconspicuous as possible, so children will not feel self-conscious wearing them. The receiver of the hearing aid may be incorporated into eyeglasses, molded into a plastic form that fits behind or into the ear, or housed in a small box (the size of a cell phone) that children wear on a cord around their neck or carry in a blouse or shirt pocket. Sound amplification systems are available to assist children in the classroom, such as personal frequency modulation systems in which the teacher wears a microphone that transmits directly to the child’s hearing device (Kuppler, Lewis, & Evans, 2013). Teach children to remove hearing aids before washing their hair, showering, or swimming and to turn them off when removed to preserve the life of the batteries.

Children with a hearing impairment may grow self-conscious about wearing a hearing aid at school and may be the victims of bullying. Encourage children to report bullying, so it can be stopped. Be certain they value themselves as someone capable of overcoming great odds rather than as someone with a disability to hide.

*Cochlear implants* are mechanical devices consisting of a microphone, a speech processor, a transmitter/receiver, and an arrangement of electrodes that send impulses from the receiver directly to the auditory nerve. The auditory nerve then transmits the impulses to the brain where they are interpreted as words or common noises. The implant consists of an external portion that sits behind the ear and a second portion that is surgically implanted under the skin (Haynes, Gifford, & Rivas, 2016).

Approximately 38,000 children in the United States have received cochlear implants (National Institute on Deafness and Other Communication Disorders [NIDCD], 2012). These implants do not restore normal hearing but do allow for sounds to be received. Although adequate for communication, many children report hearing with a cochlear implant as sounding “muffled” or “under water.” Months of training may be necessary to help a child correctly interpret these distorted impulses. Some adults with hearing impairment are reluctant to consent to a cochlear implant for their child because they believe the change from a child with hearing impairment to a hearing status will remove their child from their deaf culture. Support parents with the choice they make regarding the implant; at the end of adolescence, children who have not received a cochlear implant can independently make the choice whether to have one. Children who spoke with an impediment before cochlear implantation usually need speech therapy afterward to improve their speech pattern because their pronunciation of words is so ingrained at that point.

## Speech Therapy

If children who are hearing challenged are to interact as fully as possible with the world around them, they need an intensive program of speech therapy. Whether children should be introduced to sign language early is controversial; some therapists believe learning sign language early is helpful because it allows children to express their needs early, whereas others believe that by learning sign language, children decrease their need to learn to articulate speech sounds or to lip read and, for those reasons, learning sign language should not be encouraged. It is true that for real independence and to perform in regular school classes, children need to communicate by means other than sign language. For children with a profound impairment, however, learning speech sounds may be a long-term process, making sign language necessary for contact with the world around them until they can learn to speak.

### *What If . . . 50.3*

**A nurse discovers that Carla, who is hearing challenged, refuses to wear her hearing aid because another child at her school made fun of it. What**

**suggestions could the nurse give her parents to help Carla better accept wearing her hearing aid?**

## Disorders of the Ear

Ear disorders are always serious in children because hearing is such an important function for the growing child. Methods to assess hearing are discussed in [Chapter 34](#).

### EXTERNAL OTITIS

External otitis (otitis externa) is inflammation of the external ear canal. Although external ear inflammation rarely threatens hearing or causes permanent damage, it does cause discomfort in the form of itching and sometimes extreme pain ([Marais, 2015](#)).

#### Assessment

The history of children with external otitis usually reveals that they have recently been swimming, which is why this condition is popularly called *swimmer's ear*. It also can occur if a young child pushes a foreign object into the ear canal. Unlike a middle ear infection (otitis media), there is no history of a recent respiratory infection. Children first notice itching of the canal and then pain. When the external ear is touched, the pain becomes acute. The moisture in the canal left from swimming or from decay of a food substance has caused inflammation, and a secondary infection then can occur in the closed space. *Pseudomonas* and *Candida* are agents frequently involved in these infections. On otoscopic examination, the pain may be found to be due to the sharply localized, tender swelling of a furuncle, or the entire canal may be swollen shut and tender to the touch. Fungal infections tend to turn the canal brown or black; although, if mold forms around a foreign body, such as the tip of a cotton applicator, it may appear white or gray. The skin under the object will be moist, red, and eroded.

If doing a first assessment on a child, be certain to visualize the tympanic membrane if possible to be certain it is intact and that it is not inflamed or to verify if the inflammation is about to extend into the middle ear. Before the tympanic membrane can be visualized clearly, it is often necessary to remove superficial debris from the canal. A Weber test (discussed in [Chapter 34](#)) should show that hearing is not decreased in the affected ear. If the sound of a tuning fork vibrates louder in the affected ear, it suggests otitis media is present.

Removing debris by an ear curette from an infected external canal requires both patience and skill. Children must lie still for the procedure to prevent them from suddenly turning their head and causing the curette to puncture the tympanic membrane, and so they may need to be restrained. If the debris in the canal is hard and difficult to remove, it can be softened and loosened by touching it with a hydrogen peroxide–soaked cotton applicator or, alternatively, by dropping 2% acetic acid into the canal and allowing this to stand for a few minutes. Don't irrigate the external canal until it has

been shown that the tympanic membrane is intact so that infected material is not washed through a rupture into the middle ear.

## Therapeutic Management

The treatment of otitis externa differs according to the organism causing the infection. If the canal is so swollen that ear drops cannot flow back into the canal, a cotton wick moistened with Burow's solution may be threaded into the canal. The cotton extending out into the auricle is kept moistened by rewetting it periodically for the next 24 hours with Burow's solution. This usually reduces the swelling of the canal to a point where further cleaning can be accomplished.

Ear drops containing hydrocortisone, an antibiotic, or an antifungal mixture may be prescribed. Hydrocortisone reduces inflammation, and the antibiotic or antifungal preparation will reduce the infection. If ear pain is present, an analgesic, such as acetaminophen or ibuprofen, may be necessary to control discomfort. It is important that children keep the ear canal dry until the inflammation subsides, so they need to avoid swimming and washing their hair during this time. If they shower, they should first insert ear plugs into the external meatus or wear a shower cap to keep out moisture.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Deficient knowledge related to technique for ear drop instillation or other care measures

**Outcome Evaluation:** Parents demonstrate proper instillation of ear drops; parents state the importance of continuing prescribed treatment to completion.

Administering ear drops can be a challenging task for parents because children invariably are reluctant to have any fluid dripped into their ear. Demonstrate to parents how this is done (see [Chapter 38](#)) before they leave the healthcare facility. Caution them to give the medication for the full period prescribed. Otherwise, especially if the child is resistant, parents may administer the ear drops only until the pain subsides (24 to 48 hours). As a result, the infection may recur.

Follow-up evaluation after the completion of treatment for external otitis should include assessment of inflammation, pain, and the parents' awareness of prevention strategies. Preventive strategies include avoiding insertion of any object into the ear canal and using ear plugs while swimming. Instillation of a dilute alcohol or acetic acid solution by dropper after swimming is a prophylactic measure that may be recommended for children who swim competitively and spend a great deal of time in water to help keep the ear canal dry.

## IMPACTED CERUMEN

Cerumen (earwax) serves the important function of cleansing the external ear canal as it gradually moves outward, bringing with it shed epithelial cells and any foreign object. Parents are often concerned that earwax will lead to a loss of hearing (or they view it as dirty) and so ask healthcare professionals to have it removed. Wax accumulation rarely is extensive enough in children that it interferes with hearing and removing it can diminish its protective function, so it should not be removed routinely. Using cotton-tipped applicators to clean ears as a regular practice can also scratch the ear canal, creating a site for a secondary infection. This practice may also push accumulated cerumen farther into the ear canal, resulting in plugging of wax.

Commercial softeners are available if cerumen accumulates to such an extent that hearing is affected. In some instances, a dilute solution of hydrogen peroxide may be necessary to dissolve cerumen. Again, this should not be done regularly because this will keep the ear canal constantly moist, an environment that leads to external otitis.

### *QSEN Checkpoint Question 50.5*

#### EVIDENCE-BASED PRACTICE

A concern about the many mobile electronic devices available today is that increased noise exposure will cause neurologic hearing injury. To investigate whether hearing loss was present in teenagers who typically listened to music through earphones, researchers tested the hearing of 381 first-year university students and then asked them to self-report their history of music exposure. The results of the study showed those students with a high level of recreational noise exposure had lower hearing thresholds than those students with less recreational noise exposure (Tung & Chao, 2013).

Based on this study, which action by Carla's teenage brother would cause a nurse the most concern?

- He listens to music on his computer while he does his homework.
- He typically listens to sports news on the radio while he eats.
- He plays varsity basketball in a noisy gymnasium once a week.
- He listens to music with earbuds when he rides the bus and subway.

*Look in Appendix A for the best answer and rationale.*

## ACUTE OTITIS MEDIA

Inflammation of the middle ear (otitis media) is one of the most prevalent diseases of childhood. It occurs most often in children 6 to 36 months of age and again at 4 to 6 years. Children most susceptible to it are males, Alaskan and Native American children, those with cleft palate, and infants who are formula-fed rather than breastfed. Formula-feeding leads to this because infants are held in a more slanted position while feeding, allowing milk to enter the eustachian tube. The incidence of otitis media is highest in

the winter and spring because it frequently follows an upper respiratory infection and is higher in homes in which a parent smokes cigarettes (Zhang, Xu, Zhang, et al., 2014). Although it occurs frequently, otitis media is a potentially serious disease of childhood because permanent damage can occur to middle ear structures, leading to permanent hearing impairment.

## Assessment

Acute otitis media usually occurs following a respiratory tract infection. Children have a “cold,” rhinitis, and perhaps a low-grade fever for several days. Suddenly, their fever peaks to about 102°F (38°C), and sharp, constant pain begins in one or both ears. Older children can verbalize they have pain and point to where the pain is felt. Infants, unable to do this, become extremely irritable and frequently pull or tug at the affected ear in an attempt to gain relief from pain. On examination, the external canal is usually free of wax because the warmth of the inflammation and fever melts the wax and moves it more readily out of the canal. In contrast to an external ear canal infection, the discomfort they feel does not increase on manipulation of the auricle. Palpate the mastoid process behind the ear to be certain it doesn’t feel tender to your touch. If it does, the infection probably has spread out of the middle ear into the mastoid cells, a very serious complication that may lead to meningitis.

The appearance of a normal eardrum shows the outline of the malleus (see [Chapter 34](#)). With an infection, the tympanic membrane appears inflamed or reddened. It may bulge forward into the external canal because of fluid and edema behind it. The landmarks of the tympanic membrane, the malleus and incus, can be visualized only poorly or not at all. The light reflex of the otoscope will not be as definite as usual because of the “pushed out” or convex shape of the eardrum. There is decreased mobility on a pneumatic examination.

## Therapeutic Management

Most middle ear infections are caused by *Streptococcus pneumoniae*, *Haemophilus influenzae* (especially in children younger than 5 years of age), or *Streptococcus pyrogenes*. An otitis media infection may resolve spontaneously; however, if it does not, antibiotic therapy may be indicated.

Other pharmacologic agents children may need are an analgesic and antipyretic such as acetaminophen (Tylenol) and decongestant nose drops to open the eustachian tubes and allow air to enter the middle ear. These are given for only 2 to 3 days because if they are given longer, a rebound effect can occur, causing edema and a subsequent increase in mucous membrane inflammation. Providing a smoke-free home environment can help prevent further episodes of otitis media (Zhang et al., 2014).

During the course of otitis media, some children experience a conductive hearing loss; this may last as long as 6 months after the acute infection. Caution parents about this, so they will not think the infection is growing worse if they first notice the

impairment. They also need to know about the possibility of hearing loss so that when the child gets hearing screening in school during the 6 months following the infection, they can account for the hearing loss. If a child still has a conductive hearing loss after 6 months (or has other symptoms), the child should be reevaluated to see whether a new infection or serous otitis media has developed. [Box 50.5](#) shows an interprofessional care map illustrating both nursing and team planning for a child with otitis media (Lieberthal, Carroll, Chonmaitree, et al., 2013).

## BOX 50.5

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR A CHILD WITH OTITIS MEDIA

Carla Vander, a 6-year-old, is brought to your pediatric clinic for evaluation. Her mother states, “She was born with a hearing loss and a cataract. Today, her eye is red and she has pain in her ear. Can you see her quickly so I can get an antibiotic for the ear infection before the drugstore closes?”

**Family Assessment:** Child lives with parents and two brothers, 7 and 14 years old, in three-bedroom suburban cottage. Father works as a travel agent; mother is a grade school librarian. Father describes finances as “middle class.”

**Patient Assessment:** Child has had two previous ear infections in the past 8 months. Child had a clear, watery nasal discharge and slight cough for 2 days. Today has thick, purulent, nasal drainage. Temperature this morning was 102.2°F (39.0°C). Observed tugging vigorously on right ear. On examination, right tympanic membrane is erythematous and bulging, with poor mobility on pneumoscopy. Left ear examination unremarkable. Child is diagnosed with otitis media of the right ear.

**Nursing Diagnosis:** Pain related to inflammation and erythema secondary to ear infection

**Outcome Evaluation:** Child no longer tugs at right ear; tympanic membrane no longer reddened or bulging; child rates pain as no higher than 2 on a FACES Pain Rating Scale.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess whether child is able to sleep or wakes with pain.	Suggest mother give prescribed antihistamine at bedtime. Urge child to sleep with affected ear	Antihistamines can make children sleepy. Sleeping on affected ear can put pressure on	Mother reports child is able to sleep through the night.

		up.	eustachian tube, which can increase pain.	
<i>Teamwork and Collaboration</i>				
Nurse/primary care provider	Assess whether child has susceptibility to ear infections or whether this could be reoccurrence of a former infection.	Meet with ear, nose, and throat service to consult on cause of frequent otitis media.	Otitis media is painful so can affect quality of life.	Consultant meets with mother to discuss cause of frequent ear infections.
<i>Procedures/Medications for Quality Improvement</i>				
Nurse	Assess whether child has experience with taking oral medicine; rate child's level of pain by FACES Pain Rating Scale.	Instruct the mother to administer acetaminophen every 4 hours or ibuprofen every 8 hours and how to instill saline nose drops.	Acetaminophen and ibuprofen are effective analgesics and antipyretics for this degree of pain; nose drops relieve nasal inflammation.	Child is able to take oral medicine cooperatively; rates pain level as not above 2 on FACES Pain Rating Scale.
<i>Nutrition</i>				
Nurse	Assess what soft foods and fluids child likes to eat.	Encourage mother to offer liquids and soft foods.	Movement of the eustachian tube, such as with chewing, may increase pain.	Child names some foods and fluid she is willing to eat; eats less than usual but adequate amount.
<i>Patient-Centered Care</i>				
Nurse	Assess how much mother and child understand about the cause of otitis media and the newer, no-	Educate the mother about the common characteristics of otitis media; reassure mother the infection will	Education promotes better understanding of the problem, alleviating some of the stress and anxiety	Mother states her prime goal is to get child well again; will follow primary care provider's recommendation

	antibiotic approach to treatment.	resolve without an antibiotic.	associated with it.	for care.
<i>Psychosocial/Spiritual/Emotional Needs</i>				
Nurse	Assess how much experience mother has with care of an ill child.	Teach mother that otitis media usually resolves without the need for an antibiotic.	Correct information helps mother accept a lack of antibiotic prescription.	Mother states she feels capable of caring for child without antibiotic prescription.
<i>Informatics for Seamless Healthcare Planning</i>				
Nurse	Assess whether child or parents have any questions about care that they still need to be answered.	Instruct the mother to contact the clinic or healthcare provider if there is no improvement within 24 to 48 hours or if the child exhibits increased pain.	Lack of improvement within 24 to 48 hours indicates the need for further evaluation; increased pain may indicate excessive fluid accumulation, which could lead to tympanic rupture.	Mother has clinic telephone number; will telephone if symptoms of complications occur.

## OTITIS MEDIA WITH EFFUSION

Otitis media with effusion occurs when otitis media becomes chronic. Normally, the middle ear is an air-filled cavity; air is supplied to it each time the eustachian tube opens with swallowing, yawning, or chewing. If this source of air to the middle ear is closed off due to inflammation or edema of the eustachian tube, the epithelial cells of the middle ear begin to secrete a thin, watery mucus. Over time, the compartment becomes so filled with this and the fluid becomes so thick and tenacious that it appears glue-like. Some children notice a feeling of fullness or the sound of popping or ringing in their ears. There may be a drop in hearing of 20 to 40 dB because of the inability of the ossicles to function effectively. Involvement is usually bilateral. The condition occurs most frequently in children 3 to 10 years of age (Robb & Williamson, 2016).

### Assessment

A child experiences muffled hearing and a feeling of pressure in the ear with otitis

media with effusion. Ooscopic examination may show a level of fluid behind the tympanic membrane. However, a fluid line will be visible only if there is also a quantity of air in the middle ear to contrast with it. As the collected fluid becomes thick, it tends to retract the eardrum. This makes the malleus more prominent and perhaps displaced to a horizontal angle as the membrane is retracted around it; the light reflex from the otoscope light becomes distorted. If a pneumatic otoscope is used, gentle introduction of air against the eardrum produces no movement of the tympanic membrane (as there would be normally).

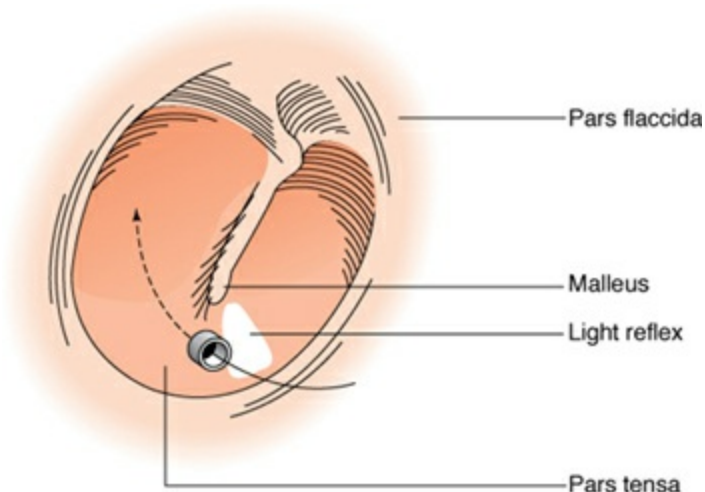

## Therapeutic Management

Therapy for otitis media with effusion may be long term. If the condition appears to be intensified by inflammation from an allergy, measures to control the allergy must be initiated. These may include avoidance of the allergen, hyposensitization, or pharmacologic alteration of the allergic response (see [Chapter 42](#)).

Definitive medical treatment is aimed at supplying air to the middle ear. For mild involvement, the daily administration of an antihistamine or a nasal decongestant to shrink the mucous membrane of the eustachian tube may be enough to achieve an air supply. In a few children, the eustachian tube is blocked by enlarged adenoids, and their removal is indicated. Fluid from the middle ear can be removed by **tympanocentesis** (a needle inserted through the tympanic membrane); however, the fluid usually returns unless some intervention to introduce air into the middle ear (tubal myringotomy) is undertaken.

### Tubal Myringotomy

A source of air can be supplied to the middle ear by the insertion of small plastic (Teflon) tubes inserted through the tympanic membrane (tympanostomy). The insertion of such tubes is done by a myringotomy at a point in the tympanic membrane that is not instrumental for hearing, so the tube does not interfere with hearing ([Fig. 50.10](#)). Myringotomy tubes can be placed in one or both ears as an ambulatory procedure after the local injection of lidocaine (Xylocaine). Tubes tend to be extruded after 6 to 12 months. For most children, this period is long enough to halt the secretory process of the middle ear. In others, tubes must be reinserted to continue the aeration.

**Figure 50.10** A myringotomy tube provides air to the middle ear to prevent otitis media with effusion.

When myringotomy tubes are in place, the child has to be careful to not allow water to enter the ears. It's better if they bathe rather than shower, but showering is all right if ear plugs are used, especially while washing hair. Similarly, swimming is either contraindicated or allowed only with ear plugs in place.

Because the course of the process is long term, the hearing impairment associated with the condition may also be long term. Urge parents to notify the school nurse that their child has compromised hearing because of the middle ear fluid and has myringotomy tubes in place. Children may need to move to the front of the class to mitigate difficulty hearing and encourage participation in class until the condition improves.

**QSEN Checkpoint Question 50.6**

**INFORMATICS**

Carla is diagnosed as having otitis media. When interpreting the documentation in Carla's electronic health record, the nurse should recognize that this diagnosis differs from otitis externa in what way?

- a. Otitis media occurs from swimming; otitis externa typically follows a common cold.
- b. Otitis media involves the middle ear; otitis externa involves the outer canal.
- c. Otitis media involves the eardrum; otitis externa involves the cochlear nerve.
- d. Otitis media does not cause pain; otitis externa produces throbbing pain.

Look in [Appendix A](#) for the best answer and rationale.

## The Hospitalized Child With a Hearing Impairment

Conversation is usually held between 50 and 60 dB so a hearing loss greater than 49 dB

is sufficient enough to interfere with hearing conversation and developing language. Like those who are visually challenged, children with hearing deficits may be hospitalized as a direct consequence of their ear disorder or from other health problems. It can be difficult for parents to prepare children with hearing deficits for hospitalization because they are unfamiliar with words such as “surgery,” “tonsils,” “hurts,” “operating room,” and “recovery room.” Showing the child illustrated books depicting anatomical landmarks and procedures is helpful. Allowing children time to play with dolls or puppets can help them understand hospital routine. Children who are hearing challenged may have additional challenges during hospitalization.

Always allow children with hearing impairment to see you before you touch them because they will not find this nearly as startling as being touched without warning. If children are sleeping when you approach them, use a light touch to waken them gently. Some children turn off their hearing aid or remove it while they sleep. You may need to turn it on before you call them to wake them, or they may need to replace the hearing aid as soon as they awaken. Children as young as 2 years of age are effective lip readers as long as you are facing them. Position yourself at eye level, so the child can view your face. In a group, help the child follow conversation by directing the child to the person who is speaking. Assign consistent staff members to decrease the number of people with whom the child must attempt to communicate. Have a staff person accompany the child and stay with the child in all departments to help with communication.

Do not underestimate the intelligence level of children with hearing impairment. Because they do not speak clearly, others may assume children with hearing impairment are cognitively challenged. As a result, they may not be given information that the average hearing child receives, such as explanations of how things work. On a hospital unit, children with hearing impairment are unable to express how they feel about procedures especially if providers are not familiar with sign language. They need help from healthcare personnel who understand these challenges and take sufficient time to offer explanations and provide support.

Ask parents of children who are hearing challenged to draw pictures or demonstrate the sign language symbols their children use for important words such as “pain,” “drink,” and “bathroom.” Encourage children to use or draw pictures of what they want if they are still too young to write words and if you cannot understand what they are saying.

Children with hearing impairment have the right to be provided with a sign language interpreter during care. Advocate for this, especially if the parents will not be continually present.

#### *What If . . . 50.4*

**A nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to vision and hearing disorders in children (see [Box 50.1](#)). What would be a possible research topic pertinent to this goal that would**

**be applicable to Carla's family and that would also advance evidence-based practice?**

## **KEY POINTS FOR REVIEW**

- Teaching preventive measures to avoid eye and hearing injuries (using proper eye protection during sports or play and wearing goggles or ear protection as appropriate) and screening children for sensory impairments are important nursing roles.
- Refractive errors of vision such as myopia and hyperopia are the most common eye disorders in children. Amblyopia is subnormal vision in one eye. Children with these disorders need correction at the time the disorder is recognized to prevent further vision distortion.
- Coloboma is congenital and involves the incomplete closure of the pupil or lower eyelid. Ptosis is the inability to open the upper eyelid normally. Ptosis needs correction to prevent the development of amblyopia. Strabismus is unequally aligned eyes. Like ptosis, it can lead to amblyopia if not corrected.
- Infections of the lids, such as styes or chalazia, can occur in children. Conjunctivitis (inflammation of the conjunctiva) often manifests with acute symptoms. An antibiotic is necessary for therapy.
- Eye injuries such as penetration by a foreign body need a follow-up after treatment to be certain vision remains adequate.
- Children who are either vision or hearing challenged need special preparation and orientation for a hospital or ambulatory health visit that not only meets QSEN competencies but also best meets a family's total needs.
- Help children who are vision challenged to work through new experiences by letting them feel equipment as much as possible. Guide their hands through the steps of a new procedure you are teaching them.
- Otitis media (a middle ear infection) is a common childhood illness. Some children who have otitis media with effusion have myringotomy tubes inserted to relieve pressure and to supply air access to the middle ear.
- Use photographs, drawings, or demonstrations with children with hearing impairment to help them learn new skills. Contact a sign language interpreter as appropriate to be certain that children understand instructions.

## **CRITICAL THINKING CARE STUDY**

Hannah, 11 years old, wears glasses because of a severe refractive difference in her eyes. She has had a severe hearing impairment since birth and wears a hearing aid. She is admitted to your unit for dehydration secondary to influenza. Her father tells you Hannah is proficient in American Sign Language and can also read lips fairly well.

1. What special precautions do you need to take to ensure Hannah is safe in the hospital environment?
2. Hannah's parents are separated; she spends 1 week a month with her mother and the other 3 weeks with her father. Her father worries she doesn't wear her glasses during the week she's with her mother. Her mother tells you she doesn't wear them when she's with her father. What suggestions could you make to remind her to wear the glasses?
3. You notice Hannah doesn't like the taste of the oral rehydrating solution, which she needs to drink to restore her fluid volume. When you check to see if she drank all of it, even though you know you faced her squarely and spoke loudly, she says she didn't hear you tell her to drink it. What would be a better way to communicate with Hannah?

## Nursing Care of a Family When a Child Has a Musculoskeletal Disorder

*Jeffrey, a 13-year-old boy, accompanies his mother and 3-year-old sister into the hospital emergency room because his sister has pain in her arm after a fall. As you talk to Jeffrey, you notice his left lower leg is swollen, warm to the touch, and painful. When he takes off his shirt, you notice his spine is not straight. His mother tells you she noticed an infected mosquito bite on his leg 2 weeks ago. After further evaluation, Jeffrey's sister is diagnosed with a fracture of her ulna; Jeffrey is diagnosed with osteomyelitis. His mother asks you, "I know our family is prone to orthopedic problems, but how could a bone infection happen from such a simple thing as an insect bite? Are you sure he's not developing muscular dystrophy like his uncle? Or is he just having growing pains?"*

*Previous chapters described the growth and development of well children and the nursing care of children with a disorder of other body systems. This chapter adds information about the dramatic changes, both physical and psychosocial, which can occur when a child develops a musculoskeletal disorder.*

**What other information does Jeffrey's mother need to know about bone infections? How would you explain to her what has happened?**

### KEY TERMS

**apposition**

**arthroscopy**

**cartilage**

**compartment syndrome**

**diaphysis**

**distraction**

**epiphyseal plate**

**epiphysis**

**fracture**

**malleoli**

**metaphysis**

**myopathy**  
**periosteum**  
**remodeling**  
**resorption**  
**sequestrum**  
**traction**

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe common musculoskeletal disorders in children.
2. Identify 2020 National Health Goals related to musculoskeletal disorders in children that nurses can help the nation achieve.
3. Assess a child with a musculoskeletal disorder.
4. Formulate nursing diagnoses related to a child with a musculoskeletal disorder.
5. Establish expected outcomes for a child with a musculoskeletal disorder that help children and parents manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care, such as helping a child with a musculoskeletal disorder meet optimal ambulation capacity.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of children's musculoskeletal disorders with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

The skeletal system, composed of more than 200 bones connected by the joints and tendons, provides the structural casing or protective armor for the internal organs of the body and supplies the body with red and white blood cells grown in the central marrow. Skeletal muscles, which are attached to the bones by connective tissue, tendons, and ligaments, allow for voluntary movement, including gross motor activities, such as running, and fine motor activities, such as writing. Together, the skeletal and muscular systems both support the body and make coordinated movement possible.

Because their bones and muscles are still growing, children suffer from disorders of the musculoskeletal system more frequently than do adults. The difference between adults and children is growth. Childhood **fractures** (break in the continuity or structure of bone) heal much more quickly than fractures do in adults and because a child's bone

grows from the epiphysis or growth plate, a fracture within this area may cause serious complication, such as a deformity. Nurses play a key role in teaching parents ways to expose children who have muscular or skeletal disorders to the same sorts of stimuli that might be experienced if they were able to move around independently. Because the maintenance of musculoskeletal function and locomotion is so important, these are addressed by 2020 National Health Goals (Box 51.1).

### BOX 51.1

#### Nursing Care Planning Based on 2020 National Health Goals

To maintain a healthy musculoskeletal system, proper exercise is necessary. Several 2020 National Health Goals address this, including:

- Increase the proportion of the nation's public and private schools that require daily physical education for elementary grade students from a baseline of 3.8% to 4.2%.
- Increase the proportion of the nation's public and private schools that require daily physical education for middle or junior high students from a baseline of 7.9% to 8.6% and for senior high students from 2.1% to 2.3%.
- Increase the proportion of adolescents who meet current federal physical activity guidelines for aerobic physical activity and for muscle-strengthening activity (developmental).
- Increase the proportion of children and adolescents aged 2 years through 12th grade who view television, videos, or play video games for no more than 2 hours a day from 78.9% to 86.8%.
- Increase the proportion of trips that children and adolescents make by walking (Developmental) (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by educating children about the importance of physical activity, serving as consultants for school systems in designing physical education programs, and being certain to ask children about their usual activity level at health maintenance visits.

#### *Nursing Process Overview*

### FOR CARE OF A CHILD WITH A MUSCULOSKELETAL DISORDER

#### **ASSESSMENT**

Unlike many other diseases in children, disorders of the skeletal system usually manifest with specific, localized symptoms; therefore, parents usually bring children to healthcare facilities early in the course of such illnesses. Disorders of the muscles or joints, however, such as juvenile idiopathic arthritis (JIA), may manifest insidiously; when the disorder is diagnosed, parents may feel guilty for not having sought health care earlier.

One condition whose seriousness parents may underestimate is a childhood limp. A limp is never normal, and it may be the first manifestation of a serious hip or knee problem. When weighing or measuring children at healthcare visits, take the opportunity to assess gait (whether a child walks naturally or stiffly, on tiptoes or on the whole foot; whether the feet are in good alignment; and whether the back is held straight). Such assessments may detect that a child brought to a healthcare center because of an upper respiratory condition, for example, has another, perhaps more important, musculoskeletal problem requiring an evaluation. It is also important to note that skeletal injuries can be a sign of child maltreatment; thus, careful history taking is necessary at all health visits (see [Chapter 55](#)).

### **NURSING DIAGNOSIS**

The nursing diagnoses most frequently identified for children with musculoskeletal disorders include those that deal with pain, lack of mobility, and, because of immobilization, a need for diversional activities. Children, especially adolescents, who require a walker or other equipment to aid in skeletal support or locomotion may encounter problems with self-esteem. Examples of some typical nursing diagnoses include:

- Pain related to chronic inflammation of joints
- Impaired physical mobility related to a cast on the leg
- Deficient diversional activities related to a need for imposed activity restriction for 4 weeks
- Situational low self-esteem related to the continuous use of a body brace

### **OUTCOME IDENTIFICATION AND PLANNING**

Many musculoskeletal problems in children require long-term care. Despite current therapies, some disorders may leave a child with a permanent disability. Before a child is discharged from an ambulatory or inpatient setting, help parents plan how they will manage any necessary restrictions at home. For example, at first, a cast on an arm seems exciting: It is something for a school-age child to show off and an excuse not to write in school. After a few days, however, the cast may feel more frustrating than enjoyable. Take the time, therefore, to review what wearing the cast will mean to the child in everyday situations. Will the cast fit through required school uniform shirts with tight cuffs? Will a preschooler with a large cast fit into a car seat? If the child must stay home from school, do the parents know how to arrange for tutoring? If both parents work outside their home, will they need to arrange for childcare?

Depending on the child's and family's circumstances, the answers to these problems can differ greatly. Taking the time to sit down with the parents and ask them whether these concerns will pose problems, however, not only initiates problem solving but also allows parents to prepare solutions with a concerned person rather than by themselves at home.

Referral to an appropriate organization can be helpful if a child has a long-term

condition. Examples of these are the Arthritis Foundation ([www.arthritis.org](http://www.arthritis.org)), The Muscular Dystrophy Association ([www.mda.org](http://www.mda.org)), the Osteogenesis Imperfecta Foundation ([www.oif.org](http://www.oif.org)), and the National Scoliosis Foundation ([www.scoliosis.org](http://www.scoliosis.org)).

### IMPLEMENTATION

Many nursing interventions for children with musculoskeletal disorders involve care of a child in a cast or in traction (treatment involving pulling on a body part in one direction against a counter pull exerted in the opposite direction) or teaching about common concerns, such as posture or children's shoes. Parents and children who are kept well-informed in these matters are much more likely to be able to cope with circumstances that occur from growth.

### OUTCOME EVALUATION

Children with musculoskeletal disorders invariably need follow-up care after discharge from an ambulatory visit or inpatient care because bone healing is a slow process. Both parents and children may need support at reevaluation visits if they learn that a cast or brace must stay on longer than they thought or if they must continue exercises. Praise for their management so far is an effective intervention for helping parents and the child realize that, because they have coped with the situation so far, they can continue to cope with the situation into the future.

During reevaluation visits, spend time assessing children's body image and self-esteem or the total effect of their condition on growth and development. The success of treatment cannot be achieved if a child's self-concept has been diminished by an injury or disease.

Some examples indicating achievement of outcomes include:

- Child states he feels no pain or numbness in the extremity after the application of a cast.
- Child demonstrates allowable weight-bearing activities with casted lower extremity.
- Parents accurately state the child's care needs both in and out of the hospital.
- Child states positive aspects of self, participates in activities, and establishes friendships with peers.

## The Musculoskeletal System

### BONES AND BONE GROWTH

Bones are generally classified by their shape as long (those found in extremities), short (those of the wrist or ankle), flat (those of the skull, ribs, scapula, and clavicle), or irregular (the vertebrae, the pelvis, and the facial bones of the skull).

The mark of a long bone is a lengthy central shaft (the **diaphysis**), a rounded end portion (the **epiphysis**), and a thin area between them (the **metaphysis**) (Fig. 51.1).

Increases in the length of long bones occur at the **cartilage** (connective tissue) segment (the **epiphyseal plate**), between the epiphysis and the metaphysis. Injury to this area in a growing child is always potentially serious because it may halt growth, stimulate abnormal growth, or cause irregular or erratic growth.

**Figure 51.1** The structure of a bone.

The central shafts of long bones are covered by an outer sensitive layer of **periosteum**. Bone width increases by growth at the inner surface of this. Injury to the periosteum, such as may occur with osteomyelitis, has the potential to also threaten bone growth (Tafin-Kampé & Kamsu-Foguem, 2013). Although it is easy to think of bones as rigid, solid structures, they are, in fact, active living tissue to which nutrients must be supplied for growth. Calcium, one of the main components of bone, is important for both original bone formation, **remodeling** (replacement of old by new bone tissue), and **resorption** (bone breakdown). These processes are strongly influenced by vitamin D and the parathyroid hormone calcitonin. “Bone age” in children can be determined by an X-ray of the wrist that shows the ossification level of the bones.

The inner core of long bones is filled with yellow and red marrow and is responsible for the formation of platelets, red blood cells, white blood cells, and adipose (fat) cells. Red marrow is primarily involved in blood component production, whereas yellow marrow is chiefly involved in adipose cell formation. The blood supply to bones is abundant so that the marrow can actively supply enough blood components for the entire body. As with other tissues, if the blood supply is cut off, bone cells die and blood cell production is hindered.

## MUSCLE

The skeletal muscular system is composed of striated muscle (differentiated from the

smooth muscle found in body organs, which is responsible for such activities as intestinal peristalsis). Activation of skeletal muscle occurs with innervation from a motor nerve and is under voluntary control. **Myopathy**, or disease of the muscular system, can be inherited (as in muscular dystrophy) or acquired (as in myasthenia gravis).

## Assessment of Musculoskeletal Function

In addition to a history and physical examination, diagnostic tests are frequently necessary to detect musculoskeletal dysfunction. These may include X-ray and bone scans, bone and muscle biopsies, electromyography, and arthroscopy. Ultrasound and magnetic resonance imaging (MRI) studies are used to reveal soft tissue disorders. Furthermore, obtain information on how parents and children are adjusting to a potential disability because poor acceptance of a condition can limit a child's potential as much as the physical involvement (Box 51.2).

### BOX 51.2

#### Nursing Care Planning to Respect Cultural Diversity

Economic globalization has led medical device companies to incorporate cultural diversity into the companies' engineering. Companies are now taking into account how cultural differences will influence effectiveness of medical device use.

Depending on the type of medical device and the developmental age of the child, caregivers are likely to be involved. This involvement may seem natural to most, but depending on the relationships between different family members, this is not always straightforward. When educating caregivers on medical devices, always assess the cultural and social context (the relationship between family members). Other cultural needs to be addressed may involve issues that appear simple, such as colors. In certain cultures, colors have significant meaning. For example, in Japan, the color red is associated with prosperity; because of this, the start button on IV pumps is not green but rather red (Liu, Hoelscher, & Yao, 2013).

## RADIOGRAPHY

Because bones are opaque, they outline well on an X-ray or computerized tomography (CT) scan to provide information about a specific bone or a joint. Other tests, however, are indicated to confirm problems with cartilage, tendons, and ligaments. X-rays in children are limited to the least number necessary for diagnosis or prognosis because excessive radiation is associated with the development of malignancies, such as leukemia (Adelstein, 2015). Radiation of epiphyseal plates can lead to uneven growth.

## BONE SCAN (SCINTIGRAPHY)

A bone scan is a study of the uptake by bone of intravenously injected radioactive substances ([American College of Radiology, 2014](#)). Areas of increased metabolic activity cause the substance to concentrate in that area, often providing information on very early stages of bone disease and healing, possibly before they are visible on an X-ray.

## ELECTROMYOGRAPHY

Electromyography studies the electrical activity of skeletal muscle and nerve conduction to determine the location and cause of disorders such as myasthenia gravis, muscular dystrophy, and lower motor neuron and peripheral nerve disorders ([Karakis, Liew, Darras, et al., 2014](#)).

For the test, surface electrodes are placed over the muscle or needle electrodes are inserted into the muscle. The electrical activity of the muscle at rest and in motion is then detected by audio amplification and recorded on an oscilloscope screen. Normally, resting muscle is quiet. If fasciculations are present, abnormal noises or oscilloscope spikes will be observed.

Although the needle electrodes are small, if they are used, the test can be frightening for children because they are pricked by needles. They need support from someone they know during the procedure. Before and after, provide opportunities for therapeutic play so a child can express anxiety and feelings about such an invasive procedure.

## MUSCLE OR BONE BIOPSY

Both muscle and bone biopsies involve removal of a tissue sample for examination of its microscopic structure. They can provide evidence about infection, malignant bone growth, inflammation, or atrophy of the area. Either type may be done during surgery or as an ambulatory procedure.

Biopsies of these types are usually done using conscious sedation or a local anesthetic. If local anesthesia is used, caution children they will feel the initial prick of an anesthetizing needle; they will then feel additional momentary pressure as the biopsy needle is inserted. You can assure them the amount of tissue that will be taken from them is no larger than the inner bore of the biopsy needle, comparable to the size of the graphite in a pencil.

## ARTHROSCOPY

**Arthroscopy** involves direct visualization of a joint with a fiber optic instrument. It is usually done under local anesthesia in an ambulatory care setting. Arthroscopy allows a joint, most commonly the knee, but also the hip, shoulder, elbow, or wrist, to be examined without a large incision. It is most often used to diagnose athletic injuries and to differentiate between acute and chronic joint disorders ([Jeong, Lee, & Ko, 2012](#)).

## Health Promotion and Risk Management

Health promotion for children with musculoskeletal disorders focuses on thorough assessment at all health maintenance visits. A child's ability to achieve developmental milestones, specifically gross and fine motor abilities, provides important information about musculoskeletal function. Screening for musculoskeletal disorders, such as for scoliosis in the prepubescent child and the adolescent, is an extremely important health promotion nursing role.

Safety precautions and anticipatory guidance for parents is essential to minimize the risk of injury, specifically to extremities. As a child grows and becomes active in sports, parental and child education about the importance of using bike helmets for bike riding, or protective gear for organized sports, takes on an even greater role.

Nutrition education is important to ensure adequate calcium and vitamin D intake for bone growth and healing. However, if a child requires bed rest, calcium intake should be moderated to reduce the risk of renal calculi formation resulting from immobilization. The teenage years are an important time for both males and females to build calcium stores to protect against osteoporosis later in life (Matkovic & Visy, 2015).

## Therapeutic Management of Musculoskeletal Disorders in Children

Various methods are used as therapy for children with musculoskeletal disorders, including casts, traction, distraction, and open reduction. Amputation, a rare necessity, is discussed in [Chapter 53](#).

### CASTING

Casts are used to treat a wide range of musculoskeletal disorders, from simple fractures in the extremities to correction of congenital structural bone disorders.

#### Cast Application

Casts are created from either plaster of Paris or fiberglass. Fiberglass is an attractive material to use for children's casts because it is light in weight; comes in attractive colors; and, when a special waterproof liner is used, can be immersed in water. Unfortunately, it is more expensive and may not be practical for casts that need frequent changing, such as those used to correct talipes disorders, a common congenital disorder that requires serial casting.

Children need an explanation of what to expect with casting. To maintain alignment of body parts, a healthcare provider may gently exert a pull on the body part being casted during the cast application. If a large body cast is being applied, children may be positioned on a special cast table with a traction apparatus at the chin and pelvis to

initiate tension. Allow a support person to accompany children to a cast room to hold their hand or talk to them during the application. Most children (and adults) are unaware that casts are formed from strips or rolls of material impregnated with the casting material. The normal curiosity of children as they watch a cast grow and mold to their body part usually makes casting a pleasant procedure. Some children voice that they regard the cast as a badge of courage, or at least, a conversation piece.

Before a cast is applied, a tube of stockinette is stretched over the area and soft cotton padding is placed over bony prominences. At the end of the application, the stockinette will be pulled up and over the raw edges of the cast to create a smooth, padded surface (Fig. 51.2). If a plaster cast is to be applied, caution children that, at first, the wet strips of plaster of Paris feel cool. Almost immediately, however, the strips begin to generate heat as evaporation begins and body parts start to feel warm. If the cast is a full-body cast, children may become uncomfortably warm, with perspiration possibly running from their forehead. Assure them this feeling of warmth is transient and is never enough to cause a burn.

**Figure 51.2** Cast application. (A) A cast is applied to a young boy's

leg over a stockinette. **(B)** Casts do not cover the toes so these can be assessed for color and warmth. (© Blend images/Alamy.)

A plaster cast takes 10 to 72 hours to dry depending on its size. Fiberglass casts usually dry within 5 to 30 minutes. A “window” may be placed in a cast if an infection is suspected, so that the area can be observed. If the child has a body or hip spica cast, windowing can prevent uncomfortable abdominal distention and allow bowel sounds to be assessed.

**Compartment syndrome** is a phenomenon that can occur when a cast or tight constrictive dressing puts pressure on an enclosed space such as the forearm. This pressure can result in severely decreased blood flow that potentially threatens damage to and necrosis of surrounding soft tissue or nerves. The pathophysiology of the condition remains uncertain, although mechanisms involving artery compromise are involved. An injury to a major artery with inadequate collateral circulation can lead to decreased perfusion and ischemia of both capillaries and muscles, resulting in an increase in permeability of the capillary walls and, ultimately, edema (Lee, Lightdale-Miric, Chang, et al., 2014).

Assess fingers or toes carefully for warmth, pain, and function after application of a cast to be certain a compartment syndrome is not developing. If signs of compartment syndrome are present, the cast will need to be released immediately to prevent permanent nerve and tissue damage. A fasciotomy (surgically opening the compartment) may be necessary to further prevent nerve damage.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for ineffective peripheral tissue perfusion related to pressure from cast

**Outcome Evaluation:** Child states she feels no pain or numbness in extremity; distal nail bed blanches and refills in less than 3 seconds; pedal pulses are palpable.

If an extremity has been casted, keep it elevated by a pillow to prevent edema. Check circulation frequently, such as every 15 minutes during the first hour, hourly for the next 4 hours, and then every 4 hours throughout the first day. Assess for color, warmth, presence of pedal or radial pulses, and sensations of numbness or tingling. Signs of impaired neurovascular function include pallor (including blueness or coldness of the distal part), pulselessness, pain in the casted part, paresthesia (numbness or tingling in the part, as if it were “asleep”), and paralysis. Children younger than 6 or 7 years of age have difficulty describing paresthesia; however, they may whine or cry with the discomfort of the sensation. Edema that does not improve

with elevation is also an important sign. Any of these symptoms requires immediate attention because neurovascular impairment can lead to nerve ischemia and destruction, possibly causing permanent paralysis of an extremity.

Preventing the flow of urine under the edges of a cast can be a problem with full-body or high-leg casts in non-toilet-trained children. If a cast surrounds the genital area, cover the edges with plastic or waterproof material to help keep it dry. Keeping children in a semi-Fowler position by using pillows or raising the head of the bed helps to direct urine and feces downward and away from the cast. Because a cast is heavy, infants tend to slip down in bed a great deal, so they need frequent repositioning to remain in this raised position.

If young children have a body cast, make certain they have a bib or cover over the top edge of their cast so crumbs or fluids do not spill inside. Choose toys carefully so small parts cannot drop inside. A piece of food inside a cast will mold and macerate the skin; a small part of a toy could cause irritation and a pressure ulcer. If food or fluid is spilled on the outside of the cast, the cast can be cleaned with a damp cloth.

**Nursing Diagnosis:** Parental health-seeking behaviors related to care of child with cast at home

**Outcome Evaluation:** Parents state plans for adapting home environment and lifestyle to accommodate child with cast; parents demonstrate measures to check neurovascular status.

If a child has an upper extremity cast, be certain the parents understand how to position the extremity properly, such as with a sling. If the cast is on a lower extremity, be certain parents and the child understand the amount of weight bearing allowed on the affected extremity and how to use crutches safely, if prescribed.

Handling a child in a large cast can seem so overwhelming for parents that they do not see how they will be able to care for their child at home. Assure them the child is quite comfortable in the cast despite its awkward, constricting appearance. Role model moving the child to show them that it is not an impossible task. Be sure to caution them that if an abduction bar is used with a cast, it must never be used as a handle for lifting. Such use can break the bar from the cast or weaken its support.

Parents need to use good body mechanics (lift with the thighs, not the back) when turning or positioning the child in a full-body cast. They may appreciate suggestions on ways to move the child from room to room, such as using a toy wagon with a flat board on top or using a skateboard for children to propel themselves forward. Point out that all children thrive on being touched. Children in large body casts need their head and arms stroked (or any areas of the body that are not covered by the cast) so they receive this. Demonstrate how even a child in a large hip spica cast can be held, cuddled, and supported for feeding.

Many children report a sensation of itching inside a cast at about the end of the first week. If the area is immediately under the edge of the cast, the itching is probably the result of dry skin caused by the drying effect of the cast. Reaching a

hand under the edge of the cast and massaging the area usually relieves the itching. Applying hand lotion may relieve the dryness. If the area is unreachable, blowing cool air through the cast with a fan or a hair dryer set on cool air may relieve the uncomfortable feeling. Caution both the child and parents not to use implements such as a coat hanger or knitting needle to scratch the area. These can injure the skin, causing an infection under the cast (Box 51.3).

### BOX 51.3

## Nursing Care Planning to Empower a Family

### CAST CARE AT HOME

**Q.** Jeffrey's sister has a fiberglass cast fitted onto her arm. Her mother asks you, "Is there any special things I have to do?"

**A.** Some helpful tips to care for your child's cast at home include:

- Keep the casted body part elevated on a pillow for the first day to decrease swelling.
- Observe the hands and fingers (the body part distal to the cast) for swelling or blueness and ask your child to move her fingers about every 4 hours for the first 24 hours. If she is unable to move her fingers or if she has swelling, blueness, or pain, telephone your healthcare provider. These signs could mean the cast is pressing on a nerve or constricting a blood vessel.
- Encourage usual activities so your child remains active but monitor strenuous activities, such as roughhousing, while the cast is in place.
- Ask your child to think through how wearing a cast will change her day, such as making it difficult to eat at preschool or to join in play at the playground, and brainstorm how to solve these problems.
- Explain to your child not to put anything inside the cast. If itching occurs, blowing some cool air into it from a hair dryer can be comforting.
- Keep the cast dry (cover it with a plastic bag to shower); no swimming is allowed. Remind her not to use magic markers for autographs because fiberglass is a porous material.
- Keep your return appointment for follow-up care because children can outgrow a cast rapidly. Outgrowing a cast can put pressure on nerves and can lead to permanent disability.

Transporting the child in a car, particularly fitting a bulky cast into an infant car seat, can be a major problem for parents. They may need to purchase a larger car seat than intended for their child to transport the child safely. Before any child with a cast is discharged from a healthcare facility, give parents a telephone number to call if they have any questions about cast care or their child's condition because they often

do not realize what questions they will have until they return home.

## Cast Removal

Most casts remain in place for 4 to 8 weeks and are then removed using an electric cast cutter with a rapidly vibrating, circular disk (Fig. 51.3). Cast cutters are frightening because the disk makes a very loud noise as it cuts through the cast material and also generates heat. To the child, the disk appears capable of cutting through not only the plaster but also an arm or leg as well. The person removing the cast usually demonstrates that the disk does not cut skin by touching a thumb to the edge of it. Not all children are totally convinced by the demonstration, however, and may require additional support while the disk moves from one end of a cast to the other, such as saying, “It’s all right to cry; I know this looks scary” or by holding your hands over the child’s ears to lessen the noise.

**Figure 51.3** Cast removal. (A) A cast cutter is used to begin the removal of a fiberglass cast on an adolescent’s leg. (B) The fiberglass

cast is lifted off. (C) The underlying stockinette and padding are removed. (© Will and Deni McIntyre/Science Source/Photo Researchers.)

The skin of the child's extremity looks macerated and dirty after a cast is removed; a good bath usually washes away most of this. If an arm has been casted in flexion, the elbow may feel stiff and even sore when the child is asked to extend it for the first time. Children often continue to use extremities with caution after a cast has been removed. Advise parents to allow children to begin using extremities again at their own pace. As children naturally play and reach for objects, they gradually forget to favor the arm or leg, and full function then returns. Once healing has taken place, the extremity is as strong as it was before the fracture. The child does not need to continue to favor the extremity to protect it from a second fracture.

## **MEDICAL BOOTS (FRACTURE BOOTS) OR SPLINTS**

In some instances, a fracture does not require a cast for immobility but can be immobilized by a supportive boot or splint. The child wears the boot or arm splint continuously as if it were a cast; an advantage is that, if a complication should occur, it can be readily removed by its Velcro attachments. Ask at return appointments if children who are prescribed boots or splints are wearing the immobilizer continually. Be certain children who say they take them off "a little" are not actually describing taking them off often and, therefore, are not receiving the support necessary for effective bone healing.

## **CRUTCHES**

Crutches are prescribed for children for one of three reasons: to keep weight off one or both legs, to support weakened legs, or to maintain balance. Usually, a physical therapist measures crutch length and gives beginning instruction in crutch walking. Being familiar with how crutches are measured and having crutch walking supervised not only allows you to offer emotional support to children as they learn to use crutches but also helps you assess progress at follow-up visits.

### **Fit and Adjustment**

If crutches are properly fitted, there should be a space of 1 to 1.5 in. between the axilla crutch pad and the child's axilla. When the child stands upright and places his hands on the hand rests of the crutches, the elbows should flex about 20 degrees. This degree of flexion ensures that when the child bears weight on the crutch, the body weight will be borne by the arm, not the axilla. Pressure of a crutch against the axilla could lead to compression and damage of the brachial nerve plexus crossing the axilla, resulting in permanent nerve palsy. Teach children not to rest with the crutch pad pressing on the axilla but to always support their weight at the hand grip.

Always assess the tips of crutches to be certain the rubber tip is intact and not worn through because the tip prevents the crutch from slipping. Be certain the child is walking with the crutches placed about 6 in. to the side of the foot. This distance furnishes a wide, balanced base for support.

Before discharge from a healthcare facility, explore with children any problems crutches may cause with their daily activities. If they carry books to school, for example, they will need to wear a backpack so their hands are free for the hand rests. Caution parents to clear articles such as throw rugs, small footstools, or toys out of paths at home.

### Crutch Walking

Two main crutch-walking patterns are used (Fig. 51.4). A two-point gait is used when a child needs support for weakened muscles or balance but may bear weight on both lower extremities. The child places the right crutch and left foot forward, then the left crutch and right foot forward, and so on. Using the crutch opposite a foot provides a wider base of support than using the crutch next to the foot. Caution children to take small steps until they feel confident.

**Figure 51.4** Crutch-walking patterns. **(A)** The two-point gait. **(B)** The swing-through gait.

A three-point swing-through gait is used when no weight bearing is allowed on one foot. For this, the crutches are both brought forward. The weight of the body is then shifted forward as both legs are swung through the crutches. The child bears weight on

the unaffected (good) leg and moves the crutches forward again. It takes strong arm support to bear full weight on crutches this way. Be certain the child is bearing weight on the hands and not on the axillae. Some children use a swing-through gait rather recklessly and need to be advised to slow their pace to a safer one.

To walk downstairs using a swing-through gait, children place their crutches on the lower step and then swing the unaffected (good) foot forward and down to that step. To go upstairs, they place their unaffected (good) foot on the elevated step and then raise the crutches onto the step and lift themselves up. To help children remember this pattern, the following saying can be taught: “Angels” (the good foot) go up; “devils” (the bad foot with the crutches) go down.

### *QSEN Checkpoint Question 51.1*

#### **INFORMATICS**

Jeffrey is prescribed crutches to take weight off his affected leg. What teaching point should the nurse include in his health education?

- a. His crutches should be at least 6 in. longer than he is tall.
- b. He should lean forward at a 45-degree angle while walking.
- c. He should bear weight on his arms to avoid pressure on his axillae.
- d. It is unsafe to walk downstairs with crutches; walking upstairs is acceptable.

*Look in Appendix A for the best answer and rationale.*

#### **TRACTION**

**Traction**, which is used to reduce dislocations and immobilize fractures, involves pulling on a body part in one direction against a counterpull exerted in the opposite direction. Although still necessary for some conditions, the use of intramedullary rods is making its use unnecessary in many instances. In straight (running) traction, the child’s body weight serves as the counterpull. In suspended or balanced traction, the body part is suspended by a sling, and the counterpull and primary pull are accomplished by pulleys and weights. Either skin traction (in which skin provides the counterpull) or skeletal traction (in which bone provides the counterpull) may be used. Skin traction is used if only minimal traction is necessary; the child’s skin must be in good condition for this procedure. Skeletal traction is used if a longer period of traction or a greater strength of traction pull is needed. Types of tractions are illustrated in [Figure 51.5](#). Use of traction in the home shortens hospital stays and enables a child to interact with family members, so it should be encouraged when possible.

**Figure 51.5** Types of skin traction: (A) Buck extension, (B) Russell, and (C) cervical skin traction. Types of skeletal traction: (D) balanced suspension, (E) 90 degrees, and (F) Dunlop traction with pin insertion.

## Skin Traction

Skin traction means a child's extremity is wrapped in a material such as an elastic bandage and then suspended from a nearby pole or frame so the weight of the body part produces traction. Bryant traction, used for fractured femurs in children younger than 2 years of age, is an example of skin traction (Fig. 51.6). It also may be used in preparation for surgical repair of congenital developmental disorders, such as developmental hip dysplasia (see Chapter 27). This type of traction is used less frequently now because the elevation of the extremities causes blood to pool at the hips. This and the possible tourniquet effect of the traction strips, bandages, and traction itself increase the risk for vasospasm and avascular hip necrosis.

**Figure 51.6** An infant in Bryant traction. It's important that the infant's hips do not rest on the bed due to bulkiness of a diaper. (© BSIP/Custom Medical Stock Photograph.)

Buck extension is an example of skin traction used for immobilizing lower extremity fractures in older children. Dunlop traction is used to immobilize an upper extremity. Cervical skin traction may be used to decrease muscle spasms in the back. This type of traction uses a halter-type device attached to weights. The head of the bed is elevated to provide countertraction.

### **Skeletal Traction**

Skeletal traction involves the use of a pin, such as a Steinmann pin, or a wire, such as a Kirschner wire, that is passed through the skin into the end of a bone. The pin or wire can be inserted in an emergency department under local anesthesia if the child can hold absolutely still, but usually, it is done under general anesthesia in the operating room. With skeletal traction, ropes strung over pulleys and attached to weights exert a pull on the extremity at the pin site. Cotton gauze squares are usually placed around the ends of the pin on the outside. The sites are cleaned with half-strength hydrogen peroxide using sterile technique to keep them free of drainage. Be certain to observe pin sites daily for drainage because odorous or excessive drainage or local erythema may be a sign of infection.

### **Traction-Related Care**

Children in traction need to be assessed carefully for neurovascular impairment, the same as children in casts. Assess the extremity in traction every 15 minutes during the first hour, hourly for 24 hours, and every 4 hours thereafter for signs of pallor (or

blueness), lack of warmth, tingling, absent peripheral pulse, edema, or pain. Traction can lead to hypertension because the head typically is positioned lower than the lower extremities. Assess once a day for this possibility by taking blood pressure readings.

Be extremely careful when changing a child's bed linens or carrying out nursing functions that you do not move the weights or interfere with the traction. Provide good skin care on the child's back, elbows, and heels because they may become irritated from friction against the sheets. A trapeze bar suspended over the bed provides a great deal of mobility and assists children in using a bedpan or positioning themselves in bed.

Being in traction is not as dramatic for children as being placed in a cast. There is an unspoken feeling from other children that "if what you have is really serious, you'd have a cast." Explain to children why this type of treatment is best for them. Keep parents and children informed of X-ray assessments (e.g., "The fracture is being held in just the right position; the bone is beginning to reform"). Although they cannot see progress, this information can help assure them that progress is occurring.

Children in traction usually are not "ill" children. They feel well except for the leg or arm being held in its correct position. Therefore, they have the energy and the need for stimulation of well children. Child life specialists or volunteers can be helpful in keeping them occupied. Being certain they are involved in activities (perhaps using a wireless computer or texting) is an important part of nursing care (Fig. 51.7).

**Figure 51.7** Children in skeletal traction need engaging activities and therapeutic play so they can remain in this confined position. (© Gary Wagner/Stock Boston.)

Helping children maintain contact with their school friends through cards, letters, or recorded messages, social media, or texting is also important. If hospitalized, position their bed so they can see unit activities. Whether at home or in the hospital, encourage

frequent visitors of their own age to help maintain peer relationships.

## DISTRACTION

**Distraction** is the use of an external device to separate opposing bones, which then encourages new bone growth. It can be used to lengthen a bone if one limb is shorter than the other. It also can be used to immobilize fractures or to correct defects if the bone is rotated or angled.

A device such as the Ilizarov external fixator is used to achieve distraction (Fig. 51.8). It consists of wires that are inserted through the bone then attached to either full or half rings, which are secured to telescoping rods. For bone lengthening, the rods are adjusted approximately 1 mm each day to stimulate bone growth until the desired length is achieved. The device remains in place until consolidation is complete; there is no pain, limp, or edema; and the bone is healed and can bear weight.

**Figure 51.8** An Ilizarov device in place to treat a comminuted fracture when bone is splintered or crushed.

Both the child and parents need thorough preparation for the surgery, application of the device, how it will appear, and the usual reaction of others to it (surprise). If it seems important to parents, provide suggestions of ways to minimize the device's appearance, such as wide-legged pants with adjustable closures. If parents will be adjusting the telescoping rods, providing care to the wire insertion sites, or restricting activity, be certain they have full and clear instructions on what to do as well as how to assess for signs and symptoms of infection. Ascertain that they have follow-up appointments because continued care is essential to ensure an optimal outcome for their child.

## OPEN REDUCTION

Open reduction is a surgical technique used to align and repair bone. If there is a spinal fracture or both bones of a forearm or lower leg are fractured, open reduction and insertion of a rod or screw (open reduction) stabilizes the bones.

Once an open reduction is completed, the area usually is casted to provide support. Invariably, at least a small amount of serosanguineous fluid oozes from the open reduction site into the cast. Outline with a ballpoint pen any stain that suggests oozing from a surgical incision, so that an increase in the size of the mark can be detected. Do not use a magic marker for this because the fluid tends to penetrate through the cast (use a pen or crayon). Add the time at which you make the mark so you can tell how rapidly the spot is increasing. Because children with an open reduction are prone to infection, the same as any child with a surgical incision, be aware as well of systemic symptoms (e.g., increased pulse, increased temperature, lethargy) as well as local signs (e.g., edema, pain, tingling, blueness or coolness of the distal extremity) of infection.

## Disorders of Bone Development

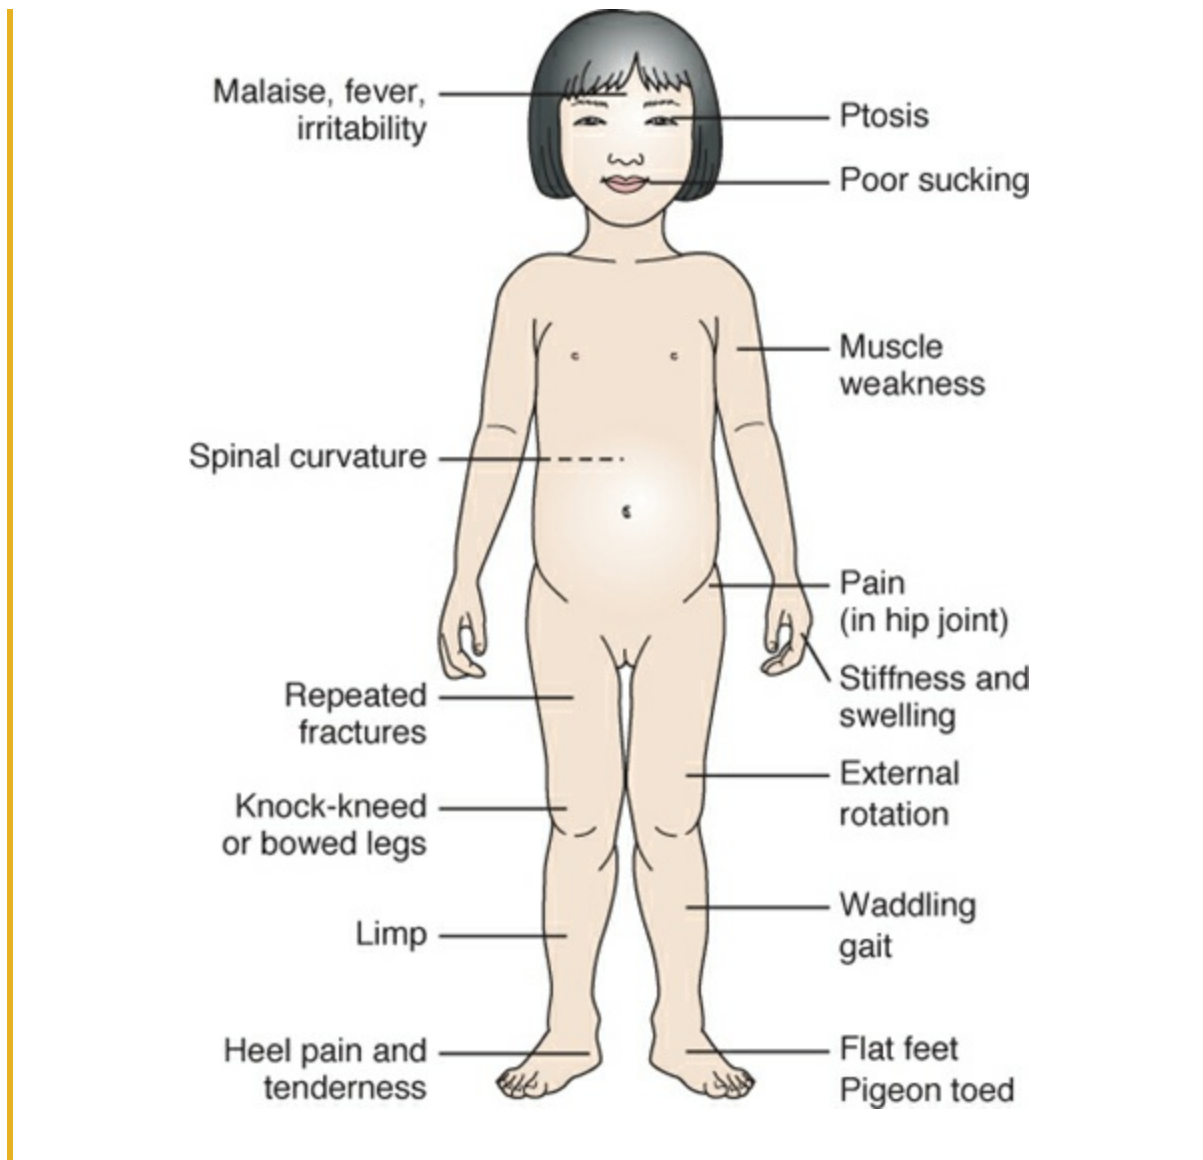

Many common musculoskeletal disorders in children are first noticed during routine physical exams (Box 51.4).

BOX 51.4

### Nursing Care Planning Using Assessment

#### ASSESSING A CHILD FOR SIGNS AND SYMPTOMS OF A MUSCULOSKELETAL DISORDER

## FLAT FEET (PES PLANUS)

The term *flat feet* refers to relaxation of the longitudinal arch of the foot ([American Academy of Orthopaedic Surgeons \[AAOS\], 2013](#)). Although it is rare, many parents become concerned because their newborn's foot is flatter and proportionately wider than an adult's foot. In actuality, a transverse arch rarely is visible in newborns, and a longitudinal arch may not be present until the child has been walking for months.

Evaluate children's feet at healthcare visits by having them stand on tiptoe. In this position, a longitudinal arch should be visible. Observing whether children are able to stand on their heels with the soles of the feet off the ground is another good assessment. Lastly, examine the ankle joint to be certain a full range of motion is present and the Achilles tendon is not shortened. Tarsal and metatarsal joints should also show a full range of motion.

Some children experience foot pain at the end of the day because of poor arch development. Their arch can be strengthened and the pain diminished if the child walks

on tiptoe for 5 to 10 minutes daily or practices picking up marbles with the toes. For an older child, standing pigeon toed (toes pointed in) and throwing the weight forward onto the lateral aspect of the feet also tends to strengthen arches.

Children do not need a high top or rigid shoe in order for the arch to develop. A sneaker is an example of a shoe that not only offers enough support but that also allows normal arch development.

## BOWLEGS (GENU VARUM)

Genu varum is lateral bowing of the tibia. If this is present, the **malleoli** (rounded prominence on either side of the ankles) will be touching and the medial surfaces of the knees will be more than 2 in. (5 cm) apart (Fig. 51.9A). Children develop this condition as part of normal development; it is seen most commonly in 2-year-olds. It also can occur in athletes who play load-bearing sports such as football (Zbinden, Rutz, Jacobson, et al., 2015).

**Figure 51.9** (A) Genu varum. (B) Genu valgum.

Record the extent of the bowing at health maintenance visits by approximating the medial malleoli of the ankles and measuring the distance between the patellas (knees) for changes. Genu varum gradually corrects itself in young children by about 3 years of age or, at the latest, by school age. If the problem is unilateral, becomes rapidly worse, or persists beyond this time, the child needs referral to an orthopedist for further evaluation.

## **KNOCK KNEES (GENU VALGUM)**

Genu valgum, or knock knee, is the opposite of genu varum. The medial surfaces of the knees touch, and the medial surfaces of the ankle malleoli are separated by more than 3 in. (7.5 cm) (see [Fig. 51.9B](#)).

This is seen most commonly in children 3 to 4 years old and corrects itself by school age as the child grows. Children who continue to have this problem and those in whom the abnormality is unilateral or becomes more pronounced need a referral to an orthopedist for further evaluation because obesity as well as both vitamin D and calcium deficiencies can cause the deformity.

## **BLOUNT DISEASE (TIBIA VARA)**

Blount disease, also known as tibia vara, is a developmental disorder of unknown etiology that primarily affects the posteromedial portion of the proximal tibial growth plate and results in bowed legs. Unlike the normal developmental aspect of genu varum, Blount disease is usually unilateral and is a serious disturbance in bone growth that requires treatment ([Sabharwal, 2015](#)).

Because it is not possible to rule out Blount disease by appearance alone, almost all children with bowed legs have an initial X-ray to identify if Blount disease is present. In those with Blount disease, the medial aspect of the proximal tibia will show a sharp, beaklike appearance on X-ray.

Either bracing or osteotomy may be necessary to correct this deformity or prevent it from becoming more severe. Parents may need an explanation of why their child requires treatment or surgery when another child on their block with a similar appearance (developmental genu varum) is predicted to outgrow the problem.

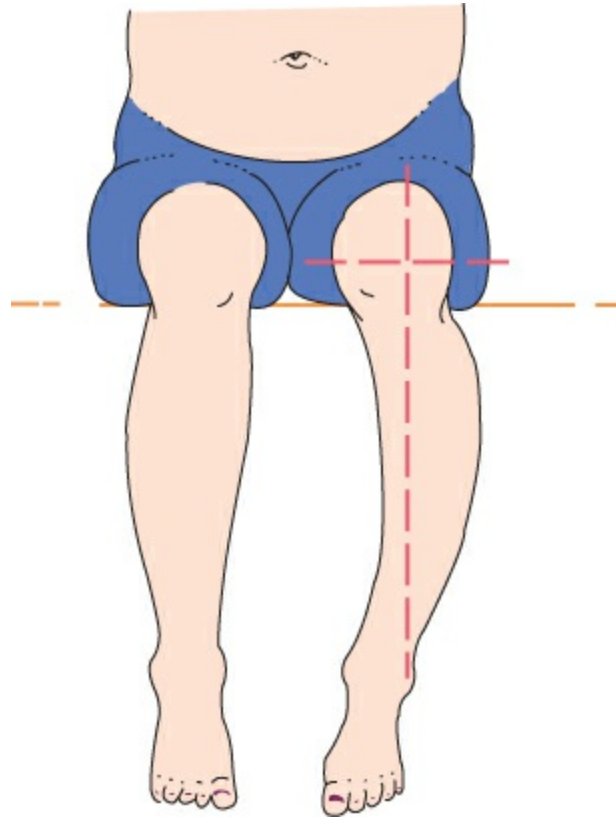

## **TOEING-IN**

Toeing-in may occur as a result of foot, tibial, femoral, or hip displacement. Assess for these conditions if parents describe their child as “always falling over the feet” or “awkward.” *Metatarsus adductus* is turning in of the forefoot. The heel is in good alignment; only the forefoot is turned in. This condition may develop or become more pronounced in infants who sleep prone with the feet adducted and in older children who watch television by kneeling and turning their feet in. If you stand the child on a copying machine and make a print, the turning in of the foot can be well demonstrated.

Most instances of metatarsus adductus resolve without therapy. Those that persist beyond 1 year can be corrected by passive stretching exercises; a few infants with extremely rigid, incorrect foot posture may require casts or splints for correction. Early detection of these extreme instances is important because treatment for metatarsus adductus is most effective if it is begun before an infant walks. With early treatment, the prognosis is excellent.

Inward tibial torsion also may be evidenced as toeing-in. This condition is diagnosed when a line drawn from the anterior superior iliac crest through the center of

the patella intersects the fourth or fifth toe (or a position even more lateral) (Fig. 51.10) because, ordinarily, such a line should intersect the second toe.

**Figure 51.10** Toeing-in caused by inward tibial torsion. In good alignment, a line drawn from the anterosuperior iliac crest through the patella should intersect the second toe.

Tibial torsion usually improves as the tibia grows, so this requires no treatment. Parents need a good explanation of why no treatment is necessary, however. Reassure them at periodic health maintenance visits that patience and time will correct tibial torsion (Mudge, Bau, Purcell, et al., 2014). Inward femoral torsion can be detected if you ask a child to lie supine and attempt to rotate the leg internally and then externally at the hip. Normally, internal rotation is about 30 degrees, and outward rotation is about 90 degrees. With inward femoral torsion, the internal rotation is closer to 90 degrees. In some children, the femur rotates so far that the patellar bones face each other. As with tibial torsion, no treatment is necessary. Inward femoral rotation will not correct itself, but a compensating tibial torsion will develop and make feet appear straight.

A fourth cause of toeing-in may be improper hip placement or developmental hip dysplasia, a problem that is very serious and needs early therapy for correction (see Chapter 27).

## GROWING PAINS

Listen to parents carefully when they state their child has “growing pains” because what

they are reporting may be symptoms indicative of rheumatic fever or JIA rather than a simple, transient phenomenon. Growing pains occur most frequently in the muscle of the calf, never in a joint. They are reported most often in preschool- and school-age children, who wake at night because of the pain. Such cramping usually follows a day of vigorous activity or wearing new shoes with a heel of a different height than before. Some children, especially adolescents, who report they have growing pains may actually be reporting restless leg syndrome. This syndrome (involuntary leg movements that cause insomnia) is thought to be associated with genetics and brain iron deficiency that causes decreased dopamine production (Hoogwout, Paananen, Smith, et al., 2015; Stehlik, Ulfberg, Hedner, et al., 2014).

## OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta is a connective tissue (collagen) disorder in which fragile bone formation leads to recurring (pathologic) fractures (Morello & Esposito, 2012). Although as many as eight types have been identified, the disease occurs most frequently as a severe autosomal dominant form that is recognized at birth (osteogenesis imperfecta type I) or an autosomal recessive form where symptoms, including hearing and cardiovascular anomalies, develop later in life (osteogenesis imperfecta type III).

Children with type I disease may be born with countless fractures already present from the force of birth. They develop many more fractures from the everyday activities of childhood. X-rays reveal a particular ribbonlike or mosaic pattern in their bones, which aids in diagnosis. The sclera of the eye is unusually blue because of poor connective tissue formation.

Children with the type III form may have associated deafness and dental deformities (Morello & Esposito, 2012). In both instances, the major clinical manifestation is a tendency for bones to fracture easily because of the poor collagen formation. In some children, the bones are so fragile that fractures can result not only from trauma, such as a fall, but also from simple walking. Because the child has such frequent injuries, parents may be accused of child maltreatment before the child's condition is firmly diagnosed and documented (Morello & Esposito, 2012).

As the child grows older, the multiple breaks tend to cause limb and spinal column deformities, interfering with alignment or growth. Lessened rib motility leads to interference with respirations. Bisphosphonates are widely used in the palliative treatment of osteogenesis imperfecta with the intention of reducing fracture risk. Bisphosphonates increase bone mineral density (BMD) but do not prevent fractures (Hald, Evangelou, Langdahl, et al., 2015). Lightweight leg braces or intramedullary rod insertion techniques may also be prescribed (Morello & Esposito, 2012).

Parents need to protect children from trauma, fractures need to be aligned and casted, and children need to be educated about a lifestyle that is productive yet minimizes the risk of trauma. Always be careful when caring for a child with this disorder not to cause any trauma to bones. Be certain to raise side rails on cribs or beds. Keep floors dry, and remove objects that could cause falls. Always lift children gently

and avoid lifting them by a single arm or leg to avoid placing strain on a bone.

### *What If... 51.1*

**Jeffrey's parents report that he has been waking up at night because of "growing pains." Is there such a thing? What might "growing pains" actually suggest?**

## **LEGG-CALVÉ-PERTHES DISEASE (COXA PLANA)**

Legg-Calvé-Perthes disease is avascular necrosis (a lack of blood flow resulting in destruction) of the proximal femoral epiphysis (AAOS, 2015b). The disorder occurs more often in boys than in girls and has a peak incidence between 4 and 12 years of age. It usually occurs unilaterally but may occur bilaterally.

A child with Legg-Calvé-Perthes disease looks well and often has no fever. The child is ambulatory and can have a limp, which may be subtle. There is little pain on motion of the hip, but there is guarding of the hip while moving it (Cook, 2014). X-ray studies distinguish the condition from simple synovitis (inflammation of the hip joint), which begins with the same symptoms. X-ray changes may not be apparent when a child is first seen, but they appear after about 3 weeks. For this reason, most children seen for synovitis of the hip joint are asked to return in 3 weeks for a repeat film.

Children with Legg-Calvé-Perthes disease pass through four stages. First is the synovitis stage or a period of painful inflammation. Next is a necrotic stage, during which bone in the femur head shrinks in size and shows increased density on an X-ray. This stage lasts 6 to 12 months. The third stage is a fragmentation stage; resorption of dead bone occurs over a 1- to 2-year period. The fourth stage, a reconstruction stage, marks the final healing, with deposition of new bone.

Treatment for Legg-Calvé-Perthes disease in children younger than 6 years of age usually focuses on pain reduction with nonsteroidal anti-inflammatory drugs (NSAIDs) plus keeping the head of the femur within the acetabulum by a containment device. The acetabulum then acts as a mold to preserve the shape of the femoral head and maintain range of motion. In children older than 6 years of age, reconstructive surgery (an osteotomy to center the femur head in the acetabulum followed by cast application) is most often prescribed. This technique returns the child to normal activity within 3 to 4 months in contrast to many months of restricted activity required by non-weight-bearing devices (AAOS, 2015b).

Parents and children need thorough education about treatment and care because most of this occurs on an ambulatory basis. It can be difficult for young children to accept the extended treatment period involved with this disorder. Be certain that both parents and children understand there are long-term consequences if rest is not followed conscientiously. Without treatment, the femur head tends to remold into a mushroom shape, making the hip unstable thereafter and leading to degenerative changes later in

life, which lead to chronic pain, reduced mobility of the hip joint, and possibly permanent disability. Parents may need assistance with devising appropriate activities for the child during the time that activity is limited and weight bearing is not allowed.

## **OSGOOD–SCHLATTER DISEASE**

Osgood–Schlatter disease is the thickening and enlargement of the tibial tuberosity resulting from microtrauma probably caused from overuse (AAOS, 2015a). It occurs more often in boys than girls and at preadolescence or early adolescence probably because of rapid growth at these times. Children notice pain and swelling just below the knee that is aggravated by running or squatting.

Therapy depends on the extent of the bone changes. Administration of NSAIDs, ice, and limiting strenuous physical exercise may be all that is necessary for effective healing (Kabiri, Tapley, & Tapley, 2014). Occasionally, immobilization of the leg in a walking cast or immobilizer for about 6 weeks may be required.

## **SLIPPED CAPITAL FEMORAL EPIPHYSIS**

Slipped capital epiphysis is, as the name implies, a slipping or displacement of the capital femoral epiphysis (femoral head) from the femoral neck (metaphysis) through the epiphyseal plate (Bennison & Horn, 2015). The proximal femoral head displaces posteriorly and inferiorly, allowing an avascular necrosis—similar to that observed in Legg-Calvé-Perthes disease—to begin. If the cartilage covering the femur head is destroyed, permanent loss of motion of the femoral head in the acetabulum can result. Surgical reconstruction of the hip joint will then be necessary to correct the problem (Loder & Dietz, 2012).

This disorder occurs twice as frequently in young Blacks than in children of other races and twice as frequently in boys as in girls. It occurs most frequently in preadolescence and its highest incidence is in obese children. This suggests that it occurs because of the influence of growth hormone and excessive weight bearing on the hip joint.

The onset of symptoms occurs gradually. Children begin to limp as well as hold the leg on the affected side externally rotated to relieve stress and pain in the hip joint. Although the involvement is actually in the hip, they may report pain first in the knee because favoring the hip joint puts abnormal stress on the knee. On physical examination, internal rotation of the hip is difficult and painful. An X-ray reveals the slipped epiphysis at the femoral head.

Early detection of the condition is important because correction is easiest if it is attempted before the necrosis has progressed to epiphyseal destruction. Percutaneous in situ fixation remains the standard of care for stable slipped capital femoral epiphysis. The goal of this treatment is to prevent further slippage and achieve stable closure of the proximal femoral physis while avoiding potentially devastating complications such as osteonecrosis and chondrolysis (Escott, De La Rocha, Jo, et al., 2015). In some

children, a total hip replacement is advised to fully restore hip function (Traina, De Fine, Abati, et al., 2012). With either surgery, the child will have activity restrictions for an extended time afterward.

Because the disease is most common in preadolescence, help children to understand the potential seriousness of the condition. Although they may not like being restricted or confined to bed, supportive communication and education can help them accept the treatment as necessary to maintain good healing and function of their hip joint. Encourage frequent visits and telephone calls with friends to provide optimal growth and development.

Although this condition usually is unilateral, some children later develop the same condition in the opposite hip. All children with a slipped capital epiphysis, therefore, need follow-up care, with careful attention to the condition of the opposite hip. If children are obese, they need nutritional counseling to bring weight back to a healthy level and to relieve strain on the lower extremities.

### *What If . . . 51.2*

**A nurse notices Jeffrey is overweight. He also rarely eats green vegetables. Although he just participated in a 2-mile school walkathon, he said it wasn't as much fun as he thought it would be. Which of his features make him at highest risk for developing slipped capital epiphysis?**

## Infectious and Inflammatory Disorders of the Bones and Joints

All bone infections are potentially dangerous because bones have such a rich blood supply that infection can easily spread and become systemic (septicemia).

### OSTEOMYELITIS

Osteomyelitis is an infection of the bone (Tafin-Kampé & Kamsu-Foguem, 2013). Acute osteomyelitis is often the result of a hematogenous spread of bacteria such as *Staphylococcus aureus* in older children and by *Streptococcus pyogenes* in younger children. Children with sickle-cell anemia have a special susceptibility to *Salmonella* invasion in long bones. The infection may occur after extensive impetigo, burns, or something as simple as a furuncle (skin abscess) when the infectious organism is then carried through the blood supply to the bone. It also may occur directly by outside invasion from a penetrating wound, open fracture, or contamination during surgery.

The age of the child often determines where the infection will take place. In children younger than 1 year of age, the capillaries near the epiphysis are often the transport for bacteria. In older children, the rich sluggish blood flow makes the metaphysis the most common site based on the location of the vascular sinusoids (Schreiber, Illingworth, &

Ward, 2016).

## Assessment

Osteomyelitis usually begins with acute symptoms. Children show systemic malaise, fever, and irritability. They experience sharp pain at the bone metaphysis site. By the second day, the area of skin over the infected bone feels warm to the touch, and edema is also usually present. Edema formation is serious because it reduces the blood supply to a large expanse of bone, causing the death of bone tissue. This dead bone tissue, which appears dense on an X-ray, is called **sequestrum** and is an important marker for diagnosis. An MRI can be helpful to reveal if the infection has spread to nearby soft tissue (Kim & Rosenblum, 2014).

Diagnostic labs will reveal an increased white blood cell count, C-reactive protein level, and sedimentation rate; blood culture results usually are positive for the offending organism. CT scans are helpful to demonstrate early-stage bone changes. Simple X-rays, in contrast, may not reveal bone changes (the formation of sequestrum) until 5 to 10 days after the beginning of the infection.

## Therapeutic Management

Medical therapy includes a limitation on weight bearing on the affected part, bed rest, immobilization, and a short administration of an intravenous (IV) antibiotic such as oxacillin, as indicated by the blood culture. IV therapy is usually initiated in the hospital and then continued at home for as long as 2 weeks by use of an intermittent infusion device or peripherally inserted central catheter (PICC). After this, the child will be prescribed an oral antibiotic for 3 to 4 more weeks.

If pus forms under the periosteum, it may be aspirated using a technique similar to bone marrow aspiration. After the procedure, a catheter may be inserted into the area for instillation of an antibiotic solution. A drainage tube may be inserted and attached to suction to evacuate the subperiosteum area.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Parental health-seeking behaviors related to care of the child with osteomyelitis

**Outcome Evaluation:** Parents accurately identify child's care needs in the hospital and at home; parents demonstrate procedure for IV antibiotic administration.

When planning care for a child with osteomyelitis, because of the long-term immobilization that may be necessary, parents may need to make major changes in their lifestyle such as taking a temporary leave from work or employing a home care

nurse.

Parents usually have many questions when osteomyelitis is diagnosed because the defect may not initially show on a routine X-ray. This can leave them puzzled as they hear their primary healthcare provider advising them about the need for 6 weeks of antibiotic therapy. They need support and education to make an informed decision about treatment because they may be suspicious, anxious, and afraid that hospitalization and administration of IV antibiotics are excessive. Keep in mind that young children are active even if they are on bed rest and need age-appropriate activities so they maintain rest, not activity. If a child had surgery and drainage tubes are in place, institute infection-control precautions because the drain evacuates infected material. Always handle the extremity gently when giving care because movement can cause pain. Provide instructions to the parents about good food sources of calcium and protein for bone healing.

When the child is discharged from the hospital, review measures to care for the antibiotic IV line with parents if this will be continued at home. Also, review the signs and symptoms of reinfection, measures for wound care and infection control, and possible adverse effects of the prescribed antibiotic (see [Box 51.5](#), an interprofessional care map for a child with osteomyelitis). Ask if parents would like a referral for home care follow-up to ensure continued support and education.

## BOX 51.5

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR A CHILD WITH OSTEOMYELITIS

Jeffrey, a 13-year-old boy, accompanied his mother and 3-year-old sister into the hospital emergency room because his sister had pain in her arm after a fall. As you talked to Jeffrey, you noticed his left lower leg was swollen, warm to the touch, and painful. When he took off his shirt, you noticed his spine was not straight. His mother said she noticed an infected mosquito bite on his leg 2 weeks ago. Jeffrey is diagnosed with osteomyelitis and admitted to the hospital for intravenous antibiotic therapy. His mother asks you, “How could he get a bone infection from such a simple thing as an insect bite? Are you sure he’s not just having growing pains?”

**Family Assessment:** Child lives with 10 and 3-year-old sisters and two parents. Father works as a family court judge. Mother works part time as a court reporter. Child rates finances as, “Okay. Although I’d like a better bicycle.”

**Patient Assessment:** Left lower extremity pale but warm; pedal pulses present. Capillary refill time in toes is 3 seconds. States he had pain on admission, rated at 4 on a numerical scale of 1 to 10. Relieved with prescribed ibuprofen. During morning assessment, child states, “I’m so bored. If I have to stay in bed for a whole week, I’ll go stir crazy.” Child normally enjoys playing baseball with friends and video games.

**Nursing Diagnosis:** Risk for peripheral neurovascular dysfunction related to the effects of bone infection

**Outcome Criteria:** Child's extremity remains pink and warm with palpable pedal pulses and capillary refill time of 3 seconds or less; pain is no more than 2 on a scale of 1 to 10; states he is complying with bed rest by choosing activities carefully.

<b>Team Member Responsible</b>	<b>Assessment</b>	<b>Intervention</b>	<b>Rationale</b>	<b>Expected Outcome</b>
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess whether child understands he should not bear weight on affected leg.	Review with child the importance of not bearing weight on infected leg.	Infected bone is weakened, and so it could fracture more easily than usual.	Child states he understands he should not put pressure on leg.
<i>Teamwork and Collaboration</i>				
Nurse/primary healthcare provider	Assess whether orthopedic service will be needed to consult on antibiotic therapy.	Consult with orthopedic service if needed to assure antibiotic regimen is adequate.	Bone infections are deep seated, so antibiotics must be selected for specific organisms and tissue penetration.	Orthopedic service consults as necessary to help decide best therapy.
<i>Procedures/Medications for Quality Improvement</i>				
Nurse	Assess whether child has past experience with intravenous (IV) therapy.	Orient child to IV therapy and importance of small armboard to guard against infiltration.	Infiltration interferes with antibiotic infusion and can cause tissue necrosis.	Child states he understands importance of continuous IV therapy and will work to guard site.
<i>Nutrition</i>				
Nurse/nutritionist	Meet with child to discuss what are his favorite foods.	Discuss importance of not gaining weight while on bed rest.	Child will be fitted with an orthopedic brace for his back. Gaining weight will	Child states he understands the importance of not gaining weight and will cooperate with nutritionist's

interfere with recommendations.  
correct fit.

*Patient-Centered Care*

Nurse	Assess what child understands about the cause of bone infections.	Review association between skin infection and osteomyelitis.	Osteomyelitis is often caused by extension of a skin infection such as impetigo or infected insect bite.	Child and mother state they understand outcome should not result in loss of function.
-------	---	--	--	---

*Psychosocial/Spiritual/Emotional Needs*

Nurse	Assess what activities child would enjoy during bed rest.	Talk to child about importance of keeping busy because he will not feel systemically ill during this time.	Bed rest is difficult for children when they feel well except for one body part.	Child names at least two activities besides schoolwork he could do to keep busy and help relieve boredom.
-------	---	--	--	---

*Informatics for Seamless Healthcare Planning*

Nurse	Assess whether child has had experience taking oral medication at home.	Explain necessity to continue antibiotics even though symptoms are lessening.	If child does not understand purpose of long-term therapy, he may neglect to take antibiotic once symptoms fade.	Child and mother state they understand importance of continuing antibiotic and will keep the return appointment.
-------	---	---	--	--

Most children recover without serious consequences; however, if osteomyelitis is not entirely eradicated with the initial treatment, it will return and result in a chronic infectious process with open, draining sinuses and bone deformity in years to come. Growth plates can be destroyed, leading to shortening of the affected extremity.

**QSEN Checkpoint Question 51.2**

**SAFETY**

A nurse is planning care for Jeffrey, who has osteomyelitis. Which of the following

interventions should the nurse prioritize in the care plan?

- a. Maintain Jeffrey's IV antibiotic therapy.
- b. Teach his parents about the root causes of his infection.
- c. Restrict his fluid intake to increase his hematocrit level.
- d. Fully assist Jeffrey with his activities of daily living.

---

*Look in [Appendix A](#) for the best answer and rationale.*

---

## TRANSIENT SYNOVITIS

Transient synovitis is an acute, nonpurulent inflammation of the synovial membrane of a joint that occurs most commonly in the hip joint in children, with an age of incidence between 2 and 10 years, peaking at age 6 years. The exact etiology is unknown; however, there is usually a prodrome of upper respiratory symptoms (Cook, 2014). Children notice pain in the groin, in the lower portion of the thigh or knee, or in the buttocks. Pain is intense and is most noticeable in the morning when they first awaken. Children may wake at night or in the morning, crying from the pain of turning over. Pain again becomes worse later in the day when the child becomes tired.

Aside from the localized pain, children feel well except they usually hold the joint flexed in a position of comfort. On physical examination, a child with transient synovitis will look well, often playing with toys in the examination room but not moving the hip. There is no or, at most, low-grade fever ( $<38^{\circ}\text{C}$ ). There can be pain of the hip with passive range of motion. Unlike a child with a septic hip who refuses to walk, the child with transient synovitis may also refuse to walk or will walk with a limp (Cook, 2014). A pelvic X-ray or MRI may reveal capsular swelling at the involved joint.

Because this is inflammation, not infection, the treatment of synovitis is the prescription of an NSAID such as ibuprofen (Motrin) and limited activity until muscle spasm from the pain has passed. In most children, a few days of rest reduces the synovitis. Some children, however, may need as many as 10 to 14 days of rest and a short course of oral corticosteroids to completely reduce the symptoms.

Synovitis must be differentiated from septic arthritis or Legg-Calvé-Perthes disease based on child's age, presentation, and diagnostic markers. Septic hip tends to occur in younger children ( $<2$  years), and Legg-Calvé-Perthes typically occurs between the ages of 4 and 9 years. Children with septic hip typically look ill, and the joint will be held in a position that maximally increases the volume of the affected joint (Cook, 2014). Children with Legg-Calvé-Perthes disease look well and often do not have fever. The child is ambulatory and can have a limp, which may be subtle. There is little pain on motion of the hip, but there is guarding of the hip while moving it (Cook, 2014).

Explain to both children and parents that synovitis, although painful, is a simple inflammation process that will heal without sequelae. Rest is important for this recovery, however, so they must be prepared to enforce this (which is not easy to do with active children).

## APOPHYSITIS

Calcaneal apophysitis (sever injury/disease) is considered an overuse injury that is self-limiting. It is a common injury in active, often overweight, predominantly male children. Symptoms usually start between the age of 8 and 15 years in boys and 8 and 13 years in girls (Aiyer & Hennrikus, 2014; Wiegerinck, Zwiers, R., Sierevelt, et al., 2016).

Pain usually can be relieved by adding a lift or cup to the heel of shoe on the affected side, thus reducing the tension on the heel cord and bone. Other helpful treatment modalities include ice application before and after athletic events, nonsteroidal anti-inflammatory medications, and possible activity modification. After the pain has subsided, the adolescent needs to practice exercises to stretch the heel cord, such as standing on a slanting board that elevates the foot and toes above the level of the heel for 20 minutes about three times a day.

Although not a serious condition, it can be debilitating for adolescents who want to excel in sports because it may recur.

## Disorders of Skeletal Structure

Spinal disorders in children may include kyphosis (an outward curvature of the cervical spine) or lordosis (an inward curving of the lumbar spine), but idiopathic scoliosis (an S-shaped curve) is the most commonly seen type of these disorders.

### FUNCTIONAL (POSTURAL) SCOLIOSIS

Scoliosis is a three-dimensional spine deformity characterized by lateral and rotational curvature of the spine (AAOS, 2015c). The spinal deformity is characterized by a lateral (sideways) curve of the spine of 10 degrees or more (Hresko, 2013). Scoliosis affects the spine in all three planes: axial, coronal, and sagittal. It may involve all or only a portion of the spinal column, such as the thoracic vertebrae. It may be functional (a nonrotated spinal curve caused by a secondary problem, such as a leg length discrepancy) or structural (a primary deformity such as an underlying neuromuscular disorder). Scoliosis may also be the initial presenting sign of underlying conditions such as heritable collagen diseases, neurologic conditions, or skeletal dysplasia that may have been undetected until adolescence (AAOS, 2015c).

### STRUCTURAL SCOLIOSIS

The most common form of scoliosis occurs in or near adolescence and is termed *idiopathic scoliosis* (Fig. 51.11). The primary curve is often a right thoracic convexity. As the original curve becomes severe, rotation and angulation of vertebrae also occur. The thoracic rib cage rotates to become very protuberant on the convex curve. Vertebral growth may halt because of extreme pressure changes.

**Figure 51.11** Assessing scoliosis. (A) Normal position and spinal curves. (B) Scoliosis indicators.

A family history of curvature of the spine is found in up to 30% of children with scoliosis, although no specific inheritance pattern has been documented. It is 5 times more common in girls than in boys and has a peak incidence at 8 to 15 years of age. As long as the child is growing, the spinal curves will become more severe, which is why the symptoms become most marked at prepuberty (a time of rapid growth). If the child bends forward (Adams test), the curve becomes even more noticeable.

### Assessment

Screening examinations for spine deformity occur at different locations and remain controversial because prospective, randomized, controlled studies on population screening for scoliosis have not been done. The Scoliosis Research Society (SRS), AAOS, Pediatric Orthopaedic Society of North America (POSNA), and American Academy of Pediatrics (AAP) believe that screening examinations for spine deformity should be part of the medical home preventive services visit for females at age 10 and 12 years and for males at age 13 or 14 years (see [Chapter 34](#)). Often, the condition develops insidiously and is prominent before it is noticed because of the preadolescent's and adolescent's need for privacy and the lack of pain that accompanies the condition. A parent might notice when doing laundry that a daughter's bra straps are adjusted to unequal lengths. A girl may find it difficult to buy jeans that fit correctly because of uneven iliac crests or she may notice that a skirt or dress hangs unevenly.

A scoliometer is a commercial device that can be used to document the extent of a spinal curve. With this device (a specialized inclinometer), a reading greater than 7 degrees equals a 20-degree scoliotic curve detected by an X-ray.

MRIs, X-rays, and CT scans all play a role in estimating the extent of the deformity and in providing a baseline description. If the child has a vertebral rotation causing rib

imbalance, pulmonary function studies and a chest X-ray may be obtained to document the effect on lung capacity. Children's bone age is established by an X-ray of the left wrist or iliac bones. If bone growth is complete or almost complete and the curve is less than 50 degrees, little more deformity will result, so no correction may be necessary. If the child has 1 to 2 years of bone growth remaining, however, some correction most likely will be recommended.

## Therapeutic Management

Usually, if the spinal curve is less than 20 degrees, no therapy is required except for close observation and X-rays about every 6 months until the child reaches growth maturity. If the curve is greater than 20 degrees, treatment can consist of a conservative, nonsurgical approach using a body brace; it could include surgery or a combination of both surgical and nonsurgical measures. Curves greater than 40 degrees may require surgery with spinal fusion. The goal of both surgery and mechanical bracing is to maintain spinal stability and to prevent further progression of the deformity until bone growth is complete. Because of this, regardless of the type of treatment chosen, the child and family must be prepared for long-term treatment.

During prepuberty and adolescence, children tend to be very concerned about body image and so can become very impatient with scoliosis correction. Offering them a great deal of support at healthcare visits to help them cope can be an important nursing contribution.

## Bracing

For slight spinal curves in a child who is still skeletally immature, bracing—one of the oldest forms of correction—is still a prime intervention (AAOS, 2015c). The Milwaukee brace was the first type used for this purpose, so, although today's braces look much different, they may still be referred to by this name. Originally, these braces extended to the neck and were almost impossible to conceal under clothing; today, they are underarm thoracolumbar supports (e.g., a Boston brace) that fit under clothing (Fig. 51.12). Braces are now designed by computer-aided techniques to ensure that the brace will be both comfortable and will accomplish maximum correction (Cobetto, Aubin, Parent, et al., 2016).

**Figure 51.12** A teenage girl is fitted with a thoracic-lumbar-sacral orthotic device for treatment of scoliosis. (© Aaron Haupt/Science Source/Photo Researchers.)

The child wears the prescribed brace for 23 hours per day, removed only for showering or participation in a structured athletic program such as soccer. At night, a child may be prescribed a Charleston bending brace that confines the spine to an overcorrected position. Assess whether children and parents know how to safely apply these braces. Frequent follow-up healthcare visits are necessary to check that the device still fits snugly without rubbing on bony prominences, such as the iliac crests. Caution children and parents not to loosen straps if rubbing occurs because this causes the brace to fit loosely, thus not allowing for it to exert adequate compression and traction on areas that are curved. Alert parents and children to notify their healthcare provider instead.

Assess that the child is wearing the brace over a T-shirt to prevent the plastic pads from touching skin surfaces and causing skin excoriation. During the first couple of weeks they wear a brace, children may notice slight muscle aches resulting from the new straighter back alignment. A mild analgesic such as acetaminophen (Tylenol) will decrease this discomfort in most children. Rest also provides considerable relief. Caution children not to remove the brace during this time because taking it off compounds the problem of discomfort by prolonging the period of adjustment.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Situational low self-esteem related to obviousness of the brace used for scoliosis correction

**Outcome Evaluation** Child states positive aspects of self; participates in activities; establishes friendships with peers.

Adjusting to wearing a brace may be a major problem for some children. Help them to concentrate on things they can do with the brace in place, such as having a friend over or going to the movies, rather than those things they cannot do because of the brace (e.g., playing a contact sport) (Box 51.6).

### BOX 51.6

#### Nursing Care Planning Tips for Effective Communication

Jeffrey returns to the orthopedic clinic to be fitted with a scoliosis brace.

*Tip:* Be careful to recognize the adolescent's cues about body image and self-esteem and move toward solving the problem rather than demanding compliance. In the following scenario, the nurse asks follow-up questions to explore Jeffrey's underlying fears and assumptions to ensure they are addressed more completely.

**Jeffrey:** I can't wear anything like that!

**Nurse:** It is awkward, but it's not too bad. You'll see.

**Jeffrey:** All my friends are going to laugh at me! I'll look like a freak!

**Nurse:** Why do you think that?

**Jeffrey:** How can I wear my clothes? What do I do in gym class?

**Nurse:** Let's talk about those things. What do you usually wear to school for a start?

Encourage children to remain as socially active as possible. They may comment at first that they feel awkward or "so much taller" that they are afraid they will fall. However, the only way to get comfortable with a brace is to walk and get used to the new sensation of actually being a little taller. Braces may be awkward at school if chairs are attached to desks. Advocate for the child with the school nurse for seating arrangements that are comfortable.

Friends typically ask questions about why the child needs the brace. The sooner children expose the brace to friends and family, the sooner these questions cease. A brace may need adjustment about every 3 months to accomplish more alignment, and even more frequent visits may be required so children can express the problems they are having with social and school adjustment. Do not underestimate, however, an adolescent's ability to adjust to new situations. Children can see by looking in a mirror that their spine is curved, and they want this corrected. They will endure necessary discomfort if they have hope they will emerge at the end of the correction period without an obvious physical deformity.

In some instances, parents must be firm about insisting their child continuously wears the brace. Be certain children do not envision spinal surgery (which they will need if bracing is ineffective) as a simple and quick procedure, similar to an appendectomy, because, if they think this, they may deliberately avoid wearing the brace, hoping that surgery will then be prescribed. Do not, however, depict spinal surgery as horrible. In some children, even with conscientious bracing, the scoliosis continues to worsen, and surgery will still be necessary.

Scoliosis braces are typically worn until children's spinal growth stops (about 24 months postmenarche in girls, 16.5 years in boys), as demonstrated by a spinal X-ray. The child is usually weaned from the brace gradually because some demineralization and weakening of vertebrae may have occurred during the long period of bracing. Gradual resumption of activity and wearing the brace for a shorter period of time each day allows both remineralization and continued spinal support.

## Halo Traction

Halo traction is the use of opposing forces to straighten and reduce spinal curves that are severe when first diagnosed (over 80 degrees) or that are progressing despite bracing. Halo traction is achieved using a ring of metal (a halo) held in place with about four stainless steel pins inserted into the skull bones (Koller, Zenner, Gajic, et al., 2012). Countertraction is applied by pins inserted into the distal femurs or the iliac crests (Fig. 51.13). A halo traction apparatus is bulky and looks frightening. Children cannot help but worry that when the pins are inserted into their skull (under general anesthesia), they will slip and penetrate their brain. They may worry the apparatus will be so heavy it will strain or break their neck.

**Figure 51.13** A 9-year-old girl in halo traction. (© Caroline Brown, RNC, MS, DEd.)

Halo traction is typically used for those children who have such severe scoliosis that they experience respiratory involvement or cervical instability or have a high thoracic deformity or decreased vital capacity from severe spinal curvature and rotation. If at all possible, children need to see photographs of the apparatus or should be able to talk to children who have the apparatus in place before having it applied. This gives them time to express their feelings about being placed in such a cumbersome device. Because it is so cumbersome, some children react to the apparatus physically, with nausea or diarrhea, or emotionally, with chronic sadness, until they realize they can adjust to it. Be certain that orientation is as thorough for the parents as it is for the child. Otherwise, parents may also show symptoms of stress for the first few days after the application of such traction. After application, parents may feel unsure and appreciate practical pointers in how to care for their child. Emphasizing positive aspects, such as what the child can do, and explaining how the traction will help the spinal curvature is helpful to allow both children and parents to accept such extreme traction.

Halo traction is prescribed until optimal spinal correction is achieved. For the first 24 hours after application, most children experience a nagging level of pain at the pin insertion sites and perhaps in their back; offer analgesia as prescribed.

Children in halo traction need frequent care at the pin sites according to practitioner or hospital policy. In the absence of skin sensitivity, pin sites should be cleaned once weekly using an alcoholic chlorhexidine solution and nonshedding gauze (McClung, 2015). Encourage children to be self-sufficient and do as many things as they are able.

After optimal spinal correction has been achieved with the device, the equipment is easily removed. The pin sites in the skull heal within 1 week without obvious scarring.

### Surgical Intervention: Spinal Instrumentation

Surgical correction usually is necessary if the spinal curvature is greater than 40 degrees. Instruments such as rods and screws are placed next to the spinal column to provide firm reduction of the curvature; the spine is then fused in the corrected position (Fig. 51.14A). A disadvantage of fusion is that it prevents further spinal growth and limits motion of the lumbar section if involved—a concern that can be solved by the use of fusionless interventions such as intervertebral stapling or expandable rods (Dede, Demirkiran, & Yazici, 2014). Although this is back surgery, the surgical approach may be either from the back (posterior) of the child or from the front (anterior) through the abdomen.

**Figure 51.14 (A)** Cotrel-Dubousset rods to correct scoliosis. A short distraction rod is linked to a longer one to correct the major curve. A convex rod is then applied. **(B)** Preparing to log roll. Two nurses use a draw sheet to roll the child in one coordinated movement to the side-lying position.

### *Preoperative Nursing Care*

Before spinal instrumentation, extensive X-rays are taken to plan the exact location of instrumentation, such as rods and screws or staples. Ensure children have a good explanation of what they can expect before and after surgery (see [Chapter 36](#)). Deep-breathing exercises will be particularly important for children whose scoliosis has caused chronically reduced lung capacity, so introduce these plus incentive spirometry preoperatively. A nasogastric tube usually is inserted before surgery to prevent abdominal distention because major surgery may cause temporary paralytic ileus and a lack of bowel tone. Because this surgery involves major muscle and tendon shifts, the child will have pain afterward. It is a major operation, so they can also expect to feel

tired and “not themselves” for several days. Young adolescents appreciate learning about these feelings before surgery as well as appreciate being treated like adults. Be aware, however, that early adolescents are not adults, and, although they seem eager to breathe deeply and cooperate with routines before surgery, these requests can be overwhelming for them postoperatively; their behavior postoperatively may not be nearly as mature as they anticipated it would be. Epidural anesthesia offers a great deal of pain relief. Allowing children to use an IV or epidural patient-controlled analgesia system offers both pain relief and a feeling of control.

### *Postoperative Care*

Following surgery, repositioning is important to prevent pressure areas and to maintain care of instrumentation. Repositioning may be performed by using a log-roll technique (see [Fig. 51.14B](#)). Along with postoperative assessment of the incision and/or drainage, assess vital signs and pain per hospital policy. Some children spend the first 24 hours in the pediatric intensive care setting for pain management and frequent assessment. Neurologic complications (e.g., nerve root, cauda equina, spinal cord deficit) are not common, but neurologic assessment is essential following spinal surgery. Careful neurologic assessment of upper and lower extremity function should be continued for at least 48 hours after surgery. Delayed neurologic complications may be caused by progressive spinal cord ischemia secondary to traction or to the development of an epidural hematoma. Blood pressure should be monitored carefully and mean arterial blood pressure should be maintained at greater than 80 mmHg to help maintain spinal cord perfusion ([Stepanovich, Mundis, & Yaszay, 2015](#)). Another rare complication following surgery may involve proximal small intestinal obstruction due to increased pressure generated by contraction of the angle between the superior mesenteric artery and the aorta ([Keskin, Akgül, Bayraktar, et al., 2014](#)). Circulatory pressure changes resulting from realignment of the chest cage and reduced rotation of the spine may result in circulatory impairment. There is usually extensive blood loss during spinal fusion surgery, which may cause shock and hypotension. A drainage system, such as a Hemovac, may be inserted next to the incision to evacuate any accumulating blood. The amount collected from this needs to be recorded. Other postoperative complications include wound infection, ileus, and atelectasis.

Children are usually prescribed nothing by mouth until bowel sounds return (usually 12 to 24 hours). An indwelling urinary catheter, placed during surgery, is usually left in place for 24 hours because voiding may be difficult. This also allows for an assessment of kidney function.

Although a child’s parents have been prepared for the fact that spinal rod insertion is major surgery, they may still be shocked by the child’s appearance after surgery. They may be afraid to touch their child at a time when the child would probably enjoy being hugged because of feeling so ill and frightened. Role model touching and talking to the child to help parents overcome their concern as quickly as possible.

As soon as bowel sounds are present, a child can begin to take fluids and then

solids. Usually on day 1 postop, physical therapy is initiated to help children learn how to change position and ambulate. They may feel dizzy at first; therefore, allow them to get used to sitting by attempting it for only short periods at a time at first. Activity is then increased to a normal level with few restrictions.

Because removing rods is as extensive a procedure as inserting them, instrumentation rods are left in place permanently unless they cause irritation or infection later. The average child becomes unaware the rods are in place.

Children may be afraid to move freely after rod insertion or stapling because if they have worn a brace beforehand, they have been in some type of restraining device for a long time. They may need to be reassured frequently that, following surgery, their scoliosis is corrected with an “internal” brace or instrumentation.

### *What If... 51.3*

**Jeffrey, who was diagnosed with having scoliosis, was prescribed a brace to wear 23 hours a day. During the past month, he dropped out of the school band and the one after-school club to which he belonged. He tells the nurse he dropped these activities “to have more time to study.” Why might the nurse be concerned?**

## **Disorders of the Joints and Tendons: Collagen Vascular Disease**

Collagen is composed of bundles of protein-rich fibers that form the connective tissue of tendons, ligaments, and bones. Because this tissue is found throughout the body, collagen diseases are systemic. They tend to be painful, involve inflammation, and are long term.

### **JUVENILE IDIOPATHIC ARTHRITIS**

JIA, also called simply juvenile arthritis (JA) or juvenile rheumatoid arthritis (JRA), primarily involves the joints of the body, although it also affects blood vessels and other connective tissues. Three groups have developed sets of criteria to classify children with arthritis:

- American College of Rheumatology (ACR)
- European League Against Rheumatism (EULAR)
- International League of Associations for Rheumatology (ILAR)

The ACR-accepted terminology for JIA includes children younger than 16 years of age who have chronic arthritis (swelling or effusion, or presence of two or more of the following signs: limitation of range of motion, tenderness or pain on motion, and increased heat) in one or more joints (lasting more than 6 weeks) and in whom no other specific cause of arthritis can be identified. Onset type is defined by type of disease in

the first 6 months. The organization recognizes the following three subtypes:

- *Polyarticular*: five or more inflamed joints, often involving weight-bearing joints. Rheumatoid nodules may be seen in patients with rheumatoid factor (RF)-positive disease and symmetrical involvement of small joints in the hands.
- *Pauciarticular*: less than five inflamed joints. Large, weight-bearing joints, such as the knees and ankles, are typically affected.
- *Systemic*: arthritis in one joint for at least 6 weeks' duration in a child age 16 years with or preceded by fever of at least 2 weeks' duration that is documented to be daily ("quotidian") for at least 3 days and accompanied by one or more of the following: evanescent erythematous rash, generalized lymphadenopathy, hepatomegaly or splenomegaly, and serositis (Ringold, Weiss, Beukelman, et al., 2013)

Three separate subtypes of JA exist (Table 51.1).

**TABLE 51.1 COMPARING DIFFERENT TYPES OF JUVENILE ARTHRITIS**

Characteristic Polyarticular		Pauciarticular	Systemic Onset
Number of joints involved	Five or more	Four or less	Any number
Joints affected	Small joints of fingers and hands, also possibly weight-bearing joints Often same joint on both sides of body	Usually large joints, such as knees, ankle, or elbow Usually one joint on one side of body	Any joint
Gender affected	More girls than boys	More girls than boys (most common type)	Boys and girls equally
Body temperature	Low-grade fever	Low-grade fever	High spiking fever lasting for weeks or months
Other symptoms	Stiffness and minimal joint swelling, leading to limited motion Rheumatoid nodules or bumps on elbow or other body area receiving pressure from chairs,	Eye inflammation; painless joint swelling with little redness (+)ANA titer (possible)	Macular rash on chest, thighs Inflammation of heart and lungs

shoes, or other object	(+)HLA antigen	Anemia
(+)Rheumatoid factor (in approximately 20% of children)	(possible in boys)	Enlarged lymph nodes, liver, and spleen
(+)ANA titer (possible)		Rarely +
Elevated white blood cell count, complement, and sedimentation rate		rheumatoid factor and ANA titer
		Elevated white blood cell count

ANA, antinuclear antibody; HLA, human leukocyte antigen.

The ILAR classification of JIA includes the following six categories:

- *Systemic-onset JIA*: characterized by spiking fevers, typically occurring once or twice each day, at about the same time of day, with temperature returning to normal or below normal
- *Oligoarticular JIA*: oligoarthritis (pauciarticular disease): less than five inflamed joints. Large, weight-bearing joints, such as the knees and ankles, are typically affected.
- *Polyarticular JIA*: polyarthritis: five or more inflamed joints, often involving weight-bearing joints. Rheumatoid nodules may be seen in patients with RF-positive disease and symmetrical involvement of small joints in the hands.
- *Psoriatic arthritis*: usually mild. Onset of arthritis precedes that of psoriasis in approximately half of children.
- *Enthesitis-related arthritis*: frequently presents as evening and postexercise pain. Attention should be given to buttock pain and back pain that improves with activity (inflammatory back pain). These children cannot lie in bed all morning but have to get up due to back pain.
- *Undifferentiated arthritis*: diagnosed if the patient's manifestations either do not fulfill the criteria for any one category or fulfill the criteria for more than one (Sherry, Bhaskar, Poduval, et al., 2016)

The EULAR proposed the term *juvenile chronic arthritis* (JCA) for the heterogeneous group of disorders that manifest as JA. The diagnosis requires that the arthritis begins before age 16 years and lasts for at least 3 months. The EULAR criteria for JCA recognize the following subtypes based on characteristics at onset:

- Pauciarticular (one to four joints)
- Polyarticular (five or more joints)
- Presence of RF (two positive tests at least 3 months apart)
- Systemic onset with characteristic features
- Positivity for RF
- Juvenile ankylosing spondylitis

- Juvenile psoriatic arthritis

The cause of JA is unknown, although it is thought to be an autoimmune process in which a child develops circulating antibodies (immunoglobulins) against body cells. This is revealed by the presence of antinuclear antibodies (ANA), RF, and human leukocyte antigen (HLA)-B27 in blood serum. A genetic predisposition may also be present and increases the risk in some children (Soep, 2012).

### Assessment

Children with systemic JA are usually brought to a healthcare facility because of a persistent fever and rash, symptoms that present even before the pain and stiffness of joint involvement begins. Regardless of the type of JA, assess children for the effect their disease is having on self-care. Do they need help eating, dressing, ambulating, or toileting? Also, assess the child's and parents' understanding of the illness and the therapy planned because children and parents will typically bear the major responsibility of evaluating further symptoms and for carrying out therapy at home.

Children with pauciarticular arthritis need screening with a slit-lamp examination every 6 months for uveitis (inflammation of the iris, ciliary body, and choroid membrane of the eye) because severe uveitis can lead to blindness (Soep, 2012).

### Therapeutic Management

Because JA is a long-term illness, therapy includes a balanced program of exercise, rest, and medication administration to relieve pain, restore function, and maintain joint mobility.

#### Daily Activities and Exercise

An activity such as sitting on the toilet may be uncomfortable if hip and knee joints are painful. Using an elevated toilet seat can be helpful because it reduces the amount of bending required at the knee. Children may also be unable to dress themselves because they are unable to button or zipper due to painful finger joints. Modifying these activities by using loops or Velcro strips not only helps children feel good about themselves but also increases their overall level of activity despite joint involvement (Fig. 51.15).

**Figure 51.15** The knees of a child with juvenile arthritis. Note the degree of joint enlargement and swelling. (Photograph courtesy of A. I. duPont Institute, Children's Hospital, Wilmington, DE.)

Because a set exercise program has the potential to help preserve muscle and joint function, children are prescribed a set program of daily range-of-motion exercises designed to strengthen muscles and put joints through their full range of motion. They can do these independently, although participating in a group is usually appealing to children at this age.

It is best if these exercises can be incorporated into a dance routine or a game, such as Simon Says because this not only makes exercises enjoyable but can also make the exercise a family participation time to be anticipated rather than a dull routine that must be followed daily. Swimming and tricycle or bicycle riding are excellent exercises because they provide smooth joint action. Also, encourage children to do as much self-care as they can because the natural motions of activities such as dressing and brushing teeth exercise joints. In contrast, to reduce joint destruction, activities that place excessive strain on joints, such as running, jumping, prolonged walking, and kicking, should be avoided. School-age children can cooperate to avoid these activities. Parents of preschool children need to create interesting alternative activities, so the child avoids such motions.

Children should continue to attend school if at all possible because this increases activity that hopefully leads to fewer contractures and less decalcification of bones. Children with JA fatigue easily, however, so they may need a shortened school day; moving their starting time to midmorning can be a way to implement this. This late start can allow a child time for a warm bath in the morning, an activity that not only reduces pain but also increases movement in the involved joints.

## Heat Application

Heat reduces pain and inflammation in joints and so increases comfort and motion. Heat can be applied by the use of a heating pad or warm water soaks for 20 to 30 minutes. Paraffin soaks can be useful for wrist and finger inflammation. Caution parents that young children frequently play with the controls on a heating pad, so they should tape the control to its medium temperature to help guard against burns.

## Medication

NSAIDs such as ibuprofen (Motrin) or naproxen (Naprosyn) are the analgesics of choice for children with JA because they not only control pain and inflammation, thereby reducing joint swelling, joint discomfort, and morning stiffness, but also may contribute to improvement in malaise and irritability. NSAIDs are taken about four times a day and must be taken for at least 6 to 8 weeks to ensure effectiveness.

Because taking so many NSAIDs can cause gastrointestinal upset and bleeding, be certain parents know to always give the medication with food. Most parents think of NSAIDs as a drug to give children only when they have pain. Teach that they should continue to give the drug even if the child has no noticeable pain at the time of administration because the drug's anti-inflammatory action is just as important as its pain prevention.

Slow-acting antirheumatic drugs (SAARDs), also called *disease-modifying antirheumatic drugs* (DMARDs), can be used if NSAIDs are ineffective. In contrast to the immediate pain relief or anti-inflammatory effect of NSAIDs, these drugs modify the natural progress of the disease over weeks to months (Ringold, Weiss, Colbert, et al., 2014).

Methotrexate, a cytotoxic drug, is the second drug usually prescribed. Steroids, such as prednisone, are only added to the drug therapy if the disease is extremely severe or is an incapacitating systemic disease that has not responded to other anti-inflammatory agents. Steroids are injected directly into the affected joint. The first biologic medication, etanercept (Enbrel), was approved to treat JIA in the United States in 1999. Therapies continue to include the administration of medications called tumor necrosis factor (TNF) inhibitors, such as etanercept (Enbrel) or infliximab (Remicade). These drugs reduce inflammation by blocking the action of TNFs, which cause inflammation. Etanercept is subcutaneously injected every week, so parents need detailed instructions on the technique to do this as well as the importance of guarding against infections because children are more susceptible to infection than usual while taking these drugs. Infliximab is given IV and so usually requires a short-term healthcare facility stay for safe administration. The newest targets for arthritis treatment are the kinase inhibitors, such as tofacitinib. Tofacitinib is an oral medication that has shown clinical response in as little as 2 weeks with sustained response up to 12 months. Other orally bioavailable therapeutic treatments are also in trials for clinical effectiveness.

## Nutrition

Children with JA, like those with other chronic diseases, may eat poorly because of joint pain and fatigue. Some children experience mild gastric irritation from NSAID therapy. Help parents plan mealtimes at the “best times” of the day to overcome these problems.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Deficient knowledge related to care necessary to manage disease symptoms

**Outcome Evaluation:** Parents and child follow instructions regarding exercise and medication.

Help parents and children to understand the necessity for them to take an active role in therapy by planning exercise and medication programs around school or other activities. Children with JA commonly experience irritability and fatigue, which may interfere with plans. Assist them with devising a schedule that allows for a balance of rest periods with exercise to maximize the possibility of success.

Evaluate how well children are managing their symptoms in addition to how they view themselves (hopefully feeling well after a long period of pain and illness). The few children who develop joint contractures may require soft-tissue surgery, such as contracture release, tendon reconstruction, and synovectomy, or orthopedic surgery, such as equalization of leg length or orthoplasty, at a later date. Surgery of these types are usually delayed until growth is complete, so further growth will not influence the outcome.

About half of children with JA recover at the end of adolescence. The others will continue to have the disease into adulthood. Until the disease does reach remission, children need a great deal of support to perform exercises and take daily medication as prescribed.

### *QSEN Checkpoint Question 51.3*

#### **PATIENT-CENTERED CARE**

Jeffrey’s 10-year-old sister has JA, and her mother is eager to explore alternative methods of pain control in addition to standard approaches of analgesia. The standard approach to analgesia with JA is:

- a. Applying ice to painful joints to reduce inflammation
- b. Having joints scraped biannually during an arthroscopy
- c. Applying topical hydrocortisone to affected joints
- d. Taking an NSAID on a daily basis

## Disorders of the Skeletal Muscles

### MYASTHENIA GRAVIS

For nerve conduction to cause muscles to contract effectively, a neurotransmitter, acetylcholine (ACh), must be released at synaptic junctions. The release of ACh is governed by the enzyme cholinesterase. With myasthenia gravis, there is interference in ACh processing, which leads to symptoms of progressive muscle weakness or inability to contract. The fault may be impaired synthesis or storage of ACh, insufficient ACh release, inadequate ACh receptors present at motor end plates, opposition of ACh by an anti-ACh factor, or excessive cholinesterase. In adults, the defect is probably most often a motor end plate insufficiency (a decreased number of ACh receptors are present). In children, myasthenia gravis probably occurs most often from an autoimmune process (autoantibodies may block receptor sites for ACh or other receptors such as muscle-specific kinase (MuSK) receptors (VanderPluym, Vajsar, Jacob, et al., 2013).

The disease occurs in three forms in childhood: neonatal transient myasthenia, congenital myasthenia, and juvenile myasthenia.

#### Assessment

With neonatal transient myasthenia, the mother has myasthenia gravis and the infant demonstrates transient disease symptoms at birth because of the transfer of antibodies from the mother. The newborn appears “floppy,” sucks poorly, and has weak respiratory effort. Ptosis (drooping eyelids) may be present. The symptoms disappear within 2 to 4 weeks, but if they are not recognized when present, they could prove fatal because of respiratory muscle dysfunction.

Congenital myasthenia appears to be an inherited disorder that results in faulty ACh transmission or reception. Juvenile myasthenia gravis is an autoimmune process that occurs most typically at 10 to 13 years of age and in girls more frequently than in boys. Most children with this form have thymus hypertrophy; this sign helps document the autoimmune process (VanderPluym et al., 2013).

With all forms, children gradually begin to develop double vision (diplopia) and ptosis because of weakness of the extraocular muscles. Symptoms grow intense as facial, neck, jaw, swallowing, and intercostal muscles become affected. Fatigue is extreme, becoming more noticeable as a day progresses. All symptoms increase with emotional stress, fatigue, menstruation, respiratory infections, and alcohol intake. In the most severe form, all muscles, including those of respiration, become unable to contract.

Obtaining an accurate history, especially documenting whether a child can perform repetitive movements, is important. Ask a child to look upward and hold that position. Children with myasthenia gravis, unlike others, will gradually demonstrate ptosis. Other

repetitive motions, such as walking up stairs or clapping, may also be tested, although the time spent doing this should not be prolonged because it is tiring and does not reveal much more information. Most children have myography performed to document their poor muscle function. An MRI or a CT scan demonstrates the enlarged thymus gland.

Edrophonium (Tensilon) is a drug that prolongs the action of ACh and therefore increases muscle strength. If the child's muscle strength improves moments after an injection, the child's diagnosis is positive for myasthenia gravis (Karch, 2016).

## Therapeutic Management

The goal of treatment for myasthenia gravis is to improve the strength and endurance of a patient by facilitating neuromuscular transmission (Liew, Powell, Sloan, et al., 2014). Myasthenia gravis is treated by the administration of neostigmine (Prostigmin) or pyridostigmine bromide (Mestinon), acetylcholinesterase inhibitors that prolong the action of ACh (Box 51.7). The dosage of these agents must be individually determined. If toxicity occurs, symptoms similar to those of the original disease occur because excessive ACh leads to continued neurotransmitter stimulation and the inability of muscles to repolarize for a new contraction. In some children, prednisone or an immunosuppressant such as azathioprine may be added to their medication regimen to decrease the amount of anticholinesterase medication required. In still others, plasmapheresis to remove immune complexes from the bloodstream or the administration of IV immunoglobulin to provide immune suppression will reduce symptoms (Bird, 2016).

### BOX 51.7

#### Nursing Care Planning Based on Responsibility for Pharmacology

##### NEOSTIGMINE (PROSTIGMIN)

**Classification:** Neostigmine is a cholinesterase inhibitor that acts as an antimuscarinic agent.

**Action:** Neostigmine increases the concentration of acetylcholine at nerve endings, prolonging and exaggerating its effects and facilitating neuromuscular transmission (Karch, 2016).

**Pregnancy Risk Category:** C

**Dosage:** orally, 2 mg/kg daily in divided doses every 3 to 4 hours; or 0.01 to 0.04 mg/kg per dose intramuscularly, intravenously, or subcutaneously every 2 to 3 hours, as needed

**Possible Adverse Effects:** salivation, dysphagia, increased peristalsis, cardiac arrhythmias, increased respiratory secretions, urinary frequency, pupil constriction, and diaphoresis

##### Nursing Implications

- Assess the child for increased muscle weakness, indicating possible cholinergic crisis. Keep atropine sulfate readily available as the antidote.
- If giving neostigmine orally, administer the drug with food or milk to minimize gastrointestinal upset. Instruct parents to administer the drug exactly as prescribed.
- Plan to administer larger portions of the divided doses approximately one-half hour before anticipated times of greater fatigue.
- Advise parents to watch for signs of excessive salivation, emesis, or frequent urination and to notify their healthcare provider if these occur.
- Encourage parents to control the child's environmental temperature as much as possible to prevent diaphoresis from too hot or too humid an environment.
- Inform parents an increase in muscle weakness may be related to either drug overdose or exacerbation of the disease. Urge them to report any signs of increased weakness to their healthcare provider immediately.

Excision of the thymus gland may also effectively reduce symptoms, although this is a last resort because it may leave the child open to additional autoimmune disorders in the future.

Teach parents and children that symptoms become worse under stress; therefore, parents need to adequately prepare children for new experiences such as menstruation, high school, a parental divorce, or surgery in order to minimize stress. Help children plan their day to include rest periods, possibly advocating for a special school schedule if necessary. If chewing and swallowing are difficult, ensure a rest period before meals. Even so, children may need to take their medication about an hour before mealtime, eat a soft diet, and learn to eat slowly and cautiously to avoid choking and aspiration. If symptoms of muscle weakness suddenly become very severe, parents should call 911 because the loss of function of intercostal muscles may lead to respiratory arrest. Atropine, an anticholinergic agent and the antidote for an overdose of anticholinesterase drugs, should be available to administer as necessary both for parents at home and on a hospital unit that cares for children with this disease.

## DERMATOMYOSITIS

Dermatomyositis occurs from the degeneration of skeletal muscle fibers. The cause of the disorder is unknown, although either a viral infection or an autoimmune basis is suspected. It is more common in girls than in boys and occurs between the ages of 5 and 14 years (Soep, 2012). Symptoms usually begin insidiously, with muscle weakness that presents with difficulty in swallowing or that prevents children from performing tasks they could manage previously, such as competing in gym classes, lifting objects, or climbing onto a high stool. Skin symptoms such as swollen and discolored upper eyelids, a confluent rash on the cheeks that increases to become telangiectatic, and scaling begin to develop. Subcutaneous calcifications may appear, making the skin feel unusually firm. Muscle breakdown leads to the appearance of creatine phosphokinase

and aldolase in the serum. A muscle biopsy or electromyography reveals a lack of electrical activity in muscle fibers.

High-dose corticosteroids, methotrexate, or specific immunosuppressants are the drugs of choice to improve muscle strength. Children who survive beyond the first year after diagnosis have a good prognosis for prolonged remissions, although they are more susceptible to developing cancer later in life.

## THE MUSCULAR DYSTROPHIES

The muscular dystrophies are a group of more than 30 genetic diseases characterized by progressive weakness and degeneration of the skeletal muscles that control movement. Duchenne muscular dystrophy is caused by an absence of dystrophin (a protein in the muscles) that is necessary for muscle contraction due to genetic mutation ([The Muscular Dystrophy Association, 2016](#)).

### Types

Muscular dystrophies seen in children are classified into three main types: congenital myotonic dystrophy, facioscapulohumeral muscular dystrophy, and pseudohypertrophic muscular dystrophy (Duchenne disease).

#### Congenital Myotonic Dystrophy

Congenital myotonic dystrophy is inherited as an autosomal dominant trait. Because the disease process begins in utero, the infant may already have severe myotonia (muscle weakness) at birth. Muscle degeneration continues until adequate respiratory muscle movement becomes difficult. Diagnosis is by serum enzyme analysis and muscle biopsy. Most of these infants die before they are 1 year old because they cannot sustain respiratory function.

#### Facioscapulohumeral Muscular Dystrophy

Facioscapulohumeral muscular dystrophy is inherited as a dominant trait carried on chromosome 4. Symptoms begin after the child is 10 years old. The predominant symptom is facial weakness. The child becomes unable to wrinkle the forehead and cannot whistle. Serum enzyme analysis and muscle biopsy are used in diagnosis. The symptoms usually progress so slowly a normal life span is possible.

#### Pseudohypertrophic Muscular Dystrophy (Duchenne Disease)

Duchenne disease, the most common form of muscular dystrophy, is inherited as a sex-linked recessive trait. Therefore, it occurs only in boys, although a mother who carries the gene may demonstrate some symptoms. Symptoms are usually apparent by 3 years of age.

## Assessment

Children with Duchenne muscular dystrophy usually have a history of meeting motor milestones, such as sitting, walking, and standing, but they reach these milestones later than does the average infant. By about 3 years of age, symptoms become acute and obvious as boys develop a waddling gait and have difficulty climbing stairs. They can rise from the floor only by rolling onto their stomachs and then pushing themselves to their knees. To stand, they press their hands against their ankles, knees, and thighs (they “walk up their front”), called a Gower sign. They may walk on their toes, which leads to the development of a short heel cord. Speech and swallowing become difficult. It may be awkward to lift a young child with this condition by placing your hands under the axillae because the child seems to slip through your hands due to the lax shoulder muscles. In contrast, calf muscles are hypertrophied (measure larger than normal) because the muscles become so degenerated they are replaced by fat and connective tissue.

As the disease progresses, muscle weakness becomes more and more pronounced. Scoliosis of the spine and fractures of long bones may occur from abnormal muscle tension and lack of muscle support. By junior high school age, most boys become wheelchair dependent. Tachycardia can occur as the heart muscle weakens and enlarges. Pneumonia develops easily as the child’s cough reflex becomes weak and ineffective. Death from pulmonary dysfunction tends to occur at about 20 years of age.

The diagnosis is based on the history and physical findings, a muscle biopsy showing fibrous degeneration and fatty deposits, electromyography showing a decrease in amplitude and duration of motor unit potentials, an increased concentration of serum creatine phosphokinase, and genetic analysis.

## Therapeutic Management

Encourage boys with muscular dystrophy to remain ambulatory for as long as possible by a program of active and passive daily range-of-motion exercises. Splinting and bracing may be necessary to maintain lower extremity stability and to avoid contractures. If children become overweight, remaining ambulatory becomes even more difficult for them. Therefore, encourage a low-calorie, high-protein diet to avoid excessive weight gain. In addition, to prevent constipation because of poor abdominal muscle tone, encourage a high intake of fiber and fluids. Advocate for a stool softener if necessary. In the meantime, corticosteroid therapy is helpful to increase function and strength at least on a short-term basis; help parents understand the importance of this and have a set schedule of administration. Newer therapies include cell repair, gene transfer, and stem cell (Strehle & Straub, 2015).

The average life expectancy of these patients has doubled and now stands at about 25 years (Strehle & Straub, 2015). Because the disease is progressive, assist the child and family with achieving the optimal level of activity within the child’s limitations. Provide support for parents to assist them with coping because they can become

depressed as disease symptoms progress.

### QSEN Checkpoint Question 51.4

#### QUALITY IMPROVEMENT

Jeffrey's mother said she was worried her son might be developing muscular dystrophy. A clinical care map for children who have this disease should prioritize which action?

- Urging them to rest most of the day to avoid systemic fatigue
- Helping them to avoid weight gain so they can be mobile longer
- Cautioning them not to eat foods that contain purines
- Encouraging a diet rich in calcium to prevent osteoporosis

Look in [Appendix A](#) for the best answer and rationale.

## FRACTURES

A fracture is a break in the continuity or structure of bone. Because children experience falls during their growth years, fractures of long bones are common childhood injuries. Various types are described in [Table 51.2](#). Fractures in children tend to be different than in adults because:

- Bone in childhood is fairly porous, allowing bones to bend rather than break.
- The periosteum is thick, so the bone may not break all the way through.
- Epiphyseal lines may cushion a blow so that the bone does not break.
- Healing is rapid as a result of overall increased bone growth.

**TABLE 51.2 COMMON FRACTURES IN CHILDREN**

Type of Fracture	Description
Plastic deformation (bend) 	Bone bends, causing a microscopic fracture line that does not cross the bone; most common in the ulna and fibula
Buckle (torus) 	Fracture on the tension side of the bone near softened metaphyseal bone, causing a buckling and raised area on the harder diaphyseal bone (opposite side)
Greenstick 	Bone bent with fracture beginning but not crossing through the bone
Complete 	Bone divided (either transversely [crosswise at right angle to long axis of bone], obliquely [slanted but straight], or spirally [slanted and

circular]); bone remnants possibly attached by a periosteal hinge

Because of the high resilience of immature bone, many fractures in early childhood are the greenstick variety (one side of a bone is broken; the other is only bent). These fractures cause minimal pain, swelling, or deformity, the usual hallmarks of a fracture.

Many fractures in children, however, occur at the epiphyseal line. These types of fractures can be serious because bone growth occurs at this point. Damage to the area can lead to undergrowth, overgrowth, or uneven growth, resulting in angulation. If a fall occurred from a high distance or was caused by a violent force, such as a speeding automobile, breaks may be complex, or the formation may be compounded (the bone pierces the skin) or comminuted (parts of the bone are fragmented). These injuries are always serious because the severed bone may lacerate nerves or blood vessels. The open wound may become infected, and correction will most likely involve surgery with the risks of anesthesia.

The healing of bone is relatively slow compared with other body injuries. Immediately after a fracture, a hematoma forms at the site of the break; over the next several days, granulation tissue is laid down. Over the next several weeks, osteoblasts invade this new tissue, and calcium is deposited (termed *callus*) to form new bone. By the time a callus formation is extensive (enough for movement at the fracture site to be impossible), clinical healing or clinical union has occurred. Complete healing does not occur until all of the temporary callus formation has been replaced by mature bone cells and the bone has once more regained its normal shape and contour.

Several complications may occur during this process. One is fat embolus, which is the release of fat from the marrow of the broken bone into the bloodstream. This embolus then travels to the cerebral vessels and causes symptoms such as confusion or hallucinations as the oxygen supply to brain cells is shut off. It also could become a pulmonary embolus, producing dyspnea, tachycardia, and cyanosis. A second problem that can occur is *compartment syndrome*, which was discussed previously (Najarian, 2013).

If there is a great deal of edema present in the injured part, a splint or a cast may be applied but split or bivalved on each side to allow for swelling to decrease to avoid compartment syndrome. If the growth plate was severely involved in the injury, some children may need bone-lengthening or bone-shortening procedures later in life to assure equal and adequate bone growth.

## Assessment

When children are seen in an emergency department for multiple trauma, observe the extremities closely for the hallmark signs of fracture (deformity, edema, and pain). If you do suspect a fracture, splint the extremity to avoid further trauma. Splinting also reduces pain because it prevents further movement of the bone. Splints should extend

from a joint above to a joint below the suspected fracture site to prevent movement and muscle tension, which could cause further dislocation of the fracture. For example, for a fracture of the forearm, the splint should reach from above the elbow to below the wrist. If an extremity is so seriously deformed by the break that it will not conform to the contour of a splint, do not attempt to move it into a splint position. Immobilize the extremity by placing sandbags on the sides of the arm or leg and leave it in that position.

Perform a thorough history of how the fracture occurred. Some fractures in childhood occur from child maltreatment. This must be ruled out for all unintentional injuries.

### Therapeutic Management

All children with a suspected fracture need an X-ray to confirm the diagnosis and to determine the alignment and **apposition** (the amount of end-to-end contact there is of the bone fragments). Apposition is not as important in children as it is in adults, so bayonet or side-to-side apposition may be established for children up to 10 or 12 years old. With this, as the child grows and remodeling occurs, the bone will develop with normal contour and length. Side-to-side apposition has the advantage of allowing for a rapid, strong union and actually is the preferred position for some fractures.

If skin over the fracture site has been broken, the child may need tetanus prophylaxis and IV antibiotics. A hematocrit determination to estimate blood loss and cross-matching for replacement therapy may be necessary if a long bone such as a femur was fractured in trauma.

All children with fractures are in some pain. Usually, they are frightened not only from the pain, the appearance of the fracture, and their inability to use the extremity but also from the frightening situation that led to the fracture such as a fall from a bunk bed or an automobile accident. Spend time comforting and helping children to realize they are now safe and will not be injured further. Provide analgesia so they can relax enough to not move the fractured extremity, decreasing the pain. Reassure both children and parents that, unless the bone has been crushed, bone fragments can be brought back into line, allowing the break to heal with the same strength the bone had prior to being fractured.

### Types of Fractures

#### Forearm Fractures

Because children often fall on an outstretched arm, fractures of the forearm are a common type. Most forearm fractures in children involve the distal third; a smaller number of such accidents occur in the middle or proximal third. Only the radius, both the radius and ulna, or a displacement of the epiphyseal plate of the radius may be involved. In young children, the injury usually is a greenstick or an incomplete fracture.

If a greenstick fracture is slight so that the degree of angulation is not great, it may

not be reduced or brought into a straight line; as callus is formed and the bone remodels itself, it will naturally straighten into good alignment. Sometimes, greenstick fractures are broken completely before casting to prevent the bone's resuming its "bent" position within the cast. Refer to this as "straightening" the bone rather than "breaking" the bone so it sounds less frightening.

If the fracture is complete and overriding is excessive, traction to the fingers may be used as a part of the cast. This "banjo" traction is cumbersome and limits the child's use of that hand. You may need to reassure parents that, although the cast is more cumbersome than they anticipated, their child will be able to manage it well with a little practice.

### Elbow Fractures

If a child falls and stops the fall with a hand, the elbow may hyperextend, transmitting the force of the blow to the distal humerus and causing a supracondylar fracture of the humerus. Fractures of this kind are reduced and stabilized with an arm cast, a splint, traction, or open surgery depending on the position of the fracture. Elevating the cast on pillows or suspending the hand by a strip of gauze or traction apparatus reduces edema. Although the fracture may be minor, the child needs to be assessed carefully for signs of blood vessel or nerve compression (Volkmann contracture).

### Volkmann Ischemic Contracture

When an arm is flexed and put into a cast, the radial artery and nerve can be compressed at the elbow, causing nerve injury or severe impairment of circulation. If symptoms of compression are present but not detected within 6 hours, Volkmann contracture and possible permanent damage to the arm will result. The arm is left permanently flexed at the elbow. The wrist is hyperextended, and the fingers assume a flexed, clawlike, and useless position. If a child is going to be discharged from a healthcare facility after application of a cast, inform parents about the symptoms of compression so they can continue to assess for its development. If a child is admitted to the hospital after cast application, the radial pulse (if palpable at the edge of the cast) should be taken hourly, along with checks for coldness, blanching, and color of the fingers, during the first 8 hours. In some instances, a cast is applied incompletely for 24 hours, the elbow portion being simply splinted and wrapped with elastic bandages. After 24 hours, when edema has subsided and the chance of compression is less, the rest of the arm is then casted.

### Epiphyseal Separations of the Radius

If a child breaks a fall with an outstretched arm, the separation of the epiphysis of the distal radius may result. When this occurs, the wrist must be casted to restabilize the epiphysis. Although epiphyseal injuries are always serious, distal radial injury rarely causes serious sequelae in children. Advise parents, however, that it is important to keep appointments for follow-up visits so that growth disturbances can be detected early.

Stapling the epiphysis or stimulation of the epiphyseal line may be done to arrest abnormal growth if it occurs.

## Clavicle Fractures

When young children catch themselves during a fall with an outstretched arm, the force of the blow can be transmitted to the clavicle, causing a fracture of the clavicle or dislocation at the sternal joint. Clavicles also may be fractured during birth and are often fractured playing football. These fractures need to be evaluated carefully because they also could be a mark of child maltreatment.

### *QSEN Checkpoint Question 51.5*

#### **TEAMWORK & COLLABORATION**

A nurse is collaborating with a licensed practical nurse in the care of a child with an elbow cast. What information about an elbow cast should all care team members to be aware of?

- a. The cast must be constructed from fiberglass, not plaster of Paris.
- b. Edema at the elbow from a too tight cast can cause severe nerve damage.
- c. The child should expect to have low-grade pain following application.
- d. These casts often get dirty and so lead to humeral osteomyelitis.

*Look in [Appendix A](#) for the best answer and rationale.*

Swelling is often present at the site of the break. In the newborn, a Moro reflex can only be demonstrated on the unaffected side. An older child refuses to use the arm, leaving it hanging at the side. Crepitus (crackling) can be felt over the clavicle. After an X-ray diagnosis, if the bone fragments are not displaced, the child is placed in a commercially manufactured or figure-of-eight splint or stockinette placed over the shoulders and under the axilla, which keeps the arm adducted and flexed across the chest. Caution the parents to keep the splint dry—no swimming or showering during this time—and how to observe it every morning to check that it is firmly in place or if it needs tightening. Because the splint is left in place for about 3 weeks, the wrap becomes extremely soiled. Parents are usually apologetic about the appearance of the splint when they return for a repeat X-ray. They may be worried the soiled appearance of the splint reflects the quality of their housekeeping or child care. You can assure them that a soiled appearance is expected and proof they followed instructions well to leave the splint in place.

Some parents may need reassurance that a simple splint is adequate therapy. Acknowledge their concern but also assure them that treatment for nondisplaced broken clavicles are the exception to the usual fracture treatment. Indications for operative treatment include fractures that are open, complicated comminuted fractures, and fractures with neurovascular compromise or greater than 100% displacement (width of the clavicle) where skin is tented ([Arora, Fichadia, Hartwig, et al., 2014](#)).

## Dislocation of the Radial Head

If a small child is lifted by one hand, as happens when a parent pulls on one arm to lift the child over a curb or up a step, the head of the radius may escape the ligament surrounding it and become dislocated (nursemaid's elbow) (Vitello, Dvorkin, Sattler, et al., 2014). The child holds the arm flexed at the elbow with the forearm pronated. The child winces with pain when the radial head is palpated.

A simple dislocation of the radial head can be reduced in an emergency room by gentle pressure on the radial head while the arm is flexed and supinated. Relief of pain is immediate, and the child begins to use the arm again.

Parents feel guilty because they caused this dislocation. You can reassure them that this is a common injury in small children but that they need to avoid lifting their child in this manner again. Be aware, however, that a dislocation of the radial head can occur from extremely rough handling, as is seen in child maltreatment. Investigate the circumstances of the injury closely (Cicero, 2013).

### *QSEN Checkpoint Question 51.6*

#### **EVIDENCE-BASED PRACTICE**

Young children between the ages of 1 and 4 years frequently sustain dislocation of the radial head at the elbow that is often associated with the history of a pull to the arm, such as when a child is lifted by their arm or pulled at the wrist to prevent a fall. This is often referred to as nursemaid's elbow or a radial head subluxation. The left arm is affected more often than the right in both males and females, likely due to right hand dominance; and for unclear reasons, females are at greater risk for sustaining the injury (Vitello et al., 2014).

Based on this literature, which activity should the nurse advise Jeffrey not to do with his preschool sister?

- a. Swinging her by the arms to make her laugh
- b. Encouraging her to practice hip-hop dancing
- c. Helping her to fly her kite on a windy afternoon
- d. Helping her take off a tight sweater or shirt

*Look in Appendix A for the best answer and rationale.*

## Fracture of the Femur

Children who are involved in automobile accidents or who fall from considerable heights and land on their feet may suffer a fractured femur. Child maltreatment should be considered in an infant who sustains a fractured femur because there are few normal instances when a fracture of this magnitude should occur in an infant. That the break was caused by the presence of a bone malignancy (see Chapter 53) is a third possibility.

Even with closed femoral fractures, blood loss can be extensive because of the size of the bone broken. As the child lies on the examining table in the emergency

department, the child tends to hold the leg externally rotated and the thigh may appear abnormally short or deformed. Often, the child is in a great deal of pain, possibly with signs of shock from pain and blood loss. Children are frightened as well by the force of the accident that caused such a severe injury.

In the past, fractured femurs were not casted immediately because strong tendon spasms cause poor alignment and overriding of the femur segments. Only after the muscle spasm had been reduced enough by skeletal or Bryant traction to allow close approximation of the bone edges (7 to 14 days) was the child removed from traction and placed in a hip spica cast. Today, a child may be taken to surgery immediately to have an intramedullary rod placed to align and stabilize the fracture. No cast may be required. Help children and families identify ways for children to continue contact with friends or enjoy usual activities during the time of restricted activity.

### *What If . . . 51.4*

**A nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to musculoskeletal disorders in children (see Box 51.1). What would be a possible research topic pertinent to this goal that would be applicable to Jeffrey's family and that would also advance evidence-based practice?**

## **KEY POINTS FOR REVIEW**

- Bone and muscle disorders tend to be long-term disorders. Help children and their families to think about how the disorder will affect tasks of daily living to help a child better adjust to interventions such as a cast or brace. Help children plan self-diversional activities as necessary, so they can continue to grow developmentally while confined to a cast or traction.
- As a rule, children with a broken bone need additional calcium in their diet to aid bone healing. If they are on strict bed rest, however, this should only be a moderate addition to their diet to prevent renal calculi from forming.
- Many children have casts applied to allow broken bones to heal. If broken bones cannot be easily aligned, children are placed in traction.
- Developmental disorders that occur in children include flat feet (pronation), genu varum (bowlegs), and genu valgum (knock knees). The majority of these disorders are corrected naturally by normal growth.
- Slipped capital epiphysis is the slipping of the femur head in relation to the neck of the femur at the epiphyseal line. It occurs most frequently in obese or rapidly growing boys. It may require surgery or possibly a total hip replacement for treatment.
- Osteomyelitis is an infection of the bone. Because it can result in extensive destruction of bone, both IV and oral antibiotic therapy is necessary.

- Scoliosis is a lateral curvature of the spine. It is treated by bracing or surgery.
- JIA occurs in several different forms: polyarticular, pauciarticular, and systemic onset. Therapy includes exercise, heat application, and the administration of medications such as NSAIDs or methotrexate. Stressing the importance of these measures helps in planning nursing care that not only meets Quality & Safety Education for Nurses (QSEN) competencies but also best meets a family's total needs.
- Myasthenia gravis can occur in three types: neonatal transient myasthenia, congenital myasthenia, and juvenile myasthenia. Anticholinesterase drugs such as neostigmine, which prolong ACh action, are used.
- Muscular dystrophies are a group of disorders that lead to progressive degeneration of skeletal muscles. Common types that occur in children include congenital myotonic, facioscapulohumeral, and pseudohypertrophic. Children and parents need support throughout this long-term illness.
- A fracture or bruise of soft tissue can result from any trauma, including child maltreatment. Be certain to secure a detailed history of all injuries to be certain the history is consistent with the degree of injury.
- Volkmann ischemic contracture is a complication that occurs when an arm is casted in a bent position, which causes the radial artery and nerve to become compressed at the elbow. Frequent assessments of finger color and warmth are safeguards to detect if this is occurring when an arm cast is in place.

### CRITICAL THINKING CARE STUDY

Bonnie Sue is a 12-year-old who is discovered to have scoliosis during a routine school nurse assessment. She lives with her mother and stepfather on her family's dairy farm. Her chores include helping with milking two times a day and keeping her own room clean. Her mother had "slight scoliosis" as a teenager, which didn't require treatment.

1. Bonnie's mother is concerned that her daughter developed scoliosis because she insists on wearing sneakers plus she doesn't get enough exercise because she rides a bus to school. Could these factors have contributed to the development of her scoliosis?
2. Bonnie is fitted with a spinal brace. When you see her at a return appointment, her mother tells you Bonnie has to take the brace off at night to be able to sleep and sometimes during the day because it gets too hot. What further health teaching does this family need?
3. When you ask if Bonnie Sue drinks milk daily, her mother answers, "We live on a dairy farm. What do you think?" When you ask if Bonnie Sue is able to do her usual chores, her stepfather answers, "Well, she doesn't help with milking anymore." Could you be certain from these answers that Bonnie Sue is receiving a good source of calcium necessary for strong bone growth and is adjusting well to

wearing her brace?

## Nursing Care of a Family When a Child Has an Unintentional Injury

*Jason Varton is 10 years old; his sister Sage is 4 years old. An electrical fire started while the Varton family was sleeping. Jason jumped out of a window and hit his head on a cement walkway when the carpet caught on fire. Although his only visible sign of trauma is a reddened edematous area on his forehead, his temperature is 99.4°F (37.5°C); respirations are 18 breaths/min; pulse is 62 beats/min; and blood pressure is 110/62 mmHg. His left pupil appears more dilated than his right, and it reacts sluggishly to light. The children's father was able to rescue Sage and exit the house through the door but not before she suffered third-degree burns on her arms, hands, and neck.*

*Previous chapters described the growth and development of well children and care of children with disorders of specific body systems. This chapter adds information about the characteristic changes, both physical and psychosocial, that occur when children experience an unintentional injury.*

**Suppose you are a triage nurse. Would you rate Jason and Sage as children who need to be seen immediately, or could they be given second priority?**

### KEY TERMS

**allografting**  
**autografting**  
**contrecoup injury**  
**debridement**  
**drowning**  
**escharotomy**  
**otorrhea**  
**plumbism**  
**rhinorrhea**  
**sprain**  
**strain**  
**stupor**

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe the causes and consequences of common unintentional injuries in childhood and measures to prevent them.
2. Identify 2020 National Health Goals related to children who have experienced trauma that nurses can help the nation achieve (Box 52.1).
3. Assess a child with unintentional injuries.
4. Formulate nursing diagnoses related to an unintentionally injured child.
5. Establish expected outcomes for an unintentionally injured child that can help parents manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care for a child with an unintentional injury, such as providing pain relief.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of unintentional injury in children with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to achieve quality maternal and child health nursing care.

According to the Centers for Disease Control and Prevention (CDC, 2017) Childhood Injury Report updated in 2015, the leading cause of morbidity and mortality among children in the United States is unintentional injuries caused by burns, drowning, falls, poisoning, and motor vehicle accidents. More than 12,000 children die and 9.2 million are treated in emergency departments due to unintentional injuries yearly in the United States. For this reason, all healthcare providers must be aware of how to prevent, care for, and treat childhood injuries.

The National Action Plan for Child Injury Prevention was developed by the CDC to help raise awareness about child injuries and how they affect our nation, highlighting prevention goals and strategies, and to mobilize coordinated efforts to reduce childhood injuries (see the CDC website for additional information at [www.cdc.gov/safechild/publications.html](http://www.cdc.gov/safechild/publications.html)) (CDC, 2016b).

### BOX 52.1

#### Nursing Care Planning Based on 2020 National Health Goals

Because prevention of unintentional injuries could have both immediate and long-term effects on the nation's health, several 2020 National Health Goals are concerned

with preventing unintentional injuries in children:

- Reduce the number of drowning deaths each year from a baseline of 1.2 per 100,000 to 1.1 per 100,000.
- Reduce sports and recreational injuries from 46.6 per 100,000 to 41.9 per 100,000.
- Reduce the rate of firearm-related deaths from a baseline of 10.2 per 100,000 to 9.2 per 100,000.
- Prevent an increase of poisonings deaths from a baseline of 13.1 per 100,000 (maintain baseline value).
- Reduce the number of deaths caused by suffocation in infants age 0 to 12 months from a baseline of 22.5 per 100,000 to 20.3 per 100,000 infants.
- Reduce unintentional injury deaths from 40.1 per 100,000 to 36.0 per 100,000 (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by providing counseling on safety precautions to parents and children. Always help assess whether injuries were unintentional or possibly a result of child maltreatment or self-injury.

### *Nursing Process Overview*

## FOR CARE OF A CHILD WITH AN UNINTENTIONAL INJURY

### **ASSESSMENT**

When children are seen at healthcare facilities because of unintentional injuries, neither they nor their parents may be functioning at their optimal level because of the stress of the situation. Both may be apprehensive and frightened not only about what *has* happened but also about what could have happened. Children often feel guilty and worry they will be scolded or punished. Their parents can feel equally guilty because they realize they could have been watching more closely, causing them to act defensively. Remember people under stress do not process information well, so parents may not perceive the information you give them correctly. All information you supply in an emergency department, therefore, may need to be repeated after the immediate care is completed.

Children are likely to be in pain and may be confused because they count on their parents to keep them safe, but yet they have been hurt. Trust is momentarily broken. How can they be safe in the hospital if their parents are no longer protecting them?

### **NURSING DIAGNOSIS**

Nursing diagnoses need to address not only the physical injury a child sustained but also the psychological or emotional trauma both the child and the parents are experiencing. Examples of possible nursing diagnoses are:

- Pain related to fractured tibia from sports injury
- Ineffective airway clearance related to effect of burned esophageal tissue
- Impaired physical mobility related to severe burn injury

- Disturbed body image related to change in physical appearance from thermal injury
- Parental fear related to outcome after head injury in child
- Interrupted family processes related to child's unintentional injury
- Anxiety related to apprehension and lack of knowledge regarding medical treatment of child

## **OUTCOME IDENTIFICATION AND PLANNING**

Parents in an emergency department are rarely ready for long-term planning; they often have great difficulty in just answering the most straightforward, immediate questions. As a result, long-term planning may have to be delayed until the shock of the injury has passed.

On discharge from the emergency department, be certain parents have printed as well as oral instructions about the child's care, the name and number of the person to contact if they have questions about care or progress, and an appointment (or the number to call for a return appointment) for follow-up care. If a child is admitted to the hospital from the emergency department, it's helpful if the nurse who cared for the child in the emergency department can accompany the child to the hospital unit because the first person who cares for a child after an injury assumes a very important role to the child and parents because that person was the first one to recognize their distress. A transition period, or "passing on of care," helps a parent accept the child's new caregivers as being as dependable and trustworthy as the emergency department staff.

A key component of nursing intervention in an emergency department is to help parents understand why an injury happened and plan ways to make their immediate or community environment safe for children. Organizations that might be appropriate for referral are the American Association of Poison Control Centers ([www.aapcc.org](http://www.aapcc.org)), the American Burn Association ([www.ameriburn.org](http://www.ameriburn.org)), the American Academy of Pediatrics ([www.aap.org](http://www.aap.org)), and, for advice on cardiac resuscitation, the American Heart Association ([www.heart.org](http://www.heart.org)).

## **IMPLEMENTATION**

The extent of a child's injury depends on the injuring agent, the part of the body that was injured, and often the immediate care, including both physical and psychological management that a child receives.

Be certain to maintain standard infection precautions in emergency situations the same as at any other time. Remember parental consent must be obtained for treatment procedures even in an emergency, except for lifesaving actions, such as cardiopulmonary resuscitation (CPR) (it is assumed parents would consent to lifesaving procedures, and delaying procedures until they can be located could result in permanent disability or death).

## **OUTCOME EVALUATION**

After an injury, children need follow-up care to be certain the immediate

interventions were adequate and successful healing is taking place. Evaluation visits are also a time to determine whether the child's environment has been changed so the child is safer now than at the time of the injury (if applicable).

If an injury could not have been anticipated, parents appreciate hearing one more time that such an injury could not have been avoided and that they are good parents because this helps them maintain adequate self-esteem to continue to function well as parents.

Examples of expected outcomes suggesting achievement of goals are:

- The child swallows fluids without distress after esophageal burns.
- The child states pain is at tolerable level within 20 minutes after administration of pain medication.
- The child demonstrates full range of motion in hand after thermal injury.
- The child states he understands that wearing a seat belt is an important safety measure.
- The child states she will wear a helmet when riding a bicycle in the future.

## Health Promotion and Risk Management

In every care setting, nurses have the important opportunity among healthcare professionals to provide child and family teaching concerning the prevention of unintentional injuries. After an injury has occurred, nurses can provide valuable instruction to families about safeguarding their children against future injuries. This chapter will discuss safety tips after each section that can help prevent injuries during childhood.

### *QSEN Checkpoint Question 52.1*

#### **EVIDENCE-BASED PRACTICE**

As children develop new skills and attempt new activities, they are at increased risk for unintentional injuries. [Damashek and Corlis \(2017\)](#) interviewed mothers to obtain a history of their child's injuries to identify whether the behavior of the mother had a predictive relationship on the frequency of the child's injuries. Injury severity scales and measures of supervision were obtained. Supervision was defined with the following three categories: proximity, visual, and auditory. The results found that visual and proximity in combination are predictive in preventing injuries. More specifically, if the mother was near the child and in view of the child, injuries were less frequent than any single or different combination of supervision. As the number of children in the household increased, the frequency of unintentional injuries increased.

Sage is 4 years old and sustained a burn that required hospitalization when her 10-year-old brother attempted to cook a meal while their mother was in the living room watching television. The nurse is preparing Sage for discharge from the

hospital. Based on the evidence presented, the most effective advice the nurse could give to the mother to prevent future unintentional injuries is to:

- a. Discuss that it is difficult to supervise children's activities when they are out of sight.
- b. Inform her that a 10-year-old is not old enough to cook.
- c. Suggest in the future that she keep the volume on the television low, so that she can hear what the children are doing.
- d. Ask her if she has working smoke detectors and a fire extinguisher in the home.

*Look in Appendix A for the best answer and rationale.*

## The Injured Child

Because the emergency department nurse is often the first person who sees a child after an injury, nurses need to be prepared to make a preliminary assessment of the extent of a child's injuries. Remember that children may be seriously hurt but not crying because they are in shock. They may be hemorrhaging, but if they are bleeding internally, no blood may be visibly evident. Unintentional injuries become fatal when lung, heart, or brain function becomes inadequate. These three body systems, therefore, must be evaluated first (airway, breathing, circulation, and disability, or an ABCD evaluation). [Table 52.1](#) lists signs and symptoms to assess when determining the respiratory, cardiovascular, and neurologic status of an injured child.

**TABLE 52.1 IMPORTANT ASSESSMENTS ON INITIAL EXAMINATION OF AN INJURED CHILD**

Body System	Assessment
Respiratory system	Rate and quality of respirations Any sound of obstruction (wheezing, stridor, retractions, coughing?) Color (cyanotic?) Oxygen hunger (restlessness, inability to lie flat?)
Cardiovascular system	Color (pallor from hemorrhage or cardiovascular collapse?) Evident bleeding Pulse rate (increases with hemorrhage) Blood pressure (decreases with hemorrhage) Feeling of apprehension from altered vascular pressure
Nervous system	Level of consciousness (child answers questions coherently, infant attunes to parent's voice?) Pupils (equal and reacting to light?) Bumps or bruises on head or spinal column Loss of motion or sensory function in a body part

While conducting a preliminary assessment of a child's major body systems, take a brief history of the injury. What happened? How long ago did it happen? Was the child using protective equipment such as a helmet or a secured seat belt? What have the parents done? If the child fell, how far was the fall? On what body part did the child land? What do the parents think is the child's major injury (children may report one body part hurts at first but then a small cut elsewhere begins to bleed, and they focus on the minor bleeding as their major injury). If parents say, "At first, he acted as if his stomach hurt," this may be the first suggestion that he has a serious abdominal injury such as splenic rupture.

Evaluating children in an emergency department is difficult because they may be unconscious, too young to communicate, or so frightened that they cannot stop crying to report which body parts are painful or to indicate which parts should be assessed first. Spend a few minutes attempting to calm children and get them past this initial fright, unless symptoms of major body system disturbances require you to direct your immediate efforts elsewhere. Parents need frequent explanations while their child is being evaluated because as long as parents are worried and tense, children cannot be calmed easily.

A proportion of unintentional injuries in children result from child maltreatment. Conflicting histories (a parent and child recounting different stories) are a hallmark of maltreatment. Nurses are mandated reporters of child maltreatment. If you suspect an injury is intentional, a report must be made to the abuse registry so that child protection specialists can further explore the incident (see [Chapter 55](#)).

## Head Trauma

Head injuries occur commonly in childhood, and most head trauma in children is minor and not associated with brain injury or long-term consequences.

Children often receive head injuries when they are involved in multiple-trauma injuries, such as motor vehicle accidents, or when they fall from swing sets, windows, or bunk beds. Other children receive head injuries by being struck on the head by an object such as a baseball, rock, or hockey puck or by falling off a bicycle, especially if they're not wearing a protective helmet. Falls are the leading cause of traumatic brain injuries followed by unintentional blunt trauma and thirdly motor vehicle accidents (CDC, n.d.-b).

When providing patient education, head injury prevention tips to share with parents and children include:

1. Children should always wear a helmet when riding a bicycle, skating, or skiing.
2. Watch children closely while biking.
3. Bicycling on the street requires good bike control and ability to follow traffic rules. Young children should never be allowed to ride on the street.
4. Install car seats correctly and use the seat every time the child rides in a car.
5. Children under 4 ft 9 in. tall must sit on a car/booster seat when riding in a car.

6. Use window gates and guards to protect children from falling out.
7. Teach children how to cross the street safely by looking both ways for cars (CDC, 2017).

Head injuries are always potentially serious not only because the immediate injury can be life-threatening to the child but also because the injury can lead to complications that can be equally severe. Following a depressed skull fracture, for example, recurrent seizures and abnormalities on an electroencephalogram (EEG) as a result of scar tissue may occur.

Some children experience minor personality changes, memory deficits, or symptoms such as headache, irritability, and blurry vision (CDC, n.d.-a).

Behavioral manifestations may also include aggressiveness or poor school performance, although it may be difficult to determine whether these symptoms are organic or the result of being treated differently than before the injury by anxious parents.

## IMMEDIATE ASSESSMENT

All children with head trauma need to have their neck stabilized with a brace until cervical trauma has been ruled out. They also require a neurologic assessment as soon as they are seen and again at frequent intervals to detect signs and symptoms of increased intracranial pressure (ICP) because increasing pressure puts stress on the respiratory, cardiac, and temperature centers, causing dysfunction in these areas. The mark of increased pressure is a decrease in pulse and respiratory rate and an increase in temperature and pulse pressure (the distance between the diastolic and systolic pressure). The child's pupils also become slow or unable to react immediately. Level of consciousness and motor ability also decrease.

Important assessments include vital signs, observation of the child's pupils to be certain they are equal and react to light, level of consciousness, and motor function.

## IMMEDIATE MANAGEMENT

After a head injury, brain edema is likely to occur because fluid rushes into the inflamed and bruised area. ICP monitoring should be initiated (see [Chapter 49](#)). A computed tomography (CT) scan or magnetic resonance imaging (MRI) will determine areas of edema or bleeding. A central venous or central arterial line may be inserted, so pressure can be reduced with the administration of a hypertonic intravenous (IV) solution such as mannitol. As this is infused, it increases intravascular pressure and causes the edema fluid to shift back into the blood vessels. Administration of a steroid such as dexamethasone and keeping the child's head elevated are other ways to decrease inflammation and edema and lower ICP.

Nursing diagnoses for children with head injuries address both the physical abnormalities that need to be corrected and the psychosocial stress that such a serious injury generates.

**Nursing Diagnosis:** Risk for excess fluid volume related to administration of hypertonic solution

**Outcome Evaluation:** Child's respiratory rate remains between 16 and 24 breaths/min; specific gravity of urine is between 1.003 and 1.030; pulse remains between 60 and 100 beats/min; blood pressure remains consistent for height and age; lungs are clear to auscultation.

When hypertonic solutions are infused intravenously to reduce cerebral edema, fluid shifts from interstitial spaces into the bloodstream, possibly resulting in blood volume overload. To detect this, assess vital signs frequently. The body evacuates this fluid by the kidneys, so it is important to keep an accurate intake and output record to ensure the kidneys are functioning; test the specific gravity of urine to detect whether pituitary compression is leading to over- or underproduction of antidiuretic hormone.

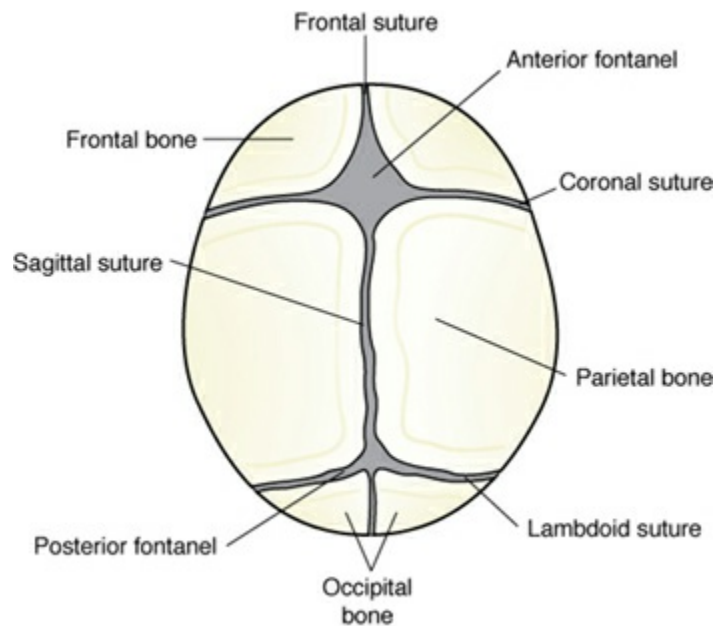

**Nursing Diagnosis:** Risk for delayed growth and development related to late sequelae of head injury

**Outcome Evaluation:** Child shows no evidence of any alteration in thought processes, seizure activity, or memory at follow-up visits. Cognitive and physical development proceed appropriately.

Caring for a child after a head injury can be difficult for parents because they are so worried about the child's condition. To help them feel a sense of control, offer information on the child's progress as it becomes available. Help parents become partners in the care of their child during the hospitalization.

## SKULL FRACTURE

A skull fracture is a crack in one of the bones of the skull. Detecting skull fractures in children is important because associated cerebral injury often occurs under the fracture. Many fractures are simple linear types; most involve the parietal bones. In some children, instead of a bone fracturing, the suture lines separate. This occurs more commonly in the lambdoid suture line; a coronal suture separation is rare and, if present, indicates severe trauma (Fig. 52.1).

**Figure 52.1** Location of suture lines of the skull.

### Assessment

Skull fractures are confirmed by a skull X-ray. Make sure you have a thorough history of the injury so the mechanism of injury can be determined. If the base of the skull is fractured, a child usually exhibits ecchymosis around the eyes or behind an ear.

**Rhinorrhea** or **otorrhea** (clear fluid draining from the nose or ear, respectively) may be noticeable. The fluid is cerebrospinal fluid (CSF) and is a serious finding because it means that the child's central nervous system is open to infection. If it is not clear whether the fluid is CSF or rhinitis from an allergy, test the fluid with a glucose reagent strip. CSF will test positive for glucose, whereas the clear, watery drainage from an upper respiratory tract infection or allergy will not.

If a skull fracture is linear with no underlying pathology, no treatment except observation and prescription of an analgesic is necessary. In about 3 weeks, a repeat X-ray will confirm that healing has taken place. You can assure parents that a second X-ray this soon is not harmful but necessary.

If a fracture is depressed (a bone fragment is pressing inward) or compounded (bone is broken into pieces), surgery will be necessary to remove or repair broken fragments and halt any bleeding that is occurring from a blood vessel being cut by a bone fragment. Cranial surgery of this type is discussed in [Chapter 49](#).

### Therapeutic Management

If CSF is draining from the nose or ear, a child will be admitted to the hospital for observation because this implies the force of the blow was severe. Keep the child in a semi-Fowler's position so fluid drains out, not inward, to reduce the possibility of introducing infection. Make certain children do not hold their nose or pack their nostrils with something to halt the drainage so the amount escaping can be judged. If the

drainage is excoriating to the upper lip, coat the space with an ointment such as petrolatum. Children may be prescribed a prophylactic antibiotic to reduce the risk of meningitis. If the drainage does not stop within a few days, surgery will be necessary to repair the fracture and reduce the danger of meningitis. Air that entered intracranial spaces at the time of the injury usually is absorbed rapidly. If X-rays at 72 hours still show air in the cerebral spaces, this implies a skull defect remains, and surgery may be indicated to close the defect.

### Potential Complications

A long-term complication of even a linear fracture of the skull may be a *leptomeningeal cyst*. This results from projection of the arachnoid membrane into the fracture site. With the interfering tissue, bone cannot heal and actually erodes, so the fracture site becomes progressively larger, not smaller. The follow-up X-ray will help determine if a leptomeningeal cyst is occurring. If a child develops focal seizures or symptoms of increased ICP after a skull fracture, a leptomeningeal cyst should be suspected. The defect may be palpated on the skull as an underlying indentation. Surgical resection is necessary to remove the cyst.

### SUBDURAL HEMATOMA

Subdural hematoma is venous bleeding into the space between the dura and the arachnoid membrane (Fig. 52.2A). Subdural hematomas tend to occur in infants more often than in older children. Symptoms can occur within 3 days or as late as 20 days after trauma. Infants usually have symptoms of increased ICP, such as seizures, vomiting, hyperirritability, and enlargement of the diameter of the head. Anemia caused by the substantial blood loss may occur. Angiography, MRI, or ultrasound will reveal the extent of the hematoma.

**Figure 52.2 (A)** Subdural hematoma. The red area in the upper left area of the drawing is the hematoma. Note the shift of structures. **(B)** Epidural hematoma. The red area in the lower left area of the drawing is the hematoma. Note the broken blood vessel and the shift of midline structures.

In infants, accumulated subdural blood is removed by a subdural puncture through the anterior fontanelle, if it is still patent, by a procedure similar to a lumbar puncture. Infants receive conscious sedation for the procedure and must be held extremely still so that they do not move and cause the aspiration needle to be inserted incorrectly.

Subdural punctures may need to be repeated daily to empty the subdural space. If bleeding is still present after 2 weeks, surgery usually is necessary to reduce the space and halt bleeding. In older children, surgery usually is necessary from the beginning because the anterior fontanelle is closed and the space cannot be reached by puncture.

## EPIDURAL HEMATOMA

Epidural hematoma is bleeding into the space between the dura and the skull and occurs when head trauma is severe (see [Fig. 52.2B](#)). Whereas subdural hemorrhage is usually venous bleeding, epidural hemorrhage is usually a result of rupture of the middle meningeal artery and thus is arterial bleeding. The bleeding can be severe and cause rapid brain compression.

At the time of the injury, children are apt to become momentarily unconscious. They then regain consciousness and, to the untrained eye, appear to be well for minutes or hours. Then, signs of cortical compression, such as vomiting, loss of consciousness, headache, seizures, or hemiparesis (paralysis on one side), begin to develop. On physical examination, unequal dilation or constriction of the pupils may be present. Decorticate posturing (see [Chapter 49](#)) may be seen, indicating extreme pressure on upper cortical centers. If the pressure is allowed to continue unchecked, it may grow so great that brain stem, respiratory, or cardiovascular function become impaired.

The treatment is surgical removal of the accumulated blood and cauterization or ligation of the torn artery. The earlier the process is recognized and treated, the less likelihood of residual damage from extreme pressure or anoxia to the involved portion of the brain.

## CONCUSSION

Concussion is the temporary and immediate impairment of neurologic function caused by a hard, jarring shock to the skull ([Purcell, 2012](#)). It may occur on the side of the head that was struck (a *coup injury*) or as the brain recoils from the force of the blow and strikes the opposite surface of the skull (a **contrecoup injury**; [Fig. 52.3](#)). Children have at least a transient loss of consciousness at the time of the injury and may vomit and show irritability after regaining consciousness. They typically have no memory (amnesia) of the event that led up to the injury or of the injury itself. For some children,

this makes being asked questions about the injury extremely upsetting because they do not remember anything that happened and feel a frightening loss of control. A skull X-ray or MRI is needed to rule out skull fracture, and observation for 24 hours is needed to rule out severe brain trauma, edema, or laceration. A child can be observed at home by the parents if they are able to assess the child's level of consciousness every 1 to 2 hours while the child is awake. Parents usually are instructed not to keep waking children during the night because multiple wakings are disorienting and can make it difficult to tell if the child is confused or not. Parents should wake the child at least once during the night, however, and to be certain they are conscious, ask them to name a familiar object, such as a favorite toy, or to name the color of some object shown to them. Being able to tell parents their name or where they live is equally revealing.

**Figure 52.3** Etiology of (A) coup and (B) contrecoup injuries.

There is an old belief that if children fall asleep after a head injury, they will die in their sleep; this belief can cause parents to keep shaking their child awake or to make the child walk continually. Be certain they understand that it is okay for children to sleep, but they must wake them at least once to assess their status (see [Box 52.2](#) for an interprofessional care map for a child with a concussion). As a final instruction, be certain parents have a telephone number to call if they have any questions or worries about their child's care.

**BOX 52.2**

**Nursing Care Planning**

**AN INTERPROFESSIONAL CARE MAP FOR A CHILD WITH A**

## CONCUSSION

Jason, a 10-year-old boy, is seen in the emergency department because he jumped out of a window and hit his head on a cement walkway escaping a house fire. He's upset and crying, although his only visible signs of trauma are a reddened and edematous area on the middle of his forehead.

**Family Assessment:** Child lives with his parents and a 4-year-old sister (burned in the house fire). Father is an insurance salesman; mother works part-time as a physical therapist. Home was badly burnt in fire; mother describes present finances as "shaky" because their home insurance won't begin to cover the cost of repairs to their home.

**Patient Assessment:** Height and weight at 75th percentile for age. Child unable to report or recall anything about the incident.

**Vital signs:** Temperature, 99.4°F (37.5°C); respirations, 18 breaths/min; pulse, 62 beats/min; and blood pressure, 110/62 mmHg. Left pupil is more dilated than his right; it reacts sluggishly to light. Glasgow Coma Scale score is 10. Alert enough to name baseball cards he brought in with him. A 1.5-cm raised area noted on forehead. Skin intact without evidence of bleeding. Child cries when area is touched. Negative otorrhea or rhinorrhea. Able to move all extremities through range of motion.

**Nursing Diagnosis:** Risk for injury related to effects of concussion

**Outcome Criteria:** Child remains alert and oriented; easily arousable. Pupils equal, round, react to light and accommodation; vital signs within age-acceptable parameters; exhibits no signs or symptoms of neurologic dysfunction.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Take history of injury; document distance child fell.	Assess child's vital signs, level of consciousness, and neurologic function initially and then every 30 minutes until discharge.	Changes in vital signs, level of consciousness, or neurologic function could indicate increasing intracranial pressure.	Parent describes injury and reactions of child since injury.
<i>Teamwork and Collaboration</i>				
Nurse/primary care provider/trauma care team	Assess who is available from trauma team for consult; assess if child has ever	Help trauma care team assess child because child has been told not to talk to	Symptoms of concussion can develop slowly over the next few hours after	Trauma care team examines child; prescribes follow-up care. Child cooperates

	had magnetic resonance imaging (MRI) before.	strangers. Accompany child to MRI service.	injury. MRI can help detect bleeding and edema.	with MRI.
--	--	--	---	-----------

*Procedures/Medications for Quality Improvement*

Nurse/primary care provider	Assess whether child's demeanor (crying) is from fright or pain.	Institute measures to calm the child. Encourage the parents to hold and reassure him.	Crying increases intracranial pressure. Involving the parents provides them with a concrete activity, helping to provide some sense of control over the situation.	Parents are able to calm child to allow for better evaluation of condition.
-----------------------------	--	---	--	---

*Nutrition*

Nurse	Assess whether child has vomited since head injury.	If not nothing by mouth (NPO), offer clear fluid to be certain child does not have vomiting.	Vomiting is a symptom of increased intracranial pressure.	Child drinks some fluid without vomiting.
-------	---	--	---	---

*Patient-Centered Care*

Nurse	Assess what parents understand about concussion in children.	Teach parents how contrecoup injuries occur and what symptoms they cause.	A contrecoup injury causes injury or edema to the posterior brain.	Parents state they understand why their child has posterior (eye control) symptoms and the assessment they will need to continue after discharge.
Nurse	Children often have no memory of events with concussion.	Parents and child state they understand procedures being carried		

Orientation and explanation help to minimize a child's fear of the unknown and of his situation. out. Voice confidence in care.

*Informatics for Seamless Healthcare Planning*

Nurse/primary care provider	Assess whether parents understand why child will be admitted to observation unit overnight.	Child needs continuing care such as being roused every 2 hours during night to ensure he is conscious.	Assessing consciousness is important to assess whether complications are occurring.	Parents state one of them will remain with child in hospital to help reduce child's fear of strangers and better accept needed procedures.
-----------------------------	---	--	---	--

**CONTUSION**

A brain *contusion* occurs when there is tearing or laceration of brain tissue (Fig. 52.4). It is also known as bruising on the brain. The symptoms are the same as for a concussion but more severe. In addition, symptoms related to the specific brain area that is lacerated such as a focal seizure, eye deviation, or loss of speech will occur. Surgery may be necessary to halt bleeding. The child's prognosis depends on the extent of the injury.

**Figure 52.4** Intracerebral hemorrhage. The central large dark area represents the hemorrhage. Note the midline shift.

### *What If . . . 52.1*

**In the emergency department, after Jason’s head injury, his parents tell the nurse they both had a gastrointestinal “flu” last week. They assure the nurse that the reason Jason is vomiting now is probably because “he’s caught their flu.” How could the nurse evaluate whether the vomiting is from the head injury or a gastrointestinal infection?**

## COMA

*Coma* (unconsciousness from which a child cannot be roused) or **stupor** (grogginess from which a child *can* be roused) may occur in children after severe head trauma. Because these are both symptoms of underlying disorders, it’s important to obtain a thorough history of the injury so treatment can be directed specifically toward the cause.

## Assessment

For assessment, obtain a history from a parent or an observer of the event that caused the injury to determine what happened immediately before the time the child became comatose (e.g., the child fell, was choking, or took a recreational drug).

Undress the child completely so you can inspect all body parts. Although head injury is most likely to be the underlying cause of coma or seizure, metabolic disturbances such as diabetes mellitus, dehydration, severe hemorrhage from another

body part, or drug ingestion also must be considered as possible causes. Count respirations and pulse and measure blood pressure to establish baseline values because changes in these values often provide good clues as to the cause of coma. A child with increased ICP, for example, will show decreased pulse and respiratory rates and increased blood pressure. The child with diabetes, in contrast, will develop increased respirations. Internal hemorrhage will lead to an increased pulse rate and decreased blood pressure. Drug ingestion may lead to either increased or decreased measurements, depending on the drug ingested.

Always turn an unconscious child on the side because if brain stem compression is present, the child cannot swallow effectively; lying on the side allows saliva to drain from the mouth to prevent aspiration. Observe the child's eyes for signs of dilated pupils, which could indicate increased ICP. If both pupils are dilated, irreversible brain stem damage is suggested, although such a finding may also be present with poisoning with an atropine-like drug. Pinpoint pupils suggest barbiturate or opiate intoxication. One pupil dilated or one eye deviated downward or laterally more than the other suggests third cranial nerve compression or a tentorial tear (laceration of the membrane between the cerebellum and cerebrum) with herniation of the temporal lobe into the torn membrane. This situation requires immediate surgery to correct temporal compression.

Lack of a doll's eye reflex (see [Chapter 49](#)) suggests compression of the oculomotor nerves (third, fourth, or sixth) or brain stem involvement. Observe for posturing, such as decerebrate posturing, which suggests cerebral compression and dysfunction. If the retina of the eye reveals papilledema (swelling), it suggests that increased ICP has been long-standing (more than 24 to 48 hours).

Metabolic or renal disorders that cause unconsciousness are revealed by blood analysis; therefore, studies such as blood glucose, electrolytes, blood urea nitrogen (BUN), liver function tests, blood gas studies, and toxicology tests may be prescribed to rule out possible causes. A lumbar puncture and a CT or MRI will be done if a head injury is the most likely cause ([Sigurtà, Zanaboni, Canavesi, et al., 2013](#)).

Lumbar puncture may have little value at first in predicting the severity of a head injury. The procedure is contraindicated if increased ICP is present because release of fluid with the puncture could cause brain stem compression into the cord, a serious complication.

Coma is graded according to a standard scale so that changes in the level of consciousness can be evaluated and deterioration or improvement can be documented. [Figure 52.5](#) shows the Glasgow Coma Scale, the most commonly used evaluation system for coma ([Rhine, Wade, Makoroff, et al., 2012](#)). Because this system was devised as an adult assessment scale, it must be modified for use with children or infants. Such a modification is shown in [Box 52.3](#).

Glasgow Coma Scale			AM			PM			AM						
Assessment	Reaction	Score	8	10	12	2	4	6	8	10	12	2	4	6	8
Eye opening	Spontaneously	4	X						X	X	X	X	X		
Response	To speech	3		X				X							
	To pain	2			X	X	X								
	No response	1													
Motor response	Obeys verbal command	6	X						X	X	X	X	X		
	Localizes pain	5		X	X										
	Flexion withdrawal	4				X		X							
	Flexion	3					X								
	Extension	2													
	No response	1													
Verbal response	Oriented x3	5	X						X	X	X	X	X		
	Conversation confused	4		X				X							
	Inappropriate speech	3			X										
	Incomprehensible sounds	2				X	X								
	No response	1													

**Figure 52.5** Glasgow Coma Scale scoring for a child. A score of 3 to 8 denotes severe trauma; 9 to 12, moderate trauma; 13 to 15, slight trauma. Notice the gradual improvement from coma in this example.

### BOX 52.3

#### Scoring for Glasgow Coma Scale

##### EYE OPENING

4. Child opens eyes spontaneously when you approach.
3. Child opens eyes in response to speech (spoken or shouted).
2. Child opens eyes only in response to painful stimuli, such as pressure on a nail bed.
1. Child does not open eyes in response to painful stimuli.

##### MOTOR RESPONSE

6. Child can obey a simple command such as “hand me a toy” (infant smiles or attunes).
5. Child moves an extremity to locate a painful stimulus applied to the head or trunk and attempts to remove the source.
4. Child attempts to withdraw from the source of pain.
3. Child flexes arms at the elbows and wrists in response to painful stimuli to the nail beds (decorticate rigidity).
2. Child extends arms (straightens the elbows) in response to painful stimuli (cerebrate rigidity).
1. Child has no motor response to pain on any extremity.

##### VERBAL RESPONSE

5. Child is oriented to time, place, and person (child >4 years old knows name, date, and where he or she is; infant appears to recognize parent).
4. Child is able to converse, although not oriented to time, place, or person (does not know who or where he or she is; infant says words but does not appear to differentiate parents from others).
3. Child speaks only in words or phrases that make little or no sense (“I want frazzle no”; infant’s vocabulary is less than it is normally).
2. Child responds with incomprehensible sounds, such as groans.
1. Child does not respond verbally at all.

Modified from Teasdale, G., & Bennett, B. (1974). Assessment of coma and impaired consciousness: A practical scale. *Lancet*, 2(7872), 81–84.

On the scale, a score of 3 to 8 suggests severe trauma (a number less than 5 suggests a very severe prognosis); a score of 9 to 12, moderate trauma; and 13 to 15, slight trauma.

## Therapeutic Management

If children are unconscious for longer than a transient period, they usually are admitted to an observation unit for further assessment. An IV route is established so that, when specific measures such as blood replacement, electrolyte replacement, or fluid replacement are needed, a route for immediate administration is available. Oral suctioning to remove mucus from the mouth and pharynx may be necessary. Measure oxygen saturation by pulse oximetry. If a child has acute signs of respiratory difficulty or oxygen saturation is low, endotracheal intubation may be necessary to ensure respiratory function.

Obtain the child’s vital signs and assess neurologic status, such as state of consciousness and the ability of pupils to react to light, every 15 to 20 minutes or as prescribed, so a picture of gradual change can be detected.

A child’s prognosis after coma depends on the initial cause of the coma and the immediate care the child receives. If the increased ICP can be relieved before any permanent brain damage results, the effects of the coma will be transient. Prognosis is always guarded, however, because coma is a serious, possibly life-threatening, response until ruled otherwise.

## Nursing Diagnoses and Related Interventions

Care of the child in coma is directed toward maintaining body function in an optimal state until the child reawakens.

**Nursing Diagnosis:** Risk for ineffective airway clearance related to brain stem

pressure

**Outcome Evaluation:** Child's respiratory rate remains between 16 and 20 breaths/min; no retractions or signs of obstruction are present.

Some children who are comatose require endotracheal intubation or tracheotomy with mechanical ventilation to ensure an open airway and adequate oxygenation. An endotracheal tube may be replaced with a tracheotomy after 3 to 7 days to prevent necrosis of the pharynx from pressure of the endotracheal tube.

**Nursing Diagnosis:** Risk for impaired skin integrity related to lack of mobility

**Outcome Evaluation:** Child exhibits no areas of broken or irritated skin.

Bathe children who are comatose daily to stimulate skin circulation; include the hair as part of the bath about every 3 days. Change the child's position at least every 2 hours to prevent pressure ulcer formation or development of hydrostatic pneumonia from pooled secretions in the lungs. Keep the linen on the bed dry and free from wrinkles. Use of a sheepskin, an egg-carton foam, or an alternating-pressure or water mattress can help to decrease skin pressure. Perform thorough passive range-of-motion exercises to maintain muscle tone and prevent contractures.

**Nursing Diagnosis:** Risk for imbalanced nutrition, less than body requirements, related to inability to take in oral food or fluid

**Outcome Evaluation:** Child has good skin turgor; weight is not falling percentiles on the growth curve; hourly urine output remains greater than 1 ml/kg.

Children who are unconscious cannot be fed orally due to the risk of aspiration into the lungs. Therefore, nutrition is maintained by nasogastric (NG) or gastrostomy tube feedings, IV fluid administration, or total parenteral nutrition (TPN). IV fluid is only a short-term option, because adequate protein and fat cannot be supplied solely by this route. Always aspirate NG or gastrostomy tubes for stomach contents before giving a feeding to check tube placement and assess gastric residual amounts. As a rule, return any amount of stomach residue aspirated because if this is discarded each time, a child will lose a large amount of stomach acid, possibly leading to alkalosis. Because children's stomach size is small, check whether the amount of the feeding should be reduced by the amount of fluid remaining in the stomach before feeding the full amount of prescribed formula.

Give mouth care at least twice daily with clear water and a padded tongue blade. Coat lips with petrolatum or a commercial ointment to prevent drying and cracking. If a child's eyes tend to be dry, close them to prevent corneal ulceration. Artificial tears (methylcellulose) may be prescribed to keep eyes from drying until the child regains consciousness.

*QSEN Checkpoint Question 52.2*

## PATIENT-CENTERED CARE

Jason's parents are in distress because they fear that his ICP is increasing. The nurse wants to reassure his parents that Jason is being monitored closely. Which event would be most indicative that his ICP is increasing?

- a. Jason refuses to let the nurse assess his tympanic temperature.
- b. Jason asks the nurse to read the same story to him over and over.
- c. Jason can't remember a thing about how his injury happened.
- d. Jason's temperature and blood pressure are both slowly increasing.

*Look in [Appendix A](#) for the best answer and rationale.*

## Abdominal Trauma

Abdominal trauma can result from an object such as a baseball bat, a high-speed motor vehicle accident without restraint or with a seat belt without a shoulder strap, child maltreatment, or a fall from a height greater than 20 ft (Klimek, Lutz, Stranzinger, et al., 2013). Children are more apt to experience injury to their spleen and liver than adults because these organs are more exposed in children than they are in adults. The injury may be difficult to detect, however, because, unlike obvious signs of head or respiratory injuries, abdominal trauma usually presents with much more subtle signs.

### ASSESSMENT

To detect abdominal trauma, assess vital signs for a baseline and then continue measurements to reveal whether abdominal hemorrhage could be occurring; rapid respirations, hypotension (less than 80 mmHg systolic pressure in an older child; less than 60 mmHg in an infant), and increasing pallor usually suggest that hidden internal bleeding is present. An additional suggestion that internal bleeding is present is that a low blood pressure shows little improvement when IV fluid is administered.

If abdominal trauma is suspected, an NG tube may be passed. Stomach contents are then aspirated to be assessed visually for fresh and occult blood, and the tube is then attached to low intermittent suction to allow for continued stomach observation. An indwelling urinary (Foley) catheter may be inserted into the bladder to evaluate urine for blood and urine output; evidence of blood in the urine suggests bladder damage, and a decreased output suggests accompanying kidney trauma. A paracentesis (introduction of a catheter into the abdomen to aspirate for the presence of blood) is another way to detect internal bleeding. Keep in mind that procedures such as NG tube or catheter placement are extremely frightening for young children (unsure of their anatomy, they have no clear idea where the tubes are going). Developmentally appropriate education prior to the procedure will help remove some of the fear (Box 52.4).

### BOX 52.4

## Nursing Care Planning Tips for Effective Communication

Jason, 10 years old, has no memory of how he sustained a head injury and thus needs additional assessments to rule out other trauma.

*Tip:* Be sure to help establish a sense of support and trust in addition to obtaining consent for procedures. Nurses sometimes focus on getting needed care done while failing to recognize the fear, apprehension, and loss of self-esteem the parent is feeling. In the following scenario, the nurse listens and thus recognizes and attends to the parent's fears.

**Mr. Varton:** Why are you looking at his belly? He didn't hurt that.

**Nurse:** He needs a thorough assessment to be sure there aren't any other problems.

Next, I'll be putting in an IV line and urinary catheter and then taking him for an MRI.

**Mr. Varton:** How much will all that cost?

**Nurse:** I can see you have a lot of worries and concerns on your mind, your son's health, your home, being able to pay for health care, and having a place to live. This must be an extremely stressful time for you.

**Mr. Varton:** My daughter is burned. My house is ruined. I should have been able to get the children out before they got injured.

**Nurse:** Would you like to speak to a trauma counselor? It may help to organize your thoughts about all of the events that have occurred in such a tragic situation.

An abdominal X-ray, MRI, or ultrasound may help rule out a ruptured liver or spleen or a fractured pelvis, all conditions that could be contributing to blood loss. Air under the diaphragm on an X-ray suggests gastric or intestinal rupture with escape of air from these organs into the peritoneal cavity. Free fluid in the abdomen suggests leakage of bowel fluid, liver or splenic rupture, and pooling of blood.

Parents may not seek immediate medical attention after abdominal trauma because they are unaware a serious injury has resulted. Because often, there are no obvious signs of injury with abdominal trauma, it is vital to educate parents and patients on the degree of concern with abdominal bleeding and the need to perform diagnostic procedures to help determine the severity of the injury.

## Nursing Diagnoses and Related Interventions

Major features of abdominal injury are pain and a feeling of "fullness," both from edema and possibly internal bleeding. If parents did not recognize their child was injured, guilt and fear on their part may compound the child's care. Goal setting is usually concerned with the immediate diagnostic procedures or anticipated surgery.

Interventions differ according to the specific injury present.

**Nursing Diagnosis:** Pain related to abdominal injury

**Outcome Evaluation:** Child states that level of pain is tolerable or rates it as low on a pain rating scale; does not grimace or guard when abdomen is palpated.

Routinely, analgesics are not administered to children after abdominal trauma, unless their pain is severe, to avoid masking increasing pain and, also, because the location of the pain can help identify which organ may be injured. Offer support until analgesia can be given. Being held by a parent or lying absolutely still on an exam table helps prevent abdominal organs from shifting and thus may help reduce the degree of pain.

## SPLENIC RUPTURE

In children, the spleen is the most frequently injured organ when there is abdominal trauma because of its location under the lower left ribs (McCance & Grey, 2012). Frequent causes of injury involving the spleen are inappropriately applied seat belts in automobiles, handlebar injuries in bicycle accidents, or skateboard or snowboard accidents. The child will have tenderness in the left upper quadrant of the abdomen, especially on deep inspiration, when the diaphragm moves down and touches the spleen. The child may hold the left shoulder elevated so that the diaphragm is raised on the left side to keep this from happening or report radiated left shoulder pain while lying in a supine position (Kehr sign).

An X-ray will show little about the spleen itself but may reveal a broken rib over the spleen, suggesting the extent of the trauma to that area. An MRI will rule out damage not only to the spleen but also to the left kidney just behind the spleen, which may also have suffered trauma. A complete blood count is done to detect blood loss and determine kidney involvement. An IV line is begun immediately and blood is typed and cross-matched, so that blood can be readied for replacement if necessary. Children with suspected splenic injury are usually admitted to an observation unit if the blood loss from rupture appears to be mild. If bleeding is severe, immediate surgery, such as a partial or total splenectomy, may be necessary to halt the bleeding and save the child's life.

After a splenectomy, children are very susceptible to infection. Vaccines such as *Haemophilus influenzae* type b, pneumococcal, and meningococcal are recommended to protect these children against bacterial infections.

## LIVER RUPTURE

The liver is also more prone to rupture in children than in adults because the liver, like the spleen, is not completely sheltered by the rib cage in children (Shao, Zou, Li, et al., 2013).

Children with liver rupture or laceration usually have severe abdominal pain that is most marked on inspiration, when the diaphragm descends and touches the liver. They also show symptoms of blood loss, such as tachycardia, hypotension, anxiety, and pallor. Their hematocrit level will be low or falling. Such children need to be prepared for immediate surgery because the liver is a highly vascular organ, and blood loss can be life-threatening.

Occasionally, a communication between an artery and the bile duct occurs at the time of liver trauma. In this situation, symptoms are not immediate, but gastrointestinal (GI) bleeding, such as hematemesis (vomiting blood) or melena (blood in stool), may be seen a few days after the injury. The child may report colicky upper abdominal pain relieved by emesis. An MRI plus a liver study, such as a liver arteriogram, is necessary to reveal the extent of the injured artery.

After either liver or spleen surgery, children need careful observation for return of bowel function, assessment for the possibility of peritonitis, and slow reintroduction of oral nutrition.

When providing patient education, abdominal trauma prevention tips for parents and children include:

1. Using guards on windows, stair gates, and guard rails to prevent children from dangerous tumbles
2. Checking that playground equipment is well maintained and supervising young children at all times when they are out at play
3. Knowing how to install and use car seats, booster seats, and seat belts appropriately
4. Using car seats on every trip no matter how short
5. Setting a good example by always using a seat belt yourself ([CDC, 2016a](#))

## Dental Trauma

Injuries to teeth occur most often from falls in which a child strikes the upper front incisors or from blows to the face by objects such as baseball bats or hockey sticks. Such injuries are always potentially serious because they can lead to aspiration of the injured teeth or malalignment of future teeth. If a tooth is knocked out of the mouth, parents should rinse the tooth in water, drop it in a salt solution or milk, and bring it to the emergency department with them. Deciduous teeth may not be replaced, but if a permanent tooth can be saved, washed with saline or an antiseptic in the emergency department and then replaced and wired into place, there is a good chance it will reimplant successfully ([McTigue, 2013](#)).

The child will usually be prescribed a course of oral antibiotic, such as penicillin, to prevent infection. Stress to the parents the importance of giving the full course of the antibiotic and allowing only soft food until the tooth has firmly adhered (approximately 2 weeks).

If a blow to a child's teeth was extensive, an X-ray may be necessary to rule out an

accompanying mandibular or maxillary fracture. If a portion of a tooth cannot be located, the possibility of aspiration must be considered and confirmed or ruled out by a chest X-ray. In young children, often a tooth is not knocked free but is pushed back up into the gum. These teeth gradually regrow, and although they may darken in color, they usually are healthy. If the affected tooth is a deciduous tooth, the permanent tooth is rarely injured even though it is already formed underneath in the gum. At the appropriate time, the permanent tooth will erupt without difficulty.

When providing patient education, dental trauma prevention tips for parents and children should focus on using mouth guards and face protection when playing contact sports.

## Drowning

**Drowning** is death caused by suffocation from submersion in liquid when the inhaled water fills the lungs and therefore blocks the exchange of oxygen in the alveoli. More than 3,500 children die from drowning annually, making it one of the most frequent causes of death by unintentional injury among children in the United States (CDC, 2016d).

When providing patient education, drowning prevention tips for parents and children should include:

1. Use secure fencing and gating around swimming pools.
2. Ensure adequate adult supervision at all times with all children during all water activities.
3. Use flotation devices while swimming or boating.
4. Toddlers can drown in shallow areas, including toilets and buckets and therefore should always be adequately supervised (CDC, 2016d).

Most infant drownings occur in bathtubs; 1- to 4-year-old children most frequently drown in artificial pools; older children most frequently drown in bodies of fresh water. The majority of drowning injuries that take place outside the home occur in the summer months, when more children are swimming and boating. These may occur in young children because parents overestimate the child's swimming ability (Morrongiello, Sandomierski, Schwebel, et al., 2013). In older children, male adolescents are particularly at risk, although both sexes may take dares to swim farther than they are capable of or may swim under the influence of alcohol, which impairs their decision-making ability and their physical coordination.

## PATHOPHYSIOLOGY OF DROWNING

When a child's head is submerged and water inhalation occurs, the natural response is to cough to remove the irritation in the nose and throat caused by the water. If the child cannot get the head out of the water at this point, water enters the larynx, causing the larynx to spasm and prevent any further water from entering. This mechanism unfortunately also prevents air from entering the trachea, resulting in asphyxia. If

ventilation occurs at this point, the likelihood of effective treatment is good because there is little water in the lungs.

If ventilation is not given at this point, the larynx relaxes from the asphyxia and water enters the lungs. Oxygen can no longer be exchanged as the alveoli fill with water. Hypoxia deepens, and cardiac arrest occurs.

Additional changes that occur when water enters the lungs depend on whether the water is fresh or salt. Salt water is hypertonic, so fluid osmoses from the bloodstream into the alveoli in an attempt to dilute the aspirated water, increasing the amount of fluid in lung tissue and increasing hypoxia. Blood viscosity increases as shown by an increased hematocrit level; both tachycardia and decreased blood pressure from hypovolemia result.

Fresh water is hypotonic, causing the aspirated water to shift from the lungs into the bloodstream, again, because of osmotic pressure. This can lead to hemolysis of the red blood cells, a dilution of plasma, and possibly hypervolemia with tachycardia and increased blood pressure. If the release of potassium from destroyed red blood cells is large enough with fresh-water drowning, cardiac arrhythmias may occur. In both instances, loss of surfactant from lung alveoli, caused by introduction of the water (adult respiratory distress syndrome), can lead to alveolar collapse on expiration ([CDC, 2016d](#)).

When very young children dive into very cold water, a mammalian diving reflex occurs that helps them survive drowning (immediately after plunging into cold water, a lifesaving bradycardia and shunting of blood away from the periphery of the body to the brain and heart occur). This reflex is triggered when water is 70°F (21°C) or less and the face is submerged first. The phenomenon explains why very young children survive more often than older children after being submerged in icy wintertime water.

## **EMERGENCY MANAGEMENT**

When a child is pulled from the water after drowning, mouth-to-mouth resuscitation and CPR should be started at once (discussed in [Chapter 41](#)). This is an exception to the advice to use hands-only resuscitation as the child's lungs are filled with water, which must be displaced ([CDC, 2016d](#)). Assuming CPR is effective, the child then needs follow-up care at a healthcare facility because the child is certain to be acidotic from accumulated carbon dioxide and hypoxic from lack of oxygen caused by water retained in the alveoli. There also is a high risk for respiratory infection from contaminants in the water.

Follow-up care aims to increase the child's oxygen and carbon dioxide exchange capacity by using the lung areas that are not filled with water. Attach a pulse oximeter to monitor oxygen saturation. If respiratory efforts remain severely compromised, a child is intubated with a cuffed intratracheal tube; mechanical ventilation with positive end-expiratory pressure may be necessary to force air into the alveoli. A cuffed tube is used because water that has been swallowed will be vomited as the child revives and the cuff will prevent vomitus from being aspirated. The child is usually given 100% oxygen

so that as much space as possible in the available lung alveoli can be used. In addition, an NG tube is inserted to decompress the stomach, prevent vomiting, and free up breathing space. A bronchodilator such as albuterol may be administered by aerosol to prevent bronchospasm and, again, to allow the child to make maximum use of the oxygen administered. If the child aspirated salt water, plasma may be administered to replace protein being lost into the lungs and prevent hypovolemia.

If the child's body temperature is very low, it is generally better to allow gradual warming (not using a warming blanket) so the child's metabolic requirement does not rise sharply before alveolar space is ready to accommodate this increased oxygen need. Extracorporeal membrane oxygenation (ECMO) may be necessary when most of the lung has water aspiration.

Unfortunately, a danger of drowning is that neurologic damage can occur due to the amount of oxygen deprivation to the brain. If the child is awake or only lethargic at the scene of the injury and immediately afterward in the hospital, the prognosis is greatly improved over that of the child who is comatose.

## Nursing Diagnoses and Related Interventions

Drowning has both physical (lack of oxygen) and emotional (extreme fright) components, so both areas need to be addressed in planning care.

**Nursing Diagnosis:** Risk for infection related to foreign substance in respiratory tract

**Outcome Evaluation:** Child's tympanic temperature remains within normal parameters; rales are absent on lung auscultation; respiratory rate is within age-acceptable parameters.

After drowning, a child is usually prescribed prophylactic antibiotic therapy to prevent pneumonia or additional airway interference. Assess vital signs and auscultate lung sounds frequently for adventitious sounds, such as rales or fine rhonchi. Turning the child every 2 hours if on bed rest and encouraging deep breathing and incentive spirometry every hour to help aerate the lungs fully and prevent the accumulation of fluid, which promotes infection.

**Nursing Diagnosis:** Fear related to drowning experience

**Outcome Evaluation:** Child discusses fear; states she understands that although frightening, the experience is over, and she is now safe.

Children may be admitted to an observation unit for monitoring of oxygenation until water from the alveoli is absorbed and they once again can ventilate effectively on their own. Nightmares that revisit the drowning episode may occur and interfere with the child's sleep. Encourage children to verbalize the fright they feel about the

experience. Assure them they are now safe and definitely out of the water. Because drowning is such a frightening experience, a child may need support from parents before they are willing to try swimming again. The goal is to get the child to an emotionally comfortable state where he or she can regain confidence with swimming. Encourage solid swimming skills to help prevent future drowning experiences.

## Poisoning

According to the American Association of Poison Control Centers, there are more than 1 million reported poison exposures among children younger than 6 years of age yearly. For children 6 years and older, the estimated yearly reported exposures drops to about 300,000. Because many poisoning exposures are not reported, these numbers are most likely an underestimate. Poisoning occurs in all socioeconomic groups, and 90% of the time it occurs in the child's home. The substances most frequently ingested in children 5 years and younger include cosmetics/personal care products, household cleaning products, analgesics, foreign bodies such as toys, and topical preparations. Children younger than 6 years of age are at high risk for ingesting pharmaceutical agents. Nearly 9,500 children will be hospitalized yearly for unsupervised ingestion of prescription medications. The most commonly ingested medications include opioids and benzodiazepines, acetaminophen, cough and cold remedies, ibuprofen, and diphenhydramine.

Reference from: [AAPCC.org](http://AAPCC.org) (American Association of Poison Control Centers)

When providing patient education, poison prevention tips for parents should include ([www.aapcc.org](http://www.aapcc.org)):

1. Keep medicines and toxic products locked and away from children.
2. Add the poison control number (1-800-222-1222) in your cell phone and make sure all caretakers do the same.
3. Call the poison control center if you think your child has ingested anything that may be poisonous. Keep in mind that the child may be awake and alert and acting normally.
4. If your child has ingested a poisonous product and collapses or stops breathing, call 911.
5. When administering medications, be sure to read labels carefully and to administer the appropriate amount.
6. Safely dispose unused, unneeded, or expired medications and vitamins ([CDC](http://CDC), 2015).

## Nursing Diagnoses and Related Interventions

Poisoning tends to occur when parents are preoccupied or highly stressed; nursing

planning needs to address not only immediate care measures but also education to prevent poisoning from occurring again.

**Nursing Diagnosis:** Risk for injury related to young maturational age of child and presence of unsecured poisons in the home

**Outcome Evaluation:** Parents identify poisonous and toxic items in the home and describe how they are stored safely; parents state local poison control center number; parents describe measures to take if poisoning occurs.

## EMERGENCY MANAGEMENT OF POISONING AT HOME

If poisoning occurs, parents should telephone the National Poison Control Center (1-800-222-1222) to ask for advice regarding what to do. Instructions are specific to what the child ingested. The parent should be prepared to provide the following information to the poison control center:

- What was swallowed; if the name of a medicine is not known, what it was prescribed for and a description of it (color, size, shape of pills)
- The child's weight and age and how long ago the poisoning occurred
- The route of poisoning (oral, inhaled, sprayed on skin)
- An estimation of how much of the poison the child took (a bottle of cleaner or medicine should say how many pills or how much liquid it originally contained)
- The child's present condition (sleepy, hyperactive, comatose)

If the poison was in pill form, parents should check whether there are pills scattered under a chair before they assume they were swallowed. If one child in a family has swallowed a poison, parents should investigate whether other children have also poisoned themselves because a preschooler often shares “candy” with a younger sibling. If the poison control center advises parents to make the child vomit, the best way to do this is to place a finger at the back of the child's throat. Old remedies such as giving mustard or salty water are not that effective and waste time that could be spent telephoning an emergency service (911) for help or transporting the child to the hospital.

### *What If . . . 52.2*

**A nurse has learned that Jason's younger sister, Sage, 4 years old, suffered a mouth burn a year ago when she sprayed her mouth with oven cleaner. What preventive tips and patient education could the nurse provide to Sage and her mother?**

## EMERGENCY MANAGEMENT OF POISONING AT THE HEALTHCARE FACILITY

In the emergency department, the best method to deactivate a swallowed poison is the administration of activated charcoal either orally or by way of an NG tube to halt the action of the poison.

Activated charcoal is supplied as a fine black powder that is mixed with water for administration. Adding a sweet syrup to the mixture can make it more palatable. Caution parents that, as the charcoal is excreted through the bowel over the next 3 days, stools will appear black so they do not mistake the color for blood (Box 52.5).

## BOX 52.5

### Nursing Care Planning Based on Responsibility for Pharmacology

#### ACTIVATED CHARCOAL

**Classification:** Activated charcoal is an antidote for poisoning.

**Action:** absorbs toxic substances that have been swallowed to prevent them from being absorbed by the stomach (Karch, 2013)

**Pregnancy Risk Category:** C

**Dosage:** provided as a powder that must be mixed with water and administered orally or by way of nasogastric (NG) tube

**Possible Adverse Effects:** vomiting, diarrhea, black stools

#### Nursing Implications

- Administer orally to conscious victims only.
- Give the drug as soon as possible after poisoning.
- Store the drug in a closed container because if it absorbs gases from the air, it is inactivated.
- Recognize that the solution feels gritty and tastes disagreeable so young children often have difficulty swallowing it, which is why it may have to be administered by NG tube.
- Caution child and parents that stools will be black for several days after administration.

#### ACETAMINOPHEN POISONING

Acetaminophen (Tylenol) is an over-the-counter medication that is frequently involved in childhood poisoning today because parents use acetaminophen to treat childhood fevers and have it readily available in the home. They may delay bringing the child for emergency care, thinking it is a harmless drug. Acetaminophen in large doses, however, is not innocent; it can cause extreme permanent liver destruction (Ogilvie, Rieder, & Lim, 2012).

Immediately after ingestion, the child develops symptoms of anorexia, nausea, and usually vomiting. Serum aspartate transaminase (AST [SGOT]) and serum alanine transaminase (ALT [SGPT]), liver enzymes, rise. The liver may feel tender on palpation

as liver toxicity occurs.

In the emergency department, activated charcoal or acetylcysteine, a mucolytic agent and also the specific antidote for acetaminophen poisoning, will be administered. Acetylcysteine prevents hepatotoxicity by binding with the breakdown product of acetaminophen so that it will not bind to liver cells. Unfortunately, acetylcysteine has an offensive odor and taste. Administering it in a small amount of a carbonated beverage can help the child to swallow it. For small children, it may be administered directly into an NG tube to avoid this difficulty. If the child is admitted to an observation unit, continue to observe for jaundice and tenderness over the liver and assess ALT and AST levels.

## Nursing Diagnoses and Related Interventions

Parents feel guilty after acetaminophen poisoning because they realize they should have been more careful with storing all medicine out of their child's reach. Be aware that, because it is a drug commonly available in the average home, acetaminophen poisoning may be the cause of unidentified coma or self-injury.

**Nursing Diagnosis:** Situational low self-esteem of parents related to child's poisoning

**Outcome Evaluation:** Parents state guidelines for continued assessment of child at home; state ways they can improve "childproofing."

After the child is stabilized following the poisoning episode, take some time to talk with the parents about the event. Remember, poisoning tends to happen in homes where there is stress. If stress was already present, how has this poisoning event added to it?

Before the child is discharged from a healthcare facility, be certain the parents are comfortable with any further assessment measures they will need to continue at home, such as temperature taking and pushing high fluid intake. Be certain they understand the importance of liver function tests for follow-up care to detect any long-term liver injury.

### *QSEN Checkpoint Question 52.3*

#### QUALITY IMPROVEMENT

The nurse notices that Sage was seen in the emergency department last year for acetaminophen poisoning. The hospital's algorithm for dealing with acetaminophen overdose should specify what action?

- a. Advise the parents their child must never take acetaminophen again.

- b. Be prepared to administer either acetylcysteine or activated charcoal.
- c. Palpate the child's abdomen to assess whether the bladder feels tender.
- d. Administer potassium chloride elixir immediately.

*Look in Appendix A for the best answer and rationale.*

## CAUSTIC POISONING

Ingestion of a strong alkali, such as lye, which is contained in certain toilet bowl cleaners or hair care products, causes burns and tissue necrosis in the mouth, esophagus, and stomach. It's very important that parents do not try to make a child vomit after ingestion of these substances because they can cause additional burning as they are vomited (Rumack & Dart, 2012).

### Assessment

After a caustic ingestion, the child has immediate pain in the mouth and throat and drools saliva because of oral edema and an inability to swallow. The mouth turns white immediately from the burn and the child may vomit blood, mucus, and necrotic tissue. The loss of blood from the denuded, burned surface may lead to systemic signs of tachycardia, tachypnea, pallor, and hypotension. Tissue in the mouth turns brown as edema and ulceration develop. At times, there may be such marked edema of the tongue that it is difficult to examine past the lips. Activated charcoal should not be administered because it is ineffective and obstructs an endoscopic view.

### Therapeutic Management

When parents whose child has ingested a caustic substance call a poison control center to ask for advice on how to proceed, they will be advised to immediately take the child to a healthcare facility for treatment because there is a high possibility that pharyngeal edema will become severe enough to obstruct the child's airway. This can occur as quickly as 20 minutes after a burn and is why ingestion of caustic substances can be life-threatening.

In the emergency department, relieving the child's pain is a first step. Advocate for a strong analgesic, such as IV morphine, to achieve pain relief for this level of injury. A chest X-ray may then be prescribed to determine whether the aspirated poison has caused an esophageal perforation that will allow swallowed fluid to seep from the injured esophagus into the mediastinum. A laryngoscopy and esophagoscopy under conscious sedation or general anesthesia may be done to assess the lungs and esophagus, although these must be done cautiously because of the possibility that an examining scope could perforate the burned esophagus or trachea.

Assess vital signs, especially the respiratory rate, and attach a pulse oximeter to establish a baseline and for continued monitoring to help detect if edema of the pharynx is obscuring the child's airway. In infants, increasing restlessness is an important accompanying sign of oxygen deprivation. For some children, intubation or a

tracheotomy may be necessary to provide a patent airway, although, again, any intubation must be done cautiously because the throat is edematous and could be injured easily. To protect against stomach reflux to the burned esophageal area, a proton pump inhibitor may be prescribed intravenously. Even though the child has denuded mouth or throat areas, prophylactic antibiotic therapy is not usually necessary. Once a mainstay of therapy to reduce esophageal stricture, the use of a corticosteroid such as dexamethasone (Decadron) is now controversial and may or may not be prescribed.

## Nursing Diagnoses and Related Interventions

Poisoning with a caustic substance is a true emergency because care must be initiated to preserve the child's airway. Providing adequate nutrition is a second concern because the child is unable to swallow through an edematous throat or esophagus.

**Nursing Diagnosis:** Risk for imbalanced nutrition, less than body requirements, related to esophageal stricture from burn scarring

**Outcome Evaluation:** Child's diet meets recommended daily allowance requirements for age.

Oral intake commonly will be a problem for the first week, following a caustic injury because of soreness in the child's mouth; an NG tube is contraindicated, so the child may be fed by TPN or gastrostomy feedings during this time. After about a week, liquids are introduced because liquid passing through the burned and scarred esophagus can help maintain esophageal patency or be therapeutic for the burn as well as nutritious for the child. Observe children carefully the first time they attempt to drink something for coughing, choking, or cyanosis, which are signs that suggest the liquid is not able to pass through the esophagus and is being aspirated into the lungs. Be certain parents have clear explanations of how to offer soft food for as long as the child's mouth or throat is sore and the need for follow-up care to be certain the child's esophagus has not stenosed. After 2 weeks, a barium swallow or esophagoscopy will be performed to reveal the final extent of the esophageal burns and determine any further therapy needed. Some children require periodic dilation of the esophagus by endoscopy during the first year after the injury. To correct complete obstruction, repeated surgical procedures such as transplantation of intestinal tissue or a synthetic graft will be required to replace the obstructed esophagus. Because there is a correlation with the development of esophageal carcinoma later in life in individuals who swallowed a caustic substance, both the parents and the child need to be alerted to this possibility and to the signs of esophageal cancer (e.g., weight loss, difficulty swallowing) (Mas, Breton, & Lachaux, 2012).

## IRON POISONING

Iron is frequently swallowed by small children because it is an ingredient in vitamin preparations, particularly in prenatal vitamins. When ingested, a large amount of iron is corrosive to the gastric mucosa and leads to signs and symptoms of severe gastric irritation in the child (Chang & Rangan, 2011).

The immediate effects include nausea and vomiting, diarrhea, and abdominal pain. After 6 hours, however, these symptoms seem to fade, and the child's condition appears to improve. Internally, however, hemorrhagic necrosis of the lining of the GI tract continues to occur. By 12 hours, melena (blood in stool) and hematemesis (blood in emesis) are revealed. Lethargy and coma, cyanosis, vasomotor collapse, coagulation defects, and hepatic injury may also occur. Hypovolemic shock may result from blood loss and decreased cardiac output. Long-term effects include gastric scarring from fibrotic tissue formation.

### Assessment

It is difficult to estimate the amount of iron a child has swallowed because the amount of elemental iron in compounds varies and parents can only guess at the number of pills that were in the bottle before the ingestion. Obtaining blood for a serum iron level analysis should be performed to establish a baseline.

### Therapeutic Management

In the emergency department, activated charcoal is not given because it is not effective at neutralizing iron. Stomach lavage is done instead to remove any pills not yet absorbed. A cathartic may be given to help the child pass enteric-coated iron pills before they can be activated. A soothing compound such as Maalox or Mylanta (aluminum hydroxide and magnesium hydroxide) or a proton pump inhibitor can help decrease gastric irritation and pain.

If a child has ingested a potentially toxic dose of iron, an exchange transfusion can be used to remove excess iron from the body. Administration of a chelating agent such as IV or intramuscular (IM) deferoxamine can also be effective because this combines with the iron and allows it to be excreted harmlessly from the body in the urine. To avoid concern, caution parents that deferoxamine causes urine to turn orange. Parents may be asked to test the stool for 3 days for occult blood to assess for stomach irritation and subsequent GI bleeding. Be certain that parents understand how to do this accurately.

For follow-up, an upper GI X-ray series and liver studies may be performed 1 week after the ingestion to screen for long-term effects. The goal is that the iron load is removed from the stomach in time so that not all of it gets absorbed and long-term effects are prevented.

## Nursing Diagnoses and Related Interventions

Many parents are unaware that iron can be toxic because they have been told so often that iron is necessary for good blood cell formation.

**Nursing Diagnosis:** Deficient parental knowledge related to the danger of iron as a poison

**Outcome Evaluation:** Parents state they understand the danger of iron ingestion for children; state ways they have safeguarded their child from future iron exposure.

Pregnant women may not realize prenatal vitamins contain high levels of iron (25 to 60 mg compared to 18 mg in children's vitamins) and thus may not be as conscientious about storing these in a safe place, an action that can lead to iron poisoning in a child. Because many children's vitamins are manufactured in the shapes of familiar television or cartoon characters, children can think of these as candy and overdose on them if not supervised.

Whenever you instruct parents on taking an iron supplement for themselves or their children, stress that overdoses can be fatal to small children. Help them think of iron as they would any other medicine and keep it out of the reach of small hands.

## LEAD POISONING

When lead enters the body, it interferes with red blood cell function by blocking the incorporation of iron into the protoporphyrin compound that makes up the heme portion of hemoglobin in red blood cells and leads to a hypochromic, microcytic anemia (Lee & Marcadante, 2011). In addition, kidney destruction may occur, causing excess excretion of amino acids, glucose, and phosphates in the urine. The most serious effect, however, is lead encephalitis or inflammation of brain cells because of the toxic lead content. Lead poisoning (**plumbism**), like all forms of poisoning in children, tends to occur most often in children younger than 6 years of age. Children living in poverty and in older housing are at greater risk.

When providing patient education, lead prevention tips for parents should include:

1. Keep children away from peeling paint or chewable surfaces painted with lead-based paint.
2. Children should not be present in homes built before 1978 that are undergoing renovation.
3. Use contact paper or duct tape to cover holes in the walls or to block children's access.
4. Regularly wash children's hands and toys with water.
5. Regularly wet-mop floors and wet-wipe windows/windowsills to avoid lead dust from surfacing on the objects and floors in the home.

6. Take off shoes when entering the house to prevent bringing in lead from the outdoors.
7. Keep children from playing in bare soil and away from the sides of the house.
8. Test all children for lead at 1 and 2 years of age and anytime there is reason to suspect lead poisoning (CDC, 2016c).

### Assessment

There is no safe level of lead accumulation in a child's body. Lead poisoning is said to be present when the child has two successive blood serum lead levels greater than  $5 \mu\text{dl}$  (CDC, 2012). Ingestion of lead and chronically elevated lead levels can be identified through radiology of the intestinal tract and long bones (Fig. 52.6). The usual sources of ingested lead are lead-based paint and lead-contaminated dust. Lead was banned from paint in 1978. More than 4 million homes in the United States have lead-contaminated paint and dust and have one or more young children living in them (CDC, 2014, 2016c).

**Figure 52.6 (A)** Ingested paint chips (white crescents) in the intestinal

tract. **(B)** A radiograph of the long bones of a child with chronic lead ingestion showing the characteristic “lead line” or white marking at the epiphyseal line. (Radiographs courtesy of Dr. Jerald P. Kuhn, Children’s Hospital, Buffalo, NY.)

Paint tastes sweet, so a child will repeatedly pick up paint chips off the floor or off the walls to taste them. If a crib rail or a windowsill is painted with lead paint, a child can ingest it by teething the rail or sill. In fishing communities, swallowing lead sinkers can be a common source. Restoring an older home saturates the air with lead dust. In such homes, lead plumbing also may contaminate the drinking water.

Studies have shown that even low lead levels in children can affect the child’s IQ and cause learning disability and behavioral attention problems. The effects of the lead exposure cannot be corrected; therefore, preventing lead exposure before it causes any harm is the goal.

### **Therapeutic Management**

A child with a blood lead level over 5 µg/dl needs to be rescreened to confirm the level and then active interventions are required to prevent further lead exposure such as removal of the child from the environment containing the lead source or removal of the source of lead from the child’s environment. Removal of the lead source is not an easy task in homes because simple repainting or wallpapering does not necessarily remove the source of peeling paint adequately. After some months, the new paint will begin to peel because of the defective paint underneath. The walls must therefore be covered by paneling or drywall or other solid protective material in order to completely remove the lead exposure in the home.

Some children with lead levels greater than 10 to 20 µg/100 ml will be prescribed an oral chelating agent such as dimercaptosuccinic acid (DMSA) or succimer. Children with blood lead levels of greater than 45 µg/100 ml are treated with stronger chelation therapy such as dimercaprol (British anti-Lewisite [BAL]) or edetate calcium disodium (CaEDTA) (Karch, 2013).

Chelating agents (except BAL) remove the lead from soft tissue and bone (although not from red blood cells), allowing it to be eliminated in the urine. CaEDTA can be given intravenously or by IM injection into a large muscle mass. IM injection of CaEDTA is painful and should be combined with 0.5 ml of procaine for administration. BUN, serum creatinine, and protein in urine are assessed to ensure kidney function is adequate because CaEDTA can lead to nephrotoxicity or kidney damage if it cannot be excreted. Be certain to measure intake and output to assess that kidney function is adequate to excrete the lead.

CaEDTA is so effective as a chelating agent that it unfortunately has the side effect of also removing calcium from the body; children who receive CaEDTA, therefore, must have serum calcium measured periodically to determine whether their calcium level is adequate.

BAL has the advantage over CaEDTA of being able to remove lead from red blood cells as well as other tissues, but because of the danger of severe toxicity, it is prescribed only for children who have severe forms of lead intoxication.

## Nursing Diagnoses and Related Interventions

Care planning can be difficult when a child is diagnosed with lead poisoning because parents are immediately upset at learning their child has been exposed to a source of lead. They may experience a loss of self-esteem and a sense of powerlessness as they realize their housing situation has hurt their child.

**Nursing Diagnosis:** Deficient knowledge related to the dangers of lead ingestion

**Outcome Evaluation:** Parents state they understand the importance of preventing further lead exposure; identify measures to take to reduce lead in the environment.

Parental education about the risk of lead poisoning is crucial. Parents may have to move to a new home or locale or extensively renovate their home. As temporary measures, placing the television or an overstuffed chair against a lead-based windowsill or placing the child's crib about 3 ft away from the walls can be helpful to prevent the child from picking at loose wallpaper or exposed lead-based plaster. Be certain parents understand that all children with elevated lead levels need careful follow-up to determine the seriousness of their condition and to ensure they are being kept away from the lead source. Because children who recover from symptomatic lead poisoning have a high incidence of permanent neurologic damage, all children with elevated blood lead levels need appropriate follow-up care to evaluate development and intelligence (CDC, 2016c).

### *QSEN Checkpoint Question 52.4*

#### INFORMATICS

Sage is found to have an elevated serum lead level. What is the most common source of lead poisoning in young children that would contribute to this assessment finding?

- Smelling lead fumes from cooking utensils
- Swallowing batteries that fall out of toys
- Drinking lead-contaminated drinking water
- Chewing on chips of flaking lead-based paint

*Look in Appendix A for the best answer and rationale.*

## Foreign Body Obstruction

Foreign bodies can become lodged in a child's esophagus, ear canals, nostrils, or lungs, causing direct obstruction of the airway or long-term stasis of secretions and infection. Whether a foreign substance is inhaled or embedded elsewhere, nursing interventions should focus first on comforting the child and aiding in removal of the object and later on teaching the child and parents ways to avoid such occurrences in the future.

## **FOREIGN BODIES IN THE EAR**

Any child with a history of draining exudate from the ear canal needs an otoscopic examination to determine the cause. With toddlers and preschoolers, the drainage often is the result of a foreign body such as a small toy, a piece of paper, a small battery, or food, such as a peanut that gets pushed into the ear canal (Sharpe, Rochette, & Smith, 2012).

Removal of a foreign body from the ear can be difficult. Fear of the instruments being used and pain make it difficult for children to keep still during the procedure. Often, it is better to wait for an otolaryngologist to care for the child because trauma to the ear canal during an attempt to remove a foreign body can cause edema and make removal even more difficult.

In many instances, if the object is in the outer canal, it can be grasped by forceps and easily removed. If the tympanic membrane is intact, irrigating the object from the ear canal with a syringe and normal saline may be possible, although this should not be done if the object is a substance that will swell when wet, such as a peanut. If there is a possibility that the tympanic membrane is ruptured, the ear canal should not be irrigated or fluid will be forced into the middle ear, possibly introducing infection (otitis media).

## **FOREIGN BODIES IN THE NOSE**

Foreign objects stuffed into the nose eventually cause inflammation and purulent discharge from the nose. The odor accompanying such impaction is often the first sign noticed by the parent. Objects pushed into the nose usually can be removed with forceps. A local antibiotic might be necessary after removal if ulceration resulted from the local irritation.

## **FOREIGN BODIES IN THE ESOPHAGUS OR STOMACH**

Children tend to not chew food well or to swallow portions that are too big to pass safely through the esophagus when they are in a hurry. Pieces of candy, such as Life Savers, are common objects caught in the esophagus in young children; coins may be swallowed by adolescents playing drinking games. Wires of orthodontic appliances that dislodged are also frequently swallowed. The mark of an object lodged in the esophagus is intense pain at the site where the object is located. If the object is one that will dissolve, such as a Life Saver or a piece of digestible meat, offer the child fluid to drink to help flush the object into the stomach. Even after the object dissolves or passes into the stomach, the child will feel transient pain at the original site of the obstruction.

Magnets, particularly those in watches or hearing aids, are also frequently swallowed by young children. These need to be removed by endoscopy as soon as possible because they can lead to bowel perforation or volvulus from their acid content. Objects, such as a part of a toy, a chicken bone, or a large coin that will not dissolve or be passed, are also removed by endoscopy (Avey, Euathrongchit, & Stern, 2012).

Small coins, such as pennies and dimes, usually pass by themselves without difficulty. Parents and older children need to observe stools over several days to determine that the coin does pass through the GI tract (about 48 hours after ingestion). Without frightening them, caution parents to observe for signs of bowel perforation or obstruction, such as vomiting or abdominal pain, until the coin has passed. If there is any doubt, an X-ray taken 3 to 7 days after ingestion will establish whether the coin has been evacuated from the body.

## SUBCUTANEOUS OBJECTS

Children get many wood splinters in the hands and feet. These items can be removed easily with a probing needle and tweezers after cleaning with an antiseptic solution. If the penetrating object is metal, such as a sewing needle or nail, its presence can be detected by X-ray. If the object is one that would have been in contact with soil, such as a rusty nail, the child will need tetanus prophylaxis after extraction of the object if the child's tetanus immunization is not current.

### *What If... 52.3*

**Sage's mother tells the nurse she thinks the reason Sage has an elevated lead level is because she swallowed a penny a month ago and it must still be inside her. What additional information would the nurse request from the mother? What patient education would the nurse provide?**

## Bites

Children are bitten by snakes and animals such as dogs or raccoons; they occasionally are bitten by other children. In an emergency room, the source of a bite needs to be documented because human bites can also result from child maltreatment.

## MAMMALIAN BITES

Dog bites account for approximately 90% of all bites inflicted on humans, and children and adolescents are involved in one third to one half of reported incidents. The dog is usually one owned by the child's family. Cat bites, wild animal bites, and human bites also constitute a threat, although these are less common in children. All of these bites can cause abrasions, puncture wounds, lacerations, and crushing injuries related to the size of the animal and the location of the bite (Dyring-Andersen, Menne, & Skov,

2012).

The biggest concerns associated with animal bites are the scarring and disfigurement and the possibility of infection, especially rabies, from the presence of microorganisms in the animal's mouth. Rabies and the vaccine for rabies are discussed in [Chapter 43](#).

## **SNAKEBITE**

Snakebites tend to occur during the warm months of the year, from April to October. A few fatal bites in the United States occur from cottonmouth moccasins or coral snakes (both found in southeastern states), but the majority of fatal snakebites (envenomations) are from copperheads or rattlesnakes. Copperheads are found in eastern and southern states; rattlesnakes are found in almost every state. The effect of the bite of a rattlesnake, copperhead, or cottonmouth moccasin (all pit vipers) is the almost immediate failure of the blood coagulation system ([Warrell, 2012](#)).

Coral snakes are known for the small coral, yellow, and black rings encircling their body. Fortunately, they are shy and seldom bite. However, the venom injected through the bite of these snakes leads to neuromuscular paralysis.

### **Assessment**

Immediately after a pit viper bite, a white wheal surrounding the puncture marks begins to appear, accompanied by excruciating pain at the site. Purplish erythema and edema extend rapidly from the site.

By the time a child is seen at a healthcare facility, sanguineous fluid may be oozing from the bite. Systemic symptoms, such as dizziness, vomiting, perspiration, and weakness, may be present. Because snake venom interferes with blood coagulation, the child may have hematemesis or bleeding from the nose, intestines, or bladder because of subcutaneous or internal hemorrhage. The pupils may be dilated, showing the potent effect on cerebral centers. If the envenomation is not treated, seizures, coma, and death may result.

### **Emergency Management at the Scene**

At the scene of a snakebite, parents should apply a cold compress to the bite because this can decrease the spread of the venom and reduce edema formation. Urging the child to lie quietly, with the bitten extremity dependent also helps to slow circulation.

Commercial snakebite kits have rubber suction cups in them that can be used to suction out the venom, so if available, they should be used. Excising the bite with a knife and sucking out the venom orally (often shown in old western movies) is of questionable value and if the person administering the treatment has open mouth lesions, such as carious teeth, the procedure could be dangerous to that person (venom is not dangerous when swallowed, only when absorbed through open lesions). Excising the bite also may lead to secondary infection and, if done too vigorously, may injure tendon or muscle. It is vital to transport the child to a healthcare facility as quickly as possible.

## Emergency Management at the Health Facility

In the emergency department, ask the child or the caretaker to describe the snake. In areas where snakebites are frequent, keep available photographs of the venomous snakes commonly found because even a preschooler may be able to identify the snake by pointing to a photograph. Specific antivenin depending on the type of snake is then administered. Because rattlesnakes, copperheads, and cottonmouth moccasins are all one type of snake (pit vipers), one form of antivenin acts against all of these bites. Specific antivenin is prepared for coral snake or cobra bites (not typically kept in emergency departments but obtained from most zoos). If a child receives antivenin promptly after a bite, the prognosis for full recovery is good.

Antivenin may contain a horse-serum base. Therefore, before the serum is injected intramuscularly or intravenously, a skin test may need to be performed to prevent a possible anaphylactic reaction to the horse serum. If giving the serum IM, do not inject it into an edematous body part because medication will be poorly absorbed from edematous tissue; you may need to assure the parents that giving antivenin into the limb opposite the bitten limb is just as effective as administering it into the bitten limb. If the child's immunization status is unknown or it has been more than 10 years since a tetanus immunization was given, ask if tetanus prophylaxis should be administered.

## Nursing Diagnoses and Related Interventions

Snakebites are frightening; therefore, nursing diagnoses need to address both calming the child and parents as well as administering immediate interventions.

**Nursing Diagnosis:** Fear related to seriousness of child's condition

**Outcome Evaluation:** Parents and child state they are able to cope with the degree of fear present.

Following a venomous snakebite, children need a great deal of support from healthcare personnel because their parents may be too frightened to offer adequate support. As a final care measure, teach children the following common safety rules for avoiding snakebites:

- Look for snakes before stepping into underbrush.
- Be aware that snakes sun on warm rocks.
- Do not lift up rocks without looking at what could be under them.
- Listen for the telltale sound of a rattlesnake.
- Know the markings of poisonous snakes to help avoid them.

## Athletic Injuries

Although participating in athletics promotes growth and development and teaches concepts of teamwork and perseverance, this can unfortunately also lead to injury. More than 2.6 million children each year are treated in emergency departments for sports and recreational related injuries (CDC, 2016c).

Playing on backyard trampolines, in particular, is a dangerous activity for children because neck and spine injuries can result (American Academy of Pediatrics Council on Sports Medicine and Fitness, 2012). Strategies to prevent sports injuries include preparticipation health examinations, proper coaching, attention to safety, adequate hydration, proper officiating, availability of first aid and medical coverage at all sporting events, and proper equipment and field or surface playing conditions.

## KNEE INJURIES

Participation in sports such as football, skateboarding or snowboarding, skiing, soccer, and track running is a frequent cause of knee injuries in children that usually involve the ligaments surrounding the knee—the medial, lateral, posterior, and cruciate ligaments. Immediately after the injury, the child reports severe pain in the knee, and localized edema becomes evident. An X-ray or MRI will be done to rule out fracture and the extent of the ligament damage. If the injury is mild (only a few torn fibers), bed rest with an ice pack applied to the knee is often the only therapy needed. After 24 hours, heat is applied to the knee to hasten healing.

If the injury is more severe, the knee joint may fill with fluid. In addition to bed rest and an ice pack applied to the joint, the abnormal synovial fluid may be aspirated and a compression dressing applied to discourage accumulation of further fluid. After 24 hours, heat treatments hasten healing.

If the injury is severe, arthroscopy is necessary to visualize and surgically repair the knee ligaments. Arthroscopic surgery makes repair of ligaments or cartilage a minor procedure and limits the necessity for immobilization and a cast. Children who have one anterior cruciate ligament injury need to be aware that they may suffer another in their other knee and may be more prone to osteoarthritis in the affected knee later in life (Smith, Vacek, Johnson, et al., 2012).

If a child experiences a severe twisting motion to the knee, a dislocation of the patella (kneecap) can result (the kneecap moves to the posterior surface of the knee). The knee appears immediately deformed, and the child feels acute pain. An ultrasound or MRI will reveal if there is accompanying ligament damage. Immediate treatment for a dislocated kneecap is to slide the patella back to the front of the knee. After this realignment, the pain subsides, but the child may have to be fitted with a leg immobilizer for about 1 week to keep the kneecap in good alignment. Quadriceps exercises (straight-leg raising) are important to prevent the dislocation from reoccurring. These exercises strengthen the leg muscles and tendons. If the problem becomes chronic or occurs frequently, surgery to strengthen the knee ligaments may be necessary (Felus & Kowalczyk, 2012).

## THROWING INJURIES

Throwing an object such as a baseball places repeated stress on an upper extremity, particularly the elbow joint. The injury that occurs is caused either by the forward motion of the arm or during the follow-through. After the injury, a child is unable to extend the elbow completely because of minute tears and fibrous contractures in the muscle that can occur for 24 to 48 hours postinjury. Pain and tenderness are marked. Resting the arm and applying ice packs for 15 to 20 minutes three times a day relieve the pain. An anti-inflammatory agent (nonsteroidal anti-inflammatory drug) will also relieve the pain. A limited number of cortisone injections into the elbow musculature may be necessary for complete healing. Exercises to strengthen flexor muscles help to prevent this type of injury.

“Little leaguer’s elbow” is epiphysitis (inflammation) of the medial epicondylar epiphysis caused by repeated throwing motion. An X-ray of the elbow will reveal increased growth, separation, and fragmentation of the medial epicondylar epiphysis. Children need extra protection against this type of injury by limiting the amount of time spent in practice or games until the epiphyseal growth centers at the elbow have fused. This typically occurs between 14 to 17 years of age (Hoang, Coel, Vidal, et al., 2012).

Treatment for little leaguer’s elbow is rest and immobilization until pain, tenderness, and limitation of movement has resolved. This is important because if the injury is not treated adequately, permanent damage to the epiphyseal line and elbow deformity can occur (Fleisig & Andrews, 2012).

## Injuries of the Extremities

### FINGER INJURIES

It is common for a child to sustain a finger injury from a slammed car door. This injury, which causes a crushing blow to the tip of the finger, is excruciatingly painful. The fingernail may be lacerated and detached. As blood accumulates under the fingernail, pain continues to increase unless an incision under the distal end of the nail or a stab wound through the nail helps to relieve the pain. Fingernails often are lost after these injuries, but they grow back readily with little scarring. You can assure parents that although the fingernail may be lost, the cosmetic effect will invariably not be a problem.

Parents may feel embarrassed and guilty when they bring a child to a healthcare facility for this type of injury. The injury usually occurred because they closed a door without looking out for the child’s finger. They appreciate how much this hurts and are angry for being so careless. Reassure parents that this is a common childhood injury and unintentional injuries do happen.

An X-ray of the fingertip may be obtained to be certain the tip of the distal phalanx is not broken. The rule, “If the child can bend it, it’s not broken,” does not apply to this injury because the fracture may be distal to the last phalangeal joint. The open wound needs to be cleaned well. If the distal phalanx is fractured, the finger needs a splint

applied to stabilize the bone. A follow-up visit will be necessary to ensure healing has occurred.

## STRAINS AND SPRAINS

A **strain** is a muscle–tendon injury. A **sprain** is a ligament injury. Strained or sprained ankles are common and slow-to-heal childhood injuries (Tiemstra, 2012). Immediately after an injury, the affected joint feels painful and gets swollen. Such injuries typically occur from inline skating or snowboarding or skateboarding. When X-ray reveals no fracture, a child may feel as though someone has said the injury is not serious but “just a sprain.” This makes the extent of the swelling and pain baffling.

Help the child and parents to understand that strains and sprains are truly painful. Because a cast is not used and the ankle is not immobilized but just wrapped in an elastic bandage, strains and sprains can be more painful than fractures.

If the injury is recent, apply an ice pack for approximately 20 minutes to reduce edema at the site; repeat this for 4 to 7 days at home. The child may be fitted for crutches to limit weight bearing for the next 3 or 4 days or fitted with a supportive medical boot. Make certain the parents understand how the elastic bandage is applied so that it can be rewrapped if it loosens and be certain the child is using the crutches or boot properly before being discharged from the emergency department.

When providing patient education, sports injury prevention tips for parents should include:

1. Make sure children wear protective equipment that fits appropriately and correctly at all times during sports and recreational activities.
2. Make sure children are well hydrated with water (avoid sugary drinks) and appropriately dressed to avoid heat-related injuries or illness.
3. Parents should be good role models and wear helmets and protective equipment when participating in sports and recreational activities (CDC, 2016c).

## Thermal Injuries

Thermal injuries include those caused by either cold (frostbite) or excessive heat (burns).

### FROSTBITE

Frostbite is tissue injury caused by freezing cold; the extreme cold causes peripheral vasoconstriction, cutting off the oxygen supply to surrounding cells (Castellani & Young, 2012). In children, the body parts involved usually are the nose, fingers, or toes.

### Assessment

The severity of frostbite is classified by degree:

- First degree: mild freezing of epidermis; appears erythematous with edema

- Second degree: partial- or full-thickness injury; appears erythematous; blisters and pain occur after re-warming
- Third degree: full-thickness injury (epidermis, dermis, and subcutaneous tissue); appears white
- Fourth degree: complete necrosis with gangrene and possible ultimate loss of body part

Frostbite occurs most frequently in children who have been skiing, snowmobiling, or snowboarding for long periods. Frostbite of the lips or tongue can occur from sucking on a popsicle and from inhalant abuse. Always explore the cause and circumstances of frostbite with careful history taking because it can also result from neglect or child maltreatment.

### Therapeutic Management

Always warm frostbitten areas gradually because sudden warming increases the metabolic rate of cells which can cause additional damage. Administration of a vasodilator and use of hyperbaric oxygen may help reduce the effect on body cells.

### Nursing Diagnoses and Related Interventions

Frostbite may not be recognized immediately. Children generally have pain and blistering by the time they are seen for emergency care.

**Nursing Diagnosis:** Pain related to damage of cells because of freezing temperature

**Outcome Evaluation:** Child states that pain is controlled at a tolerable level.

As soon as warming of the frostbitten body part begins, the part becomes extremely painful because the cells that are injured register their anoxic state. Pain management is essential at this time.

During the next few days after severe frostbite, necrosis of destroyed tissue occurs; the affected tissue then sloughs away. Apply or change dressings as necessary to avoid secondary bacterial contamination of the necrotic injury site. Assess body temperature frequently to detect early symptoms of infection. Be certain that children understand the cause of the injury so they take more precautions against cold injury in the future.

### BURNS

Burns are injuries to body tissue caused by excessive heat (heat greater than 104°F [40°C]). Burns are the second most common unintentional injuries seen in children 1 to 4 years of age and the third most common cause in children 5 to 14 years of age. Every day, there are more than 300 children treated in emergency rooms for burn-related

injuries. Younger children are most at risk for scald burns that are caused by hot liquids or steam. Older children are more apt to be burned from flames after they move too close to a campfire, heater, or fireplace; touch a hot curling iron; or play with matches or lighted candles (CDC, 2016c). Eye burns occur from splashed chemicals doing home projects or in science classes. Always keep in mind when evaluating burns that some (particularly scalding) can also be caused by child maltreatment (Blackburn, Levitan, MacLennan, et al., 2012).

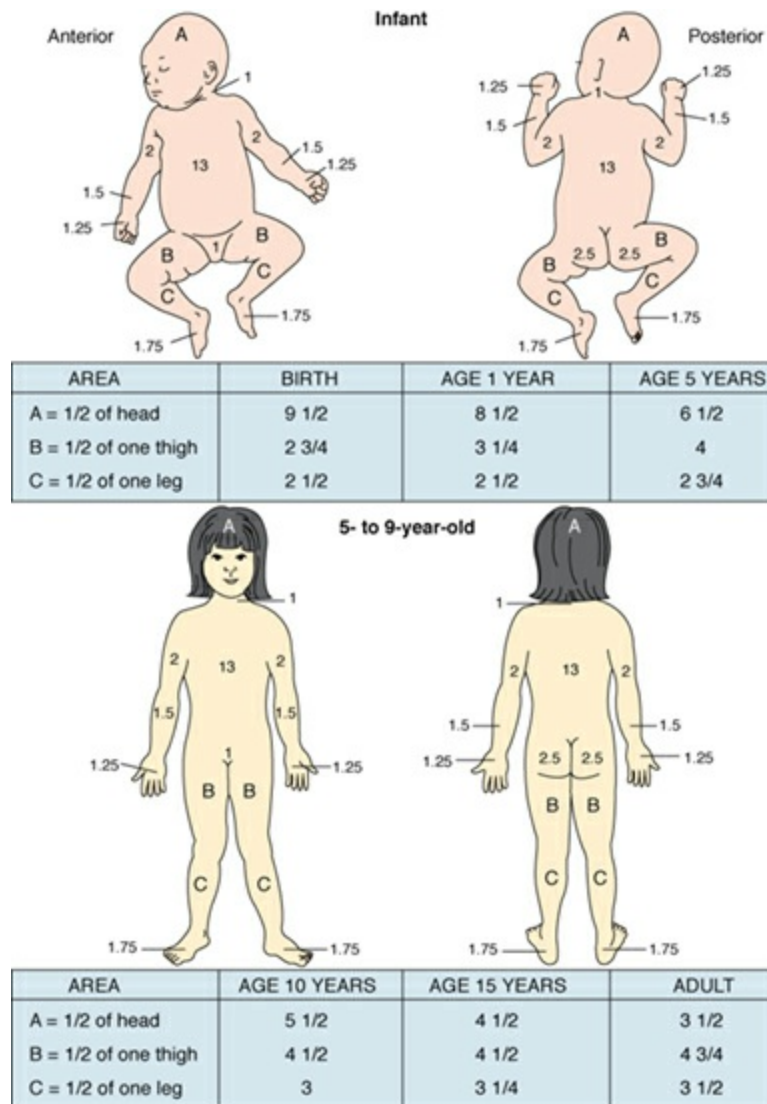

Burn injuries tend to be more serious in children than in adults because the same size burn covers a larger surface of a child's body. Many burns can be prevented with improved parent and child education. When providing patient education, burn prevention tips for parents include:

1. Install smoke alarms in the home, on every floor, and near all rooms in which family members sleep.
2. Maintain smoke alarms by testing them monthly to make sure they are working properly and by using long-life batteries.
3. Create a family fire escape plan, involve the children in the planning, and practice frequently.
4. Never leave food unattended on the stove and always supervise or restrict the use of stoves, ovens, and microwaves with children.
5. Check the water heater temperature and make sure that the thermostat is set to 120°F or lower. Always test the water before children enter the bathtub or shower (CDC, 2016c).

## Assessment

Because burns are classified as to degree, when children with a burn injury are brought to a healthcare facility, the first questions asked must be “Where is the burn?” and “What are its extent and depth?” (Nicole & Huether, 2012). Along with the size and depth, be certain to assess and document the location of the burn. Face and throat burns, for example, are particularly hazardous because there may be accompanying but unseen burns in the respiratory tract that could lead to respiratory tract obstruction. Hand burns are also hazardous because if the fingers and thumb are not positioned properly during healing, adhesions will inhibit full range of motion in the future. Burns of the feet carry a high risk for secondary infection. Genital burns are also hazardous because edema of the urinary meatus may prevent a child from voiding.

With adults, the “rule of nines” is a quick method of estimating the extent of a burn. For example, each upper extremity represents 9% of the total body surface; each lower extremity represents two 9s, or 18%, and the head and neck represent 9%. Because the body proportions of children are different from those of adults, this rule does not always apply and is misleading in the very young child. Data for determining the extent of burns in children are shown in Figure 52.7. Computer analysis is now available to rapidly assess the extent of burns.

**Figure 52.7** Determination of extent of burns in children.

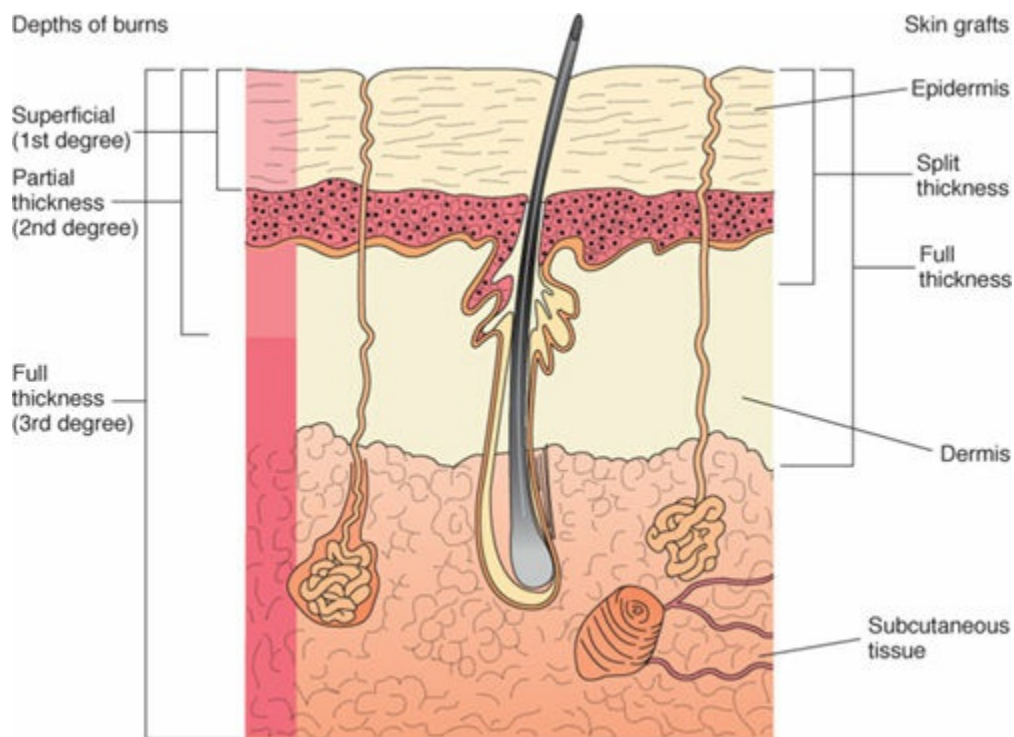

### Depth of Burn

When estimating the depth of a burn, use the appearance of the burn and the sensitivity of the area to pain as criteria. Descriptions of tissue at various burn depths are shown in [Table 52.2](#) and illustrated in [Figures 52.8](#) through [52.11](#).

**TABLE 52.2** COMMON CLASSIFICATIONS AND DESCRIPTIONS OF BURNS

Degree	Description	Common Cause
First degree	Involves the epidermis or outer layer of skin. Appears reddened, dry, and feels mildly painful. Heals by simple regeneration so takes 1–10 days to heal.	Sunburn ( <a href="#">Fig. 52.9A</a> )
Second degree	Involves the epidermis and part of the dermis layer of skin. Appears red, blistered, and may be swollen. Very painful.	Scalding ( <a href="#">Fig.</a> )

	Heals by regeneration of tissue over 2–6 weeks.	52.9B)
Third degree	Involves the epidermis and full extent of the dermis. Appears white or charred and lacks sensation as the nerve endings are destroyed. Skin grafting is usually necessary, and healing takes months. Scar tissue will cover the final healed site.	Flames (Figs. 52.10 and 52.11)
Fourth degree	Full-thickness burn extending into muscle or bone. Skin grafting is necessary; muscle and bone may be permanently damaged; scarring will cover the healed site.	High-voltage electric or severe fire

**Figure 52.8** Depths of burns.

**Figure 52.9** Partial-thickness burns. (A) An infant with a first-degree burn on the arm and chest caused by scalding with hot water. (B) A

toddler with a second-degree burn caused by scalding. The area appears severely reddened and moist with some blistering. (A, © Dr. P. Marazzi/SPL/Science Source/Photo Researchers. B, © NMSB/Custom Medical Stock Photograph.)

**Figure 52.10** Full-thickness (third-degree) burn of the foot. Both layers of skin are involved with this type of burn. (© Dr. Michael English/Custom Medical Stock Photograph.)

**Figure 52.11** (A) An adolescent's hand scarred from third-degree burns. Note the proper extension and alignment of the hand and fingers, which were maintained by the use of splints during healing (B). (© Dr. P. Marazzi/SPL/Science Source/Photo Researchers.)

Many burns are compound, involving first-, second-, and third-degree burns, or there may be a central white area insensitive to pain (third degree), surrounded by an area of erythematous blisters (second degree), and surrounded by another area that is erythematous only (first degree).

Be certain to undress children with burns completely in order to inspect the entire body. Because a first-degree burn is painful and a third-degree burn is not, a child may be crying from a superficial burn that is obvious on the arm, although the condition needing the most immediate attention is a third-degree burn on the chest covered by a jacket.

Be certain to ask what caused the burn because different materials cause different degrees of burn. Hot water, for example, causes scalding, a generally lesser degree of burn than one caused by flaming clothing. Ask where the fire happened because fires in closed spaces are apt to cause more respiratory involvement than those in open areas.

Lastly, determine whether other family members were burnt as well. Parents, for example, may have burned hands from putting out the fire on the child's clothes and need equal care, but in their anxiety about the child's condition, they do not mention this. If they picked up and brought the burned child to the hospital quickly, they may have left other children unprotected at home. They also may be so concerned about the burn that they neglect to mention the child has a secondary health concern such as diabetes or allergy to a common drug unless specifically asked.

### **Emergency Management for Minor Burns**

All burns, including minor burns, need immediate care because of the potential pain involved (Mandt & Grubenhoff, 2012). Although minor burns (typically first-degree partial-thickness burns) are the simplest type of burn, they involve pain and death of skin cells and therefore must be treated seriously. Immediately apply cool water to cool the skin and prevent further burning. Application of an analgesic–antibiotic ointment and a gauze bandage to prevent infection is usually the only additional treatment required. Be certain that parents have a follow-up appointment in about 2 days to have the dressing changed and the area inspected for a secondary infection. Caution parents to keep the dressing dry (no swimming or getting the area wet while bathing until the burn is healed—about 1 week).

### **Emergency Management for Moderate Burns**

Moderate or second-degree burns typically are blistered. Do not rupture these blisters because doing so denudes the site and invites infection. The burn should be covered with a topical antibiotic such as silver sulfadiazine and a bulky dressing to prevent damage to the burned site and promote healing. The child usually is asked to return in 24 hours to assess that pain control is adequate and there are no signs and symptoms of infection. Broken blisters may be debrided (cut away) to remove possible necrotic tissue as the burn heals.

### QSEN Checkpoint Question 52.5

#### SAFETY

A nurse is with Jason when he spills scalding hot water onto his hand. Which of the following would be the best emergency action?

- Apply a layer of vegetable oil over his hand.
- Cover his hand with a gauze dressing.
- Pour cool water from a faucet over his hand.
- Apply soothing hand lotion to keep the area moist.

Look in [Appendix A](#) for the best answer and rationale.

### Emergency Management for Severe Burns

The child with a third-degree or fourth-degree burn is critically injured and requires immediate care. Sure care, including fluid therapy, systemic antibiotic therapy, pain management, and physical therapy. The goal is to prevent disability caused by scarring, infection, or contracture.

### Emergency Management for Electrical Burns of the Mouth

If a child puts the prongs of a plugged-in extension cord into the mouth or chews on an electric cord, the mouth can be burned severely. When electrical current from a plug is conducted for a distance through the skin and underlying tissue it can cause an ulcer (Yeroshalmi, Sidoti, Adamo, et al., 2011). If blood vessels were burned, active bleeding from the lesion will be present.

The immediate treatment for electrical burns of the mouth is to unplug the electric cord and control bleeding if present. This can be done by pressing a towel against the burn site. In the emergency room, pain management and wound care are essential. Clean the wound with an antiseptic solution, such as half-strength hydrogen peroxide, or as otherwise prescribed to reduce the possibility of infection (a real danger in this area due to the amount of bacteria present in the mouth).

Most children with electric burns are admitted to an observation unit for at least 24 hours because edema in the mouth could lead to airway obstruction. Eating will be a challenge for the next week because the child's mouth is so sore. Soft foods and fluids may be easiest to swallow.

Electrical burns of the mouth turn black as local tissue necrosis begins. They heal with white, fibrous scar tissue, possibly leaving a deformity of the lips or cheeks and difficulty speaking clearly afterward. This can be minimized by using a mouth appliance, which helps maintain lip contour. Many children need follow-up care by a plastic surgeon to restore the lip contour.

## Nursing Diagnoses and Related Interventions

Because pain and anxiety often accompany burn care, relieving them is always an important concern in burn care.

**Nursing Diagnosis:** Pain and anxiety related to thermal damage to body cells

**Outcome Evaluation:** Child states that pain and anxiety are at a tolerable level; rates pain at 2 or below on a pain rating scale.

Morphine sulfate IV or via epidural injection is commonly the agent of choice for pain relief. Performing burn care such as debridement (the removal of necrotic tissue from a burned area) may be done with the use of patient-controlled analgesia or conscious sedation.

In addition to having pain from a burn, children may be required to remain in awkward positions to keep joints overextended so the skin over them does not heal with a contracture. If the anterior throat is burned, for example, the child's head needs to be hyperextended to keep the scar tissue that forms on the anterior neck from pulling the chin down against the chest in a permanent position. If children have burns over extremity joints, they may have splints applied over their burn dressings to maintain the joints in extension. This will help decrease contractures from developing. Be certain parents understand the importance of keeping the splint in place at all times.

Encourage children to talk about their injury and how it occurred (a form of debriefing) so they can integrate this unexpected event into their life.

Although most children are awake and very aware of the pain and treatments involved, children who experience smoke inhalation from the fire that caused their injury may become unconscious from brain anoxia. After the first week following a major burn, some children develop symptoms of delirium, seizures, and coma that result from toxic breakdown of damaged cells, sensory deprivation, isolation, and lack of sleep. Nursing care aimed at reducing unnecessary stimuli and providing adequate pain relief helps to prevent these late symptoms from occurring.

**Nursing Diagnosis:** Deficient fluid volume related to fluid shifts from severe burn

**Outcome Evaluation:** Skin turgor remains good; hourly urine output is greater than 1 ml/kg, with specific gravity between 1.003 and 1.030; vital signs are within acceptable parameters for child's age.

Immediately after a severe burn, there is an increased permeability of capillaries (or direct damage to capillaries). This leads to a loss of plasma, which oozes from blood vessels into the burn site and then sequesters in edematous tissue surrounding the site resulting in hypovolemia. The phenomenon is most marked during the first 6 hours after a burn. It continues to some extent for the first 24 hours.

In addition to hypovolemia, because so much of the child's skin surface may be exposed for examination, a child is prone to hypothermia (keep body parts not burned well covered). Children may also develop a severe anemia following a burn because

of injury to red blood cells caused by the heat and loss of blood at the wound site. The large amount of sodium lost from the bloodstream into the edematous burn fluid and the release of potassium from damaged cells can lead to both immediate hyponatremia and hyperkalemia (Table 52.3).

**TABLE 52.3 FLUID SHIFTS AFTER BURN INJURY**

<b>Fluid Shifts in First 24 Hours</b>	<b>Remobilization of Fluid After 48 Hours</b>
Burn	Edematous tissue surrounding burn area
↓	↓
Increased capillary permeability	Intravascular compartment
↓	↓
Hypoproteinemia	Hypervolemia
Hyponatremia	Hypernatremia
Hyperkalemia	Hypokalemia
Hypovolemia	

To detect whether extreme hypovolemia is occurring, monitor vital signs closely even with relatively minor burns; lactated Ringer's solution is the commercially available solution most compatible with extracellular fluid, so that or normal saline will be administered for fluid replacement. A child may also need plasma replacement and a source of glucose such as 5% dextrose in water. Do not administer a potassium additive immediately after a burn until kidney function is evaluated to be certain extra potassium can be eliminated. IV fluid is usually administered by the most convenient venous access, so that an analgesic for pain can be administered. A more stable fluid line may then be inserted.

The amount of fluid necessary is calculated carefully based on predicted insensible fluid loss and loss that can be predicted because of the burn (2,000 ml/m<sup>2</sup> of body surface per 24 hours plus 5,000 ml/m<sup>2</sup> of body surface burned over 24 hours). Fluid is administered rapidly for the first 8 hours (half of the 24-hour load) and then more slowly for the next 16 hours (the second half). It is important that fluid administration is continued beyond the time of increased capillary permeability (at least the first 24 hours), so be certain to protect the administration site to prevent infiltration. A central venous pressure or pulmonary artery catheter may be inserted to determine hemodynamic and fluid volume status and evaluate that the child is receiving adequate fluid. If many red blood cells were destroyed at the burn site, the child may need packed red blood cells to maintain an adequate hemoglobin level.

About 48 hours after the burn, as inflammation decreases, the extracellular fluid at the burn site begins to be reabsorbed into the bloodstream. Edema at the burn site begins to subside; the child begins diuresis and loses weight. The heart rate increases

because of temporary hypervolemia. The hematocrit level will be low because red blood cells are diluted. The child needs frequent evaluation of electrolyte levels to determine if the hypervolemia is not overwhelming. Potassium supplements may be necessary to maintain normal heart function because although potassium is released into the serum from destroyed cells, it is rapidly excreted by the kidneys.

**Nursing Diagnosis:** Risk for ineffective tissue perfusion related to cardiovascular adjustments after burn injury

**Outcome Evaluation:** Child's vital signs stay within normal limits for age; hourly urine output remains greater than 1 ml/kg of body weight per hour.

A complete blood cell count, blood typing and cross-matching, electrolyte and BUN determinations, and blood gas studies to ascertain blood levels of oxygen and carbon dioxide are important to obtain to monitor the shifts in fluid and electrolytes that occur.

Take height, weight, and vital signs on admission of a child with a burn and continue to take vital signs every 15 minutes until they are stable. Once these are stabilized, record pulse, blood pressure, and central venous pressure closely until the child passes the immediate danger of shock (at least 24 hours). Another important monitoring period occurs at 48 hours after the injury when fluid is returning to the bloodstream. Remember that gradual but persistent changes in blood pressure may be as informative as sudden changes.

**Nursing Diagnosis:** Risk for ineffective breathing patterns related to respiratory edema from burn injury

**Outcome Evaluation:** Child's respiratory rate remains within normal range for age; lung auscultation remains bilaterally clear without adventitious sounds.

If a child inhaled smoke from a fire, the injury from the smoke inhalation can be more serious than the skin surface burns received because smoke coming from a fire is at the temperature of the fire or is the same as exposing the upper respiratory tract to open flame. In addition, toxic substances and soot given off by the fire may cause local irritation to the respiratory tract. If carbon monoxide is inhaled with the smoke, it enters red blood cells in place of oxygen, shutting off the oxygen supply to body cells. If this is extensive, it can lead to loss of consciousness because of cerebral anoxia. If the trachea is burned, edema fluid will pass into the injured bronchioles and trachea, causing pulmonary edema or obstruction and limiting air inflow, leading to dyspnea and stridor. About 1 week after the smoke inhalation, the child is at risk for the development of pneumonia because of infection of the denuded tracheal and bronchial tract areas. Because parents are usually relieved that their child has suffered only smoke inhalation from a fire, they may need an explanation of the physiologic consequences that can result from pulmonary injury and why hospitalization is necessary.

To help rule out smoke inhalation, obtain a history to assess whether the fire

occurred in a closed space, such as a garage. Assess for burns of the face, neck, or chest, which would indicate the fire was near the nose and respiratory tract. Assess the quality of the child's voice (it will be hoarse if the throat is irritated from smoke). Carefully monitor the respiratory rate of all burned children because respiratory rate increases with respiratory obstruction. A child also may become restless and thrash about because of lack of oxygen. Measurement of oxygen saturation will demonstrate the degree of hypoxia present from carbon monoxide intoxication. The best therapy for displacing carbon monoxide and providing adequate oxygenation to body cells is the administration of 100% oxygen. The child may need endotracheal intubation or a tracheostomy with assisted ventilation to ensure adequate oxygen is reaching the lungs. Intubation is best because tracheostomies can lead to infection, and this child is at a much higher risk for pneumonia than the average child.

Bronchodilators and antibiotics may be prescribed as a prophylactic measure because symptoms of smoke inhalation may not occur immediately but only 8 to 24 hours after the burn when the child's temperature increases or a chest X-ray reveals collecting edematous fluid and decreased aeration. High-frequency ventilation may be helpful to keep alveoli functioning. Some children need ECMO support because smoke inhalation has compromised their lung function to such a great extent.

**Nursing Diagnosis:** Risk for impaired urinary elimination related to burn injury

**Outcome Evaluation:** Child's urine output is greater than 1 ml/kg of body weight per hour.

Because the child's blood volume can decrease immediately after a burn, renal function can be threatened just when it is needed in order to rid the body of breakdown products from burned cells. Monitor blood volume conscientiously to detect whether hypovolemia is occurring and maintain IV fluid administration so urinary output can be maintained at about 1 ml/kg of body weight per hour. Monitor the specific gravity of urine as well to determine whether the kidneys are able to concentrate urine to conserve body fluid (failing kidneys lose this ability rapidly). In the days after the burn, because products of necrotic tissue and toxic substances must be evacuated by the kidneys and antidiuretic hormone and aldosterone levels may increase in response to low blood pressure, kidney function may fail again. If free hemoglobin from destroyed red blood cells plugs kidney tubules (acute tubular necrosis), urine color will turn red or black because of the hemoglobin present.

Because maintaining kidney function is so important, throughout the child's hospital stay, observing urinary output is a major nursing responsibility. An indwelling urinary (Foley) catheter should be inserted in the emergency department for a child with a large burn to obtain a baseline urine for analysis and allow for continued specimens to be obtained. If hemoglobin in tubules becomes a threat, a diuretic may be administered to flush this from the kidneys (urine will turn to its usual straw color if this is effective).

**Nursing Diagnosis:** Risk for imbalanced nutrition, less than body requirements, related to burn injury

**Outcome Evaluation:** Child's weight remains within 1 standard deviation from prior age-appropriate growth percentiles; skin turgor remains good; urine specific gravity remains between 1.003 and 1.030.

After burns, the metabolic rate increases in children as the body begins to pool its resources to adjust to the insult. If children do not receive enough calories in IV fluid to accommodate this increased metabolic need, their body will begin to break down protein for use, a particularly dangerous problem because the child needs protein to be available for burn healing. Additionally, if the breakdown of protein is extreme, it can lead to severe acidosis.

After a severe burn, some children feel nauseated because bowel peristalsis halts (paralytic ileus) from the systemic shock. Symptoms of intestinal obstruction, such as vomiting, abdominal distention, and colicky pain, follow within hours of the burn. To prevent aspiration of vomitus, an NG tube will be inserted and attached to low, intermittent suction. It then remains in place until bowel sounds are detected to make certain that the GI tract is again functioning (as long as 24 to 72 hours in severely burned children). Fluid suctioned from an NG tube may appear blood tinged (coffee-ground fluid) because of bleeding caused by stomach vessel congestion. Closely observe this drainage for a change to fresh bleeding, which can be caused by the development of a stress ulcer (Curling ulcer) from the overall trauma of the burn. This type of ulcer can be prevented by administering a histamine-2 receptor antagonist, such as cimetidine (Tagamet) or a proton pump inhibitor such as omeprazole (Prilosec), which reduce gastric acidity (Pilkington, Wagstaff, & Greenwood, 2012). If a bleeding ulcer does occur, gastric lavage with iced saline may be necessary. Blood for transfusion should be readily available because the blood loss from a GI ulcer can be rapid and severe.

Because of these potential GI concerns, children with severe burns usually are placed on nothing by mouth (NPO) for 24 hours. After this time, most children are able to eat, and oral feedings are begun as soon as possible. To supply adequate calories for increased metabolic needs and spare protein for repair of cells, the diet is high in calories and protein (Medlin, 2012). Children may also need supplemental vitamins (particularly B and C), iron supplements, and high-protein drinks between meals to ensure an adequate protein intake (Latenser, 2013).

In addition to this oral intake, it may be necessary to supplement the child's diet with IV or parenteral nutrition solutions or gastrostomy tube feedings. As methods of stimulating interest in eating, encourage school-age children to help add intake and output columns, help the dietitian add a calorie-count list, or keep track of their own daily weight (taken at the same time each day in the same clothing). It may be helpful to make contracts with older children to agree to eat at least some of each food offered on their plate.

**Nursing Diagnosis:** Risk for injury related to effects of burn, denuded skin surfaces, and lowered resistance to infection with burn injury

**Outcome Evaluation:** Child's temperature remains at 98.6°F (37°C); skin areas surrounding burned areas show no signs of infection such as erythema or warmth.

There appears to be some defect in the ability of neutrophils to phagocytize bacteria after burn injury, and the formation of immunoglobulin G antibodies also apparently fails. For these reasons, a child has reduced protection against infection for some time after a severe burn. *Staphylococcus aureus* and group A  $\beta$ -hemolytic streptococci are the gram-positive organisms and *Pseudomonas aeruginosa* is the gram-negative organism most likely to invade burn tissue. In addition to bacteria, fungi such *Candida* also may invade burns (White, Swales, & Butcher, 2012). Children are usually prescribed an antibiotic to prevent these infections and tetanus toxoid to prevent tetanus.

Bacteria and fungi can penetrate the burn eschar readily, so this tissue offers little protection from infection, necessitating nose, throat, and wound cultures to be done immediately and then daily to detect whether offending organisms are present. Fortunately, granulation tissue, which forms under the eschar 3 to 4 weeks after the burn, is resistant to microbial invasion.

Systemic antibiotics are not totally effective in controlling burn-wound infection, probably because the burned and constricted capillaries around the burn site cannot carry the antibiotic to the area. For this reason, any equipment used at the burn site must be sterile to avoid introducing infection. Children are placed on a sterile sheet on the examining table, and personnel caring for the severely burned child should wear caps, masks, gowns, and gloves, including during emergency care.

Even if their burns are covered by gauze dressings, children usually are cared for in private rooms to help reduce the possibility of infection. Helping children maintain their self-esteem and keeping them from withdrawing from social contacts when such strict infection control precautions are a challenge and must be addressed creatively within nursing care.

### **QSEN Checkpoint Question 52.6**

#### **TEAMWORK & COLLABORATION**

A nurse is helping a fellow nurse care for Sage, Jason's younger sister who has a third-degree burn on her arms and neck. Which statement by the fellow nurse on the second day of Sage's care would alert the nurse that the care team needs more instruction on burn management?

- "I'm guarding her IV site so she has an open route for pain management."
- "I'm measuring her oral and IV fluid intake to help prevent hypervolemia."
- "I'm monitoring urine output so I can be certain her kidneys are functioning."
- "I'm urging her not to talk so she doesn't relive the house fire over and over."

Look in *Appendix A* for the best answer and rationale.

## Therapy for Burns

Second- and third-degree burns may receive open treatment, leaving the burned area exposed to the air, or closed treatment, in which the burned area is covered with an antibacterial cream and many layers of gauze. These two methods are compared in [Table 52.4](#). As a rule, burn dressings are applied loosely for the first 24 hours to prevent interference with circulation as edema forms. Be certain not to allow two burned body surfaces, such as the sides of fingers or the back of the ears and the scalp, to touch, because, as healing takes place, webbing will form between these surfaces. Do not use adhesive tape to anchor dressings to the skin; it is painful to remove and can leave excoriated areas, which provide additional entry sites for infection. Netting is useful to hold dressings in place because it expands easily and needs no additional tape.

**TABLE 52.4** COMPARING OPEN AND CLOSED BURN THERAPY

Method	Description	Advantages	Disadvantages
Open	Burn is exposed to air; used for superficial burns or body parts that are prone to infection, such as perineum	Allows frequent inspection of site; allows child to follow healing process	Requires strict isolation to prevent infection; area may scrape and bleed easily and impede healing
Closed	Burn is covered with antibiotic cream and nonadherent gauze; used for moderate and severe burns	Provides better protection from injury; is easier to turn and position child; allows child more freedom to play	Requires dressing changes that can be painful; possibility of infection is still present because of dark, moist environment

### Topical Therapy

Silver sulfadiazine (Silvadene) is the drug of choice for burn therapy to limit infection at the burn site in children. It is applied as a paste to the burn, and the area is then covered with a few layers of mesh gauze. Because silver sulfadiazine has a sulfa base, it is an effective agent against both gram-negative and gram-positive organisms and even against secondary infectious agents, such as *Candida*. It is soothing when applied and tends to keep the burn eschar soft, making debridement easier. It does not penetrate the eschar (the tough, leathery scab that forms over moderately or severely burned areas) well, however, which is its one drawback.

If *Pseudomonas* is detected in cultures, nitrofurazone (Furacin) cream may be applied. If a topical cream is not effective against invading organisms in the deeper

tissue under the eschar, daily injections of specific antibiotics into the deeper layers of the burned area may be necessary.

If a burned area, such as the female genitalia, cannot be readily dressed, the area can be left exposed. The danger of this method is the potential invasion of pathogens.

### Escharotomy

As natural protection for a burned area, a rigid scab (an eschar) forms over moderately or severely burned areas. Fluid accumulates rapidly under an eschar, putting pressure on underlying blood vessels and nerves. If an extremity or the trunk has been burned so that both anterior and posterior surfaces both have eschar formation, a tight band may form around the extremity or trunk, cutting off circulation to distal body portions. If distal parts feel cool to the touch and appear pale, any tingling or numbness is present, pulses are difficult to palpate, and capillary refill is slow (longer than 5 seconds), an **escharotomy** (cut into the eschar) may be performed (Kupas & Miller, 2010). Some bleeding will occur after escharotomy. Packing the wound and applying pressure usually relieves this.

### Debridement

**Debridement** is the removal of necrotic tissue on which microorganisms could thrive from a burned area to reduce the possibility of infection. This may be done using collagenase (Santyl), an enzyme that dissolves devitalized tissue, or manually. For manual debridement, children may have 20 minutes of hydrotherapy beforehand to soften and loosen eschar, which then can be gently removed with forceps and scissors. Debridement is painful, and some bleeding occurs with it. Premedicate the child with a prescribed analgesic and help the child use a distraction technique during the procedure to reduce the level of pain. Transcutaneous electrical nerve stimulation (TENS) therapy or patient-controlled analgesia also can be helpful pain management measures. Extensive debridement is done using conscious sedation. Praise any degree of cooperation. Plan an enjoyable activity afterward to aid in pain relief and also to help reestablish some sense of control over the situation (Fig. 52.12).

**Figure 52.12** A nurse provides comfort and support to a child before debridement. (© Kathy Sloane/Science Source/Photo Researchers.)

If burned areas are debrided in this manner day after day, granulation tissue forms underneath. When a full bed of granulation tissue is present (about 2 weeks after the injury), the area is ready for skin grafting. In some burn centers, this waiting period is avoided by immediate surgical excision of eschar and placement of skin grafts.

### Grafting

**Allografting** is the placement of skin (sterilized and frozen) from cadavers or a donor on the cleaned burn site. These grafts do not grow but provide a temporary protective covering for the area. In small children, *xenografts*, or skin from other sources, such as porcine (pig) skin, may be used. **Autografting** is a process in which a layer of skin of both epidermis and a part of the dermis (called a *split-thickness graft*) is removed from a distal, unburned portion of the child's body and placed over the prepared burn site, where it will grow and replace the burned skin (Coruh & Yontar, 2012). The advantage of both types of grafting is that they reduce fluid and electrolyte loss, pain, and the chance of infection.

Skin for a split-thickness graft is removed from the buttocks or inner thigh under general anesthesia. Large burn areas may require mesh grafts (a strip of partial-thickness skin is slit at intervals so that it can be stretched to cover a larger area; Fig. 52.13).

**Figure 52.13** Mesh grafting is necessary to cover large areas of the body such as in this young child with third-degree burns. (© CC Studio/SPL/Photo Researchers Inc.)

After the grafting procedure, the burned area is covered by a bulky dressing. The donor site on the child's body is also covered by a gauze dressing. So that the growth of the newly adhering cells underneath will not be disrupted, don't remove or change the dressings. To detect infection at the sites, observe both the donor and graft dressings for fluid drainage and odor, and assess for pain and body temperature, all of which might indicate infection. Autograft sites heal so quickly that they can be reused every 7 to 10 days, so any one site can provide a great deal of skin for grafting.

Full-thickness grafts involve both layers of the skin and are used for deep or very severe burned areas. Skin for these is usually removed from the back or abdomen; because the amount of skin removed is so extensive, the donor site may require a split-thickness graft for healing. An alternative to skin grafting in a child who doesn't have enough unburned skin surface for autografting is the technique of using artificial skin to cover the burn. Artificial skin consists of synthetic fibers that, when placed over the denuded burn area, are filled in by fibroblasts and blood vessels and nerve fibers from surrounding healthy tissue to create a new dermal layer. Artificial skin is not rejected as

is an allograft or a xenograft but is dissolved as the new skin replaces it. Another option is removing a small number of the child's skin cells and allowing them to grow in a culture laboratory until they can be used as a graft. Because skin cells grow fairly rapidly, this supplies an unlimited supply of available skin for large burn areas.

## Nursing Diagnoses and Related Interventions

For children who survive the immediate insult of a large burn, infection becomes their chief threat.

**Nursing Diagnosis:** Social isolation related to infection control precautions necessary to control spread of microorganisms

**Outcome Evaluation:** Child states he understands the reason for infection control precautions; accepts it as a necessary part of therapy.

Infection control measures involved in the care of children with major burns consist of more than just placing the child in a private room. Aseptic technique and appropriate barriers are necessary to reduce the risk of exposing the child to infection by the use of gowns, masks, caps, and sterile gloves by healthcare providers, creating a situation where the child is doubly isolated—by distance and by never being touched directly.

It is easy for children with burns (who were told measures such as not to play with matches or go too close to the fireplace) to interpret confinement in a room as punishment. Make every effort to make the child's environment as warm and comforting as possible despite infection control procedures. Place children's beds so they can see as much unit activity as possible. Decorate walls in front of them with cards they receive or with a changing gallery of pictures drawn by staff members of things in which the child appears interested.

Provide time for children to discuss their feelings about being kept in a room by themselves. A question such as "It's hard to understand a lot of things about a hospital; do you understand why your bed is in this special room?" gives children a chance to express their feelings.

Show parents how to put on gowns, gloves, and masks if required so they can feel comfortable participating in the child's care. Parents may not offer to help with care when their child is severely burned because they are still in a state of shock or grief. They may perceive the bulky dressings as making it impossible for them to hold the child. You can assure them the closed bulky dressings on the burned area are what make it *possible* for them to hold the child. If it is not possible for them to do this, help them see how stroking their child's face or touching a hand (even with gloves in place) gives the child a feeling of still being loved and not totally removed from

warm contact.

Remember that, even if children's chests, abdomens, and hands are burned, they do not stop thinking and thus need stimulation in their restricted environment. A television set is good for passing time, but for longer than 1 day, it is not adequate as the child's main communication with the outside world. Listening to favorite music with them, reading stories to them, talking about what is going on at home or what they normally do at school, and doing schoolwork are also important.

Make certain to visit a child in isolation to talk or play a game at times other than procedure or treatment times so the child can view the nursing staff as friends and caregivers, not as busy people who can't be interrupted. Frequent visits also convey that the child is not alone and others are aware of important needs.

**Nursing Diagnosis:** Interrupted family processes related to the effects of severe burns in a family member

**Outcome Evaluation:** Family members state that they are able to cope effectively with the degree of stress to which they are subjected; family demonstrates positive coping mechanisms.

Children with severe burns always have a difficult hospitalization because of the pain, restrictions, and (at some point) awareness of the disfigurement that accompanies major burns. Some parents have exceptional difficulty adjusting to what has happened because they are grieving so deeply over the child's condition or are so concerned with other upsetting factors in their lives (many burns happen because of situational crises in the family; the family may have lost their home and possessions to the fire that burnt the child) that their interaction with the child seems to falter or be very difficult for them. Because they may not be able to stay with the child constantly because they also have to meet with financial advisors, insurance inspectors, or home construction people to begin to get their home back in repair, assure them their child is in good hands during the time they must be away to help relieve stress at least in this one area.

**Nursing Diagnosis:** Disturbed body image related to changes in physical appearance with burn injury

**Outcome Evaluation:** Child expresses fears about physical appearance; demonstrates desire to resume age-appropriate activities.

Children with burns are often forced to become extremely dependent on the nursing staff because of the position in which they must lie and because the bulky dressings that cover their arms or hands prevent them from feeding themselves. They respond to this forced dependence at first with gratitude. They are hurt, and someone is taking care of them. After a period, however, their response may become less healthy; young school-age children or preschoolers may revert to bed-wetting or baby talk. Older children may respond by open aggressiveness such as refusing to eat or to lie in a position that is best for them in order to reestablish independence and counteract their

feelings of helplessness. To help avoid these reactions, make certain to allow independent decision making whenever possible. Be careful to avoid questions such as “Can I change your dressing now?” or “Will you swallow this pill?” because these imply choices when there really are none as these measures are important for healing.

Allow secondary choices instead. Children, for example, must take the 10 o’clock medicine, but they can choose the fluid they want to swallow after it. They must be fed meals because of the bulky dressings over their hands, but they can decide which food they will eat first. They must have their dressings changed, but they can choose the story you will read them afterward.

Immediately after a severe burn, children (if they are old enough to understand) and their parents are most concerned with whether the child will live. After body systems have stabilized and the parents have been assured the child will live, thoughts turn to the child’s cosmetic appearance. At first, it is easy for children and parents to ignore this problem because the burned areas are covered by dressings. Even when the dressings are removed for debridement or whirlpool therapy, it’s easy for children to assume the appearance of the burned area is only temporary and that the area will eventually heal and have a good appearance. They have probably never seen anyone with a scar from a second- or third-degree burn and have no reason to worry about it.

When children begin to see others on the hospital unit with burn scars, however, they do begin to realize that healing may result in permanent scarring ([Fig. 52.14](#)). Parents and children need time to talk about their feelings about this because they may feel a great deal of guilt about the incident and ways they could have prevented the burn from happening ([Bakker, Van Loey, Van Son, et al., 2010](#)).

**Figure 52.14** Extensive scarring on the chest of a 9-year-old boy following a third-degree burn. (© Dr. P. Marazzi/SPL/Science Source/Photo Researchers.)

Both boys and girls are concerned about whether their face will be scarred. A girl may be extremely concerned if her chest is burned because she is worried breast tissue will not develop (a very real concern, depending on the extent of the burn).

Children watch you as you care for them to see if you find them unattractive. As dressings are removed, children may expose parts of their body seemingly inappropriately to see if you are shocked or revolted by them. It is easy to think that you will not react this way, but for everyone, the first sight of a severe burn is a shock and it is difficult not to react accordingly. Imagining how children feel and realizing that this mutilated skin is their skin can help healthcare providers maintain a professional attitude. As a rule, the appearance of scar formation can be improved by the application of pressure dressings that the child wears 24 hours a day.

Returning to school can be difficult for all children who have been hospitalized or have been receiving home care for a long time. Their old friends have new friends, so they may feel cut out of school activities. It may be particularly difficult if the child is left with burn scars. Ask how the child is adjusting at follow-up visits. Some children

need referral for formal counseling to help rebuild their self-image. Some parents need formal counseling also to help them accept their child's changed appearance and work through lingering guilt.

### *What If... 52.4*

**A nurse is particularly interested in exploring one of the 2020 National Health Goals related to unintentional injury in children (see [Box 52.1](#)). What would be a possible research topic pertinent to this goal that would be applicable to Jason's family and also advance evidence-based practice?**

## **KEY POINTS FOR REVIEW**

- Children need total body assessment after an unintentional injury because they may be unable to describe other injuries besides the primary one they have suffered.
- Be aware that some trauma in children occurs as a result of child maltreatment. Screen for this by history and physical examination. Make sure to assess the entire body for physical findings.
- Head injuries are always potentially serious in children. Many different types such as skull fractures, subdural hematomas, epidural hematomas, concussions, and contusions can occur. Coma (unconsciousness from which a child cannot be roused) may be present after severe head trauma.
- Abdominal trauma can result in rupture of the spleen or liver and may occur in connection with multiple trauma.
- Drowning can occur in either salt or fresh water. The physiologic basis for complications after drowning differs depending on the type of water in which the child was submerged.
- Children place anything in their mouth. Common substances children swallow that result in poisoning include prescription medications, over-the-counter medications, and caustic substances. Teach parents to keep the number of the National Poison Control Center next to their telephone or as a contact number in their cell phone (1-800-222-1222) and always call first for advice before administering an antidote for poisoning.
- Lead poisoning most frequently occurs from the ingestion of paint chips in older housing units. Educating parents on how they can prevent this is a major nursing responsibility.
- Burns are classified as first, second, third, and fourth degree—depending on the depth of the burn. Use sterile technique when caring for a child who has been burned to prevent infection. Be aware that burns produce systemic body reactions and require long-term nursing care.

## **CRITICAL THINKING CARE STUDY**

Meredith is a 2-year-old girl you see in an emergency room. Meredith lives with her mother, Antoinette, and her mother's boyfriend in a three-bedroom suburban home. Meredith swallowed three of her mother's birth control pills earlier this evening. On the way to the hospital, Antoinette ran her car into a pick-up truck. Meredith was thrown out of the car and trapped against the exhaust pipe of the truck. The dress she was wearing is partially burned away; her chest is reddened and blistered and weeping fluid. She's obviously in pain. "Can anything else go wrong?" Antoinette asks you. "I received my divorce papers today. My college loan wasn't approved. And now my car is ruined."

1. Antoinette doesn't understand why Meredith swallowed the pills. She says, "I've told her over and over medicine is for grown-ups." What factors in this family's background made this a day when poisoning was apt to occur? Did Antoinette take the best first-aid step for an unintentional poisoning?
2. Meredith has a second-degree burn on her chest, so insertion of an IV line with an infusion of normal saline is prescribed. You're concerned that, because the burned area is losing fluid, Meredith needs electrolytes replaced as well as fluid. What do you need to know to safely add a potassium supplement following a severe burn?
3. While hospitalized for her burn, Meredith had her serum lead level assessed, and it was found to be 15 µg/dl. What is the safe level of lead in children? If Meredith is prescribed CaEDTA to be infused IV, what do you need to know before administration? What is the purpose of this drug?

## Nursing Care of a Family When a Child Has a Malignancy

**G**erri is a 6-year-old boy you meet at a health maintenance organization clinic when he arrives for a well-child checkup. His mother tells you that Gerri wakes up every morning with a headache and vomits soon after waking; he is then able to have a normal breakfast and seems fine. The problem began just after he started a new school in the fall, so the mother is certain the vomiting is related to this. His teacher has suggested that Gerri needs an eye examination because he cocks his head to see the chalkboard. When you weigh him, you notice he has lost weight. “What do I do for school phobia?” his mother asks you.

Previous chapters described the growth and development of well children and disorders associated with specific body systems. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur when children develop a malignancy, a phenomenon that can happen in any body system. Such information forms a base for care and health teaching.

**Is Gerri’s mother describing school phobia, or is this something more serious? What additional questions would you want to ask to help discover whether you need to alert her primary care provider of your concern?**

### KEY TERMS

**biopsy**  
**chemotherapeutic agent**  
**Ewing sarcoma**  
**leukemia**  
**lymphoma**  
**metastasis**  
**neoplasm**  
**nephroblastoma**  
**neuroblastomas**  
**oncogenic virus**  
**osteogenic sarcoma**

**rhabdomyosarcoma**  
**sarcomas**  
**tumor staging**

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe usual cellular growth and theories that explain why cells alter to become malignant in children.
2. Identify 2020 National Health Goals related to the care of the child with a malignancy that nurses can help the nation achieve.
3. Assess a child with a common malignant process, such as a rhabdomyosarcoma, neuroblastoma, nephroblastoma, or leukemia.
4. Formulate nursing diagnoses related to a child with a malignancy.
5. Establish expected outcomes for a child with a malignancy to help parents manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care for a child with a malignancy, such as explaining why chemotherapy is important.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of malignancy in children with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to achieve quality maternal and child health nursing care.

The terms *malignant* and *cancerous* describe cells that are growing and proliferating in a disorderly, chaotic fashion. In adults, cancer usually occurs in the form of a solid tumor. In children, the most frequent type of cancer is that of immature white blood cell (WBC) overgrowth, or **leukemia** (Brown & Hunger, 2013).

Many parents assume that a diagnosis of cancer means their child's life will be very limited. Because of the tremendous advances in cancer research and treatment over the past 20 years, however, the prognosis for children and the chances for a cure improve daily. Up to 95% of children with the most common form of leukemia, for example, can expect to be cured. To help both parents and children adjust to this serious illness, however, nursing support is necessary from the time of diagnosis throughout the long-term therapy required. Because decreasing the incidence of cancer is important to the nation, 2020 National Health Goals related to malignancies and children address this concern and are shown in [Box 53.1](#).

Several 2020 National Health Goals concern cancer prevention and children:

- Reduce the overall cancer death rate from a baseline of 178.4 per 100,000 to 160.6 per 100,000 of the population.
- Increase the proportion of adolescents in grades 9 through 12 who follow protective measures that may reduce the risk of skin cancer from 9.3% to 11.2%.
- Reduce the rate of melanoma cancer deaths from a baseline of 2.7 per 100,000 to a target level of 2.4 per 100,000 of the population (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

The health goals don't speak to leukemia because there is no screening test available as yet for hematologic types. Nurses can help the nation achieve these goals by careful history taking at health assessments to reveal the symptoms of leukemia, which are often subtle in children, and by active teaching of available self-screening measures, such as testicular examination, and preventive measures, such as avoiding excessive sun exposure.

### *Nursing Process Overview*

## FOR CARE OF A CHILD WITH A MALIGNANCY

### ASSESSMENT

The symptoms of malignancy in children are often insidious and difficult to identify because headaches or pain at a particular body site can often be explained away by other factors, such as a sports injury or fatigue. Weight loss, however, is a symptom of some forms of childhood cancer, and unintentional weight loss is never normal in healthy children. Therefore, at every healthcare visit, plot and analyze a child's height and weight carefully to document evidence of this important finding.

### NURSING DIAGNOSIS

Nursing diagnoses established for the child with a malignancy address specific symptoms caused by the malignancy itself, side effects of therapy, or coping abilities of the child and family. Examples include:

- Pain related to neoplastic process in bone
- Imbalanced nutrition, less than body requirements, related to mucositis from radiation therapy
- Risk for infection related to immunosuppressive effects of chemotherapy
- Disturbed body image related to loss of hair after radiation treatment or chemotherapy
- Compromised family coping, related to long-term chemotherapy regimen

### OUTCOME IDENTIFICATION AND PLANNING

When a neoplasm (abnormal growth that does not respond to normal growth-control mechanisms) is first diagnosed in their child, parents may be able to deal only with short-term outcomes and plans. They may concentrate on learning about the effect or toxic properties of a particular chemotherapeutic drug prescribed for their child, or they may ask how long the child's surgical incision will be. Dealing with such specifics helps them to control their anxiety because it prevents them from dealing with the overall picture or prognosis—that their child has a potentially life-threatening illness.

Be certain the family has an overall picture of the treatment protocol. Explain measures they will need to take to make their child more comfortable during therapy such as not forcing food if their child is nauseated and playing games or reading stories while an intravenous (IV) chemotherapy agent is administered.

Parents are usually eager for results of diagnostic tests. They may need support while waiting until all the findings have been assembled for an accurate assessment of staging and prognosis. Establishing a primary relationship with both the child and the parents is important so that, no matter how many hospitalizations are necessary, they know a support person is waiting to help them through this long-term illness. Be certain the child's siblings are considered in planning care, because the treatment will be long term, putting stress on the entire family.

Parents can be expected to experience grief if they learn their child's prognosis is poor and move through stages of denial, anger, bargaining, depression, and, hopefully, acceptance. During planning, be certain to take into account their current stage of grief so planning can be successful (see [Chapter 56](#)).

Organizations that may be helpful for referral are the American Cancer Society (ACS) ([www.cancer.org](http://www.cancer.org)), the National Cancer Institute ([www.cancer.gov](http://www.cancer.gov)), the Children's Oncology Group ([www.childrensoncologygroup.org](http://www.childrensoncologygroup.org)), CureSearch ([www.curesearch.org](http://www.curesearch.org)), Candlelighters for Children with Cancer ([www.4kidswithcancer.org](http://www.4kidswithcancer.org)), and the Leukemia & Lymphoma Society ([www.lls.org](http://www.lls.org)).

## IMPLEMENTATION

Nursing interventions for a child with cancer include supporting the child and parents from the time of diagnosis through procedures such as surgery, radiation therapy, chemotherapy, and continued health supervision. Increasingly, cancer treatment is offered on an ambulatory basis to keep hospitalization to a minimum, so many nursing interventions include teaching the parents how to give care or monitor for side effects while at home. Nurses play a critical role in ensuring that the parents are aware of signs and symptoms, and of steps to take, should the child develop emergent issues such as bleeding or fever while at home.

Keep in mind that the stress of long-term treatment can put the child and family at risk for developmental or family coping problems. You can be a positive force in encouraging healthy adaptation to the demands of the child's illness and in reassessing the situation periodically during therapy to be certain the child is

receiving appropriate stimulation for developmental growth. Providing comfort and alleviating pain are often primary concerns in oncology nursing. Measures for pain relief are discussed in [Chapter 39](#).

### **OUTCOME EVALUATION**

Because cancer therapy includes long-term care, children need to be evaluated periodically to be certain projected outcomes are being met and are still current. Some examples indicating outcome achievement are:

- Child keeps all appointments for chemotherapy treatments.
- Child maintains passing grades in school despite interruptions for therapy.
- Parents state they are able to keep anxiety at an acceptable level between clinic appointments.

Children with cancer need much of the same well-child maintenance care that all children do, with one exception. While they are undergoing chemotherapy, which causes a decreased immune response, they should not receive routine vaccines. The siblings in the home can receive all non-live vaccines and the entire family (including the child undergoing treatment) are encouraged to receive a yearly flu vaccine.

Follow-up visits are usually anxiety filled for both the parents and the child. The child seems well, but parents may be apprehensive while a healthcare provider palpates the child's abdomen or blood specimens are obtained. Some parents may find the strain of returning for follow-up visits too great and miss appointments (not knowing seems better than to be told bad news). Such parents need help in understanding that initial remissions can be maintained and second remissions can be achieved, so maintenance therapy must be continued. Because a child who is treated for cancer is at risk for developing long-term complications from therapy, they should have appropriate follow-up and screening according to the Children's Oncology Group Guidelines ([www.survivorship.org](http://www.survivorship.org)). If a child dies, parents may feel a need to return to the healthcare agency for support. This provides an opportunity to evaluate their adjustment and refer to a social work professional if concerns are identified. Siblings should also be assessed by a provider to assure they are coping in a developmentally appropriately way with the death of a brother or sister.

## **Health Promotion and Risk Management**

Because childhood cancers do not seem to arise from environmental contaminants as some adult cancers do, methods to reduce the risk are not as well defined. Urging parents to reduce children's exposure to secondary cigarette smoke and urging adolescents not to begin smoking, including the use of tobacco alternatives, can help reduce the incidence of lung cancer when they reach adulthood. Although it is not yet known how much sunscreen actually reduces the risk of melanoma, applying sunscreen, reducing the overall time of sun exposure, and avoiding tanning salons are measures to help reduce the development of skin cancer in later life ([Quatrano & Dinulos, 2013](#)).

Children who receive chemotherapy or radiation for one cancer have a higher incidence of developing another cancer later in life. Therefore, urging these children to continue health appointments so that any additional tumor development can be discovered as soon as it occurs is another important preventive measure. Reminding parents that both boys and girls should receive the vaccine against human papillomavirus (HPV) is an important preventive measure to reduce the incidence of cervical cancer (Petrosky, Bocchini, Hariri, et al., 2015).

Parents of a child with cancer may seek health maintenance care or evaluation for their other children more often than other parents would because they are worried that what seems like just a minor symptom is actually a sign of cancer in that child. They may need greater amounts of reassurance that their other children are well, reflecting the overall stress they feel (Cernvall, Carlbring, Ljungman, et al., 2013).

## Neoplasia

All body tissue undergoes continuing growth to develop into and maintain that specific type of tissue. Normally, the body is able to balance the proliferation necessary to replace old cells that die plus produce new cells for physical growth needs. Cancerous, or malignant, tissue, however, is unable to maintain this balance and begins to proliferate in disorderly, chaotic ways.

The word **neoplasm** means “new growth,” although it is typically used to refer to a new *abnormal* growth that does not respond to normal growth-control mechanisms. Whether this process is one that produces a solid tumor or one that involves blood-forming elements, growth begins insidiously and usually has been happening for some time before the parents or child realize it is present. Even after they are aware a change exists, some time may pass before they realize the few symptoms they feel are serious enough to require health care (Box 53.2).

### BOX 53.2

#### Nursing Care Planning to Respect Cultural Diversity

Nurses frequently care for patients from differing cultural backgrounds and practices. An understanding of how these cultural variations impact the delivery of care is important to determine early on and should be communicated to the healthcare team at large. Some aspects of care may be easily identified, for example, food preferences or specific holiday observances. Other cultural differences may be more difficult to ascertain and may require ongoing discussions to fully appreciate, for example, beliefs about the cause of disease and talking to the child about his or her disease. Many institutions have an international department which may be accessed to help promote communications and cultural sensitivity.

People in various cultures have differing beliefs regarding what causes cancer, ranging from evil spirits or evil past lives to totally environmental, genetic, or

psychological causes. Talking with the parents and the child, if old enough, about what they think is the cause of cancer can help practitioners to understand their reactions to procedures or medicine and to provide explanations that are more meaningful because they are geared to fit within the patient's and parents' beliefs.

Although cancer in children is rare compared to unintentional injury or infection, it is a leading cause of death among children younger than 15 years of age. Fortunately, the overall survival rate for children with cancer today has improved. The overall 5-year survival rate is 83%, and for acute lymphoblastic leukemia (the most common form of childhood cancer), the 5-year survival is 90% (Ward, DeSantis, Robbins, et al., 2014).

## CELL GROWTH

The normal cell cycle consists of two main divisions: an interphase (resting) phase and a mitosis (dividing) phase. The interphase has four separate stages: G<sub>0</sub>, G<sub>1</sub>, S, and G<sub>2</sub>. Activity during these periods is summarized in Table 53.1. The time span of a cell's life cycle varies based on the type of tissue involved. The rate of the cycle is slowed or increased by outside stimuli, such as hypoxia, genetic and immunologic factors, and physical and chemical agents. Normally, an organ has some cells in both resting and active cells.

**TABLE 53.1 PHASES OF THE CELL CYCLE**

Phase	Activity
G	Gap, or the phase between mitosis and synthesis
G <sub>0</sub>	Cell at rest. Cells remain in this state until some stimulant, such as death of surrounding cells, triggers the cell to enter an active phase; it is difficult to destroy cells in this resting state.
G <sub>1</sub>	Period until DNA stabilization is complete; it remains difficult to destroy cells in this phase.
S (synthesis)	Period (6–8 hr) during which DNA and chromosomes are duplicated or a cell readies itself for division into two daughter cells
G <sub>2</sub>	Cell doubling in size as preparation for dividing into two daughter cells; if protein synthesis can be stopped at this point so that the cell cannot reach a “critical mass,” mitosis (cell division) cannot take place.
M (mitosis)	Period of cell division into two like daughter cells

Cells have the ability to recognize their own type, possibly by recognizing surface enzymes or glucose particles on cell membranes. As a result, cells of like type do not migrate away from each other but instead recognize and adhere to each other to form a solid mass. In contrast, neoplastic cells seem to lose this ability to adhere to one another (they are autonomous cells). The reason for this is not well documented but may be

related to decreased calcium in the cell membrane or to an increased negative charge that repels other cells rather than bonds them together (Cooper & Hausman, 2016).

Another feature of healthy cells is that they appear to be able to recognize when they are being crowded for the space they must occupy and, at that point, are able to halt growth to reduce overcrowding. Neoplastic cells do not respond to this communication or cannot receive it, so, despite how crowded they become, they continue to grow. By the time a tumor mass is detected by palpation, it is probably about 30 times the size of its original aberrant cell (Harrington, Bristow, Hill, et al., 2013).

## NEOPLASTIC GROWTH

Neoplasms are either *benign* (growth is limited) or *malignant* (cancerous or with unlimited growth). Even when a tumor is benign, however, it doesn't mean it is completely harmless because it can cause damage by pressing on adjacent tissue. For example, brain tumors in children are often benign, but they may cause life-threatening neurologic complications by compressing other areas of the brain.

### Causes of Neoplastic Growth

The exact origin of neoplastic growth is unknown, and any growth may actually involve more than one cause. As more and more evidence is compiled on the nature of genes, specific markers in tumors that apparently fail to suppress, or stimulate, cancer-causing genes are being identified; almost all childhood cancers have such markers or a genetic trigger or predisposition to cancer.

In adults, tumors may grow because normal cell growth has been altered by environmental exposures, such as chronic exposure to chemical irritants or cigarette smoke. In adults, the skin, bladder, lungs, and intestines involve organs exposed to such outside influences and irritation and thus become common sites for abnormal growths. In children, in contrast, tumors most frequently occur in organs unexposed to the environment such as leukemia of the bone marrow, nephroblastoma of the kidney (Wilm tumor), tumors of the brain, or neuroblastoma in the abdomen, and because many tumors occur in children younger than 5 years of age who haven't had long-term exposure to environmental carcinogens, this cause of tumors is probably not a great influence in childhood cancer (Pizzo & Poplack, 2015).

Somatic mutation theory postulates that an accumulation of mutations in the cell is what ultimately results in the transformation to a neoplastic state. This theory explains why the growth of neoplastic cells is not reversible (the cells cannot return to a normal state because they are intrinsically changed at the genomic level) and why neoplasms occur in some people but not in others (both an intrinsic and an extrinsic factor, or an inherited tendency and an environmental insult, must be present). It is difficult to document this process, however, because if there is a lengthy time span between these steps, the cause-and-effect relationship is difficult to trace and in general is more pertinent to adult cancers in which decades of time contribute the amount of potential

mutations (Kennedy, Loeb, & Herr, 2012).

In other cancers, **oncogenic viruses** (cancer-causing virus) such as HPV may be directly responsible for tumor growth (Gao & Smith, 2016). According to this viral theory, oncogenic viruses have the ability to change the structure of DNA or RNA in cells. C-type RNA viruses, for example, have been implicated in leukemia. The Epstein–Barr virus (EBV) is associated with Burkitt lymphoma. This theory is supported by the fact that an immunodeficient state appears to increase the risk for development of a neoplastic growth. In some children, because of their genetics, tumor suppressor cells may not be present, allowing abnormal growth stimulated by viruses to continue.

## Assessing Children With Cancer

The incidence of various types of childhood cancers is shown in Figure 53.1. Because these cancers involve different body systems, signs and symptoms can vary greatly (Box 53.3).

**Figure 53.1** Approximate incidence of common childhood cancers. ALL, acute lymphocytic leukemia; ANLL, acute nonlymphocytic leukemia.

### BOX 53.3

## Nursing Care Planning Using Assessment

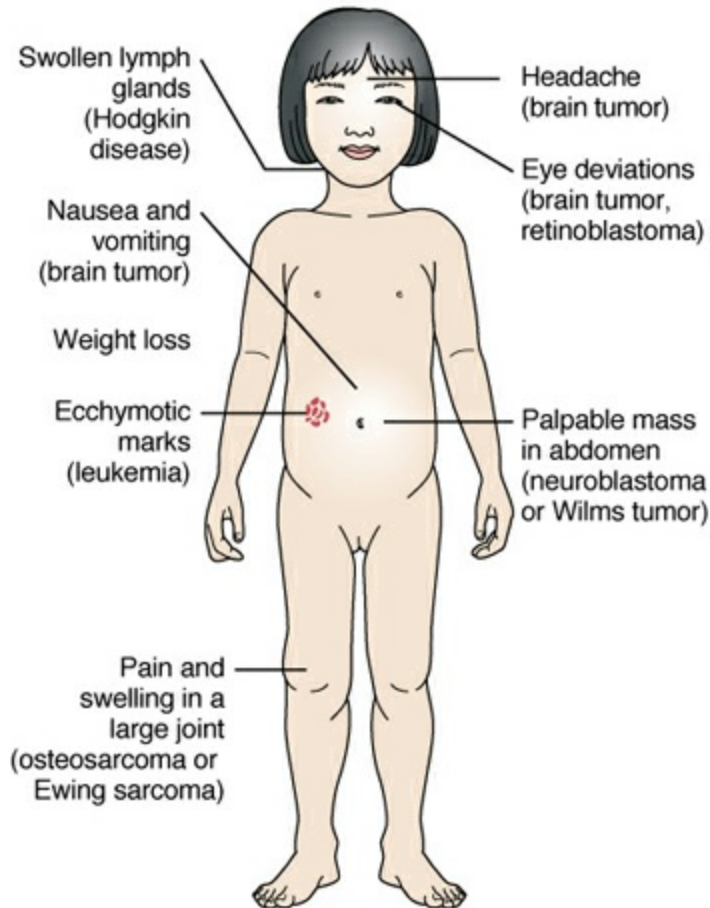

### ASSESSING A CHILD FOR SIGNS OF CANCER

### History

*Chief concern:* Weight loss, loss of appetite, easy bruising, swelling in a body part, headache, eye deviations.

*Past medical history:* Family member with a history of cancer.

### Physical examination

## HISTORY

Many of the early symptoms of childhood cancer mimic other common childhood illnesses, and cancer is rarely the immediate differential diagnosis for a routine sick visit to the pediatrician. Thorough history taking at healthcare visits is necessary to reveal the symptoms that may point to a malignancy; an abnormal intensity or duration rule may help identify the most concerning symptoms. Abnormal intensity of symptoms refers to symptoms that seem more extreme than would be expected, for example, a simple lower extremity injury that is associated with more pain than typical. Abnormal duration refers to symptoms that have lingered or increased over an unusually long period, for example, a fever that has not responded to antibiotics and has lasted longer than expected for recovery from an acute illness. Also important is discovering and appreciating systemic effects such as cachexia (loss of weight and anorexia) because these can occur if the tumor is growing so rapidly it is taking nutrients away from normal cells. Other systemic symptoms occur because of excessive hormone production (e.g.,

overproduction of antidiuretic, thyroid, or adrenocorticotrophic hormone), which results from tumor growth in a specific body area (Box 53.4).

## BOX 53.4

### Signs and Symptoms of Cancer

#### GENERAL SIGNS AND SYMPTOMS OF CANCER

- Unexplained fever
- Bleeding/bruising
- Morning headaches and neurologic changes
- Palpable abdominal mass
- Swollen lymph nodes
- Bone and joint pain
- Fatigue

## PHYSICAL AND LABORATORY EXAMINATION

Assessing height and weight followed by a thorough physical examination of children are instrumental measures in discovering malignancy. To confirm a diagnosis, a number of further diagnostic procedures may be used, including X-ray, ultrasound, magnetic resonance imaging (MRI), blood analysis, and biopsy.

## BIOPSY

Most children with a possible diagnosis of cancer will have a **biopsy** (the surgical removal of cells for laboratory analysis) performed to confirm the diagnosis. Although biopsies are classified as minor surgery and usually done on an ambulatory basis, do not treat lightly the meaning of them to a family. In addition to carrying a definite surgical risk if conscious sedation or general anesthesia is used, they are an anxiety-producing procedure. For this reason, be certain parents and children have thorough preparation for the biopsy procedure and education about any care the child will need afterward. Remember that anxious parents may not remember details and thus may need to have postoperative instructions or aftercare repeated. Bone marrow aspiration is an example of a frequent type of biopsy used with children (see [Chapter 44](#)).

## STAGING

**Tumor staging** is a procedure by which a malignant tumor's extent and progress are documented. Knowing the stage of a tumor helps the healthcare team design an effective treatment program, establish an accurate prognosis, and evaluate the progress or regression of the disease. In general, stage I refers to a tumor that has not extended into the surrounding tissue and may be completely removed surgically; stage II means there is some local spread, but the chance for complete surgical removal is good. Stage III typically means cancer cells have spread to local lymph nodes; stage IV designates

tumors that have spread systemically (**metastasis**). There are various staging systems. The TNM system describes the tumor's size (T), any presence in the lymph nodes (N), and if the cancer has metastasized or spread to other organs (M). A TNM system is most applicable to solid tumors and does not apply to malignancy of the bone marrow (leukemias).

## Overview of Cancer Treatment Measures Used With Children

Therapy for a child with cancer focuses on devising ways to kill the growth of the abnormal cells while protecting the normal surrounding cells. Treatment may include any one or a combination of surgery, radiation, chemotherapy, stem cell transplantation, and immunotherapy (biologic response modifiers).

### RADIATION THERAPY

Radiation therapy changes the DNA component of a cell's nucleus and prevents replication; the cell is not able to replicate DNA material which inhibits further cell division and growth. Radiation is delivered to the tumor in three primary ways:

1. External beam radiation
2. Brachytherapy
3. Stereotactic radiosurgery

External beam radiation delivers high-energy particles (photons, electrons, protons) from outside the body to the tumor. External beam radiation is administered in one to two treatments per day over several days to a week. Brachytherapy delivers radiation via implants directly to the tumor site (interstitial, intracavitary, or on the surface). Radioactive material is then loaded into the implant, typically over a 4- to 6-day period. Stereotactic radiosurgery delivers a single high dose of radiation to the tumor using three-dimensional (3-D) imaging to target the exact tumor space ([Ermoian, Fogh, Braunstein, et al., 2016](#)).

### Side Effects

Radiation has both systemic and localized immediate effects. Radiation sickness (fatigue, anorexia, nausea, vomiting) is the most frequently encountered systemic effect. This occurs most frequently if the gastrointestinal (GI) tract is irradiated. It also occurs to a lesser degree as a result of the release of toxic substances from destroyed tumor cells, so children may have these symptoms even when the GI tract is not in the radiation field. To counteract this, a child is often prescribed an antiemetic before each radiation treatment. Skin reactions, such as erythema and tenderness, are typical local effects. Maintaining good skin hygiene and use of mild soaps or moisturizers (non-fragrant) may help preserve skin integrity.

The long-term side effects of radiation are becoming more apparent as increasing

numbers of children who have undergone intense radiation therapy survive years beyond the radiation. Because radiation damages all cells in its path toward the tumor to some extent, any body tissue in the radiation field has the possibility of long-term complications or malignant transformation.

### **Long-Term Side Effects on Bone**

Asymmetric growth of bones, easy fracturing, scoliosis, kyphosis, and hypoplasia (not reaching full growth potential) are effects that can occur in bones. Bone tissue is most vulnerable during times of rapid growth, such as during the first years of life or during a prepubertal growth spurt. Scoliosis and kyphosis can be avoided if the entire vertebra is irradiated rather than only one side or the other; this means a larger area of bone may be irradiated than was done formerly, so that both sides of the vertebra are in the radiation path.

### **Long-Term Side Effects on Hormones**

Radiation to the head and neck can result in long-term thyroid, hypothalamic, and pituitary gland dysfunction, resulting in growth hormone deficiency, hyperprolactinemia, central adrenal insufficiency, or gonadotropin deficiency (Rose, Horne, Howell, et al., 2016). For this reason, children's growth and endocrine function need to be evaluated for decades after treatment with cranial radiation to detect these changes. It's possible to treat both hypothyroidism and hypopituitary growth failure with hormone replacement in coming years if these do occur. Radiation to ovaries or testes can also result in complications such as infertility or less estrogen or testosterone production, preventing the development of secondary sexual changes. For children past puberty, pretreatment sperm or oocyte banking may be advocated before they undergo radiation to the testes or ovaries so they have viable sperm or oocytes banked for use later in life (E. K. Johnson, Finlayson, Rowell, et al., 2017).

### **Long-Term Side Effects on the Nervous System**

Long-term effects of radiation to the nervous system are demyelination and necrosis of the white matter of the brain, which results in symptoms of lethargy, sleepiness, and possibly seizures, and effects on the gray matter, which can result in learning disabilities. Careful history related to school and learning issues is critical; neuropsychological testing is recommended to identify any weakness and assist in the development of individual education plans. In addition, children may experience headaches, cataracts, salivary gland damage, and a chronic change in or loss of taste.

### **Long-Term Side Effects on the Organs of the Chest and Abdomen**

Extensive radiation to the lungs can result in a chronic pneumonitis and pulmonary fibrosis, resulting in obstructive or restrictive chronic lung disease. Heart effects may include left ventricular dysfunction, valve abnormalities, early coronary artery disease,

or conduction abnormalities. Radiation to the GI system can result in chronic malabsorption from changes in intestinal villi; hepatic fibrosis can result in reduced liver function. Radiation to the kidney and bladder can result in nephritis and chronic cystitis.

If the child's head area is involved in therapy, permanent alopecia (hair loss), impaired growth of teeth, or reduced salivary gland function (leading to a constantly dry mouth) may result. Radiation to bone marrow may depress the production of both WBCs and platelets. The possibility of these long-term effects of radiation should be explained to parents when radiation is initially discussed, as a part of obtaining informed consent. At the early stage of diagnosis, however, parents rarely are concerned with these long-term effects. Their thoughts are understandably filled with such short-term outcomes as the achievement of a remission or destruction of the tumor.

## Nursing Diagnoses and Related Interventions

Nursing diagnoses related to radiation therapy should include not only the physical preparation or aftercare necessary but also the stress such a procedure places on families.

**Nursing Diagnosis:** Parental and child anxiety related to radiation therapy

**Outcome Evaluation:** Parents state they understand the necessity of the therapy and will help support the child during therapy.

*Before Treatment.* The points where radiation therapy will be directed are usually marked on the child's skin in indelible ink or tattoo. As a rule, parents shouldn't apply any cream or lotion to the marked areas until the treatment series is complete because if a cream contains a metal base, it could distort or interfere with the entrance of radiation. If the head will be irradiated, a dental consultation may be necessary because radiation therapy can slow healing if a tooth extraction is necessary.

*During Treatment.* Most children have previously had X-ray films taken by the time that radiation therapy is begun, so they're already familiar with thinking of the radiation machine as a giant nonthreatening camera. Because the procedure requires them to lie still for a period of time, possibly on an uncomfortable table in a room isolated from personnel or their parents, they may experience extreme fear. Reassure the parents and the child that during the treatment, just as there is no sensation from X-ray exposure, the child will experience no sensation from radiation. Infants and young children are usually sedated or have general anesthesia before therapy to ensure they are able to lie still during the needed time interval. To make this approach effective, if only a sedative will be given, keep the child fairly active early in the day and introduce calming activities after the sedative is administered so the child will be

sleepy and fall asleep during irradiation. An older child may want to plan an activity to think about during irradiation, such as selecting 10 people to take on a camping trip (and why), or choosing 10 places to visit next year—mental activities that require no movement but are still stimulating.

*After Treatment.* Children undergoing radiation therapy need their white blood cell and platelet counts monitored periodically for changes; careful assessment of skin in the radiation field is also crucial. Teaching points for parents to help their children during therapy are summarized in [Box 53.5](#).

## BOX 53.5

### Nursing Care Planning Based on Family Teaching

#### CARING FOR THE CHILD RECEIVING RADIATION THERAPY

**Q.** Gerri's mother asks you, "What sorts of things do we need to do when Gerri begins receiving radiation therapy?"

**A.** In addition to preventing infection, you need to take some special actions to meet your child's needs. Here are some tips designed to promote radiation's therapeutic benefits and minimize its adverse effects.

#### Skin Care

- If the area to be radiated is marked on the child's skin, do not erase the marks.
- Expose irradiated area to air but not to direct heat or sunlight.
- Avoid lengthy soaks in bath water or swimming pools.
- If the head is irradiated, use mild shampoo on hair and rinse gently with water. Air dry or pat excess moisture gently. Avoid rough towels and hair dryers.
- Supply a soft toothbrush to protect gums and oral mucous membranes. Keep the mouth moist by offering frequent sips of water—particularly if radiation decreases salivary gland secretions.
- Encourage clothing that fits loosely over irradiated areas.
- Because some skin preparations are drying and some interfere with radiation, do not apply creams or lotions to the irradiated area unless prescribed.

#### Nutrition

- To promote retention of nutrients, administer antiemetics as prescribed.
- Encourage high-calorie meals when child is least likely to be nauseated. Praise the child's efforts to eat. Strive for peaceful and pleasant meal and snack times.
- Provide foods identified by child as special favorites. Serve easy-to-swallow foods at best liked temperatures.

#### Hydration

- Reduce amounts of fresh fruit and vegetables rich in cellulose and eliminate apple

juice from the child's diet because these may contribute to diarrhea and subsequent fluid loss if the gastrointestinal tract is in the radiation field.

- If diarrhea occurs, administer antidiarrheal medication as prescribed.

### Activity

- Provide adequate rest periods. Schedule activities to avoid waking the child frequently at night.
- Structure the child's activities to be stimulating but not physically tiring.
- Recommend mild activity that does not stress bones that may be weakened by radiation and, therefore, easily fractured (if applicable).

### Instruction and Distraction

- Prepare the child for the effects of radiation therapy, particularly hair loss (if cranial radiation), in case they occur. Some comfort measures may include wearing a wig or special cap; introducing play things, such as dolls without hair; and most important, stressing that people like people for themselves, not for their appearance.
- Schedule a tour of the radiation department. If possible, let the child play-act and become familiar with the equipment. Provide ample time to answer questions.
- Help the child devise "mind games" to play during the procedure such as listing 10 friends to take camping, 10 activities to do, or 10 favorite games to play so the procedure is not boring but a learning experience.

### *What If... 53.1*

**The nurse finds Gerri's mother scrubbing her son's head to remove the purple marks inked there by the radiation department. How should the nurse best respond?**

## CHEMOTHERAPY

A **chemotherapeutic agent** is a drug that is capable of destroying malignant cells. In most instances, several chemotherapeutic agents of differing mechanisms are used to ensure maximal tumor cell death. Like radiation, chemotherapy is scheduled at intervals that increase the ability to destroy malignant cells throughout the cell cycle.

### Types of Chemotherapeutic Agents

Chemotherapeutic agents ([Table 53.2](#)) fall into a number of different categories and may be administered intravenously, orally, or intramuscularly/subcutaneously. Typically, any agent that needs mixing for hospital use is prepared under a specialized hood in the pharmacy to prevent unintentional exposure. When administering such agents, wear gloves and wash your hands well afterward to prevent skin exposure and absorption of the drug. Chemotherapy drugs should be considered hazardous substances

and have special handling procedures (hospital specific protocols should be followed). Caution parents, when administering such drugs at home, to use similar precautions.

**TABLE 53.2 TYPES OF CHEMOTHERAPEUTIC AGENTS**

<b>Chemotherapeutic Agents</b>	<b>Mechanism of Action</b>	<b>Exemplar Drug</b>
Alkylating agents	Cell-cycle specific; effective against cells in the G1 and S phases of growth	Cyclophosphamide (Cytosan)
Antimetabolites	Interrupts the cells metabolic processes; effective in S phase	Methotrexate
Plant alkaloids	Interferes with cell mitosis; effective in M phase	Vincristine
Antitumor antibiotics	Impairs DNA synthesis; not cell cycle-specific, effect in resting and dividing cycles	Doxorubicin (Adriamycin)
Nitrosoureas	Disrupts protein production/DNA synthesis; crosses the blood brain barrier	Lomustine (CCNU)
Corticosteroids	Binds to DNA to inhibit mitosis and probably RNA synthesis	Prednisone
Immunotherapy	Stimulates body's immune system to destroy foreign (malignant) cells	Chimeric antigen receptor T cells (CAR-T)

### **Chemotherapy Protocols**

Chemotherapy is scheduled for children at set times and days and by various predetermined routes. At first, children may remain in the hospital for a few days of treatment; later, they may report on a specific day for therapy, or parents may administer the designated therapy at home. Parents must learn about the child's treatment protocol so that they know which drug the child will be receiving each day and on which day each drug must be administered. Knowing the protocol and the specific drug therapy not only helps with accurate dosing but also helps parents begin to prepare the child for administration of a particular drug, such as increasing fiber in the child's diet for a few days before the beginning of a constipation-causing drug like vincristine.

Caution parents, while children are receiving chemotherapy, not to give them nonsteroidal anti-inflammatory drugs as they may interfere with blood coagulation, a problem that may already be present because of lowered thrombocyte levels. Instead, suggest they use acetaminophen (Tylenol) to relieve a headache or to reduce fever and

ensure they inform their oncology team of fever because infection in a child receiving cancer treatment may be life-threatening and is considered an emergency while immunocompromised. A parent who wants to give a child vitamins should check with their child’s primary healthcare provider to be certain the vitamin preparation will not interfere with a chemotherapeutic agent. Administration of a vitamin that contains folic acid, for example, could interfere with the effectiveness of methotrexate, a folic acid antagonist.

A child receiving chemotherapy is particularly susceptible to contracting an infection and thus should be kept away from people with known infections. Zoster immune globulin may be administered if the child has not been immunized against varicella and is exposed to chickenpox during chemotherapy. Caution parents that live-virus vaccines should not be given during chemotherapy because, if the child’s immune mechanism is deficient, these vaccines could cause widespread viral disease. Non-live vaccines are also not given while receiving chemotherapy since the immune system cannot mount the response necessary to create immunity.

### Side Effects and Toxic Reactions to Chemotherapy

All chemotherapeutic agents have both side effects and toxic effects. [Table 53.3](#) lists commonly used chemotherapeutic agents, their specific side effects, and their potential toxic effects. Malnutrition, nausea and vomiting, hair loss, mucositis (mouth irritation), constipation, diarrhea, cushingoid effects, and susceptibility to infection are side effects common to most of these agents. Some chemotherapy agents are referred to as vesicants and may cause extensive tissue sloughing and damage if infiltrated into the subcutaneous tissue. Therefore, monitor IV infusions of chemotherapeutic vesicants carefully, especially if not administered through a central line, to prevent tissue infiltration. All hospitals should have an extravasation policy that should be reviewed before administration of a vesicant chemotherapy drug.

**TABLE 53.3 COMMONLY USED CHEMOTHERAPEUTIC AGENTS**

Drug	Classification	Side Effects and Toxic Effects	Special Considerations
L-Asparaginase (Elspar)	Enzyme; deprives cancer cells of asparagine, leading to cell death	Anorexia, weight loss, nausea, vomiting, hepatotoxicity, central nervous system toxicity, anaphylactic reaction	Staying with child for first hour of infusion is important; take vital signs every 15 min for first hour to detect anaphylactic reaction.
Cisplatin (Platinol)	Alkylating agent; reacts with and	Bone marrow depression,	Infusion bag must be covered with

	injures cell nucleus	nephrotoxicity (renal dysfunction), nausea, vomiting, loss of taste, tinnitus, high-frequency hearing loss	aluminum foil or commercial cover to keep out light, or decomposition can result.
Cyclophosphamide (Cytosan)	Alkylating agent (nitrogen mustard derivative)	Bone marrow depression, anorexia, nausea, vomiting, mucositis, alopecia, cystitis, (hemorrhagic) hepatotoxicity	Encourage high fluid intake; maintain IV line to limit bladder irritation; test urine for blood and specific gravity.
Cytarabine (Ara-C)	Antimetabolite (pyrimidine analog)	Nausea, vomiting, bone marrow depression, mucositis, alopecia, photosensitivity	Child may need to wear sunglasses in bright light.
Dactinomycin (Cosmegen)	Antibiotic; inhibits DNA synthesis	Nausea, vomiting, bone marrow depression, mucositis	Extreme tissue inflammation occurs if it extravasates into tissue.
Daunorubicin (DaunoXome)	Antibiotic; vesicant	Alopecia, bone marrow depression	Extravasation causes severe tissue damage.
Etoposide (Toposar)	Mitotic inhibitor; inhibits DNA synthesis	Fatigue, alopecia, nausea and vomiting	Slow IV administration is necessary to avoid irritation.
Doxorubicin (Adriamycin)	Antibiotic; inhibits DNA synthesis; vesicant	Nausea, vomiting, bone marrow depression, alopecia, mucositis, possible heart toxicity	Urine may turn red; take pulse for full minute to detect arrhythmia; tissue necrosis occurs if extravasated.
Ifosfamide (Ifex)	Alkylating agent;	Leukopenia, alopecia,	Maintaining hydration

	interferes with DNA synthesis	hemorrhagic cystitis	is important to prevent cystitis.
Lomustine (CCNU; CeeNu)	Alkylating agent (nitrosourea compound)	Nausea, vomiting, bone marrow depression (after 3–4 wk)	Administration on an empty stomach enhances absorption.
Mercaptopurine (Purinethol)	Antimetabolite (purine analog)	Bone marrow depression, nausea, vomiting, mucositis, hepatotoxicity	Allopurinol delays the degradation of mercaptopurine and thus increases toxicity; question prescription if both are to be administered.
Methotrexate (MTX)	Antimetabolite	Mucositis, bone marrow depression, nausea, vomiting, alopecia, hepatotoxicity, nephrotoxicity at high dosage	Decreased effect occurs if administered with salicylates; often followed by leucovorin to decrease toxicity to normal cells
Prednisone	Corticosteroid; suppresses lymphocyte production	Weight gain, cushingoid facies, depressed systemic response to infection	Child may need support to accept changed appearance.
Procarbazine (Matulane)	Antineoplastic; interferes with DNA and RNA synthesis	Nausea, vomiting, bone marrow depression	Drug may cause blurriness of vision; avoid foods with high tyramine content.
Thioguanine	Antimetabolite	Bone marrow suppression	Monitoring of hepatic function tests is necessary.
Vincristine (Oncovin)	Plant alkaloid; vesicant	Constipation, alopecia, joint and muscle pain, muscle weakness	Paresthesia of fingers and toes; foot drop may occur; may need stool softener; tissue necrosis

occurs if infiltrated.

*Additional Agents*

Allopurinol (Lopurin, Zyloprim)	Antigout agent	Nausea, vomiting	Prevents uric acid formation from destroyed cells
Leucovorin (Wellcovorin)	Folic acid derivative		Neutralizes the toxicity of methotrexate.
Interferon	Antiviral agent	Fever	Blocks virus replication
Filgrastim (Neupogen)	Granulocyte colony-stimulating factor	Nausea, vomiting	Leukocyte count increases.
Epoetin alfa (Procrit)	Recombinant human erythropoietin	Hypertension; headache	Red blood cell count increases.

**QSEN Checkpoint Question 53.1**

**EVIDENCE-BASED PRACTICE**

Following discharge from the hospital, parents assume the responsibility of administering chemotherapy at home. To determine whether parents followed adequate protection for themselves while handling chemotherapy drugs, researchers asked 50 parents of children with acute lymphoblastic leukemia to fill in a questionnaire asking about their experience with chemotherapy drugs. Seventy-two percent of parents reported receiving instruction on safe handling of oral chemotherapy. Ninety percent of parents, however, reported they did not use protective gear such as gloves during preparation of oral chemotherapy. Although tablet crushers were designated for use with oral chemotherapy by 61% of parents, 22% used the same device to crush other nonchemotherapy medications. Over 50% of parents disposed of medication waste with regular garbage or poured the remainder down the sink (Held, Ryan, Champion, et al., 2013).

Based on this study, which statement by Gerri’s mother would cause the nurse to believe she needs additional education about safe administration of Gerri’s oral chemotherapy?

- a. “I’ll call for advice if Gerri vomits a pill or refuses to take one.”
- b. “I know his pills’ side effects and will observe for them carefully.”
- c. “I know I have to give the medicine according to a schedule.”
- d. “I know to wash my hands before handling his pills.”

## Nursing Diagnoses and Related Interventions

As with radiation therapy, nursing diagnoses related to chemotherapy need to address both physical and psychosocial aspects of care.

**Nursing Diagnosis:** Imbalanced nutrition, less than body requirements, related to nausea, vomiting, or anorexia resulting from chemotherapy

**Outcome Evaluation:** Child is able to eat frequent, small meals; calorie intake is adequate for age and size; child maintains percentile place on growth curve.

It is easy for a child with cancer to become malnourished as the fast-growing malignant cells take more than their share of nutrients from normal cells. Nausea and vomiting resulting from chemotherapy add to the difficulty of maintaining an adequate oral intake. If stomatitis (intestinal mucosal irritation) or mucositis (mouth irritation) occurs as a result of chemotherapy, eating becomes exceedingly difficult because of mouth pain (Hartnett, 2015).

If the effect of the chemotherapy is extreme, stomach and intestinal ulcers can develop and interfere with absorption. Changes in fatty acid metabolism may alter the responsiveness of body cells to insulin metabolism. Unable to use glucose effectively, cells cannot function at an optimum level, and a chronic feeling of fatigue results. Anorexia may occur from a factor produced by the tumor that acts directly on the center for hunger in the hypothalamus or from nausea produced by chemotherapy. Cyclophosphamide, a commonly used chemotherapeutic agent to treat leukemias or lymphomas, is associated with taste changes. Many children taking this drug report that foods taste bitter or do not describe foods as sweet until they are very sweet. Because of these taste changes, foods the child used to enjoy may no longer be enjoyable. Unwilling to try new foods, the child decreases oral intake.

To counteract these taste changes, you may need to suggest different foods or methods of food preparation or include a dietitian as a health team member. Chicken, for example, may taste less bitter than beef or pork. Sprinkling brown sugar on cereal may offer a sweeter taste than plain sugar. However, do not recommend honey as a sweetener. Botulism organisms can grow in honey, placing the immunosuppressed child at risk for infection. Be certain they continue careful cleaning of their teeth after eating to prevent tooth decay.

Urge parents to be careful that mealtime remains a pleasant time, even if the child isn't eating well. Encourage them to allow the child to make choices whenever possible. Offer small portions because a small meal fully finished is usually more satisfying than a large meal half finished. Being certain snack foods are nutritious (perhaps a malted milkshake rather than a cola beverage) is another way to increase

nutrient intake. Suggest eating larger meals early in the day before chemotherapy begins, when the child is less likely to be nauseated (Fig. 53.2).

**Figure 53.2** Children receiving radiation or chemotherapy often have reduced appetites. Here, a healthcare professional discusses nutrition and food choices with a 15-year-old with leukemia. (Monkey Business Images/shutterstock.com)

**Nursing Diagnosis:** Risk for deficient fluid volume related to nausea and vomiting resulting from chemotherapy

**Outcome Evaluation:** Skin turgor remains good; mucous membranes are moist; vomiting does not occur more than once a day.

Nausea and vomiting are common side effects of almost all chemotherapy agents. Nausea and vomiting may be prevented by administering an antiemetic, such as hydroxyzine (Atarax) or ondansetron (Zofran), before chemotherapy and at 4- to 8-hour intervals during the course of therapy (Box 53.6). These drugs work best in children to prevent nausea; they do not necessarily relieve it once it is present. Thus, begin these medications prophylactically or before chemotherapy begins for best results.

#### BOX 53.6

### Nursing Care Planning Based on Responsibility for Pharmacology

#### ONDANSETRON HYDROCHLORIDE (ZOFRAN)

**Classification:** Ondansetron is an antiemetic agent.

**Action:** Blocks central and peripheral serotonin receptor sites to prevent chemotherapy-induced nausea and vomiting in adults and children older than 3 years of age (Karch, 2013).

**Dosage:** Dependent on weight of child. Typically, 4 mg orally three times daily, first dose administered 30 minutes before beginning chemotherapy, with subsequent doses at 4 and 8 hours after chemotherapy continued every 8 hours for 1 to 2 days after chemotherapy treatment; or three doses of 0.15 mg/kg IV, first dose started 20 minutes before chemotherapy and given over 15 minutes, with subsequent doses at 4 and 8 hours.

**Possible Adverse Effects:** Dizziness, headache, pruritus, myalgia, pain at injection site

### **Nursing Implications**

- Be aware of timing of chemotherapeutic treatment to ensure that first dose is given 20 to 30 minutes before beginning chemotherapy.
- Instruct parents to continue oral form for 1 to 2 days after completion of chemotherapy to maximize effect.
- Advise parents to administer the oral drug every 8 hours around the clock for maximum results.

Intravenous fluids are often necessary to maintain optimal hydration during chemotherapy. Careful I & O's or urine specific gravity monitoring during treatment helps to determine if the child is appropriately hydrated.

**Nursing Diagnosis:** Risk for disturbed body image related to changes in physical appearance caused by chemotherapy

**Outcome Evaluation:** Child discusses feelings about appearance changes with nurse and parents; child states that, although she does not like them, she understands any changes are temporary.

Because chemotherapy causes changes in body appearance, both children and their parents can benefit from a frank discussion of symptoms and their feelings about these changes both before chemotherapy begins and during the therapy.

*Alopecia.* Alopecia, or hair loss, is a side effect that occurs with almost all chemotherapeutic drugs because hair cells are fast-growing and easily killed as they incorporate the drug. Even when forewarned that such a consequence is likely, most children and parents are surprised at the suddenness of the hair loss (clumps of hair may fall out at one time, and a child can become totally bald in 1 to 3 days). If a child feels self-conscious, suggest a wig, scarf, or baseball cap. Introducing a doll without hair and reminding the child that those who love the child love the whole person, not just the packaging, are also helpful (Fig. 53.3).

**Figure 53.3** A nurse uses a doll to help prepare a child for the hair loss that accompanies chemotherapy.

**Cushingoid Appearance.** Children receiving long-term corticosteroid (prednisone) therapy develop a typical “moon face,” red cheeks, and a stocky build. Like the loss of hair, a cushingoid appearance can be devastating to children or parents, the final insult in light of all the other things happening to them. Provide support and reassurance that this appearance is only temporary and will fade after they are no longer on therapy.

**Nursing Diagnosis:** Impaired oral mucous membrane related to effects of chemotherapy

**Outcome Evaluation:** Child states mouth discomfort is at a tolerable level, no signs of ulceration are present, and the child is able to eat and drink normally.

Mucositis (ulcers of the gum line and mucous membranes of the mouth) is another frequent effect of chemotherapy (Bennett, 2016). Because chewing is painful, the child needs soft foods with low acidity prescribed. Brushing, flossing, and fluoride supplements should continue when possible. Brushing teeth with a soft swab rather than a toothbrush may feel more comfortable for some children. If the child has ulcers present, an antibacterial mouthwash may be prescribed (be certain that the child understand the wash should be spit out afterward, not swallowed; demonstrate this to very young children if necessary so you’re certain they understand what “don’t swallow” means).

Another caution is to be aware that mucous membrane ulcers can occur throughout the GI tract. Rectal temperatures should be avoided in children being treated for cancer to avoid further trauma to the tissue and to reduce the risk of infection or bleeding. General measures to reduce mucositis are summarized in [Box 53.7](#).

### BOX 53.7

#### Nursing Care Planning to Empower a Family

## TIPS FOR RELIEVING THE DISCOMFORT OF MUCOSITIS

**Q.** Gerri's father tells you, "Our son has developed ulcers in his mouth from the chemotherapy. What can we do to help him feel more comfortable?"

**A.** Continuing oral care despite discomfort is important to minimize the number of germs in the mouth and ideally prevent infection. Here are some tips for relieving the discomfort:

- Use a soft toothbrush.
- Try to make oral hygiene fun. Make up a game about mouth care such as "Simon Says" (and he says "brush") that the whole family can play.
- Encourage your child to rinse his mouth with lukewarm water about three times a day for comfort and to encourage healing.
- Serve soft foods such as mashed potatoes and pudding rather than hard ones, such as toast crusts or crunchy cereal, to avoid further abrasions to tender gum lines.
- Provide nonacidic foods, such as gelatin instead of orange juice, which can sting if sores are present.
- Encourage your child to drink as much fluid as possible because proper hydration helps to keep lips from cracking.
- Keep lips well lubricated with petroleum jelly or a commercial product. This care also prevents cracking.

**Nursing Diagnosis:** Risk for constipation or diarrhea related to effects of chemotherapeutic agents

**Outcome Evaluation:** Child maintains usual pattern of bowel elimination; child reports (and parent confirms) no existence of hard or loose stools. Some chemotherapeutic agents, particularly vincristine, cause constipation. Record the frequency of bowel movements so that constipation is recognized early in its course. Anticipate the need for increasing the intake of fluids and dietary roughage and prescribing of a stool softener, such as docusate sodium (Colace), to prevent hard stools from exacerbating rectal ulcers. Diarrhea needs to be identified early to prevent dehydration. Care of a child with diarrhea is discussed in [Chapter 45](#).

**Nursing Diagnosis:** Risk for deficient diversional activity related to hospitalization or side effects of treatment

**Outcome Evaluation:** Child identifies activities in which he can participate that are compatible with current health state and environment.

Almost all children receiving chemotherapy experience fatigue and are unable to participate in their usual activities. If they develop neutropenia (reduced number of WBCs), they may require temporary seclusion from other children to prevent

exposure to and subsequent development of infection. Help children who are restricted in these ways to find an activity they enjoy, such as drawing, coloring, or playing handheld electronic games, so they can remain active.

Vincristine, a drug used as therapy for leukemias, results in specific neurologic symptoms of weakness, tingling, and numbing of the extremities and sometimes the inability to walk because of a condition called foot drop. In some children, physical therapy may be needed along with special braces or boots to prevent this. While taking the drug, children may be unable to hold a pen or pencil or maneuver small parts of toys because their fingers are so affected. These symptoms typically subside after the medication is discontinued, but in the meantime, help the child think of games that can be accomplished without fine motor control.

**Nursing Diagnosis:** Risk for infection related to therapy-induced depression of immune system

**Outcome Evaluation:** Child's temperature is no higher than 98.6°F (37.0°C); no areas of erythema or other signs or symptoms of infection are present.

Children with cancer are susceptible to infection, not only because their immune system is depressed by chemotherapy but also because they may develop a degree of malnutrition that decreases the effectiveness of macrophage and phagocytosis functions and possibly lowers the production of interferon, which is important for destroying viral invaders. A malignant process in the body also decreases the body's overall ability to recognize foreign invaders and respond with the usual efficient rejection process. IV insertion sites, disrupted mucous membranes, and ulcer formation throughout the GI tract provide ready sites for invasion of microorganisms.

Administration of a colony-stimulating factor such as filgrastim (Neupogen) can help the body quickly begin replacing damaged WBCs (Mhaskar, Clark, Lyman, et al., 2014). Even with the use of this agent, however, gram-negative bacteria such as *Escherichia coli*, *Pseudomonas aeruginosa*, and *Klebsiella pneumoniae* and gram-positive bacteria such as *Staphylococcus aureus* and streptococci commonly cause infections. Viral infections such as varicella (chickenpox), varicella zoster (shingles), herpes simplex, viral hepatitis, and cytomegalovirus also are common invaders.

*Pneumocystis carinii* pneumonia (PCP, normally a very rare pneumonia) may occur from protozoal invasion. Antibiotic prophylaxis, typically sulfamethoxazole/trimethoprim, is prescribed to prevent PCP during immunosuppression. Treating bacterial infections with antibiotics can cause overgrowth of fungal infections such as candidiasis or aspergillosis.

If infection is discovered in a child with cancer, the causative agent is identified by culture. Specific antibiotics are then prescribed. [Box 53.8](#) identifies interventions to reduce the possibility of infection occurring in a child with a low WBC count (neutropenia).

**PREVENTING INFECTION IN THE CHILD WITH NEUTROPENIA**

**Q.** Gerri’s mother asks you, “What special things should I do to help prevent my child from developing an infection until his white blood cell count returns to normal?”

**A.** Here are some suggestions to help prevent infection:

- Arrange for your child to sleep in a single bed and room, if possible, to avoid close contact with other family members who might have infections.
- Limit the child’s exposure to large crowds, such as those at movie theaters.
- Screen and prohibit visitors who have signs of infection such as runny nose, oral herpes, or rashes; who have been exposed to a communicable disease, such as chickenpox; or who have recently been vaccinated.
- Wash your hands frequently before child care and after handling potentially contaminated items such as tissues or diapers.
- Urge the child to wash hands well after using a bathroom and before eating.
- Keep child’s immediate surroundings free of plants, flowers, and goldfish, all of which could harbor mold spores.
- Be sure the child has a daily bath or shower. Clean mouth with soft toothbrush to reduce opportunity for bacteria, which are always present in the mouth, to invade.
- Inspect mouth daily for breaks in the tissue, bleeding, or white patches that suggest oral thrush (*Candida*) infection. Apply a moisturizing and protective barrier, such as petroleum jelly, to the lips to help prevent them from cracking.
- Take temperature daily or if the child feels warm. Avoid taking rectal temperatures to protect against injuring rectal tissue.
- Inspect all skin surfaces daily for scratches that could become entrances for infection. Include intravenous or intramuscular injection sites, venous access device insertion sites, and the diaper area.
- Administer stool softeners, if prescribed, to promote soft stools and bowel movements and avoid rectal tears.
- Provide high-calorie, high-protein foods and food supplements to promote healing. Avoid raw fruits and vegetables because they have the potential to harbor infectious organisms.
- Assess for respiratory tract infection by listening for cough; inspect throat for redness and nasal passage for discharge.
- Assess for possible genitourinary tract infections. Note the color, clarity, frequency, and concentration of urine. If necessary, obtain a urine specimen using a clean-catch method for testing. Promote increased fluid intake to keep urine flowing. Advise girls to wipe from front to back after voiding or defecating to avoid bringing organisms forward to the urethra. If a girl is menstruating, urge her to change pads or tampons frequently (every 4 hours).

- Avoid the administration of any vaccine until the child's immune system has recovered (exception: flu vaccine).

### *What If... 53.2*

**Gerri's mother tells the nurse that she does not want her child to have an antiemetic drug before chemotherapy because the nausea and vomiting are proof the chemotherapy is working. What action would the nurse take in response to Gerri's mother's perception?**

## STEM CELL TRANSPLANTATION

Transplantation of stem cells from the bone marrow of a well person to a child with cancer has become a frequently used treatment. The procedure allows higher doses of chemotherapy and radiation to be used because, in the event of severe bone marrow depression, the child can have healthy marrow restored. Immune cells in the transplanted marrow may actually help to kill remaining cancer cells in the child's circulation.

If stem cells are donated by someone who is histocompatible (immune compatible) with the child, this is an *allogeneic* transplant. If the child's own cord blood was preserved and frozen since birth or removed prior to chemotherapy, this is an *autologous* transplant. A *syngeneic* transplant is one between twins.

Before transplantation, the child receives a chemotherapy agent, such as cyclophosphamide, or total-body irradiation to kill as many T cells as possible, suppress the child's immune response to the transplanted tissue, and create space in the bone marrow to allow the newly transplanted cells to implant.

Stem cells are removed from the circulating blood of the designated donor or from cord blood. They are then processed and transfused into the child intravenously. The new stem cells enter the bone marrow and begin to function after about 3 weeks. Until this time, a child is at extreme risk for infection. Everyone coming in contact with the child must wash their hands well, and specific infection control precautions must be maintained. Transfusion of blood products may be necessary to maintain functional blood components until the transplanted marrow begins to function (Carson, Stanworth, Roubinian, et al., 2016).

Not all medical centers perform stem cell transplantation, so a family may have to travel a distance for the therapy. Complications of stem cell transplantation are discussed in Chapter 44 because this technique also is used for children with blood dyscrasias.

## PAIN ASSESSMENT

Because growing tumors impinge on normal tissue, pain is a common symptom experienced by children with cancer. Methods to assess pain and interventions to help

children deal with pain are discussed in [Chapter 39](#).

## The Leukemias

Leukemia is the distorted and uncontrolled proliferation of WBCs (leukocytes) and is the most frequently occurring type of cancer in children.

### ACUTE LYMPHOCYTIC (LYMPHOBLASTIC) LEUKEMIA

Acute lymphocytic leukemia (ALL) accounts for 75% of leukemias ([Brown & Hunger, 2013](#)) and involves lymphoblasts (immature lymphocytes). Because of the rapid proliferation of so many immature lymphocytes, the production of red blood cells (RBCs) and platelets declines. The abnormally proliferating cells are so immature that they may be identifiable as an immature “blast cell.”

The highest incidence of ALL is in children between 2 and 6 years of age. The prognosis in children younger than 1 year or older than 10 years at the time of first occurrence is not as good as in those between 2 and 10 years of age. The prognosis in children who have a WBC count higher than 50,000/mm<sup>3</sup> or who have more than 10% L2 cells (see classification of cells described later) in bone marrow at the time of diagnosis is not as good as in those with a lower WBC count and fewer L2 cells at first diagnosis. The incidence of ALL is slightly higher in boys than in girls, and the disease is seen more often in Hispanic and White children than in children of other races ([Vrooman & Silverman, 2016](#)).

Although it can be shown that leukemia in mice and cats is of viral origin, the cause of leukemia in children is unknown. Radiation, exposure to chemicals, or genetic factors may have some influence on the occurrence as children with Down syndrome are more likely to develop leukemia than other children.

### Assessment

With ALL, because the bone marrow overproduces lymphocytes and therefore is unable to continue normal production of other blood components, the first symptoms of ALL in children usually are those associated with decreased RBC production (anemia) such as pallor, low-grade fever, and lethargy. A low thrombocyte (platelet) count will lead to petechiae and bleeding from oral mucous membranes and cause easy bruising on arms and legs. As the spleen and liver begin to enlarge from infiltration of abnormal cells, abdominal pain, vomiting, and anorexia occur. As abnormal lymphocytes invade the bone periosteum, the child experiences bone and joint pain. Central nervous system (CNS) invasion leads to symptoms such as headache or unsteady gait.

On physical assessment, painless, generalized swelling of lymph nodes is revealed. Laboratory studies reveal an elevated leukocyte count with cells almost stopped at the blast cell stage. The platelet count and hematocrit value will be low; RBCs that are present are normocytic and normochromic (of normal size and color) but few in

number. A lumbar puncture may show evidence of blast cells in the cerebrospinal fluid (CSF).

A bone marrow aspiration (performed at the iliac crest) will be prescribed to identify the type of WBC involved, which documents the type of leukemia.

### **QSEN Checkpoint Question 53.2**

#### **INFORMATICS**

The child in the room next to Gerri's is a boy with ALL. Although his parents knew he wasn't well, they had no idea his diagnosis would be leukemia. A review of this boy's electronic health record would most likely note what early signs commonly seen in a child with ALL?

- a. Nodules and an abdominal rash
- b. Headaches and sleepiness
- c. Fatigue and leg bruises
- d. Joint pain and coughing

*Look in [Appendix A](#) for the best answer and rationale.*

### **Therapeutic Management**

Up to 95% of children with ALL will achieve a first remission. If a child experiences a relapse, the chances of long-term survival are reduced and bone marrow transplantation may be required to achieve long-term survival.

#### **Disease Classification and Prognosis**

Leukemia is classified to define subgroups of cells and to predict the response to treatment. Blasts with B-lymphocyte cell characteristics can be recognized by the presence of immunoglobulin and antigen–antibody receptors on their surfaces. B-lymphocyte cell types account for about 85% of instances of ALL; the other 15% of children have T-lymphocyte cell involvement ([Hunger & Mullighan, 2015](#)).

#### **Cure as Goal**

The goal of therapy for leukemia is complete cure, typically achieved with chemotherapeutic agents and without radiation. Prognostic factors of the disease and presentation will be discussed with the family at diagnosis. Adherence to therapy increases the chance of cure and should be stressed when discussing home-administered chemotherapy.

A chemotherapy program is aimed at, first, achieving a complete remission or absence of leukemia cells (induction phase); second, preventing leukemia cells from invading or growing in the CNS (sanctuary or consolidation phase); third, administering delayed intensive therapy; and fourth, maintaining the original remission (maintenance phase).

Chemotherapy in children is often administered by means of a central venous catheter or port because administration of drugs into a major vessel helps prevent irritation to the vessel walls. Central catheters are usually in place for the duration of treatment and parents may have maintenance responsibilities while the child is at home; for example, flushing with heparin or changing dressings for external lines. Portacaths are inserted below the skin and accessed with a needle when needed. They do not require home maintenance and allow for the greatest freedom between treatments.

The drug regimen frequently used to initiate a remission includes vincristine, prednisone or dexamethasone, L-asparaginase, and doxorubicin given over a period of 4 weeks. Because so many cells are destroyed by chemotherapy. During rapid cell destruction, a high level of uric acid must be excreted by the kidneys during treatment. To prevent kidney damage the child will be kept well hydrated or a drug such as allopurinol will be initiated to help reduce the formation of uric acid.

Although a chemotherapy protocol will achieve disease remission in 95% of children, because many chemotherapy drugs do not cross the blood–brain barrier in effective concentrations, leukemic cells in the CNS can continue to flourish. Intrathecal administration (injection of methotrexate into the CSF by lumbar puncture) is instituted to eradicate this source of leukemic cells. Cranial radiation, once used extensively for this purpose, is rarely used today due to the learning disorders that may result.

The third phase of therapy (intensification phase) strengthens the assault against leukemic cells again using chemotherapeutic agents such as vincristine, prednisone, L-asparaginase, doxorubicin, and methotrexate. A drug such as leucovorin (often called leucovorin rescue) may be administered after systemic methotrexate to neutralize its action and protect normal cells from the effect of the drug (Box 53.9).

### BOX 53.9

#### Nursing Care Planning Tips for Effective Communication

Gerri, 6 years old, was diagnosed with a brain tumor 3 months ago. His mother brings him into the emergency room because of a severe nosebleed. While you are putting pressure on his nose, you notice his eyes seem to have poor alignment.

*Tip:* When talking with parents, determine whether they are using any alternative therapies. Patients and families may seek out alternative therapies during cancer treatment. Some of them do no harm, so parents can continue to give them along with proven therapies. Others actually interfere with the action of a chemotherapy drug and are contraindicated.

In the scenario below, the parent has chosen an unproven regimen that closely resembles L-asparaginase. The nurse prioritizes current patient care but acknowledges the information given with a plan to follow up with patient education. Ignoring the possibility that this choice may be an unhelpful one (L-asparaginase does not come from asparagus) and denying the potential discovery of the recurrence of cancer would not be therapeutic and could be detrimental in the long term.

**Nurse:** Is Gerri still receiving chemotherapy, Mrs. Miller?

**Mrs. Miller:** No. He's in remission.

**Nurse:** Is he taking anything that would lower his platelet count or clotting factors?

**Mrs. Miller:** He takes asparagus powder we get from Mexico.

**Nurse:** Asparagus powder?

**Mrs. Miller:** It's the same as L-asparaginase. And so much cheaper.

**Nurse:** Let's get this nosebleed stopped. Then, we can take a minute to talk about what chemotherapy means.

## Maintenance and Monitoring

Maintenance chemotherapy aims to eliminate completely any remaining leukemic cells. Standard maintenance therapy includes a combination of daily mercaptopurine, weekly methotrexate, sporadic vincristine and prednisone, and intrathecal methotrexate and may be continued for 2 to 3 years. During the maintenance phase, the child's blood values must be monitored and are usually in a safe range, allowing the child to return to most of their pretreatment activities, including school and social activities. If there is serious bone marrow depression, medication levels may be reduced.

## Complications

Throughout therapy, the healthcare team and family need to be alert for complications of leukemia or of the therapy. Among the problems seen long term are CNS, renal, and reproductive system disorders.

## Central Nervous System Involvement

If CNS involvement occurs, it can cause significant complications. Blindness, hydrocephalus, and recurrent seizures are possible, although the meninges and the sixth and seventh cranial nerves are the structures most often affected. With meningeal involvement, the child develops nuchal rigidity, headache, irritability, and perhaps vomiting and papilledema. A lumbar puncture will reveal the presence of blast cells in the CSF. If these are discovered, the child will be treated with radiation in conjunction with intrathecal injections of chemotherapy. Always check that a child is not prescribed oral and IV methotrexate at the same time because some of the dose of intrathecal methotrexate will be absorbed systemically and could lead to a toxic reaction. Insertion of silicon tubing into a cerebral ventricle and threading it under the scalp (an Ommaya reservoir) is sometimes employed and provides easy access to the CSF for sampling or injection without the need for repeated lumbar punctures (Fig. 53.4).

**Figure 53.4** An Ommaya reservoir. Medication injected into the reservoir flows down to the ventricle and enters the cerebrospinal fluid.

### Renal Involvement

Kidney involvement, resulting from invasion of leukemia cells or obstruction of renal tubules with uric acid crystals, is another serious complication. The kidneys enlarge, and their function will be impaired. The development of renal involvement or impairment may limit the use of chemotherapeutic agents because the metabolites of these can no longer be excreted effectively.

### Testicular Invasion

Males are at risk for testicular invasion with leukemic cells which may not be destroyed with chemotherapy. Careful physical exam of the testes is necessary throughout and after treatment to identify signs of testicular involvement. If the testes are found to have leukemic invasion, local radiation is necessary for effective treatment. If a boy is past puberty and is producing sperm, sperm banking may be suggested before chemotherapy and radiation to preserve sperm for reproduction later in life (Babayev, Arslan, Kogan, et al., 2013).

## Nursing Diagnoses and Related Interventions

Nursing care for a child with leukemia centers on administering chemotherapy, providing supportive care for prevention and treatment of side effects, and helping the young child and parents adjust to the illness.

**Nursing Diagnosis:** Risk for infection related to immunosuppressive effects of therapy

**Outcome Evaluation:** Child's temperature remains lower than 98.6°F (37.0°C); no

areas of erythema or drainage are present.

Because the number of functioning WBCs is reduced and the drugs used for treatment are immunosuppressive, children with leukemia are at high risk for infection during chemotherapy. Infection in immunosuppressed children may be life-threatening and is a significant cause of mortality in this population.

While children are receiving care at home, teach parents to observe them carefully and to promptly report any indication of infection such as low-grade fever or behavior that does not seem typical of the child because the sooner the symptoms are reported, the sooner anti-infective therapy can begin.

Some children may be prescribed prophylactic antibiotics to reduce the possibility of infection. Parents may be advised to limit visitors, especially anyone with an infection, until the child's functioning WBC count improves.

**Nursing Diagnosis:** Risk for bleeding due to diminished platelet production

**Outcome Evaluation:** No evidence of hemorrhage is present (no epistaxis, hematuria, or hematemesis); pulse rate and blood pressure remain within parameters for age group.

Because platelet production is limited, children with leukemia are also prone to hemorrhage. Epistaxis (nosebleed) is the most common kind of bleeding; GI, renal, or CNS bleeding also may occur.

Digital pressure against the nose is usually effective to stop epistaxis, although the application of Gelfoam soaked in topical thrombin may be necessary. In some children, postnasal packing will be necessary, and the child will be transfused with packed RBCs to replace the lost blood volume. Platelet transfusion may be prescribed to improve the platelet count. Because the life span of transfused platelets is short (1 to 3 days), platelets may be infused frequently.

After an intramuscular (IM) injection or the removal of an IV needle, always apply firm pressure to the injection site to prevent bleeding from these sites. Because children with leukemia have blood samples drawn frequently, receive transfusions, and have IV chemotherapeutic drugs administered, provide opportunities for them for therapeutic play with empty, clean syringes or IV tubing so they can work through some feelings about these intrusive procedures (Jibb, Nathan, Stevens, et al., 2015). Advocate for intermittent infusion devices such as heparin locks or multilumen central venous catheters to minimize the need for repeated venipunctures.

**Nursing Diagnosis:** Pain related to invasion of leukocytes and replacement of marrow with leukemic cells

**Outcome Evaluation:** Child rates pain as not above 2 on a pain rating scale (if infant, child is not crying).

Children with acute leukemia experience pain because of the vast number of WBCs that invade the periosteum of the bones. Always assess pain using a validated scale

for accuracy. Handle legs and arms gently to minimize pain on movement. Use an alternating mattress or sheepskin underneath body joints to help reduce skin irritation caused by resting in a constant position. Administer analgesia as needed.

**Nursing Diagnosis:** Ineffective health maintenance related to long-term therapy for leukemia

**Outcome Evaluation:** Parents and child state importance of regular health maintenance visits; child continues chemotherapy regimen at home and keeps all ambulatory appointments.

During the maintenance phase of therapy, children can participate in usual activities and should attend regular school. Because chickenpox is serious to a child who is immunosuppressed, parents should ask the child's school to notify them if any other child in the school develops this disease so appropriate intervention can be administered. If the child has not received immunization against varicella (chickenpox) before this, varicella immune globulin will need to be administered if exposure does occur.

Evaluation of children at follow-up visits includes not only the state of their blood counts but also whether they are making forward-thinking plans or beginning to think of themselves as well children again. Parents may continue to need a great deal of support during the maintenance phase of therapy as they live from day to day, hoping the remission period will not end (Davies, Young, & Salmon, 2016).

## ACUTE MYELOID LEUKEMIA

Acute myeloid leukemia (AML) involves the overproliferation of granulocytes (neutrophils, basophils, and eosinophils). It is most often seen in adults and accounts for only about 20% of all childhood leukemias. The frequency of the disorder increases in late adolescence (Madhusoodhan, Carroll, & Bhatla, 2016).

With AML, granulocytes grow so rapidly that they are forced out into the bloodstream while still in the blast stage; these immature cells are not able to carry out normal immune functions and put the child at risk for infection. As with ALL, the overproliferation of granulocytes limits the production of RBCs and platelets.

### Assessment

Children with AML have the same symptoms as those with ALL. Comprehensive history and physical examination focused on local or systemic infections is warranted.

### Therapeutic Management

The diagnosis is established by bone marrow aspiration and biopsy. After diagnosis, chemotherapy to effect remission begins. Cytarabine (Ara-C), etoposide (VePesid), and daunorubicin (DaunoXome) make up the drug regimen commonly used for therapy. It

may take 1 to 2 months to reach a full remission. Bone marrow transplantation may be attempted after the initial remission to ensure a sustained remission (Taga, Tomizawa, Takahashi, et al., 2016).

## The Lymphomas

**Lymphomas** are malignancies of the lymph or reticuloendothelial system; they account for about 11% of all malignancies and are categorized broadly as Hodgkin or non-Hodgkin lymphomas. Non-Hodgkin lymphomas are more common worldwide in children (about 60% vs 40% Hodgkin). Both types occur more frequently in males than in females (Armitage, Gascoyne, Lunning, et al., 2017).

### HODGKIN DISEASE

With Hodgkin disease, lymphocytes proliferate in the lymph glands, and special *Reed-Sternberg cells* (large, multinucleated cells that are probably nonfunctioning monocyte-macrophage cells) develop. Although these lymphocytes are capable of DNA synthesis and mitotic division, they are abnormal because they lack both B- and T-lymphocyte surface markers and cannot produce immunoglobulins as do usual B-lymphocytes (Diefenbach, Connors, Friedberg, et al., 2017).

As with all neoplastic diseases, the etiology of Hodgkin disease is unknown, but both genetic and environmental factors probably play a part. It is rarely seen in children younger than 7 years of age, with the incidence increasing greatly during adolescence and young adulthood. Metastasis is through lymphatic channels. Untreated, late in the disease process, it spreads to lung, liver, and bone marrow.

### Assessment

Symptoms of Hodgkin disease usually begin with the enlargement of only one painless, enlarged, rubbery lymph node. Other nodes then become involved and potentially spread to the liver, spleen, and bone marrow. The child may report accompanying symptoms of anorexia, malaise, night sweats, and loss of weight. Fever may be present. The sedimentation rate is elevated as well as other markers of inflammation.

Hodgkin disease is confirmed by biopsy of the lymph nodes. Further studies (bone marrow analysis, liver function tests, chest and abdominal computed tomography [CT] or MRI scans, lymphangiography, and abdominal biopsy) are done to classify the clinical stage of the disorder. The chest CT scan may reveal enlarged mediastinal nodes; the abdominal CT may reveal enlarged lymph nodes of the abdomen.

Positron emission tomography–computed tomography (PET-CT) is typically used to stage and monitor response to Hodgkin disease treatment. The PET-CT is a nuclear medicine scan that uses a radionuclide injected into the body which is taken up by metabolically active tissue. Because cancer cells are very metabolically active, the uptake of the trace is an accurate way to identify sites and size of disease. Children

diagnosed with Hodgkin disease will have intermittent PET-CTs to gauge the response to treatment and determine the amount of therapy needed (P. Johnson, Federico, Kirkwood, et al., 2016). Preparation for the scan will include a period of fasting (usually 6 to 8 hours).

## Therapeutic Management

Although the main subcategories of Hodgkin disease are lymphocyte predominant and nodular sclerosing, mixed cellularity and lymphocyte depletion also occur. The disease is staged according to regional involvement revealed by a PET-CT scan or MRI, followed by lymph node and bone marrow biopsies.

Treatment depends on the clinical stage of the disease at the time of diagnosis. Although Hodgkin disease once was treated mainly with radiation therapy, today the standard of care is combination chemotherapy using the agents cyclophosphamide, vincristine, procarbazine, and prednisone; with radiation reserved for those who have a limited response to chemotherapy or those with recurrent/progressive disease. Current therapy results in a 98% 5-year survival rate for children, and up to 50% for those with relapsed or refractory disease. If a relapse occurs, additional chemotherapy, radiation, or bone marrow transplantation will be scheduled (Kelly, 2015).

## Nursing Diagnoses and Related Interventions

The nursing diagnoses often used with Hodgkin disease address the child's impaired immune defenses and risk for infection, fear and feelings about the diagnosis, or changed body image (particularly in an adolescent). Both the parents and the child need opportunities to express their feelings about the seriousness of this disease and how this has changed their life.

**Nursing Diagnosis:** Risk for powerlessness related to fear of disease recurrence

**Outcome Evaluation:** Child states he feels healthy during remission; participates in school and extracurricular activities; voices confidence in healthcare team to treat symptoms if they recur.

For adolescents (in whom the disease is most prevalent), some live from day to day wondering whether symptoms will recur. Encourage adolescents to attend regular school after remission, so that they can lead a normal life. Both adolescents and their parents need continued support from healthcare personnel during the long course of therapy because they worry symptoms could return (Morgan & Soanes, 2016).

### QSEN Checkpoint Question 53.3

#### PATIENT-CENTERED CARE

Gerri's father is a Hodgkin lymphoma survivor, having experienced the active disease as an adolescent. Because of his disturbing memories of having this disease, he is highly anxious that the care team assess Gerri for Hodgkin lymphoma. What is the most likely first sign that Hodgkin lymphoma is beginning to develop in Gerri?

- a. A single, enlarged submaxillary lymph node
- b. Sharp pain in joints from blocked lymph drainage
- c. Easy bruising from a shortage of platelets and RBCs
- d. Discolored fingernails from clotting in distal extremities

---

*Look in [Appendix A](#) for the best answer and rationale.*

---

## NON-HODGKIN LYMPHOMA

Non-Hodgkin lymphomas are malignant disorders of the lymphocytes (either B or T cells) and occur in a number of forms. Unlike Hodgkin disease, spread from the original site is through the bloodstream rather than directly by lymph flow, making the course of the disease unpredictable. Metastatic spread to CNS may occur early in the disease, with the common age of occurrence at 5 to 15 years.

The cause of non-Hodgkin lymphomas is undocumented, but viruses such as EBV, which causes mononucleosis; *Helicobacter pylori*, which causes stomach ulcers; and HIV have all been linked to the occurrence of lymphomas. That is not to say that the viruses cause the lymphoma, only that the viruses were recently present or are present at the same time the lymphoma develops ([Rochford & Moorman, 2015](#)). Lymphomas also occur with increased frequency in children who are receiving long-term immunosuppressive therapy, such as those who received organ transplantation ([Morscio & Toussey, 2016](#)).

### Assessment

Non-Hodgkin lymphomas tend to involve the lymph glands of the neck and chest most commonly, although axillary, abdominal, or inguinal nodes may be the first involved. If mediastinal lymph glands are swollen, the child may notice a cough or chest "tightness." Because mediastinal nodes press on the veins returning blood from the head, edema of the face may result. Diffuse, undifferentiated types manifest most commonly with an abdominal mass. Children notice abdominal pain; they may have diarrhea or constipation, and a mass may be palpable on examination.

To establish the diagnosis, biopsy of the affected lymph nodes and bone marrow is performed. Both are needed because it is often difficult to distinguish between undifferentiated lymphoma cells and ALL; if a bone marrow biopsy shows more than 25% blasts, the diagnosis is acute leukemia; fewer than this is suggestive of lymphoma. Areas of metastases are identified by X-ray, PET-CT, or CT scan.

### Therapeutic Management

Non-Hodgkin lymphomas are treated with systemic chemotherapy, similar to that used

for ALL. The initial phase of therapy is an induction phase (a time during which the child is put into remission or no tumor can be detected by clinical examination); this is followed by a maintenance phase of up to 2 years. The common drug regimen used is cyclophosphamide, doxorubicin (Adriamycin), vincristine (Oncovin), and prednisone (CHOP therapy). Intrathecal chemotherapy may be included because of the tendency for non-Hodgkin lymphoma to invade the CNS. Because the breakdown of cells is so rapid with chemotherapy, frequent blood analysis for electrolyte imbalances will be necessary. Anticipate that allopurinol may be added to the therapy to prevent uric acid accumulation and blocking of kidney tubules.

### **Burkitt Lymphoma**

Burkitt lymphoma (a non-Hodgkin lymphoma involving B-lymphocyte cells) is a rarer form of lymphoma in the United States; it is seen much more commonly worldwide. Children 2 to 14 years of age have the highest incidence, with a peak at 7 years. The same associations as in non-Hodgkin lymphoma exist regarding infection with *H. pylori*, HIV, or EBV.

The first indicators of disease are enlarged lymph nodes of the neck or abdomen. They are typically painless unless they have grown to a large size and are impinging on surrounding tissues. The abnormal cells may grow so rapidly that the cell mass may double in size in as few as 24 hours, so early diagnosis and treatment are important. Surgery may be used to remove the primary tumor or for diagnostic evaluation only. This is followed by administration of the same chemotherapy regimen used with other non-Hodgkin lymphomas. To prevent CNS involvement, intrathecal methotrexate may be given (Cortelazzo, Ferreri, Hoelzer, et al., 2017).

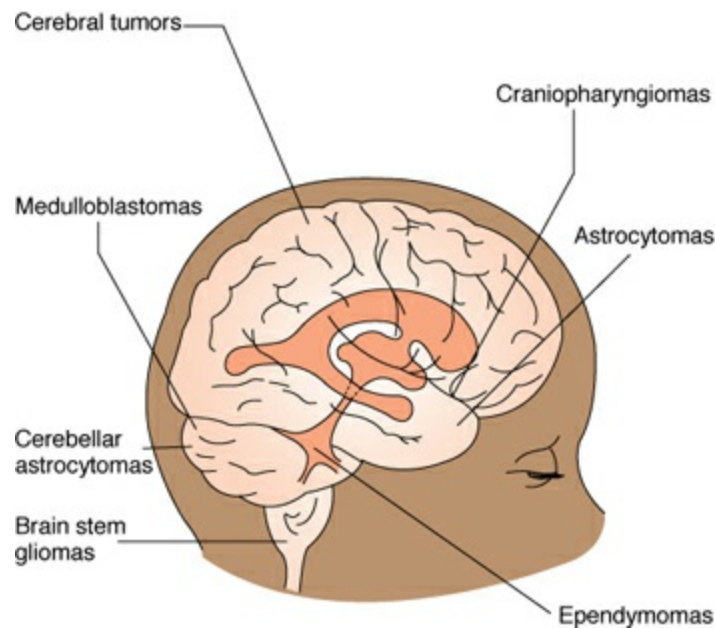

Because Burkitt lymphoma can be such a rapidly growing tumor, the condition responds dramatically to chemotherapy (the cells are almost always in a susceptible state). As with other lymphomas, tissue breakdown may be so voluminous that the uric acid level may cause renal tubule obstruction unless the child is kept well hydrated and a drug such as allopurinol is administered concurrently.

## **Neoplasms of the Brain**

Brain tumors are the second most common form of cancer and the most common solid tumor in children. Tumors tend to occur between 1 and 10 years of age, with 5 years being the peak age of incidence. In children, brain tumors tend to occur at the midline in the brainstem or cerebellum and be located beneath the tentorial membrane, a contrast to the usual site in adults, which is lateral and above the tentorial membrane. This feature is what makes brain tumors particularly difficult to remove in children without damage to normal brain tissue (Segal & Karajannis, 2016).

### **TYPES OF BRAIN TUMORS**

Common sites for brain tumors in children are shown in [Figure 53.5](#). The most common brain tumors are cerebellar astrocytomas, medulloblastomas, and brainstem gliomas.

**Figure 53.5** Common sites for brain tumors in children.

Astrocytomas are slow-growing, cystic tumors that arise from the glial or support tissue surrounding neural cells. They account for about one fourth of all brain tumors in children. The peak age of incidence is 5 to 8 years.

Medulloblastomas are fast-growing tumors found most commonly in the cerebellum. The peak age of incidence is 5 to 10 years. Usually found at the midline, they cause fourth-ventricle compression and disturbances in the flow of CSF. Brainstem gliomas often cause paralysis of the 5th, 6th, 7th, 9th, and 10th cranial nerves. They may produce symptoms of ataxia, nystagmus, and changes in respiratory and pulse findings because of pressure on these centers.

## ASSESSMENT

Children with any form of brain tumor develop symptoms of increased intracranial pressure: headache, vision changes, vomiting, an enlarging head circumference, or papilledema. Lethargy, projectile vomiting, and coma are late signs.

The headache associated with brain tumor usually occurs on arising in the morning. It may be intermittent throughout the day because of pressure changes related to position and the ability of the cranium to expand to some degree and temporarily relieve the associated pressure. It becomes intense on straining, such as occurs with coughing or bowel movements. A parent may report these symptoms as an increasingly irritable young child who is constipated because of reluctance to strain to pass stool. With some tumors, the pain is occipital. This is an important finding because this is an unusual location for a headache from any other cause.

Vomiting, like headache, most commonly occurs on arising. Unlike the child who

vomits because of GI distress, the child with a brain tumor is not usually nauseated and will eat immediately afterward. Vomiting may eventually become projectile; projectile vomiting, however, is not an initial symptom. Vomiting early in the morning is easily discounted by parents as school phobia (reluctance to attend school) because the child is able to eat again immediately and seems to recover about half an hour after getting out of bed (at the same time the school bus leaves).

Diplopia or ptosis because of cranial nerve involvement or strabismus because of suppression of vision in one eye may begin to be noticeable as the tumor continues to grow. Children may tilt their head to the side or develop a torticollis (wry neck) to compensate for the suppression and strabismus. Papilledema (swelling of the optic nerve) may be evident on fundoscopic examination.

Apart from these generalized symptoms of increased intracranial pressure, a growing tumor produces specific localized signs, such as nystagmus (constant horizontal movement of the eye) or visual field defects. As tumor growth continues, symptoms of ataxia, personality change (e.g., emotional lability, irritability), and seizures may occur.

Weeks to months may pass from the time of initial symptoms until symptoms become localized enough to arouse suspicion of a brain tumor. When this suspicion arises, a child needs a thorough neurologic examination; a bone scan, ultrasound or MRI, cerebral angiography, or a CT scan will be performed as needed. Myelography may be done to identify tumors that could have spread into the spinal column. Lumbar puncture must be done cautiously because the release of CSF can cause the brainstem (under pressure from the tumor) to herniate into the spinal cord, interfering with respiratory and cardiac function.

## **THERAPEUTIC MANAGEMENT**

Therapy for brain tumors includes a combination of surgery, radiation, and chemotherapy, depending on the location and extent of the tumor (Segal & Karajannis, 2016). Because they are located so deeply, many tumors cannot be completely surgically removed, making radiation and chemotherapy increasingly important. Radiation therapy is carefully staged because, if tumor tissue is not rapidly proliferating, cells are not easily destroyed. Chemotherapy is also limited because many chemotherapeutic agents do not readily cross the blood–brain barrier. Typical drugs used are carboplatin or a combination of thioguanine, procarbazine, lomustine, and vincristine. Administration of drugs directly into the ventricular system via a reservoir (Ommaya) may increase drug effectiveness.

The diagnosis of brain tumor at any age is always serious and stressful for parents. Closely observe a child who is admitted to the hospital for a possible diagnosis of brain tumor to detect signs of increased intracranial pressure or new localizing signs as they occur. Record pulse rate, blood pressure, and respiratory rate with extreme accuracy, so that subtle changes are apparent. Note and document episodes of irritability, drowsiness, speech difficulty, and eye involvement. Statements such as “Child says he sees two

forks when I show him one” or “Child is unable to see objects held out on her left side” are much more meaningful to a neurologic exam than “Child has difficulty seeing.” Completely describe any seizure activity observed as well, particularly the beginning movements of the seizure, because these can help localize the point of maximum brain pressure. Be certain side rails are in place for protection in case a seizure should occur while the child is in bed.

### **Preoperative Care**

Before brain surgery, a child will usually receive a stool softener to prevent straining with bowel movements. Dexamethasone (Decadron) may be prescribed to reduce cranial edema. An anticonvulsant will be prescribed if the child is experiencing seizures or if surgery is apt to induce seizures. Before surgery, a portion of the child’s head is shaved. Prepare the child for this by emphasizing that this is necessary and hair grows back very rapidly. If the child will be cared for in an intensive care unit (ICU) for the first few days after surgery, include a preoperative visit to meet the ICU staff if at all possible.

### **Postoperative Care**

Following cranial surgery, position the child as prescribed by the surgical team, as the best position for the child depends on the location of the tumor and the extent of surgery. In general, a child is positioned on the side opposite the surgical incision. Keep the bed flat or only slightly elevated, again, as prescribed, because this helps to reduce intracranial pressure from accumulation of fluid in the surgical area. Note carefully how much movement of the child’s neck is allowed. If surgery was in the low occipital area, the surgeon may want the child to be moved as though the head and neck were a single body part. A neck brace or cast may be applied to stabilize the head and neck and prevent movement.

You can expect the child to be heavily sedated or extremely lethargic for several days after surgery because of brain irritation and edema. In addition, a child may require mechanical ventilation because of pressure on the respiratory center. Many children have such extreme facial edema that they cannot close their eyelids completely or their nasal breathing space is impaired. Cool compresses over the eyes may help to reduce edema. Saline eye drops or eye dressings (with the eyes carefully closed under the dressings) may be prescribed to keep the cornea from drying and ulcerating.

Carefully assess the pulse and respiratory rates, pupillary size and ability to react to light, muscle strength (ask children to squeeze your hands), and level of consciousness (ask their name or give a simple instruction to follow) about every 15 minutes until vital signs are stable and there is no apparent increase in intracranial pressure. A child’s temperature may be either elevated or decreased immediately postoperatively because of the effect of the edema on the hypothalamus. Measures to reduce hyperthermia (sponging, antipyretics given by gavage or rectal administration because of lethargy or

coma, or a hypothermia blanket) may be necessary to reduce the temperature to less than 101°F (38.4°C).

Be certain to regulate the rate of IV fluid infusions carefully because an increase in the infusion rate has the potential to increase intracranial pressure. Children with increased pressure may have infusions of mannitol or hypertonic dextrose prescribed to aid in evacuating the cerebral hemispheres of edematous fluid. As the child regains consciousness, small amounts of oral fluid can be introduced. Make certain, when introducing fluid, the child is free of nausea from the anesthetic, to help prevent vomiting because this increases intracranial pressure.

Observe head dressings carefully for any drainage. A wet dressing is no longer a sterile dressing because pathologic organisms can filter through its folds to reach the meninges and cause meningitis. Place a sterile towel, therefore, under a wet dressing or reinforce the dressing with sterile compresses. Report signs of drainage and estimate the extent of the seepage so that you can tell later whether seepage has increased or stopped.

Children regaining consciousness after brain surgery usually are confused regarding time and place; they may have difficulty performing simple tasks they could do easily before. As the cerebral edema subsides and they begin to regain consciousness, they may need a parent to stay with them or to be restrained to stop them from touching their head dressing or IV line. Use as few restraints as possible, however, because fighting restraints is yet another way to cause intracranial pressure to increase. Help the child gradually regain independence in self-care.

When the child is ready for discharge from the hospital, talk to parents about encouraging their child to begin as near-normal activities as possible. Some children may need to wear a helmet to protect their head if a section of skull was removed or is not yet firmly closed. When the bulky head dressing is removed, the child may become aware of baldness for the first time. Some children need support to return to school because they are aware that other children will treat them differently now, having heard from their parents that they are dying or “had to have their head fixed.” Urge parents to make the school administration aware of what has happened to the child. School nurses are allies in helping the child readjust to school after a long absence (see [Box 53.10](#) for an interprofessional care map for a child who is receiving chemotherapy after surgery for a brain tumor).

#### BOX 53.10

#### Nursing Care Planning

### AN INTERPROFESSIONAL CARE MAP FOR A CHILD RECEIVING CHEMOTHERAPY

Gerri, 6 years old, has had surgery to remove a brain tumor. He is now on ambulatory care receiving additional chemotherapy postoperatively. His father states, “He refuses to take his antinausea medicine, so he’s vomiting all the time. He says he’s never going back to school because he looks so funny. This cure is worse than the disease.”

**Family Assessment:** Child lives with parents and two sisters (ages 2 and 12 years) in four-bedroom first-floor home. Father is manager of a local computer store. Mother used to work as a manicurist but is stay-at-home mom since Gerri was diagnosed with cancer. Father rates finances as, “Okay. If nothing unexpected happens.”

**Client Assessment:** Sad and pale-appearing school-age child with bald head and recent surgical scar. Weight decreased 5 lb in last 2 weeks. Skin turgor sluggish. Oral mucous membranes red and irritated. Two ulcers noted on inner aspect of left cheek at gum line. Child states, “I look like an old man.”

**Nursing Diagnosis:** Disturbed body image related to hair loss and nausea secondary to the effects of chemotherapy

**Outcome Criteria:** Child states effect of hair loss on appearance and feelings; verbalizes measures to cope with hair loss; child discusses reasons for not taking anti-emetic and develops strategy for coping with nausea; reports continued participation in age-appropriate activities.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
-------------------------	------------	--------------	-----------	------------------

*Activities of Daily Living, Including Safety*

Nurse	Assess whether child is capable of self-care in light of changes that have occurred with chemotherapy.	Encourage child to perform as many self-care activities as he did before becoming ill.	Maintaining self-care activities is a way of maintaining self-esteem and competence.	Child states that although he doesn't feel well, he will try to do self-care.
-------	--	--	--	---

*Teamwork and Collaboration*

Nurse/oncology nurse specialist	Assess whether oncology nurse specialist is available for consult with parents and child.	Contact oncology nurse, if desired, to review problems with nutrition, self-image, and mouth care during chemotherapy.	An expert can help parents to determine more effective strategies to combat and accept the nausea and appearance caused by chemotherapy.	Oncology nurse specialist arranges a home visit to review child's situation and suggest improvements in quality of life.
---------------------------------	---	--	--	--

*Procedures/Medications for Quality Improvement*

Nurse	Assess oral mucous membrane to document oral lesions.	Review importance of oral care with parents. Advise using a soft toothbrush or swabs to cleanse teeth.	Good oral care is essential to prevent further ulceration.	Child is able to maintain nutrition despite oral lesions; cooperates with toothbrushing three times daily.
-------	---	--	--	--

*Nutrition*

Nurse/primary care provider	Assess whether child is taking prescribed antiemetic and has had any relief at all.	Review with parents importance of giving antiemetic 30 minutes before chemotherapy and every 8 hours.	Antiemetics administered before chemotherapy help to prevent nausea and vomiting.	Child states he will take antiemetic as prescribed to give it a “fair chance” to work.
Nurse/nutritionist	Assess child’s intake by a 24-hour recall history.	Encourage parent to offer food early in the day before chemotherapy. Suggest frequent, high-calorie snacks, such as high-energy snack bars.	Eating before chemotherapy enhances nutrition because the child is less likely to be nauseated at this time.	Parent states she will try to have child eat highly nutritious snacks during times he is not nauseated to optimize nutrition intake.

*Patient-Centered Care*

Nurse	Assess parents’ and child’s understanding of the action of	Teach parents about the type of medications child is receiving and their usual	Understanding that side effects are expected, not unique, can help parents and child accept the	Parents/child state they understand what changes to expect and they
-------	--	--	---	---

	chemotherapy.	actions and side effects.	appearance changes that occur.	understand these are temporary.
<i>Psychosocial/Spiritual/Emotional Needs</i>				
Nurse	Assess whether child can devise any measures that would make him feel better about his changed appearance.	Brainstorm with child and parents about measures such as wearing a scarf or cap or modeling an action figure.	Fostering a positive outlook can help child accept changed appearance as a mark he is managing a stressful time of life very well.	Child states he will try to view hair loss as a positive feature, not a detrimental one.
<i>Informatics for Seamless Healthcare Planning</i>				
Nurse	Assess whether parents or child have any further questions before leaving clinic and have appointment for return visit.	Urge parent to contact clinic if child develops further ulcerations or experiences continued weight loss or an increase in nausea and vomiting.	Continued nausea and vomiting, weight loss, or development of more ulcers requires further evaluation and follow-up to minimize the risk of additional concerns for the child.	Parents and child state they feel confident in managing nutrition adequately during remainder of chemotherapy and will keep return appointment.

A number of late effects may occur in children who survive a malignant brain tumor, such as long-term neurologic and pituitary dysfunction (especially lack of growth hormone). Learning challenges may also occur, especially if a child received high doses of cranial radiation at a very young age.

## Nursing Diagnoses and Related Interventions

Because a diagnosis of brain tumor is so frightening to parents and the child, nursing diagnoses need to include both physical and psychosocial aspects.

**Nursing Diagnosis:** Fear related to diagnosis of brain tumor

**Outcome Evaluation:** Parents and child continue to maintain function as a family, visit in hospital, and plan appropriately for discharge and continued care.

Because parents bring their child to a healthcare facility in response to insidious symptoms such as vomiting, headache, or strabismus, they may not be prepared for the severity of their child's diagnosis. This can cause such distress at the time of the initial diagnosis that they cannot think of questions to ask. In the hours or days after the diagnosis, however, they often have a great need to talk to healthcare professionals who are familiar with the care of children with brain tumors to ask questions about surgery or their child's prognosis.

Most parents want to hear a definite statement about prognosis—for example, “All of the tumor can be removed; your child will be as good as new” or “Your child's chances are 1 in 4 of surviving surgery (or of having permanent effects).” Because the type of tumor, its exact location, and its extent are not fully known until surgery, these predictions are difficult to make with more than an uninformed guess. You can assure parents it is normal in these instances for a surgeon not to give more definitive information; this vagueness does not reflect an unwillingness to offer a definite prognosis or lack of interest. They also may need assurance that if they had realized their child's symptoms were serious earlier, it would not have made a difference in the final outcome. Such assurance is what makes it possible for them to live with themselves afterward and not be overwhelmed by guilt, thinking they could have prevented a bad outcome. Symptoms of brain tumor are insidious, and parents cannot be expected to recognize them for what they represent.

Help parents also to understand that because of the importance of brain tissue, brain surgery is never minor. Be certain they understand their child will have a large, bulky head dressing; may be drowsy or unresponsive; and possibly have extensive facial edema afterward. The child may be intubated and ventilated. Even parents who are well prepared are likely to be shocked at the actual sight of their child. Before you take them to the child's room after surgery, review with them once more how the child will look to be certain they are prepared for the changed appearance of their child.

Some parents may not “hear” the full extent of their child's diagnosis before surgery. After surgery, when they are told some of the tumor had to be left to preserve the brain tissue nearby, a very genuine grief reaction can occur. As a result, it may be difficult for them to sit and hold the child's hand or read to the child because their minds have already jumped ahead to the time when the child might die. The child may have difficulty relating to them because they are no longer acting like the parents the child knew before surgery. Offering parents support from the time a child is first seen, through the days of surgery, chemotherapy, and any remission, is an important nursing responsibility.

Children as young as 5 years old are aware their brain is important for functioning. They become very aware of the tone they detect in the words of parents and

healthcare personnel when they talk about a brain tumor. Because they undergo several diagnostic studies, followed by surgery and prolonged therapy, provide children with opportunities to express their feelings about intrusive procedures through play with puppets or hospital equipment. Remember that, when a person becomes unconscious, hearing is often the last sense lost. Although children do not appear to respond after surgery, they may be able to hear what is said in the room.

### *QSEN Checkpoint Question 53.4*

#### **QUALITY IMPROVEMENT**

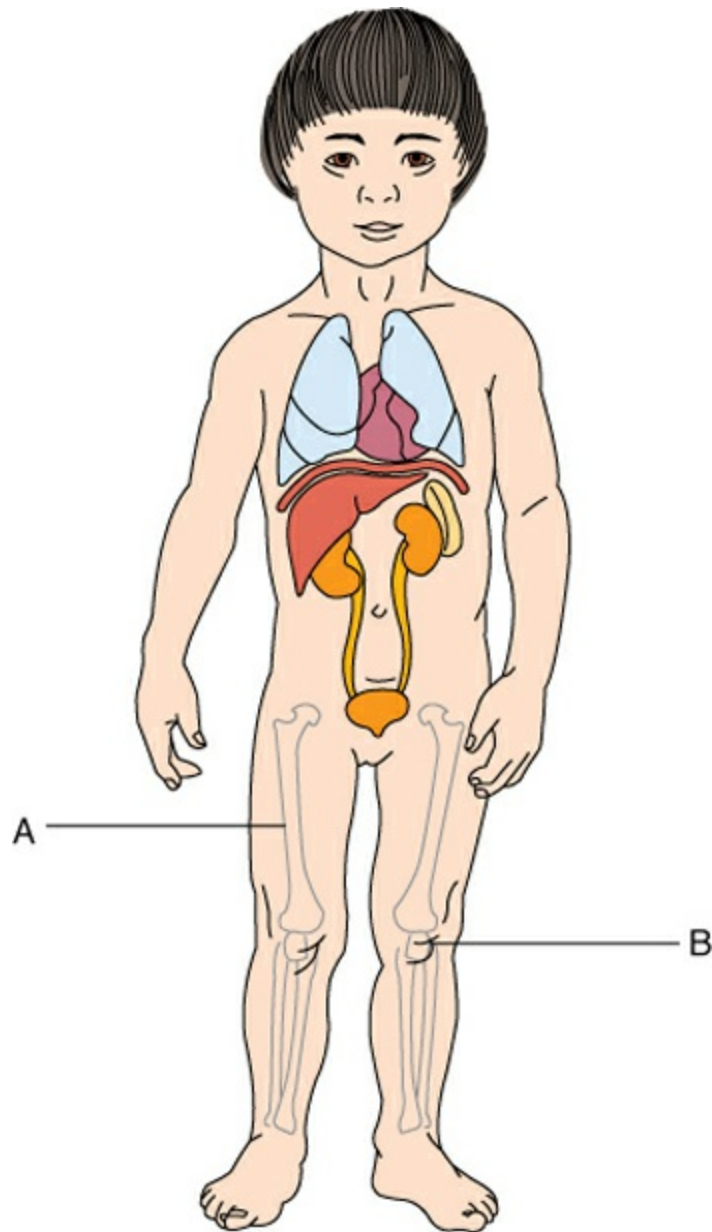

Gerri had surgery for a brain tumor 2 weeks ago. The care unit protocol specifies that the administration of stool softeners be given before and after surgery when not contraindicated. What is the rationale for this protocol?

- a. Constipation stimulates the release of pituitary hormones.
- b. Straining with bowel movements increases intracranial pressure.
- c. Constipation can lead to anal fissures, which can be a source of infection.
- d. Children in Trendelenburg positions cannot effectively move their bowels.

*Look in [Appendix A](#) for the best answer and rationale.*

## **Bone Tumors**

Tumors derived from connective tissue, such as bone and cartilage, muscle, blood vessels, or lymphoid tissue, are termed **sarcomas**. They are the second most frequently occurring neoplasms in adolescents (only lymphomas occur more frequently). Bone tumors may arise during adolescence because rapid bone growth is occurring at this time. Because girls have a puberty growth spurt a year or two earlier than boys, bone tumors tend to occur slightly earlier in girls than in boys (13 compared with 14 or 15 years of age). The two most frequently occurring types are osteogenic sarcoma and Ewing sarcoma ([Fig. 53.6](#)).

**Figure 53.6** (A) The diaphysis (midshaft) is one of the most frequent sites of Ewing sarcoma. (B) The epiphysis of a bone is a common site of osteogenic sarcoma.

## OSTEOGENIC SARCOMA

An **osteogenic sarcoma** is a malignant tumor of long bone involving rapidly growing bone tissue (mesenchymal-matrix forming cells). It occurs more commonly in boys than in girls and in children who have had radiation for other malignancies as a later life effect. The most common sites of occurrence are the distal femur, the proximal tibia, and the proximal humerus, and the tumor is often associated with locoregional pain and swelling (HaDuong, Martin, Skapek, et al., 2015). Children with a specific genetic syndrome have a higher incidence than usual of developing an osteosarcoma, so a hereditary predisposition may be present.

Metastasis occurs early with bone tumors because of the extensive vascular system in bones. Metastasis to the lungs is very common; as many as 25% of adolescents will have lung metastasis already by the time of initial diagnosis. Other common sites of metastasis are brain and other bone tissue.

### Assessment

The area may be painful and swollen; it may be inflamed and feel warm because tumors are highly vascular and therefore call increased blood into the area. Children may report a history of recent trauma to the site such as a fall playing basketball or a bump to their knee during soccer practice and attribute pain in the knee to this injury for some time. To prevent the adolescent from thinking he caused the tumor, be certain he and his parents understand trauma did not cause the process; it merely called attention to the leg or arm where a malignant process was at work.

Features of osteosarcoma are visible on radiologic studies such as MRI, but a biopsy will be done of the suspicious site to confirm the diagnosis. To determine metastasis, a complete blood cell count, urinalysis, chest X-ray, chest CT scan, and bone scans will be done. Caution children not to bear weight on an affected leg while waiting for tests or surgery because if the bone has become weakened by the growing tumor, weight bearing could result in a fracture at the tumor site.

### Therapeutic Management

Chemotherapy is prescribed to shrink the tumor before surgery. If parents are concerned with this delay, explain that, with a bone tumor, this is a helpful intervention because it will make removal of the tumor more successful. A common chemotherapy drug regimen used for treatment includes methotrexate, cisplatin, doxorubicin, and ifosfamide.

When at all possible, surgical procedures will attempt to remove the tumor without amputation. These surgeries are referred to as limb salvage. The bone that is removed is typically replaced by cadaver or man-made prosthesis (Jackson, Bittman, & Granowetter, 2016). Rarely, if the tumor is extensive at the time of diagnosis, the extremity may be amputated at the joint above the tumor.

Only a few years ago, a diagnosis of osteogenic sarcoma was ominous; few children survived into adulthood. Today, 70% of adolescents in whom the diagnosis is made early and who are treated rigorously can be cured (Brown & Hunger, 2013).

## Nursing Diagnoses and Related Interventions

Diagnosis of malignant bone tumor is a shock to both parents and children because the symptoms began so insidiously the diagnosis doesn't seem real. You can assure

parents that any delay in seeking treatment would not have had a marked effect on the chances for a cure. Neither the adolescent nor the parents could have been expected to seek medical attention any earlier than they did. This is important assurance because it can help parents function more effectively to help their child through the illness.

It may be particularly difficult for the patient and family to accept certain aspects of the disease and its impact on the future. For example, depending on the tumor site, there may be limitations to participating in specific sports or physical activities. Supporting the child and family while they incorporate their new reality is an important aspect of nursing care.

**Nursing Diagnosis:** Risk for injury related to surgery and bone prosthesis

**Outcome Evaluation:** Extremity distal to surgical incision remains warm to touch; capillary filling is less than 5 seconds.

The major danger associated with surgery for excising osteosarcoma and placement of a bone prosthesis (limb salvage surgery) is that the swelling that occurs during surgery or immediately afterward can disrupt neurologic or circulatory function to the lower leg. Always position and handle the leg carefully to prevent further disruption. Assess frequently for signs the neurologic and circulatory systems are intact distal to the surgery (toes are warm and pink; capillary filling is less than 5 seconds; adolescent reports no numbness or tingling).

### *QSEN Checkpoint Question 53.5*

#### **TEAMWORK & COLLABORATION**

Gerri's school nurse informs another nurse that his mother forbids him to play basketball because she heard a friend's son developed osteosarcoma when he was injured playing the sport. The nurses collaborate to plan a unified response to her concerns. What would be the best advice to give Gerri's mother regarding her understanding of osteosarcoma?

- Evidence has shown that bone cancer is associated with active, organized sports.
- Osteosarcoma more often occurs in girls, so the boy's diagnosis is unusual.
- The sports injury more likely led to diagnosis of the tumor but was not the cause of it.
- The boy's inadequate calcium intake was a more likely cause of his health problem.

*Look in [Appendix A](#) for the best answer and rationale.*

## **EWING SARCOMA**

**Ewing sarcoma** is a malignant bone tumor; it occurs most frequently in the bone

marrow of the diaphyseal area (midshaft) of long bones and spreads longitudinally through the bone (see [Fig. 53.6](#)). Ewing sarcoma may also present as a primary site outside the skeletal system where it is referred to as a primitive neuroectodermal tumor (PNET). Ewing sarcoma of the bone occurs primarily in young adolescents and older school-age children; it is slightly more common in boys than in girls. Metastasis is usually present at the time of diagnosis, with the lungs, other bones, the CNS, and lymph nodes being the most common sites ([Jackson et al., 2016](#)).

## Assessment

Most children have had pain at the site of the tumor for some time before seeing a primary healthcare provider. At first, the pain is intermittent, and the child attributes it to an injury (perhaps a friend punched his leg or the child bumped it against a footstool). Finally, the pain becomes constant and so severe the child cannot sleep at night. X-rays will reveal an unusual “onion-skin” reaction (overlapping fine lines disclosed on the X-ray film) surrounding the invading tumor cells. A bone scan, bone marrow aspiration and biopsy, CT scan of the lungs, and MRI will be done to determine the extent of the tumor and whether metastasis has occurred. A biopsy of the tumor site will be done for a definite diagnosis. During tests, urge the child to avoid bearing weight on the affected extremity because this could cause a pathologic fracture at the site.

## Therapeutic Management

With Ewing sarcoma, therapy consists of a combination of surgery to remove the primary tumor, radiation, and chemotherapy. The drug regimen often used includes vincristine, dactinomycin, cyclophosphamide, doxorubicin, etoposide, and ifosfamide. Radiation is typically used only when surgical resection is not possible or incomplete ([Jackson et al., 2016](#)).

About 50% of children survive for at least 5 years; older children have a better survival rate than younger children. Caution adolescents to continue to be careful about activities that cause stress on an extremity that has received radiation (e.g., football or weight lifting) because it may not be as strong as usual afterward.

## Other Childhood Neoplasms

### NEUROBLASTOMA

**Neuroblastomas** are tumors that arise from the cells of the sympathetic nervous system; cells are highly undifferentiated and invasive, occur most frequently in the abdomen near the adrenal glands or spinal ganglia, and are the most common abdominal tumor in childhood ([Matthay, Maris, Schleiermacher, et al., 2016](#)). Neuroblastoma occurs primarily in infants and preschool children; it is slightly more common in boys than in girls. These tumors may occur so early in life, in fact, that they may be detected by fetal ultrasound or shortly after birth. Common sites of metastasis include the bone marrow,

liver, and subcutaneous tissue.

## Assessment

The growing tumor is most often discovered on abdominal palpation as an abdominal mass after general symptoms of weight loss and anorexia are noticed. Pressure on the adrenal glands from the tumor may cause excessive sweating, flushed face, and hypertension. Abdominal pain and constipation may also be present. Compression on the spinal nerves or invasion into the intervertebral foramina may cause loss of motor function in lower extremities.

If the primary lesion is in the upper chest, children will report dyspnea; swallowing may be difficult, and neck and facial edema may occur from compression on the vena cava. If liver metastasis is present, children may have jaundice. If metastasis to the skin has occurred, blue or purplish nodules (prominent raised areas) on arms or legs may be seen.

The extent of the tumor and any metastases present are identified by MRI or ultrasound (a mass growing on an adrenal gland just above the kidney will demonstrate kidney compression); an arteriogram (neuroblastomas are vascular tumors and incorporate veins and arteries into their structure as they grow); ultrasound, CT, or MRI scan of the chest, abdomen, and pelvis; a gallium bone scan; or bone marrow aspiration and biopsy. If an adrenal tumor is present, it will stimulate production of adrenal gland hormones or catecholamines. To detect these substances, a urine sample will be tested for the presence of vanillylmandelic acid and homovanillic acid (the breakdown products of catecholamines). A biopsy of the tumor site will be planned so the tumor can be definitely identified.

## Therapeutic Management

Infants in the initial stages of disease may require observation only as some of these tumors will regress without intervention. If the tumor is localized (stage I or II), therapy will consist of surgical removal of the primary tumor. If the tumor is stage III (lymph nodes are involved) or stage IV (metastasis has occurred), surgery will be followed by chemotherapy combinations using agents such as doxorubicin, cyclophosphamide, etoposide, and carboplatin (Pinto, Applebaum, Volchenbom, et al., 2015).

A “second look” surgical procedure may be scheduled within several months to determine the effectiveness of therapy and to attempt the possible removal of further tumor. Immunotherapy is another possibility to eliminate residual disease after chemotherapy (Park, Bagatell, London, et al., 2013).

Stage IV disease is a unique form because it has a high rate of spontaneous regression. This occurs because the tumor either spontaneously degenerates or undergoes differentiation to normal tissue (Matthay et al., 2016).

Overall, children with neuroblastoma have a 5-year survival rate of 70% to 90%. Although most children have a positive initial response to therapy, recurrence is

common within the first year. The prognosis is better in children diagnosed before 1 year of age.

## RHABDOMYOSARCOMA

A **rhabdomyosarcoma** is a tumor of striated muscle (Williams, Fernandez-Pineda, & Gosain, 2016). It arises from the embryonic mesenchyme tissue that forms muscle, connective, and vascular tissue. The peak age of incidence of these tumors is 2 to 6 years, with a second peak occurring during puberty. Common sites of occurrence include the eye orbit, paranasal sinuses, uterus, prostate, bladder, retroperitoneum, arms, and legs. CNS invasion occurs from direct tumor extension, resulting in cranial nerve palsy, nuchal rigidity, bradycardia, or bradypnea (because of brainstem compromise). Distant metastasis most commonly occurs in lungs, bone, or bone marrow.

### Assessment

The symptoms relate to the site of the tumor (Table 53.4). A biopsy specimen of the tumor is taken and examined for tissue identification. Metastasis is ruled out by bone scan, chest X-ray, CT scan, MRI, and bone marrow aspiration.

**TABLE 53.4 COMMON SITES AND ASSOCIATED SYMPTOMS OF RHABDOMYOSARCOMA**

Site of Tumor	Symptoms
Orbit	Proptosis (extruding eye); visible and palpable conjunctival or eyelid mass
Neck	Hoarseness, dysphagia; visible and palpable mass in neck
Nasopharynx	Airway obstruction, epistaxis, dysphagia, visible mass in nasal or nasopharyngeal passages
Paranasal sinuses	Swelling, pain, nasal discharge, epistaxis
Middle ear	Pain, chronic otitis media, hearing loss, facial nerve palsy, mass protruding into external ear canal
Bladder and prostate	Dysuria, urinary retention, hematuria, constipation, palpable lower abdominal mass
Vagina	Mass protruding from uterus or cervix into vagina, abnormal vaginal bleeding
Trunk, extremities	Visible and palpable soft-tissue mass
Testicles	Visible and palpable soft-tissue mass

### Therapeutic Management

The primary treatment is surgical removal of the tumor, followed by chemotherapy combinations with agents such as vincristine, dactinomycin, cyclophosphamide, doxorubicin, etoposide, topotecan, and ifosfamide. The child receives chemotherapy every 3 to 4 weeks for 18 to 24 months. If CNS extension has occurred, intrathecal chemotherapy may be included in the regimen. Radiation is frequently used for local control of disease with intensity-modulated radiotherapy (IMRT) employed to reduce the long-term complications to surrounding tissue (Hiniker & Donaldson, 2015).

A child's prognosis depends on the size of the tumor and whether metastasis was present at the time of initial diagnosis. If the entire tumor was removed and no lymph node metastasis has occurred, the chances are as high as 80% that the tumor will not recur. If some of the tumor had to be left because of its size or location, the chance of recurrence rises to about 50%. If metastasis to the lungs or bone was present at the time of the initial diagnosis, the prognosis drops still further; about 20% of children in this situation have long-term survival. Among children who do survive, long-term complications such as cardiomyopathy and infertility may occur from the side effects of chemotherapy.

## NEPHROBLASTOMA (WILMS TUMOR)

**Nephroblastoma** (Wilms tumor) is a malignant tumor that rises from the metanephric mesoderm cells of the upper pole of the kidney (Malkan, Loh, Bahrami, et al., 2015). It accounts for 20% of solid tumors in childhood, and overall survival rates are greater than 90%. It may occur in association with congenital anomalies such as aniridia (lack of color in the iris), cryptorchidism, hypospadias, pseudohermaphroditism, cystic kidneys, hemangioma, and talipes disorders. A number of gene mutation has been identified as associated with the disease. Without therapy, metastatic spread by the bloodstream is most often to the lungs, regional lymph nodes, liver, bone, and, eventually, brain.

### Assessment

A nephroblastoma is usually discovered early in life (6 months to 5 years; peak at 3 to 4 years), although it apparently arises from an embryonic structure present in the child before birth. Nephroblastomas distort the kidney anteriorly so that the tumor is felt as a firm, nontender abdominal mass. Parents are aware their infant has a mass in the abdomen but bring the infant to their healthcare provider thinking that it is hard stool from chronic constipation. Parents often report that the mass seemed to appear overnight. This actually can happen, because tumors can hemorrhage into themselves, doubling their size in a matter of hours. If this happens, accompanying signs may be hematuria and a low-grade fever. The child may be anemic from blood loss and lack of erythropoietin formation by the diseased kidney. Although hypertension may also occur because of excessive renin production, blood pressure is not taken routinely in children of this age, so the tumor is rarely discovered by this method.

A CT scan or ultrasound reveals the primary tumor and any points of metastasis. Kidney function studies, such as glomerular filtration rate or blood urea nitrogen, will be done to assess function of the kidneys before surgery. Little time, however, can be allotted for preoperative testing, because these tumors metastasize rapidly as a result of the large blood supply to the kidneys and adrenal glands.

## Therapeutic Management

Nephroblastomas are staged to predict therapy and prognosis. The tumor will be removed by nephrectomy (excision of the affected kidney). This is usually followed immediately by chemotherapy with dactinomycin, doxorubicin, or vincristine, cyclophosphamide, and etoposide. Chemotherapy may be given at varying intervals for as long as 15 months. Radiation is usually limited to high-risk disease (anaplastic histology) or advanced disease (Dome, Graf, Geller, et al., 2015).

If tumor involvement is bilateral, the operative decisions obviously become more complex. If the tumors are small, both tumors may be removed, leaving functioning kidney on both sides intact. In other children, the kidney with the larger tumor is removed and the tumor site in the remaining kidney is then treated with both radiation and chemotherapy.

Complications such as nephritis, small bowel obstruction, and hepatic damage caused by fibrotic scarring from radiation or scar tissue from surgery can occur. In girls, radiation-related damage to the ovaries may result in sterility. Radiation to the lungs may result in interstitial pneumonia.

### QSEN Checkpoint Question 53.6

#### SAFETY

A child on the hospital unit is undergoing chemotherapy for newly diagnosed leukemia and is neutropenic. A visit arrives on the unit with a plant and flowers to put in the child's room. What should the nurse do to ensure the immunocompromised patient remains safe?

- Let the child have the plant in the room but place it far away from the bed.
- Let the child have the plant to help cheer the child up.
- Tell the visitor that the plant/flower may harbor fungus or other infectious materials and unfortunately can't be allowed in the room.
- Allow the visitor to place the plant/flower at the nurse's station so that it can be enjoyed by the patient without being placed in the room.

*Look in Appendix A for the best answer and rationale.*

## RETINOBLASTOMA

Retinoblastoma is a malignant tumor of the retina of the eye. A rare tumor, it accounts for only 1% to 3% of childhood malignancies. In about 10% of children, these tumors

develop because of an inherited autosomal dominant pattern that causes an alteration of chromosome 13. Parents who have one child with retinoblastoma have about a 4% chance of having a second child with a similar tumor. If two or more children have the tumor, the parents are probably carriers, and it can be predicted that up to 50% of their children will be affected. Because of the dominant pattern of inheritance, a person who survives retinoblastoma has an elevated chance of having a child with a similar tumor. Parents who may be carriers and children who survive the disease need genetic counseling so that they are aware of the risk to their children. Because the 5-year survival rate for children with retinoblastoma is good (at least 90%), this is an important counseling role (Rowland & Metcalfe, 2013).

Retinoblastoma occurs most often, however, as spontaneous development, not the inherited type. Children with the inherited type tend to develop bilateral disease; those with the spontaneous type may or may not have the tumor in both eyes.

### Assessment

Retinoblastoma occurs early in life, from about 6 weeks of age through the preschool period. It occurs equally in boys and girls, and there is no preference for either the right or the left eye. One tumor or many individual tumors may be present. Tumors are located on the retina or in the vitreous fluid or may extend backward into the choroid, the optic nerve, and the subarachnoid space.

On examination, the child's pupil appears white (the red reflex is absent) or is described as a typical "cat's eye." The child develops strabismus as the eye becomes nonfunctional. This tumor metastasizes readily along the course of the optic nerve to the subarachnoid space and brain; it can quickly involve the second eye. Metastasis to distant body sites, such as bone marrow and liver, is possible.

Children with a family history should have an ophthalmic exam usually under general anesthesia or conscious sedation at least three times yearly until they reach 5 years of age. CT scanning, MRI, and ultrasound may all be prescribed to detect intraocular calcification or the presence of tumor. The possibility of distant metastasis is evaluated by lumbar puncture, liver and skeletal survey, MRI, or bone marrow biopsy.

### Therapeutic Management

Retinoblastomas, if allowed to grow, will cause blindness. An important goal for children with retinoblastoma is to preserve as much vision as possible for as long as possible. If the tumor is very small at the time of diagnosis, it may be treated with cryosurgery (freezing the tumor to destroy local cells), hopefully preserving partial vision in the eye. Photocoagulation using laser surgery to destroy the blood vessels supplying the tumor or localized radioactive applicators or plaques sutured to the sclera over the tumor may also be used. If the tumor has metastasized, the child may also receive radiation treatment and chemotherapy (vincristine, cyclophosphamide, doxorubicin, carboplatin, and etoposide are components of commonly used regimens).

If the tumor is large when first discovered, enucleation of the eye may be necessary. After enucleation, the child has a large pressure dressing applied to the empty socket. Observe for bleeding on the dressing and assess vital signs frequently. To keep young children from tugging at the dressing and removing it, they may need to be restrained if a parent cannot be with them constantly. After about 48 hours, the pressure dressing is removed and a small eye patch is applied. Irrigation of the empty socket with normal saline solution or application of an antibiotic ointment may be prescribed with dressing changes.

An eye prosthesis is fitted about 3 weeks after surgery. Prostheses in children do not need to be removed and cleaned daily, and in children this young, leaving the prosthesis in place prevents the child from removing and playing with it (an interesting, colorful, round ball).

Evaluation of the child after retinoblastoma must include not only whether metastasis can be detected but also whether the child is adjusting to any loss of vision. Children who do not have binocular vision this early in life usually do not have difficulty adjusting. They notice it most at school age when they may have difficulty participating in sports that require 3-D sight, such as baseball. If radiation was used for therapy, cataracts may develop several years later. The increased incidence of osteogenic and soft-tissue sarcomas that occur following retinoblastoma may result from the therapy or an underlying genetic predisposition.

## Nursing Diagnoses and Related Interventions

A diagnosis of retinoblastoma is a devastating one for parents because, at best, it threatens their child's vision. At worst, it can be fatal.

**Nursing Diagnosis:** Decisional conflict related to approval of enucleation to save child's life

**Outcome Evaluation:** Parents and child state they can accept enucleation to save child's life.

With the diagnosis of retinoblastoma, parents may be asked to make a most difficult decision. To save their child's life, they must agree to the removal of an eye. Even after this procedure, the second eye may become involved or distant metastasis may be detected. Offer parents support in the decision they make because, if there is metastasis at a later date, they may feel guilty they agreed to enucleation, believing they have put the child through surgery without achieving a benefit. They may need help managing the degree of guilt they feel because they noticed their child's eye was abnormal but delayed seeking health care. Be certain parents understand fully what the word enucleation means (loss of the eye) before surgery. Provide time for discussion to help them work through this very emotional time in their life.

### *What If . . . 53.3*

**Gerri's mother shows the nurse a photo she took of their family, and the nurse notices that only the pupil of the left eye of Gerri's 2-year-old sister shows a typical red reflex; the other pupil appears white. Why might the nurse be concerned?**

## SKIN CANCER

One in five people in the United States develop skin cancer in their lifetime (Apalla, Nashan, Weller, et al., 2017). Three common types are involved: basal cell carcinoma (a surface epithelial growth that appears as a small ulcer that does not heal), squamous cell carcinoma (a tumor of the epidermis that appears as a white scaly lesion), and malignant melanoma (a tumor originating in melanocytes or nevi) that appears as a mole changing in appearance. All three types of skin cancer are increasing in incidence, and although the symptoms usually do not appear until late adolescence, the chief cause (excessive sun exposure) begins in childhood (Nahar, 2013). In addition, skin cancer is a leading second malignancy seen after treatment of childhood cancer.

## MALIGNANT MELANOMA

Melanomas can be differentiated from benign moles by an A-B-C-D assessment: **a**symmetry, **b**order irregularity, **c**olor (variable or dark pigmentation), and **d**iameter (over 6 mm). Melanomas are treated with surgery, radiation, and immunotherapy to improve overall survival. Nurses can play a major role in helping to reduce the incidence of skin cancer by teaching parents and adolescents ways to identify these malignancies and better protect against excessive sun exposure using measures such as:

- Apply a sunscreen or wear protective clothing if a child will be out in the sun for longer than 20 minutes.
- Avoid indoor tanning beds or ultraviolet light. If used, maintain the same precautions as with sunlight.
- Avoid sunburn because there is a direct association between two or more episodes of sunburn in adolescence and the development of malignant melanoma in young adulthood (ACS, 2015).

### *What If . . . 53.4*

**A nurse is particularly interested in exploring one of the 2020 National Health Goals that address malignancies in children (see Box 53.1). What would be a possible research topic pertinent to this goal that would be applicable to Gerri's family and also advance evidence-based practice?**

## KEY POINTS FOR REVIEW

- After a diagnosis of malignancy, parents and children should be informed that current treatment strategies provide long-term survival for the majority of patients.
- Therapy for childhood cancer may be very disruptive to family life and requires support of the entire family.
- Radiation is an important treatment modality in cancer therapy. Immediate side effects include anorexia, nausea, vomiting, and hair loss if radiation is to the head. Long-term effects may include growth restriction or learning disabilities.
- A chemotherapeutic agent is one that is capable of destroying malignant cells. Common acute side effects are similar to those of radiation therapy. Help children to use time during chemotherapy treatments in constructive ways, such as playing a game, to keep them mentally stimulated and distracted from negative associations.
- Be aware of the need to use protective equipment when preparing to administer a chemotherapy drug to protect yourself from adverse effects of the medication.
- Leukemia is the distorted and uncontrolled proliferation of WBCs and is the most frequently occurring type of cancer in children. About 90% to 95% of children will achieve remission and have a good prognosis for long-term survival.
- Hodgkin disease and non-Hodgkin lymphomas are malignancies of the lymphatic system. Hodgkin disease occurs most often in adolescents; the initial symptom is a painless, enlarged lymph node. Therapy including chemotherapy and radiation is used for advanced or slow responding disease.
- Brain tumors are the most common solid tumors occurring in childhood. Beginning symptoms are usually those of increased intracranial pressure. Therapy may include a combination of surgery followed by radiation and chemotherapy.
- Bone tumors occur in two main forms: osteogenic sarcoma and Ewing sarcoma. They can occur in any bone but often occur in extremities. Therapy consists of surgery followed by radiation and chemotherapy.
- Neuroblastomas are tumors that arise from the cells of the sympathetic nervous system. They are the most common abdominal tumor in childhood. Therapy is surgery and chemotherapy.
- Rhabdomyosarcomas are tumors of striated muscle. The peak age of incidence is 2 to 6 years. Therapy is surgery and chemotherapy.
- Nephroblastoma (Wilms tumor) is a malignancy that arises from the metanephric mesoderm cells of the kidney. It is usually discovered early in life. Therapy is surgery followed by chemotherapy and radiation for high-risk or advanced stage disease.
- Retinoblastoma is a malignant tumor of the retina of the eye. It may be inherited as an autosomal dominant pattern. Therapy is aimed at local control and preservation of vision; enucleation may be necessary if the tumor is large.
- Skin cancer is a type of malignancy that can be prevented beginning in childhood. Cautioning children about sensible sun exposure can be an important health promotion role for nurses.

## CRITICAL THINKING CARE STUDY

Jack is a previously active 4-year-old who has been running a fever on and off for the last 2 weeks. In addition, Jack's mother has noticed that he is much more tired than usual and has developed bruising and petechiae on his extremities and trunk. Jack and his parents have just been told by the oncologist that he likely has leukemia and that further workup will be necessary before he can be treated.

1. Jack's parents are very worried. What could have caused Jack to develop leukemia? Is there a risk that his brothers and sisters could catch the disease?
2. What additional tests will likely be done to further diagnose Jack's leukemia?
3. What kind of treatments will Jack likely need and for how long?

UNIT 8

The Nursing Role in Restoring and  
Maintaining the Mental Health of  
Children and Families

## Nursing Care of a Family When a Child Has an Intellectual or Mental Health Disorder

*You meet Todd, a kindergartner who was diagnosed last year with autism spectrum disorder, who is admitted to your ambulatory care unit to have plaque removed from his teeth under conscious sedation. You observe Todd coloring, repetitively drumming on the table, opening and closing the door, and lacking interest in the other children in the room. His sister Cheyenne, 15 years old, who seems very underweight, tells you she is “at her wits’ end” trying to babysit Todd in the evenings because of his short attention span and disruptive behavior. Todd’s father tells you he’s proud that his son is “all boy.”*

*Previous chapters described the normal growth and development of well children and the care of children with physiologic disorders. This chapter provides additional information about the dramatic changes that can occur when children exhibit symptoms of an intellectual or mental health disorder. Such information builds a base for care and health teaching.*

**What additional education does Todd’s family need to understand him better?  
Does his older sister need counseling as well?**

### KEY TERMS

**anhedonia**

**binge eating**

**catatonia**

**choreiform movements**

**complex motor tics**

**complex vocal tics**

**coprolalia**

*Diagnostic and Statistical Manual of Mental Disorders (5th ed.; DSM-5)*

**echolalia**

**flat affect**

**hyperactivity**

**labile mood**

**palilalia**  
**purging**  
**simple motor tics**  
**simple vocal tics**

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe common intellectual and mental health disorders that occur in children.
2. Identify 2020 National Health Goals related to intellectual or mental health disorders that nurses can be instrumental in helping the nation achieve.
3. Assess a child for an intellectual or mental health disorder.
4. Formulate nursing diagnoses related to the intellectual or mental health disorders in childhood.
5. Establish expected outcomes for a child with an intellectual or mental health disorder that help parents manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care for a child with an intellectual or mental health disorder, such as explaining ways to remember to take medicine long term.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of children with an intellectual challenge or mental illness with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to achieve quality maternal and child health nursing care.

---

Children who are mentally healthy typically master the tasks of each developmental phase of childhood, achieving new adaptive and appropriate self-regulatory skills, and grow up to possess a positive self-concept and sense of contentment within their own limits. In addition, children who display adequate mental health often benefit from a positive emotional relationship between the parents and the child and have a sense of safety and security in their home environment. Therefore, promoting suggestions for healthy individual self-regulation and family functioning during healthcare visits, providing anticipatory guidance about normal achievement of developmental milestones and needs, and listening carefully to both children and parents are important nursing actions to foster both the physical and mental health of children and families.

Sound mental health implies that a child is able to be flexible and adaptive and use coping skills that promote self-regulation appropriately in order to meet the normal, or

even extreme, stressors of life. When stressors—whether increasing school work, social pressure, or more significant trauma such as acute illness, hospitalization, abuse, natural disasters, or chronic illness—exceed a child’s ability to effectively self-regulate or extend beyond a family’s resources, many children and parents are unable to cope adequately, which can result in emotional dysregulation, family dysfunction, and/or maladaptive coping, such as self-harm, addiction, or eating disorders, and ultimately lead to a mental health diagnosis. It is important for nurses to be able to recognize how environmental stressors can overwhelm a child’s self-regulatory skills and affect children and their families and to be prepared to provide interventions, improve coping skills, and provide necessary community referrals for support (Brosbe, Faust, & Gold, 2013).

Children can develop the same mental health disorders that affect the adult population, such as depression, anxiety, and psychotic- and stress-related disorders; however, children’s symptoms present differently than symptoms in adults. In addition, several disorders such as autism spectrum disorder or separation anxiety are typically best assessed during early childhood. Current research attributes the development of some disorders that occur in children to genetic vulnerability and others to disruption in family life, child temperament, inadequate parent–child bonding and attachment, or a combination of any of the above. For best results, children with mental illness, whatever the cause, should be evaluated and treated by specialists in the child mental health field as early in their symptomology as possible. A child health nurse is often the first healthcare provider to become aware of such symptoms, and he or she can be instrumental, through brief psycho-education and appropriate community referrals, in helping a child and family to access appropriate mental health resources.

Because mental health is important to the nation, [Box 54.1](#) shows intellectual and mental health disorders addressed by the 2020 National Health Goals.

#### BOX 54.1

#### Nursing Care Planning Based on 2020 National Health Goals

Intellectual and mental health disorders in children produce major costs to the nation, as well as to individual families, because these disorders have the potential to reduce the earning power and contributions of the nation’s future citizens. Examples of 2020 National Health Goals that speak to this are:

- Decrease the proportion of adolescents 12 to 17 years of age who experience major depressive episodes from a baseline of 8.3% to a target level of 7.4%.
- Increase the proportion of children with mental health problems who receive effective treatment from a baseline of 68.9% to 75.8%.
- Prevent inappropriate weight gain (excessive or inadequate) in adolescents 12 to 18 years of age.
- Increase the incidence of primary care physicians who screen youth age 12 to 18 years for depression during office visits from 2.1% to 2.3% ([U.S. Department of](#)

Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)) (Weersing, Brent, Rozenman, et al., 2017).

Nurses can help the nation achieve these goals by educating parents about nutrition and inadequate weight gain; educating families about ways to reduce stress; and helping to identify children in school and healthcare settings who demonstrate a high level of stress, depression, or other symptoms of mental illness.

### *Nursing Process Overview*

## FOR CARE OF A CHILD WITH AN INTELLECTUAL CHALLENGE OR MENTAL ILLNESS

### **ASSESSMENT**

Both personality and mental growth potential in a child are influenced by several factors, including genetic makeup, cultural background, family environment, socioeconomic status, and access to community resources and support. It is essential that all of these are taken into account when assessing a child's intellectual or mental health. As a child health nurse, be certain to assess children for emotional as well as physical problems at regular health maintenance visits. If a mental health or intellectual problem is suspected, obtain a detailed history of the presenting concern, including onset of symptoms, current stressors, the child's developmental history including school and social aspects, family dynamics, family history of mental illness, and finally current barriers or access to community resources and supports.

### **NURSING DIAGNOSIS**

Nursing diagnoses established for children who are ill often also address mental health or the response of children and their families due to their medical condition or treatment. Examples of mental health diagnoses due to a medical condition that can affect children and their families include:

- Ineffective coping related to a medical diagnosis, surgery, or prognosis
- Caregiver role strain related to potential loss of independence secondary to traumatic injury
- Significant low self-esteem related to disfiguring scars after accident
- Dysfunctional or interrupted family processes related to accident or sudden change of independence and control in hospital environment

Examples of additional nursing diagnoses, which need to be added if a concern of intellectual or mental health is present, include:

- Knowledge deficit related to intellectual testing and subsequent diagnosis, communication disorders, autism spectrum, attention deficit hyperactivity, and motor disorders
- Impaired personal identity related to depression, anxiety, or underlying mental health condition
- Risk for caregiver role strain related to stress- and trauma-related disorders

- Impaired or dysfunctional impulse-control

### **OUTCOME IDENTIFICATION AND PLANNING**

Although the diagnosis of a mental health disorder or referral to a child mental health or psychiatric clinic does not carry the stigma it once did, many parents still worry such a referral is a mark of inadequacy or a sign of failure for themselves as a child's guardian. Help them to see that this type of referral is in their child's best interest and is no different from a referral to any specialist, such as a cardiologist or orthopedist for a purely physical reason. In fact, current research indicates that approximately 13% of children ages 8 to 15 years had a mental health diagnosis within the previous year, and a 46% lifetime prevalence for children ages 13 to 18 years ([Centers for Disease Control and Prevention, 2013](#)).

Parents can be hesitant to pursue mental health services for a child for various reasons. Nurses can reassure parents that today's world puts many pressures and stresses on children and families that they cannot control or prevent completely. Ensure parents that contact with a child mental health clinic, psychologist, or psychiatrist will be kept confidential and offer support that healthcare personnel making the referral will continue to offer episodic or health maintenance care—they are not being “transferred out” but asked to seek additional help only in this one area. Furthermore, providing additional access to psycho-educational resources can help the families understand their child's current experiences and mental health needs at the community, state, and national level.

### **IMPLEMENTATION**

Often, what parents and children need most when an intellectual or mental health disorder is identified is an empathic, nonjudgmental person to listen to their story objectively and to provide emotional support for them as they try to resolve and manage the situation to a conclusion satisfactory for the family. Serving in this capacity, the nurse can be a comfort to families and also personally satisfying.

### **OUTCOME EVALUATION**

Children who have an intellectual or mental health disorder need ongoing evaluation by healthcare personnel at routine visits because symptoms can be long term and the presentation can change through different developmental stages. In addition, it's important to determine whether any circumstance that might have led to a temporary problem has truly been corrected or only superficially changed because, if the circumstance remains the same, the child's problem may return or be manifested later in another way.

Examples suggesting achievement of expected outcomes are:

- Parents report reduction in overall anxiety symptoms to improve daily functioning due to compliance with treatment.
- Child reduces the number of self-harm behaviors during the coming month.
- Parents report decrease in child's disruptive behavior since child started therapy and/or prescription medication.

- Child with eating disorder increases daily caloric intake with no binge eating more days than not.
- Parents verbalize confidence in the care of child with an intellectual disorder and follow through with referrals and resources given, understanding child's full capabilities and limitations.

## Health Promotion and Risk Management

Nurses play a key role in assessing and promoting the mental and intellectual health of children and their families at health maintenance visits, establishing environments for children and families that can foster mental health. Although it is impossible to keep children, like adults, completely shielded from stress, preventive education and actions can be taken to increase the capacity of children and families to better cope with life's stressors and the difficulties that follow. [Table 54.1](#) lists some helpful observational and interview data for assessing these areas.

**TABLE 54.1** Guidelines for the Mental Health Interview of a Child

Observational Data	Examples of Possible Findings
General appearance	Height, weight, grooming and hygiene, nutrition, physical health, rhythmic movement or tics
Motor behaviors	Fine and gross balance, unusual motor activity
Speech and language	Receptive, expressive; content, tone, and articulation
Affect	Predominant emotion (depressed, angry, anxious, happy, labile), emotional reactions to content of interview (appropriate, inappropriate, congruent)
Thought process	Estimated intellectual level via language and knowledge base (organization and thought content); orientation (to person, place, time); perceptual distortions (hallucinations, illusions, obsessions, delusions); attention span, learning disabilities
Ability to relate to evaluator	Eye contact; attitude toward interviewer (negative, positive, shy, suspicious, withdrawn, friendly, self-centered)
Behaviors displayed during interview	Impulsivity, aggression, inhibition, distractibility, low frustration tolerance, ability to have fun, sense of humor, creativity

### Interview Data

Interpersonal relationships	Attitudes toward and perceptions of family, siblings, peers, transitional objects (inanimate objects used to allay anxiety); social skills and relationships with peers, parents, and siblings; conflicts; behavior problems; adjustment to changes in routine or new situations
Self-concept and image	Self-appraisal (does child like self?), comparison of self with others (siblings, peers). What would the child like to change about self? Sense of pride in accomplishments, sex role, and gender identity
Conscience or moral reasoning	Understands right and wrong; is able to express common judgments or values.

Various factors have been associated with an increased risk for mental health disorders in children, including trauma, poverty or neglect, difficult temperament or attachment problems, medical illness, or major losses to the family such as divorce or death. A thorough assessment of the child and family can provide clues to the existence of such possible risk factors and suggest strategies to reduce their impact through counseling or early intervention programs, helping to minimize the overall effects of the disorder on the child and family.

## Classification of Mental Health Disorders

Psychopathology in children is classified according to the American Psychiatric Association (APA) and described in the *Diagnostic and Statistical Manual of Mental Disorders (5th ed.; DSM-5)* (APA, 2013). The *DSM-5* is the fifth and newest revision of the manual that is used to facilitate a classification system for more reliable diagnoses. The manual was created in harmony with the World Health Organization's *International Classification of Diseases*, or ICD-10 (APA, 2013). The *DSM-5* is not only an important manual in the standardization of language and understanding of important health diagnoses; it is essential for billing and insurance purposes and therefore treatment of children and families with these disorders. The *DSM-5* is organized into groups of conditions based on common features including period of onset and intellectual, behavioral, and psychological symptoms.

## Neurodevelopmental Disorders

Neurodevelopmental disorders, although not related by etiology, typically share a common feature in that there is a delay in one or more areas of development such as attention span, cognition, language, affect, and social or moral behavior. Because these behaviors are interrelated, a delay in one area co-occurs with development in another

area in approximately 50% of cases ([The Arc, 2016](#)). This category includes intellectual disability, communication, autism spectrum, attention deficit hyperactivity, specific learning, and motor disorders.

## INTELLECTUAL DISABILITY

Intellectual disability is commonly defined based on two criteria: intellectual functioning significantly below average—an IQ of 70 to 75 or lower with onset during the developmental period—and concurrent deficits in adaptive functioning in conceptual, social, and practical domains ([APA, 2013](#)). The IQ level of 70 to 75 was chosen as the upper limit of intellectual disorder because most children who score below this level are so limited in functioning that they require special services, protection, and schooling. For infants, because available intelligence tests do not yield numerical values, a clinical judgment of significant sub-average mental status function is necessary.

Approximately 1% to 3% of children in the United States are diagnosed with intellectual disability ([APA, 2013](#); [The Arc, 2016](#)). This does not occur as the result of a single cause but from genetic abnormalities such as fragile X syndrome and trisomy 21 (Down syndrome) or metabolic disorders such as untreated congenital hypothyroidism. In addition, brain malformations; maternal disease such as measles and meningitis; environmental influences such as alcohol, drugs, or other toxins while in utero; or the interplay of several genes with environmental factors (multifactorial causes) are possible sources in some children ([APA, 2013](#)) ([Box 54.2](#)).

### BOX 54.2

#### Common Causes of Intellectual Disability

- Chromosomal abnormalities such as Down syndrome and fragile X syndrome
- Infection in utero, such as rubella or cytomegalic inclusion disease
- Anoxia at birth from such causes as umbilical cord compression
- Fetal alcohol spectrum disorder
- Inherited metabolic disorders such as phenylketonuria or Tay-Sachs disease
- Head trauma, lead poisoning, or hypothyroidism
- Brain malformations such as anencephaly
- Very low birth weight
- Infections such as measles encephalitis
- Autism spectrum disorder

Children with intellectual and adaptive functioning deficits are seen in healthcare settings for their specific diagnosis. They continue to come to healthcare settings throughout their lives for the same reasons as all children—for well-child or ambulatory health maintenance visits, for treatment of lacerations or urgent care needs in emergency departments, or for treatment of ongoing medical or surgical needs in-patient

care units. For these reasons, nurses need to be skilled in meeting the needs of children with intellectual disability.

## Classification

It is unfair to categorize children only according to the results of intelligence tests; therefore, intellectual disability is determined by both IQ testing that assesses intellectual functioning and careful clinical evaluation that assesses adaptive functioning. Diagnosis is specified as mild, moderate, severe, or profound, defined on the basis of adaptive functioning, as this determines the number of supports required such as communications, social ability, and independent living (APA, 2013). As a child health nurse, assessing for physical illness in children with intellectual disability is challenging because they may not appreciate the seriousness of symptoms or be able to report them as well as other children.

### Mild Intellectual Disability

About 85% of children who are diagnosed with mild intellectual disability have an IQ range between 50 and 70. During preschool age, these children exhibit difficulties in acquisition of academic skills, such as reading, writing, math, time, or money, and are typically more concrete in their problem solving (APA, 2013). Socially, they are observed as less mature, have a limited understanding of risk, and demonstrate poorer affect regulation than their similarly aged peers. As adults, they can usually achieve adequate social and vocational skills for minimum self-support and independent living but need guidance and assistance with complex daily living tasks, such as grocery shopping, banking, health decisions, or childcare.

### Moderate Intellectual Disability

Children in this category have an IQ ranging between 35 and 49 and represent about 10% of children with moderate intellectual disability. For these children, language and preacademic skills develop slowly during preschool age, and continue to advance slowly through school, typically peaking with academic skills at the elementary level (APA, 2013). Socially, communication is much less complex with poor interpretation of social cues when compared to peers of a similar age (APA, 2013). Through adolescence and into adulthood, simple activities of daily living such as dressing, eating, hygiene, and household chores can be learned through extended periods of teaching and caregiver support (APA, 2013). As adults, they may be able to contribute to their own support by performing unskilled or semiskilled work under close supervision.

### Severe Intellectual Disability

Children in this group have an IQ range between 20 and 34 and represent only about 4% of children with severe intellectual disability. These children develop a limited understanding of language and academic skills, with minimal acquisition of

communicative speech, such as with single words and phrases, or augmented means (APA, 2013). They require parental support in all activities of daily living, such as eating, bathing, and hygiene, and constant supervision is mandatory to ensure safety.

### Profound Intellectual Disability

The IQ of children in this group is less than 20. Less than 1% of children with intellectual disability fall into this group. Children demonstrate only minimal capacity for sensorimotor functioning and are nonverbal and nonsymbolic in communication (APA, 2013). Some are able to respond to training in minimal self-care, such as tooth brushing, but only very limited self-care is possible. They need a highly structured environment and are dependent on others for activities of daily living, help, and supervision for safety.

### Assessment

Assessment for children with suspected intellectual disability is completed through individualized IQ testing, culturally sensitive standardized measures, and careful clinical evaluation and judgment. Early assessment is key and should be done as soon as healthcare providers or parents become aware of a delay in motor, language, or social milestones. Early assessment and diagnosis allow parents to appreciate and understand the needs of their child, adopt realistic expectations of their child, and identify and implement appropriate resources and supports.

Intelligence is routinely measured with individualized, standardized tests and must be interpreted with sound clinical judgment by professionals in the mental health field. Adaptive behavioral functioning, which may vary in different environments, is judged according to several methods, including standardized instruments for assessing mental status, social maturity, and adaptive skills with respect to cultural differences. A composite picture of life functioning is drawn from these multiple sources including family members, teachers, or childcare providers.

Parents may initially react to the diagnosis of intellectual disability in the same way as those who have been told that their child has a chronic or fatal illness—with a grief reaction. This may manifest as denial, anger, bargaining, or depression. This grief reaction may resurface among parents, particularly at times when the child would have reached milestones in life, such as the first day of school or at the age the child would have obtained a driver's license. Be certain when working with such families to help them develop plans that are realistic for their individual child that maximize the child's capabilities and opportunities for success (Yildirim, Hacıhasanoğlu Aşilar, & Karakurt, 2013).

### Therapeutic Management

To aid in planning, parents need a realistic prognosis for their child. This may be difficult to offer in early life because infant intelligence tests are not accurate and more

sophisticated tests are difficult to administer until the preschool years. Because prediction based on these early tests involves some subjective input, a child's potential may be overrated or underrated when using these. Once parents have a realistic expectation based on the best judgment possible, however, they are ready, with guidance, to help their child achieve his or her full potential. Encourage parents to seek early intervention, education, and support in their community through involvement in support groups, parent education, agencies like The Arc (<http://www.thearc.org>), and their local chapters. Furthermore, validate parents' and caregivers' own needs, such as encouraging respite care through trusted family members, friends, or their local department of social services.

### Concept Mastery Alert

A child's ability to cope and adapt to various situations are often affected by intellectual disabilities. Ensure that caregivers are aware of the full impact of intellectual disabilities so that they may appropriately help the child to cope and adapt.

## Nursing Diagnoses and Related Interventions

Parents of children with intellectual disability have several important decisions to make concerning care of their child.

**Nursing Diagnosis:** Parental knowledge deficit related to healthcare needs for a child with an intellectual disability

**Outcome Evaluation:** The parents will be able to verbalize and identify the child's healthcare needs and demonstrate strategies to meet those needs.

*Home and Family Environment.* Children with intellectual disabilities are ideally cared for best in a consistent, nurturing, family environments with emphasis on developing their social skills, receiving adequate stimulation, appropriate supervision to monitor at-risk behaviors, and achieving mastery in their activities and skills.

This type of home environment requires parents to allocate a great deal of time, effort, and responsibility, which increases as both the child and the parents age. Parents find that their freedom to go on vacation or to have an adult life apart from the child may be restricted, and disproportionate time spent with the child may leave other children in the family feeling left out, unloved, or burdensome.

The nurse can provide parents the opportunity to discuss the challenges they have in meeting their child's needs in a nonjudgmental manner and discuss options available to the family if they are unable to care for a child at home. An in-home health aid, suitable foster home placement, or group home (6 to 12 children living in

a home with assigned counselors) may be necessary to best provide a care setting congruent with the child's needs. Finally, connect families with children with intellectual disabilities to community supports and resources.

*Health Maintenance Needs.* Children with intellectual disability need the same health maintenance supervision as all other children. At healthcare visits, reinforce and review precautions against unintentional injuries. Remind parents to treat their child according to the child's intellectual age, not the chronologic age. For instance, all 2-year-old children might turn on the burners of the stove to see the flame if they could reach them. Most 2-year-olds are unable to do this, however, because they cannot reach that high. In contrast, a child who is 6 years old but operates at a 2-year-old level can reach the burners, so parents have to maintain constant vigilance to prevent that from happening.

*Illness.* Children with intellectual disabilities are at increased risk to develop a degree of depression by school age as they attempt to fit into a school system geared for higher functioning children (McGillivray & Kershaw, 2013). It may be more difficult to detect this or other illness in children than usual because they may not communicate the severity of symptoms or be able to describe symptoms clearly. For example, children experiencing pain may respond to it by generalized crying, the same as infants, because they do not know the terms sharp, nagging, or aching. For older children, a pain scale with faces can be a helpful indicator of pain (Wong & Baker, 1988). Encourage parents to carefully observe their child for symptoms such as tugging at an ear, refusing to swallow food, rapid breathing, or limping because these symptoms will help to localize the affected area of discomfort. When they call healthcare personnel, parents may be apologetic about their lack of ability to judge their child. Let them know you understand that detecting illness in their child can be challenging. Reassure them they have done the correct thing by calling and reporting their concern.

When children with an intellectual disability are seen in an emergency department or an ambulatory setting for care, they may need more explanations of what is expected of them than other children. The average 6-year-old child, for example, sees you with a thermometer in your hand and thinks, "I'm going to have my temperature taken." When you explain what you are going to do, it is not really news, only a confirmation of what the child had already guessed. A child who is intellectually disabled may not be able to make this association between the thermometer and what you are going to do; your explanation, therefore, is the first introduction to the event, so it is necessary for it to be thorough and appealing.

When children are admitted to the hospital for continued care, be certain your nursing plan of care, again, considers the child's intellectual age, not the chronologic age, because this can help you decide the appropriate and necessary safety precautions, such as side rails or restraints or the way you explain preparations for procedures.

When children with intellectual disabilities are discharged from the healthcare facility, review with parents the signs and symptoms to look for to help ensure continued good health. Remember that such signs may be more difficult for parents to elicit, depending on the degree of the child's intellectual disability. Be sure parents have a telephone number they can call to seek further information or advice if they are unsure of their own observations in the period immediately after discharge.

*Education.* Most children who are intellectually disabled do well in preschool programs, possibly giving them a head start in learning to socialize with peers and to develop fine and gross motor coordination.

The school chosen for the child depends both on the degree of intellectual delay and on the school settings available in the community. Whenever possible, it is mandatory that children with intellectual disabilities be included in regular classes (termed inclusion or main streaming) to provide access to important educational and social experiences (Fig. 54.1) because this arrangement offers children maximum stimulation for learning. The arrangement also helps them learn to work and socialize with peers, something they will need to do for the rest of their lives. It may be necessary to advocate for a child to be reevaluated or included in a usual school classroom. By federal law, children have the right to be educated in the least restrictive environment possible. They need an individualized education plan (IEP) based on their individual learning style and projected capabilities. In addition, they need safety instructions such as how to locate the correct bus for the trip home from school and education to report bullying if this should occur.

**Figure 54.1** A young man with Down syndrome at work. With appropriate training and support, individuals with Down syndrome can grow up to find meaningful employment and make valuable contributions to their communities. (Courtesy of Getty Images.)

### **Nursing Diagnosis**

- Impaired growth and development related to intellectual disability
- Impaired verbal communication related to intellectual disability
- Risk for injury related to aggressive behavior imbalance or physical impairments
- Impaired social interaction related to difficulty speaking and adapting socially
- Interrupted family processes related to having a child with intellectual disability
- Self-care deficit related to changes in physical mobility and/or lack of developmental maturity

### **Outcome Evaluation**

- Child performs self-care within limits of disorder; expresses feelings of mastery with accomplishments.
- Families and children are able to identify coping strategies for successful communication and a safe environment for the child with an intellectual disability.

- Families are able to identify the resources in the community to care for the child with intellectual disability.

The overall goal of self-care may not be to help the child become completely independent but to help the child function at the maximum capability able to be achieved and develop sense of self-efficacy.

*Self-Care Activities.* Learning the maximum amount of self-care possible provides children with intellectual disability with a sense of control and accomplishment, essential in child development. Carefully assess at healthcare visits whether children may benefit from adaptive equipment to achieve activities of daily living, such as brushing teeth, combing hair, taking a bath, and eating, in order to develop mastery of these important skills. Even after children learn how to perform these skills, remind parents they may need to provide continued reminders or review of the skill. Additionally, if children are hospitalized, allow them to continue these skills as much as possible, in order to reinforce already mastered self-care activities (Box 54.3).

### BOX 54.3

#### Nursing Care Planning Based on Family Teaching

#### TEACHING GUIDELINES FOR THE CHILD WHO IS INTELLECTUALLY DISABLED

**Q. Todd's mother says to you, "How can we make sure our son learns as much as he's able?"**

**A.** Here are some guidelines for teaching and learning:

- Break a task down into separate small steps because short-term memory is often possible when long-term memory is not. Feeling success at learning a small step can provide motivation to continue to the next step.
- Demonstrate the skill to be learned. Seeing a skill performed is generally better than just hearing it explained.
- Reduce the number of extra stimuli present. Faced with too many stimuli, a child cannot focus attention on the task to learn (or realize the task is more important than surrounding stimuli).
- Introduce motivators for learning, such as generous praise. Remember that accomplishing even the most simple skill may be very difficult for your child. Learning to tie shoes may take the same effort as another child spends learning mathematics.
- Keep things simple. Children with intellectually disability may have difficulty with learning principles or abstractions. They may be able to learn to wash their hands, for example, but not why they should wash them (other than that it pleases you).
- Remember to be patient and flexible with the child and the task at hand. If possible, work in collaboration with the child to problem solve and improve

success.

*Play.* Children with intellectual disabilities enjoy play like any child. Play is an important activity to help children develop mastery, self-esteem, and problem-solving skills. Caution parents to provide toys that are appropriate both for the child's developmental age and chronologic age. In addition, be certain children are guided toward active as well as sedentary play experiences so they do not become obese from inactivity, a concern for children with intellectual disabilities (Casey & Rasmussen, 2013).

*Social Relationships.* Children with intellectual disabilities may become aggressive in social situations because they are unable to communicate or compete readily with peers due to delayed language development (Davies & Oliver, 2013). For some children, speech therapy may be necessary to help them articulate sounds correctly to improve these skills. Talking picture boards (boards with pictures on them, available commercially or made by parents), to which children can point if they want something, is a way for parents to help vocabulary building and effective communication.

Encourage parents to enroll children in preschool programs to help them learn to be comfortable with other children at the earliest time possible, if appropriate. For a school-age child, participating in organized groups such as Girl Scouts or Special Olympics is an excellent way to give them the opportunity to interact with others and feel successful, important tasks for any child. Teach parents to be sensitive to their child's risk of becoming victims of bullying. Review with all parents the importance of telling their child to report bullying to them so action against this can be taken and making relationships with teachers and advocates for the child at the school as well. Children with intellectual disabilities may not be able to advocate for themselves; children need to be aware of their responsibility to report bullying to protect these special children (Starke, 2011).

*Preparation for Adulthood.* As children reach adolescence, they need orientation to sexual responsibility, the same as all children. Girls are able to understand a simple explanation of menstruation and necessary menstrual hygiene. Both boys and girls need explanations of how pregnancy occurs and the measures they need to take to prevent this as well as socially acceptable sexual activities and safer sex practices.

Adolescents can be prescribed contraceptives if needed. Be mindful the level of supervision and assistance required and available. If she lives with a responsible adult, an oral contraceptive to be given to her daily by that adult. Longer acting contraceptives, such as subdermal progestin implants, which do not require daily administration, also are available. Sterilization is not recommended because adolescents with intellectual disability may not appreciate the full implications of the procedure, and therefore, consent is not fully informed. If pregnancy should occur, an adolescent with an intellectual disability can be counseled regarding the

pregnancy. Should the adolescent decide to continue the pregnancy, assisting her through the pregnancy and planning safe care for her child is an important nursing responsibility.

### *What If . . . 54.1*

**Todd, who has intellectual limitations and autism spectrum disorder, is admitted to the hospital because he is critically ill with pneumonia. The nurse recognizes there might be other underlying reasons for the delay in care. What reasons might explain the parents' actions?**

### *QSEN Checkpoint Question 54.1*

#### **PATIENT-CENTERED CARE**

Parents of children like Todd, who has a moderate intellectual disability, often develop chronic sorrow or complicated grieving. Which of the following events would most likely increase sorrow for Todd's parents?

- a. After an extended time alone as a family, such as a vacation
- b. When Todd receives his scheduled immunizations
- c. When children Todd's age reach a milestone that Todd does not achieve
- d. After spending time with Todd's extended family

*Look in [Appendix A](#) for the best answer and rationale.*

## **AUTISM SPECTRUM DISORDER**

Autism spectrum disorder (ASD) is marked by difficulties in three main areas: social deficits, communications issues, and restricted behaviors, with onset in the early developmental stages, that impair everyday functioning ([The Arc, 2016](#)). Within the first 36 months of life, children with ASD often lack responsiveness to people around them, display gross impairment in communication skills, and produce bizarre responses to various aspects of the environment. It occurs in 1% of U.S. children or occurs as frequently as 1 in 68 children and more commonly in males ([The Arc, 2016](#)). As many as 50% of children with the disorder are also diagnosed with intellectual disability; many have coexisting mental health diagnoses ([Stafford, Talmi, & Burstein, 2012](#); [The Arc, 2016](#)). Any concern that immunization may precede or cause the disorder has now been ruled out ([Kirkland, 2012](#)). Nurses should counsel parents about these misconceptions and educate them about evidence-based immunization data.

### **Assessment**

Common symptoms of ASD are summarized in [Box 54.4](#). ASDs often are typically recognizable in children between 12 and 24 months but may be noticed earlier if the

condition is more severe (APA, 2013). The first symptoms of ASD noticed by parents are delay in language development, odd communication, lack of social interest, or unusual interactions, such as avoiding eye contact, and unusual play, with repetitive play and preference becoming more apparent as the child ages (APA, 2013). Parents may bring a child to a healthcare facility for the first time due to difficulties establishing relationships, delay in communication, or odd play; however, these may be caused by other disorders such as hearing impairment, language, communication, or movement disorders; attention deficit hyperactivity disorder; or prodromal schizophrenia and therefore should be ruled out (APA, 2013).

#### BOX 54.4

### Common Symptoms in the Child With Autism Spectrum Disorder

- Failure to develop social relations
- Stereotyped behaviors such as hand gestures
- Extreme resistance to change in routine
- Abnormal responses to sensory stimuli
- Decreased sensitivity to pain
- Inappropriate or decreased emotional expressions
- Specific, limited intellectual problem-solving abilities
- Stereotyped or repetitive use of language
- Impaired ability to initiate or sustain a conversation

The impairment in communication includes both verbal and nonverbal skills, and communication may be totally absent. For children with ASD who do speak, deficiencies in grammatical structure, an inability to name objects (nominal aphasia), and abnormal speech melody, such as question-like rises at the end of statements, may exist. **Echolalia** (repetition of words or phrases spoken by others) and concrete interpretation are also common findings. Nonverbal deficiencies include abnormal eye contact, poor use and understanding of body movements and gestures, and lack of facial expressions (APA, 2013).

Bizarre responses to the environment may include intense reactions to minor changes in the environment (perhaps screaming if a toy box is moved across the room), attachment to odd objects such as always carrying a string or a shoe, and a rigid demand for routine. For children with ASD, a minor disruption in their day, such as having a substitute teacher, may cause a physical or emotional breakdown. Signs in children prior to school age include repetitive hand movements (clapping or flapping) and constant body rocking; in these cases, early assessment is advised. It may be difficult to gain the child's attention as the child becomes intensely preoccupied by music or objects that revolve, such as a fan, the swirling water in the toilet bowl, or a spinning top. Aggressive actions, such as hitting, head banging, and biting, or the inability to feel pain, may also be present.

Children are said to have a **labile mood** (crying occurs suddenly and is followed immediately by giggling or laughing or vice versa). They may overrespond to sensory stimuli, such as light or sound, but then be unaware of a major event in the room, such as the sound of a fire alarm.

In contrast to these mannerisms, long-term memory and “savant” skills (exceptional skills such as virtuoso piano playing) may be excellent (Bölte, Duketis, Poustka, et al., 2011). For example, children with ASD may be able to recall dates and spoken words from conversations that took place years before. This excellent memory previously led to the belief that most of these children have usual intelligence, but around 50% of children with ASDs have an intellectual disability as well (APA, 2013).

## Therapeutic Management

ASD is a perplexing condition because of the extreme variability a child may exhibit. Primary treatment for children with ASD includes educational, compensatory, and behavior modalities, such as the evidence-based applied behavior analysis (ABA) treatment based on the associations between behavior and learning (The Arc, 2016). Treatment such as ABA is typically very intensive and can involve the entire family, taking place in the home, at agencies, at school, or in the community; although treatment is unique to each child, parental involvement is essential to facilitate development of self-care skills and process with therapy (Carter, Lane, Cooney, et al., 2013). No specific medications are approved for the treatment of ASD; however, medications may be used to modify troublesome symptoms, such as high energy, inability to focus, depression, or seizures (Autism Speaks, n.d.).

Atypical antipsychotic medications, such as risperidone (Risperdal) and aripiprazole (Abilify), are approved by the U.S. Food and Drug Administration (FDA) for children and teens with ASD. Advantages of these agents include improving sociability while decreasing tantrums, aggressive outbursts, and self-injurious behavior (Volkmar, Siegal, Woodbury-Smith, et al., 2014). “Off-label” medications may be selected to relieve significant suffering in persons with ASD in the absence of significantly large and targeted studies. These medications include selective serotonin reuptake inhibitors (SSRIs),  $\alpha_2$  agonists, antipsychotics, mood stabilizers, and selective norepinephrine reuptake inhibitors (SNRIs) (Volkmar et al., 2014). Melatonin is an over-the-counter medication that may be recommended to reduce sleep difficulties (Scheffer, 2011).

It is important for nurses to ask at healthcare visits whether parents are finding time for both care of their child and themselves because there is a danger that excessive parental stress can lead to child maltreatment (Hall & Graff, 2012). Encourage parents of children with ASD to seek support through organizations in the community to help support their own mental well-being and that of their families.

As children mature, they develop greater awareness of and attachment to parents and other familiar adults. A day care program can help promote social awareness. Some children may eventually reach a point where they can become passively involved in loosely structured play groups. A small number of children, typically with higher levels

of functioning, may be able to lead independent lives, although social ineptness and awkwardness may continue, especially if accompanied by intellectual disability. [Box 54.5](#) shows an interprofessional care map for a child with ASD.

## BOX 54.5

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR A SCHOOL-AGE CHILD WITH AUTISM SPECTRUM DISORDER

Todd, a kindergartner, is admitted to the 1-day surgery unit to have plaque removed from his teeth under conscious sedation. You observe Todd drumming on the table, running to the door, opening and closing the door, and then throwing pamphlets out of an information rack. His sister, who seems very underweight, tells you she is “at her wits’ end” trying to babysit Todd in the evenings while their mother works because his behavior is so disruptive. Todd’s father tells you he’s proud that his son is “all boy.”

**Family Assessment:** Child lives with two parents and sister in three-bedroom condominium. Father works as a sail maker; mother works part-time in local fish market. Father rates finances as “Not good. My wife wants to work more, but we can’t find anyone to watch Todd; he’s such a handful.”

**Patient Assessment:** A 5-year-old, slightly overweight male grasping toy dog tightly in his arms. Mother states, “He talks to the dog when he’s upset.” Tends not to interact with other children. Often repeats himself, asking “What’s your name?” and “How old are you” over and over. Mother feeds him mainly fast-food meals because he throws food if he doesn’t like the taste. Toilet trained but sometimes has accidents as he “forgets” to go. Needs supervision dressing because he loses track of task at hand. Refuses to let mother brush teeth. Mother says, “He gets upset and cries easily if his routine changes.” Attends special class in public school, as he was too disruptive in regular classroom.

**Nursing Diagnosis:** Impaired social interaction related to easy distractibility

**Outcome Criteria:** Child cooperates to extent possible with intravenous (IV) therapy and bed rest after conscious sedation.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess what self-care activities child completes for	Allow child to wear own clothes until under conscious	Self-care can offer a sense of control unless it becomes	Child cooperates to help with self-care to the

	himself.	sedation to avoid confrontation.	frustrating.	extent he is capable.
<i>Teamwork and Collaboration</i>				
Nurse/childcare specialist	Assess whether childcare specialist is available for consultation.	Consult with childcare specialist about what activities would be best for child who is easily distracted.	Games can become frustrating if they can't be completed in a short time period.	Childcare specialist visits with child and suggests at least two activities for period before surgery.
<i>Procedures/Medications for Quality Improvement</i>				
Nurse	Assess whether child has past experience with IV therapy and whether he took prescribed medication today.	Begin IV line in nondominant hand. Document medication given at home.	Use of nondominant hand allows child to complete small, frequent tasks. Documentation will help avoid medication toxicity.	Mother remains with child to ensure child does not remove IV line.
<i>Nutrition</i>				
Nurse/nutritionist	Assess what mother means by "fast-food" meals.	Discuss a diet with mother that doesn't involve so many fatty foods because child is overweight.	Child is overweight, a finding that can be caused by eating fat-heavy, fast-food meals.	Mother states she will try to find healthier foods that child will eat.
<i>Patient-Centered Care</i>				
Nurse	Assess what parent understands about good tooth care.	Talk to mother about techniques to make brushing teeth a game,	Plaque will form again on teeth if they are not brushed after this	Mother suggests two different ways, such as playing "Simon Says,"

		not a chore.	procedure.	that she could use to interest child in brushing teeth.
Nurse/primary healthcare provider	Assess what parents understand about autism spectrum disorder and if they have enough support to care for child with a potentially disruptive disorder.	Educate parents that autism is a disorder, not normal boyish behavior. Explore whether the family is aware of “respite” services in community.	As long as one parent continues to think of the child’s behavior as within usual limits, it will be difficult for them to be consistent in care.	Mother and father state they understand their son’s condition is one that needs therapy.

---

*Psychosocial/Spiritual/Emotional Needs*

---

Nurse	Assess whether child can take favorite toy to operating room.	Respect that toy dog is favorite toy and important to child.	Children can find comfort and security in a favorite toy.	Toy is respected by hospital and surgery personnel.
-------	---	--	---	---

---

*Informatics for Seamless Healthcare Planning*

---

Nurse	Assess whether parents have any questions about care at home after dental procedure.	Discuss that child will be sleepy for remainder of day after conscious sedation.	Conscious sedation is necessary because of child’s resistance to new procedures.	Mother repeats care needed for next 24 hours to safeguard a still sleepy child.
-------	--	--	--	---

---

***QSEN Checkpoint Question 54.2***

**INFORMATICS**

Todd has symptoms of autism spectrum disorder. When reviewing Todd’s electronic health record, which of these symptoms does the nurse recognize as being most consistent with this disorder?

- a. Lack of short-term memory
- b. Audio hallucinations
- c. Constant whirling around in a circle
- d. Severe depression or emotional lability

*Look in [Appendix A](#) for the best answer and rationale.*

## **SPECIFIC DEVELOPMENTAL DISORDERS**

Developmental disorders in children can include all or any of the following: learning disorders, communication disorders, and motor skills disorders. They can be diagnosed at varying times during childhood.

Learning disorders occur in approximately 5% to 15% of children in the United States. Although the degree may vary, the disorders involve a discrepancy between actual achievement and what is expected based on the child's chronologic age and intelligence (APA, 2013). Learning disorders affect keystone academic skills in reading, mathematics, or writing (Batorowicz, Missiuna, & Pollock, 2012). Children need IEPs to help them achieve at the highest level possible and prevent low self-esteem or deficits in social skills (DuPaul, Gormley, & Laracy, 2013).

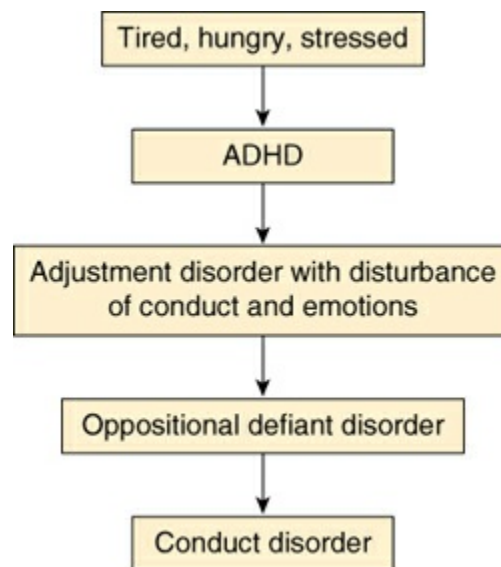

Communication disorders involve problems of speech (expressive production); language (form, function, and use) including expressive disorders, phonologic disorders, and stuttering; and communication, both verbal and nonverbal (APA, 2013). Like learning disorders, these conditions can lead to a lack of self-esteem unless a child receives support and encouragement from parents, teachers, and healthcare providers. Speech therapy is usually effective to improve these disorders and allow children to achieve sufficiently to become successful adults, and early prevention is best.

## **Attention Deficit and Disruptive Behavior Disorders**

All children can be disruptive and oppositional sometimes, particularly when tired, hungry, stressed, or upset; this type of behavior is not diagnostic of psychopathology (Melnyk & Jensen, 2013). Disruptive behaviors need to be evaluated thoroughly, and other causes ruled out. They are a diagnosis of exclusion. Attention deficit hyperactivity disorder and the disruptive behavior disorders may begin with behavior problems that are more frequent and more severe than typically observed in individuals at a comparable level of development (APA, 2013). As a result, parents may be initially unaware of the need for interventions. By the time they do seek help, they may be extremely distressed about the seeming unmanageability of their child.

Like ASD, these disorders need to be diagnosed as early as possible, before the child's behavior leads to a deteriorating level of self-esteem, compromised social skills, and complications in family functioning. The severity of behaviors associated with disruptive disorders, including attention deficit hyperactivity disorder, oppositional defiant disorder, and conduct disorder, can be specified as mild, moderate, and severe

(APA, 2013). Additionally, a large percentage of individuals diagnosed with a disruptive behavior disorder may also have comorbid conditions or may be at risk for learning disorders, depression, anxiety, substance use or abuse, or ASDs (APA, 2013). As a nurse, it is important to recognize the unique characteristics of every child and adolescent and plan accordingly. It may be helpful to consider the process of eliminating other explanations for disruptive behavior when evaluating these children and adolescents (Fig. 54.2).

**Figure 54.2** Severity continuum of symptoms in evaluating disruptive disorders. (Adapted from Lusk, P. [2013]. Disruptive disorders in children and adolescents. In B. M. Melnyk & P. Jensen (Eds.), *A practical guide to child and adolescent mental health screening, early intervention, and health promotion* [p. 179]. New York, NY: National Association of Pediatric Nurse Practitioners.)

## ATTENTION DEFICIT HYPERACTIVITY DISORDER

Attention deficit hyperactivity disorder (ADHD) is one of the most common neurobiologic conditions in childhood that can also persist into adulthood. It is a persistent pattern of inattentive or impulsive symptoms, or both, present before the age of 12 years, that causes impairment in at least two settings (APA, 2013). Conservative estimates suggest 4% to 12% of school-age children are diagnosed with ADHD, with boys affected more frequently than girls. Although the cause is unknown, environmental (such as very low birth weight [ $<1,500$  g]), genetic, and physiologic factors can contribute to ADHD; in fact, ADHD is higher in families with a biologic history of the disorder (APA, 2013). Therefore, environmental and behavior modification as well as pharmacologic therapy can be used with success, a fact that may support the theory of varying causes.

The disorder is characterized by three major behaviors—inattention, impulsiveness, and hyperactivity—and can present differently, depending on the age at presentation.

Inattention can include symptoms such as difficulty organizing tasks and a reluctance to do tasks that require mental effort over time. Impulsiveness includes a child acting before thinking and therefore having difficulty with such tasks as waiting his or her turn, blurting answers before a question is completed, and interrupting or intruding on others' conversations. With **hyperactivity**, children may shift excessively from one activity to another and can be described as “on the go” or “acts as if driven by a motor.”

## Assessment

Many parents recognize excessive motor activity when the child is a toddler, although symptoms are difficult to distinguish from normative behavior until the age of 4 years. Although the preschool-age child often presents with hyperactivity and impulsivity, as the child ages and moves through older grades, inattention may become the predominant manifestation. During adolescence, symptoms of hyperactivity are usually limited to fidgeting or an inner feeling of restlessness or impatience (APA, 2013). According to population studies, ADHD is more common in males than females, with a ratio of 2:1 in children and 1.6:1 in adults. In women, inattentive features are more common during presentation and may escape diagnosis because of less disruptive behavior (APA, 2013).

The criteria for diagnosis of ADHD includes a thorough initial history, physical examination, and completion of evidence-based rating scales by an individual who is familiar with the child, such as parents, teachers, primary care providers, and other caretakers (Melnyk & Jensen, 2013). A good initial history should include a complete birth history and environmental history and consider developmental milestones, dietary history, social history (including child abuse, neglect, and foster care), and past infections such as encephalitis. Additionally, a family history is important to review, as ADHD is more common in first-degree relatives. The physician or nurse will perform the physical examination, which is designed to rule out other causes of behavior problems. For example, a child with visual impairment who is unable to see the board may not have ADHD but gets “off-task” because he or she cannot see assignments clearly. Other medical causes will need to be examined, and testing will vary depending on the information gained from the history. Evaluations include height, weight, body mass index (BMI), vision, hearing, complete blood count (CBC) with differential (to rule out anemia), a thyroid-stimulating hormone (TSH) and free thyroxine (T<sub>4</sub>) test (to rule out thyroid disorders), a lead screen, a genetic screen, and a toxicology screen. The physical exam is also important to assess for comorbid conditions that are common with ADHD, including specific learning disabilities (10% to 40%), oppositional-defiant disorder (30% to 60%), depression/anxiety disorders, bipolar disorders, fetal alcohol affect, Tourette syndrome, and psychosocial morbidities.

As a rule, children with ADHD do not have a deficit in intelligence, although they may seem to because of their impulsive behavior and an unawareness that their behavior is upsetting to family, friends, and teachers. On physical assessment, they often show many “soft” neurologic signs, such as difficulty performing tests such as a finger-to-

nose test or rapid hand movements (touching one finger after another with the thumb). Children with ADHD also tend to show “mirroring” with these movements (their second hand imitates what the first hand is doing). Cerebellar difficulty may be evidenced by the inability to perform a tandem walk or a heel-to-shin test. Children may not show the normal responses of graphesthesia (ability to recognize a shape that has been traced on the skin) or stereognosis (ability to recognize an object by touch). When asked to stand with arms outstretched, **choreiform movements** (aimless movements), such as rising of the fingers, are often present. More definite neurologic signs, such as a unilateral Babinski reflex, may also be present. Testing children through the use of games may be necessary so that their attention is maintained long enough to complete the assessment.

IQ testing is used to document intelligence. The Wechsler Intelligence Scale for Children (WISC), the test most often chosen, consists of two portions: a verbal scale and a performance scale. A child is given three final scores: verbal IQ, performance IQ, and a combination or full-scale IQ. The child with perceptual and motor deficits tends to do poorly on the performance scale but average or better on the verbal scale. Children with language difficulty typically do poorly on the verbal scale but average or greater on the performance scale. Children with ADHD show a “scatter” pattern on both performance and verbal portions, doing well on some portions and poorly on others. Because they have difficulty filtering out stimuli, they tend to do poorly on group-administered intelligence tests. For this reason, test results are more accurate if they take IQ tests individually. Be certain that neurologic examinations are performed in rooms free of distractions such as attractive toys for this same reason. Children’s behavioral and emotional functioning skills are also assessed across a variety of settings with checklists (completed by children, parents, and teachers) and/or direct observation in classroom and home settings. Completion of evidence-based rating scales is important during the diagnostic phase as well to monitor progress with the treatment plan.

Children with ADHD are often referred to a healthcare facility by school personnel due to difficulty achieving in school. Parents may notice their child’s difficulty settling down to tasks and use excuses such as “he’s adventurous” or “every child is different.” Parents may need time to accept the child’s diagnosis as one that interferes with learning. Because caring for the child can be exhausting, parents may be unaware themselves of the strain the child’s symptoms have produced in their family system.

## **Therapeutic Management**

A variety of treatment methods are used, often in combination, in the management of children with ADHD.

### **Environmental Modification**

Construction of a stable learning environment is crucial for children with ADHD so instruction can be free from the distractions of an entire class. Some parents may have

difficulty accepting special schooling for their child (the intelligence test, after all, said their child was normal or even above average). In the school environment, ADHD may negatively affect academic performance. Children and teens with ADHD may miss important educational concepts, exhibit inconsistent development of skills, and lack organizational skills. Many children and teens with ADHD may benefit from educational accommodations provided under the federally mandated 504 Plan. These might include preferential seating, extended time for test taking, a written list of assignments and due dates, and note-taking support. Healthcare personnel can be instrumental in helping parents understand that their child's condition interferes with school functioning and that a special program will offer their child the best chance to succeed. Parents and teachers can help the child manage the specific challenges of ADHD. The main goal of behavior management is to increase appropriate behavior and decrease negative behavior. Children and teens with ADHD respond best in an environment, both at home and at school, that is structured and predictable, with clear and consistent rules and expectations. Encourage parents to be fair but firm and to set consistent limits to reduce arguments. Teach parents to give instructions slowly and to make certain they have their child's attention before beginning instructions, such as kneeling down to eye level. Breaking down a chore into several steps may help (get the toy box is one step; pick up the toys is a second). Consequences need to be established and discussed ahead of time and delivered immediately. If a child has difficulty making decisions because of easy distractibility, a question such as "Do you want to wear your red or your blue shirt today?" is less effective than a statement such as "Here is your blue shirt to wear today." Also encourage parents to understand, when they correct behavior, that anger is normal but should be directed at the child's disruptive behavior and not at some incident that happened because of the child's inability to sequence, filter, or integrate concepts. Urge parents to make sure their child recognizes their anger is at the behavior, not the child. It is easy for children with ADHD to develop poor self-esteem because, although they are intelligent, they face extra challenges in order to succeed. Helping parents build, not hinder, their child's self-esteem at every developmental stage possible is an important nursing action.

## Family Support

Parents of a child with ADHD may have more frequent healthcare encounters because of unintentional injuries, such as lacerations or simple burns. Ask parents at these visits if they are having difficulty managing the challenge of raising a child who exhibits so much activity. Help them to understand that because of a very complex and as yet ill-understood syndrome, the behavior is the best their child can achieve. Organizations such as Children and Adults with Attention-Deficit/Hyperactivity Disorder (CHADD), Attention Deficit Disorder Association (ADDA), and the Attention Deficit Information Network (AD-IN) may have local, community chapters and may also be available online.

Although hyperactivity fades with late adolescence, some children and teens with

ADHD continue to experience problems with impulsivity and inattention into adulthood. They may need counseling to find a career that fits with these behaviors and allows them to succeed as adults.

## Medication

Medication management is a proven treatment for many individuals with ADHD, but not all children and teens with ADHD need to take medication. Those with milder forms may be successful with a structured environment and firm, but fair types of discipline and reward. The decision to use medication is the parent's personal decision, and the nurse can support the parents by providing accurate information about the medications, expected response, and side effects. Several medications are helpful in reducing the excessive activity of children with ADHD as well as lengthening attention span and decreasing distractibility so they can function in school (Box 54.6). Stimulant medications, methylphenidate, and amphetamines are the most frequently prescribed for individuals with ADHD. There are short-, intermediate-, and long-acting formulations as well as methylphenidate transdermal (Daytrana) in a patch form. Stimulants work by stimulating dopamine receptors so there is more regular nerve transmission, which results in increased attention span. Unfortunately, the drug has side effects of insomnia and anorexia. Administering the drug early in the day may relieve the insomnia and decreased appetite can be addressed by administering the medication before breakfast and offering nutritionally sound snacks between meals. The nurse should be aware of the type of dosage, whether it is a prompt-release, intermediate-release, or extended-release preparation. Most prescribers will start with a prompt-release preparation and switch to an extended release product once the maintenance dose is determined. One advantage of extended-release preparation is single, daily dosing, which may eliminate the lunchtime dose and the need for a visit to the school nurse. There is a "black box warning" from the FDA regarding the risk of stimulants in those with a structural heart defect and should not be used in those with a history of alcohol or substance abuse. A thorough history should be completed and documented. Be certain at healthcare visits to measure height and weight to assess if long-term appetite suppression is causing weight loss. Caution parents that this drug offers a "high" to children who do *not* have ADHD, so their child must be conscientious that the medication is not stolen by other children to use for an euphoria effect (Viana, Trent, Tull, et al., 2012). Other medications that may be used for ADHD include nonstimulant medications, atomoxetine (Strattera), SNRIs, and centrally acting adrenergic agents, guanfacine (Intuniv, Tenex) and clonidine. Atomoxetine may be a first-line medication for children with ADHD who cannot tolerate stimulants. Atomoxetine must be used cautiously with children because of a "black box" warning about the increased risk of suicidal ideation. Additionally, it takes approximately 6 weeks for the full effect to be realized; if there is an adverse effect (AE), it could take longer to resolve than an AE with a stimulant (Klykylo, Bowers, Weston, et al., 2014). Centrally acting adrenergic agents work by strengthening actions in the prefrontal cortex, which includes regulation of attention, planning, impulse

control, and processing (Strange, 2008). Guanfacine is available in both immediate- and extended-release formulations. Kapvay, an extended-release clonidine, has been approved by the FDA for monotherapy or adjunctive to stimulants (Hejazi, 2012).

## BOX 54.6

### Nursing Care Planning Based on Responsibility for Pharmacology

#### STIMULANT MEDICATION

1. Methylphenidate hydrochloride (Ritalin, Concerta, Daytrana), dexamethylphenidate (Focalin)
2. Dextroamphetamine (Dexedrine), dextroamphetamine mixed salts (Adderall), lisdexamfetamine (Vyvanse)

**Classification:** Central nervous system stimulants

**Action:** Acts paradoxically in children with attention deficit hyperactivity disorder, possibly by stimulating dopamine receptors to calm rather than stimulate activity (Martinez-Raga, Ferreros, Knecht, et al., 2017)

**Pregnancy Risk Category:** C; Schedule II

#### Dosage:

1. Methylphenidate: Start with a prompt release formulation; once the maintenance dose is determined, an extended-release may be indicated. The starting dose is approximately 0.3 mg/kg before breakfast and lunch. Dosage can be increased by 0.1 mg/kg weekly and should not exceed 60 mg/kg/day. The transdermal system methylphenidate hydrochloride (Daytrana) is approved for children aged 6 to 17 years; initially apply one 10-mg patch for 9 hours; this may be titrated based on response and tolerability. Dosage can be increased by 5 mg weekly. Patches are available in 15-, 20-, and 30-mg doses. The patch should be applied 2 hours before the desired effect and removed 9 hours after application.
2. Dextroamphetamine, dextroamphetamine mixed salts: 0.3 to 1.5 mg/kg/day given one to three times daily. The starting dose for lisdexamfetamine is 30 mg/day in children ages 6 years and older; the dosage can be adjusted in increments of 10 to 20 mg weekly to a maximum of 70 mg/day.

**Possible Adverse Effects:** Nervousness, insomnia, anorexia, pulse rate changes, hypertension or hypotension, tachycardia, leukopenia, anemia, and growth suppression. Excessive use with caffeine-containing products (coffee, cola, tea) may cause increased central nervous system (CNS) stimulation.

#### Nursing Implications

- Administer the drug exactly as prescribed and instruct parents to do the same. Reinforce proper administration of once-daily extended-release form.
- Instruct parents to have child swallow extended-release tablets whole and to refrain from chewing or crushing them; however, dextroamphetamine (Dexedrine

Spansules), dextroamphetamine mixed salts (Adderall XR), and lisdexamfetamine (Vyvanse) capsules can be opened and sprinkled on applesauce or yogurt for children who are unable to swallow pills or capsules.

- Instruct the parents to administer oral doses of the drug before 6 PM to prevent interference with sleep.
- Advise the parents and child to avoid over-the-counter drugs, such as cold remedies and cough syrups that contain alcohol.
- Obtain baseline vital signs, including height and weight, and monitor changes at follow-up visits.
- Arrange for follow-up laboratory tests, including complete blood count, differential, and platelet count for children on long-term therapy.
- Stress the need for adequate nutrition by offering snacks between meals in light of possible anorexia.
- The safety of using methylphenidate for children younger than 6 years of age has not been established.
- The U.S. Food and Drug Administration (FDA) has approved short- and intermediate-acting dextroamphetamines for children as young as 3 years of age.

## NONSTIMULANT MEDICATION

### 1. Atomoxetine (Strattera)

**Classification:** Selective norepinephrine reuptake inhibitor (SNRI)

**Action:** Selectively inhibits the presynaptic transporter of norepinephrine to increase attention span

**Pregnancy Risk Category:** C

**Dosage:** In individuals weighing <70 kg, 0.5 mg/kg/day initially; may increase the dose every 3 days to a daily target dose of 1.2 mg/kg, given once or twice daily; for individuals >70 kg, initially 40 mg daily and may increase the dose every 3 days to a target daily dose of 80 mg/day given once or twice daily.

**Possible Adverse Effects:** Dizziness, fatigue, insomnia, nausea and vomiting, constipation, decreased appetite, and suicidal thoughts

#### Nursing Implications

- Monitor blood pressure, pulse, and growth (body weight and height).
- There is an FDA “black box warning” for suicidal ideation; monitor for notable changes in behavior that could indicate the emergence of suicidal thoughts.

### 2. Guanfacine (Tenex [immediate-release], Intuniv [extended-release])

**Classification:**  $\alpha_2$ -Adrenergic agonists

**Action:** Facilitates neurotransmitter release to the prefrontal cortex, which is responsible for activities related to executive function, such as increasing attention and decreasing impulsivity

**Pregnancy Risk Category:** B

**Dosage:** Starting dose is 1 mg to maximum of 4 mg

**Possible Adverse Effects:** Hypotension, bradycardia, drowsiness, trouble sleeping, stomach pain, constipation, and dizziness

#### **Nursing Implications**

- Immediate-release and extended-release preparations should not be interchanged.
- Monitor blood pressure and pulse, particularly during any dose adjustment.
- Monitor attention span, impulse control, and interactions with others.

### **3. Clonidine hydrochloride (Kapvay)**

**Classification:**  $\alpha_2$ -Adrenergic agonists

**Action:** Facilitates neurotransmitter release to the prefrontal cortex, which is responsible for activities related to executive function, such as increasing attention and decreasing impulsivity

**Pregnancy Risk Category:** C

**Dosage:** 0.1 mg daily at bedtime; can increase the dose by 0.1 mg and increase the frequency to twice daily; maximum dose is 0.4 mg/day

**Possible Adverse Effects:** Drowsiness, dry mouth, and constipation

#### **Nursing Implications**

- Swallow extended-release tablets whole; do not crush, break, or chew.
- Advise patients to avoid driving or other activities requiring mental alertness until response to the medication is known.
- The medication should not be stopped abruptly because of the risk of withdrawal; the dose should be tapered slowly.

## **OPPOSITIONAL DEFIANT DISORDERS**

Oppositional defiant disorders (ODDs) consist of a pattern of irritability, defiant behaviors, and vindictiveness that result in disturbed functioning in academic and social domains. Children and adolescents with ODD typically have difficulty controlling their temper; such anger is often directed at an authority figure. It is important to distinguish behavior that is within normal limits from behavior that is symptomatic. The frequency and intensity of the disruptive outbursts should be considered as well as the distress associated with those in an individual's social context (family, peer group, work colleagues), although distress can be isolated toward family interactions only (non-sibling). The disorder develops most frequently in late preschool or early school age and rarely later than early adolescence. The cause may be a combination of temperament, inheritance, and adverse social factors. Evidence-based tools, including the Vanderbilt and the Connor Rating Scale for ADD, include items that screen for ODD and include specific rating scales for parents and teachers (Lusk, 2013). Behavioral therapy and cognitive behavioral therapy (CBT) are individually designed to meet the needs of the child and includes such techniques as family therapy and anger management (Fraire &

Ollendick, 2012). The treatment of ODD and other disruptive disorders may be “particularly problematic” and often requires a multidisciplinary and multimodal approach, including psychosocial interventions and occasionally medication (American Academy of Child and Adolescent Psychiatry [AACAP], 2007b). Collaborative Problem Solving and Creating Opportunities for Personal Empowerment (COPE) are two evidence-based treatment programs for teens with ODD (Melnyk, 2003). These programs help the teen learn new tools and skills to positively influence their thoughts, emotions, and behaviors. Parent management training focuses on effective disciplining and age-appropriate supervision to increase support for positive social behavior. Recommended parent management training programs include Triple P (<http://www.triplep.net/>), The Incredible Years (<http://www.incredibleyears.com/>), and The REACH Institute (<http://thereachinstitute.org/help-for-families>).

Medication may be an additional component to psychosocial treatment for the symptoms of aggressive behavior and to treat comorbid conditions; it should *not*, however, be the only treatment intervention. Treatment with medications must include the teen’s assent in order to have a positive outcome. Some of the medications used include stimulants and atomoxetine to treat comorbid ADHD; mood stabilizers and atypical antipsychotics are commonly prescribed to address maladaptive aggression (AACAP, 2007b). The nurse should explain the importance of compliance with the medication regimen, as abruptly stopping them increases the risk of a rebound reaction. Nurses should educate the patient and the family about side effects and can monitor metabolic assessments and laboratory evaluations that are clinically relevant, comprehensive, and based on established guidelines (Center for Education and Research on Mental Health Therapeutics, 2010)

### **QSEN Checkpoint Question 54.3**

#### **SAFETY**

Todd’s family has a history of ADHD treated by medication. The nurse completes a patient history for Todd, including an assessment of Todd’s father’s reactions to medication for the same condition. Which of Todd’s father’s memories from childhood leads the nurse to believe Todd is experiencing an adverse effect of methylphenidate hydrochloride (Ritalin)?

- a. “I used to play that I was an astronaut for hours on end.”
- b. “I was the fattest kid in my gym class.”
- c. “I hardly ever slept; I would just lay awake for what felt like hours.”
- d. “I found out that I had iron-deficiency anemia in high school.”

*Look in Appendix A for the best answer and rationale.*

## **Conduct Disorders**

ODD has milder symptoms and is sometimes a precursor to conduct disorder (CD)

(APA, 2013). The symptoms of CD differ from ODD in that the child/adolescent with CD demonstrates a lack of empathy and guilt and violates age-appropriate social norms and rights (APA, 2013). Symptoms of CD that begin at a younger age are associated with a poor long-term outcome. CDs are persistent antisocial acts that involve violations of personal rights or societal rules, such as disobedience, stealing, fighting, destruction of property, fire setting, and early sexual behavior (Buitelaar, Smeets, Herpers, et al., 2013). Symptoms can be clustered as involving aggression toward people and animals, destruction of property, deceitfulness and theft, and serious violations of family and community rules.

CDs are seen in about 2% to 10% of children and occur more frequently in males than in females, particularly if property or violent crimes are involved (APA, 2013). The prevalence of CDs among girls is increasing, however, so the male predominance may reduce over time (APA, 2013). Children with the disorder seem to develop an increasing loss of self-regulation or an inability to know when to stop a disruptive action.

A number of etiologic factors are suggested as the cause of the disorder, including genetic predisposition, neurologic deficit correlates, and sociologic factors related to poverty and cultural disadvantage. The home environment may be characterized by rejection, frustration, and harsh and inconsistent discipline. Parents may have marital conflicts or substance abuse problems or children may have had a series of inconsistent caretaking by stepparents or foster parents or a history of institutional living (AACAP, 2013).

Therapy for children with CDs needs to be individualized and focus on modifying the home environment and educating the child and parent in social skills, anger management, and problem-solving skills so children can appreciate how their behavior affects others. Learning problem-solving skills can also help children learn to generate alternative solutions to situations, sharpen thinking about the consequences of choices, and evaluate responses. In most instances, parental education is essential, but this can be difficult to achieve until the parents realize this is a family concern, not an isolated child concern. If the home environment cannot be changed, removing the child from the home to a structured, consistent, and caring day care environment may produce better results.

As with ODD, treatment with medication is used to decrease explosive outbursts and decrease aggressive behaviors. Medications such as carbamazepine (Tegretol), propranolol (Inderal), and lithium carbonate may be prescribed to reduce the aggressive behavior. Long-term therapy with an agent such as buspirone (BuSpar) may be effective in helping children control temper or explosive outbursts. Nurses need to be cognizant of providing a safe environment for the affected youth and the community at large as well as themselves. Those with CD have a lower threshold for disruptive (and perhaps violent) behavior and lack the capacity to feel guilt or remorse for their actions. Healthcare providers, including nurses, have a “duty to warn” an identified target. If a patient with CD shares a desire to hurt/harm another person, that patient’s right to

confidentiality is not as great as the protection of a potential target. When working with families, make sure to put a safety plan in place, such as leaving the house and going to a neighbor's house to call emergency medical service (EMS). Homicidal behavior requires emergency psychiatric intervention.

## Anxiety Disorders

A certain degree of fear and anxiety can be a normal part of child development and should not interfere with functioning or persist beyond developmentally appropriate times. Fear is defined as “the emotional response to a real or perceived impending threat,” whereas anxiety is the “anticipation of a future threat” (Melnyk & Jensen, 2013). Children and teens with anxiety disorders experience severe and persistent distress that interferes with their daily lives. Anxiety disorders are associated with other major classes of disorders, including bipolar and related disorders, depressive disorders, disruptive disorders, eating disorders, and substance use disorders. It is important for children and teens with anxiety disorders to receive treatment, as emerging evidence shows that anxiety disorders may be part of a developmental progression in which anxiety is expressed early in life, followed by depression in adulthood (Merikangas, Nakamura, & Kessler, 2009). The spectrum of anxiety disorders can include separation anxiety, specific phobias, and social anxiety (middle childhood); panic attack or disorder and agoraphobia (late adolescence); and general anxiety disorder (GAD) into late adolescence.

Because childhood anxieties such as stranger anxiety in the 6- to 12-month-old child (discussed in Chapter 29), separation anxiety in the toddler (discussed in Chapter 30), fear of mutilation and fear of the dark in the preschooler (discussed in Chapter 31), and performance anxiety or school avoidance in the school-age child (discussed in Chapter 32) are considered part of usual development, other anxiety disorders in children may be overlooked. If these disorders are left untreated, however, children may cope with their fear by becoming overly dependent on others for support or by turning away from the problem and withdrawing into themselves, leaving them socially immature and unable to achieve in school. The development of anxieties involves a complex interaction of the environment and genetic traits, possibly related to an overactive amygdala, the part of the brain that controls the fear response (Beesdo, Knappe, & Pine, 2009).

Childhood and the teen years compose the core phase with the highest risk to develop anxiety symptoms and syndromes, ranging from transient mild symptoms to full-blown anxiety disorders (Beesdo et al., 2009). Anxiety disorders among children and adolescents include separation anxiety disorder, specific phobia, social anxiety disorder, agoraphobia, panic disorder, and GAD.

Separation anxiety is considered a disorder when an older child shows excessive anxiety about separation or the possibility of separation from parents. This causes them to be so worried they have difficulty falling asleep at night or insist on sleeping with their parents or just outside their parents' bedroom door. They experience acute distress

and perhaps frequent nightmares about separation and, when separated, show somatic symptoms of nausea, vomiting, or crying to such a degree that it prevents them from visiting at friends' houses, enjoying a camp experience, or actively participating in school (Santucci & Ehrenreich-May, 2013). A child with a specific phobia is characterized by a marked fear or anxiety about a specific object or situation, such as a fear of heights or animals, which usually starts before the age of 12 years. Social phobias, including selective mutism, occur in late childhood and early adolescence. Panic disorder, agoraphobia, and GAD have their roots in later adolescence, but a discussion of those conditions is beyond the scope of this chapter. It is important to recognize and treat children with anxiety disorder, as convincing evidence shows that anxiety disorders are associated with an increased risk of depression (APA, 2013). Risk factors for anxiety disorders include family history, negative experiences, temperament, new social or work demands, and health conditions that may draw attention, such as a physical disability. These disorders occur slightly more frequently in girls than in boys.

Treatment for anxiety disorders begins with individual therapy, such as CBT or behavioral skill building, such as COPE (Melnyk, 2003). Family interventions are focused on educating parents about anxiety management and helping them to gain greater insight into the dynamics of the problem and aid the child to gain more confidence in the ability to function independently. Nurses can educate parents and children about common signs and symptoms of anxiety and can promote environmental changes. Promoting good sleep habits, adequate nutrition (especially limiting caffeine intake), regular exercise, and the establishment of predictable routines are important for successful outcomes (Melnyk & Jensen, 2013). For some children, medication can be helpful. SSRIs and antianxiety medications such as buspirone (BuSpar) are generally the first pharmacologic agents used. Remind parents that when children take antidepressant medication, they need to be observed closely because the use of antidepressants is associated with increased thoughts of suicide (Adegbite-Adeniyi, Gron, Rowles, et al., 2012). The increasing use of antidepressant medications, including SSRIs, calls for an increased level of vigilance in monitoring the effects of these medications (Mojtabai & Olfson, 2014). Children and teens started on SSRIs should have weekly follow-ups with the prescriber, and nurses monitor for signs and symptoms of suicidality. Other medications may include SNRIs venlafaxine (Effexor), benzodiazepines, and clonazepam (Klonopin) (Melnyk & Jensen, 2013).

## **POSTTRAUMATIC STRESS DISORDER**

Posttraumatic stress disorder (PTSD) occurs in children who have experienced or witnessed a traumatic event, such as child abuse, neglect, domestic violence, a natural disaster such as a hurricane, a harrowing accident such as a house fire, a home robbery, or a near-fatal illness. A diagnostic criterion for PTSD includes symptoms that occur 1 month following the initial event. Acute stress disorder describes similar symptoms experienced several days to 1 month following the experience or witness of a traumatic event. Children continue to have recurring recollections or dreams of the event or

demonstrate intense psychological symptoms, if a reminder of the initiating event occurs. They may feel guilt they survived the event if a close family member or friend did not.

Absence of effective support can contribute to, and even exacerbate, symptoms. Therapy for children and adolescents consists of trauma-focused CBT, integrated play therapy, eye movement desensitization and reprocessing (EMDR), and family therapy. Psychological debriefing immediately following a traumatic event can help a child better understand the event and reduce the feeling of threat (Gillies, Taylor, Gray, et al., 2012).

## Eating Disorders

The *DSM-5* states that “feeding and eating disorders are characterized by persistent disturbance of eating or eating-related behavior that results in altered consumption or absorption and significantly impairs physical health or psychosocial functioning” (APA, 2013). These include pica, rumination, and food aversion in young children and anorexia nervosa and bulimia nervosa in older children.

### PICA

*Pica* is the Latin word for magpie (a bird that is an indiscriminate eater). Pica in children is the persistent eating of nonfood substances such as dirt, clay, paint chips, crayons, yarn, or paper (Bryant-Waugh, Markham, Kreipe, et al., 2010). It is a potential dangerous disorder because of the possibility of unintentional poisoning. Other complications include constipation, gastrointestinal malabsorption, fecal impaction, and intestinal obstruction. The disorder is seen predominantly between the ages of 2 and 6 years, although it may be present in adolescence, particularly with pregnancy. Often, it is not diagnosed until a child presents with a pica-induced complication, such as lead poisoning (see Chapter 52).

The prevalence of pica is high in children who have an intellectual disability, and it increases with severity of the disability, possibly because of their inability to distinguish edible from inedible substances. Environmental factors, including neglect or lack of supervision, are other prognostic factors. It is highly associated with and may be caused by iron-deficiency anemia (which is why it occurs with a high incidence in pregnant teenage girls, who also may be iron deficient) (Young, 2010). In most instances, correcting the anemia also corrects the pica. In the meantime, individualized therapy, parental education, and a safety plan can help to keep the child from ingesting inedible substances until the phenomenon fades.

### RUMINATION DISORDER OF INFANCY

The term *rumination* comes from the Latin word for “chewing the cud” (as cattle do). It is the act of repeated regurgitation and then reswallowing of previously ingested food. A

rare disorder that usually affects infants between the ages of 3 and 12 months, it is seen most often in children with intellectual disability and appears to be a pleasurable act (Bredenoord, 2011). Both organic and environmental theories have been investigated to explain the disorder. In some children, an accompanying gastroesophageal reflux disorder may be implicated and is one medical condition that needs to be excluded. It has also been postulated that rumination is a form of self-stimulation by the infant, similar to actions such as head banging and body rocking. It also may be related to a lack of stimulation in the environment, although attempts to implicate the role of the primary caregiver in contributing to the disorder are not apparent. Attachment between the child and the parents, however, may be at risk because of the anxiety experienced by parents from their infant's constant regurgitation of food and consequent lack of growth.

A parent may report a child is constantly “spitting up” or vomiting or that the child's breath smells sour. Children can lose so much fluid and electrolytes through this process that they show signs of failure to thrive (a distinct problem of under nutrition discussed in Chapter 55). Distracting infants by holding, rocking, and talking to them tends to decrease rumination. Offering cereal thickened with formula or expressed breast milk may be effective in reducing rumination because this is more difficult to regurgitate than simple milk. Parents may need support, reassurance, and education to help them maintain or reestablish a bond with the child.

## **AVOIDANT OR RESTRICTIVE FOOD INTAKE DISORDERS**

Food avoidance or restrictive intake is, as the name implies, failure to eat adequately because of lack of interest in food, sensory characteristics of the food, or related to aversive consequences (APA, 2013). The persistent failure to eat eventually results in significant failure to gain weight or actual weight loss, although no medical reason or lack of food appears to be present. The disorder begins in infancy and is usually seen in children younger than 6 years of age. Infants and young children may present as too sleepy, upset, or stressed to feed. In older children and teens, food avoidance or restriction may be associated with emotional difficulties that do not meet criteria for anxiety, depression, or bipolar and related disorders. Because the child does not eat, mealtime becomes a battlefield as parents insist on the child's eating and the child persistently refuses food or exhibits extremely faddish or bizarre food preferences.

Therapy is a combination of counseling for the parents, to help them appreciate that food refusal used this way can be a potent controlling measure, and CBT for the child, to learn to recognize hunger as a stimulant to eating rather than using food refusal as a controlling or attention-getting mechanism. By late school age, food aversion seems to fade and, along with it, the parent–child conflict.

## **ANOREXIA NERVOSA**

Anorexia nervosa is characterized by refusal to maintain a minimally usual body weight because of a disturbance in perception of the size or appearance of the body (Clarkin,

2012). It may be genetically based and includes three separate features: self-induced starvation to a significant degree, a relentless drive for thinness, and medical signs and symptoms resulting from starvation. In an era when healthcare providers concentrate on reducing obesity, it is easy to miss that underweight can be just as unhealthy as overweight (Bonsergent, Agrinier, Thilly, et al., 2013).

Specific characteristics of a child or teen with anorexia nervosa that are usually present include:

- Severely distorted body image
- BMI less than 17.5 kg/m<sup>2</sup> or less than 85% of expected weight
- Intense fear of gaining weight or becoming fat even though underweight
- Refusal to acknowledge seriousness of weight loss

Anorexia nervosa occurs most often in girls (90%), usually at puberty or during adolescence. It is also more common in lesbian, gay, bisexual, transgender, or questioning/queer (LGBTQ) youth (Austin, Nelson, Birkett, et al., 2013) and among sisters and daughters of mothers who also had the disorder (Box 54.7). Children or teens with the disorder think of themselves as overweight even though their weight is adequate and thus severely limit their intake, begin excessive exercise, or use emetics, laxatives, enemas, or diuretics (**purging**) to better reduce their weight to what they envision their weight should be (Sigel, 2012).

#### BOX 54.7

### Understanding Gender Identify and Sexual Orientation

Although society has embraced technological and healthcare delivery advances, it has been more resistant to accepting individuals who do not adhere to convention such as those who identify as lesbian, gay, bisexual, transgender, or questioning/queer (LGBTQ) (see Chapter 2) (Mead, Dana, & Carson, 2017). Approximately 4% to 10% of the U.S. population comprises the LGBTQ population (Moe, Finnerty, Sparkman, et al., 2015); however, they are at high risk for poor mental health across developmental stages. Data from studies of adults indicate elevated rates of depression and mood disorders (Bostwick, Boyd, Hughes, et al., 2010), alcohol use and abuse (Burgard, Cochran, & Mays, 2005), and suicidal thoughts or attempts (Mustanski, Garofalo, & Emerson, 2010). When comparing these findings with mental health diagnosis rates within the general population, the contrast is drastic: Almost 18% of LGBT youth met the criteria for major depression and 11.3% for posttraumatic stress disorder (PTSD), and 31% reported suicidal behavior at some point in their life. Contrast this to national rates for these diagnoses and behaviors among youth at 8.2%, 3.9%, and 4.1%, respectively (Kessler, Avenevoli, Costello, et al., 2012; Nock, Green, Hwang, et al., 2013).

Additionally, contemporary youth are disclosing their sexual or gender identities (“coming out”) at a younger age. In the 1970s, the average age of coming out was 20 years (Troiden, 1979), whereas data from samples collected since 2000 show an

average age of coming out at 14 years old (Floyd & Bakeman, 2006). This has implications, as adolescents are not financially independent and still maturing socially and developmentally. Previous studies have demonstrated disproportionate rates of distress, symptomology, and behaviors related to mental health disorders among LGBTQ youth prior to adulthood (Fish & Pasley, 2015; Needham, 2012).

It is important for nurses to identify their own biases as well as acknowledge the health care and mental healthcare needs of persons who identify as LGBTQ in order to provide quality care. As advocates, nurses can screen for alcohol and substance abuse, depression, and other mental health issues brought on by social stigma (Mead et al., 2017) and can encourage healthcare systems to include:

- Brochures and educational material for LGBTQ patients
- Assessment forms with neutral terms
- Adding transgender to the gender box on intake forms
- Asking about relationship status rather than marital status
- Displaying visible safe-space and nondiscrimination policies
- Making community resources available to patients (Matza, Sloan, & Kauth, 2015)

Multifactorial risk factors exist for anorexia nervosa, including temperament, environment, genetics, and physiology. Children who develop an eating disorder this way may have a genetic susceptibility to the illness. Stressors in their environment such as parental divorce, social pressure to lose weight, and personal psychological trauma such as sexual assault or abuse can then set into motion a chain reaction that, coupled with the genetic tendency, leads to the development of the eating disorder. Adolescents who are “overachievers” or strive to be the best academically or at sports may develop the disorder as a way of helping them improve a poor self-image or feelings of inadequacy (they cannot live up to their own or their parents’ expectations) because excessive dieting can offer them a sense of control they otherwise don’t feel. Lack of nutrition can become so extreme in these children that it causes delayed pubertal development. They develop a starved appearance and significant symptoms of dehydration and acidosis. They may develop severe osteoporosis from loss of calcium from bones (Swenne & Stridsberg, 2012).

### Assessment

Because of their intense fear of becoming obese, children with anorexia come to perceive food as revolting and nauseating; they refuse to eat or else vomit food immediately after eating. Always ask whether, in addition to not eating, the child is using a laxative, diuretic, or enemas or is extensively exercising to further lose weight. Physical examination findings and laboratory abnormalities may be present. The most remarkable finding on the physical exam is emaciation, although accompanied by a distorted body image that he or she is “fat.” The nurse may also observe significant hypotension, hypothermia, and bradycardia. If the process is allowed to continue

without therapy, it can lead to starvation, serious health problems, and even death. Some individuals may develop lanugo, fine downy body hair, as well as a yellowing of the skin associated with hypercarotenemia. Laboratory analysis may reveal anemia and leukopenia, elevated blood urea nitrogen (BUN) and creatinine levels, hypercholesterolemia, and elevated liver enzymes; endocrine studies may reveal a low triiodothyronine (T<sub>3</sub>) and T<sub>4</sub>, whereas reverse T<sub>3</sub> levels may be elevated. An electrocardiogram commonly demonstrates bradycardia and may include arrhythmias or a prolonged QTc interval. A dual-energy X-ray absorptiometry (DEXA) scan, which measures bone mineral density, may reveal osteopenia or osteoporosis, which increases the risk of fracture in affected individuals (APA, 2013).

By the time most children/teens are seen at healthcare facilities, they are already extremely underweight, pale, and lethargic, and amenorrhea may be present in girls. Often, the child's parents have tried various methods of getting the child to eat, such as threatening, coaxing, and punishing; as a result, parent-child relationships may be strained. Parents may feel guilty for insisting their child lose weight if the girl was once overweight.

## Therapeutic Management

The treatment for anorexia nervosa requires the reestablishment of dietary intake to restore physical health followed by mental health treatments. Planning and outcome identification for a child with anorexia nervosa requires a multidisciplinary team. Although the condition began as a psychosocial problem, by the time a child is seen for care, physical starvation and its effects have become a second important component. A person who has become accustomed to fasting will not be able to eat typically "normal" amounts of food. Smaller meals offered more frequently are often necessary. For some patients, hospitalization may be needed due to extreme weight loss and electrolyte imbalance, and total parenteral nutrition or enteral feeding via nasogastric tube may be necessary to provide necessary fat, protein, and calories. Teens usually accept total parenteral nutrition well because they view it as "medicine," not as food. In addition, identification of emotional triggers and education about normal nutritional needs is an important aspect of therapy. Nurses are an integral part of the multidisciplinary team in establishing trust and effective communication, which are crucial measures to help the child resolve interpersonal issues that are present (Box 54.8).

### BOX 54.8

#### Nursing Care Planning Tips for Effective Communication

Cheyenne, 15 years old, is 5 ft 8 in. tall and weighs 95 lb. She is diagnosed with anorexia nervosa.

*Tip:* Attempt to obtain more information about the patient, her image of herself, and her diet in the hope that when the nurse knows more about the patient, she can help her eat more.

**Nurse:** Let's talk about your weight, Cheyenne.

**Cheyenne:** I know I'm fat. Look at this belly of mine.

**Nurse:** You feel fat?

**Cheyenne:** I am fat. I pig out constantly.

**Nurse:** What did you pig out on for breakfast this morning?

**Cheyenne:** Well, nothing this morning, but I was in a hurry.

The goal of therapy is gradual weight gain (1 to 3 lb/week) because a rapid gain of weight can cause a child to begin dieting to reduce this weight gain. Weighing once a week is better than every day to reduce the focus on weight. There are no medications specifically prescribed for the treatment of anorexia nervosa. Medications, such as antidepressants or anti-anxiety medications may be used to treat accompanying depression, anxiety, and/or obsessive-compulsive disorder. SSRIs such as fluoxetine (Prozac), citalopram (Celexa), sertraline (Zoloft), paroxetine (Paxil), fluvoxamine (Luvox), and escitalopram (Lexapro) may be used to address comorbid anxiety or depression. Atypical antipsychotics such as risperidone (Risperdal) and quetiapine (Seroquel) may be helpful in persons with bipolar and related disorders. Children and teens who have had anorexia nervosa need continued follow-up after weight is regained to be certain they do not revert to their former dieting pattern (Fig. 54.3). Counseling may need to be continued for 2 to 3 years to be certain self-image is maintained. With adequate counseling, most teens learn more appropriate responses to stress and achieve full recovery with adulthood.

**Figure 54.3** This anorexic teen, who is in the later stages of treatment, continues to meet with a counselor to discuss her food choices,

exercise program, and overall well-being. (© Barbara Proud.)

### *What If . . . 54.2*

**Every time the nurse sees Todd’s family at the clinic, his teenage sister, Cheyenne, appears more and more underweight. Her mother tells the nurse that Cheyenne has lost 20 lb in the past 6 months. “She’s the perfect daughter, always getting straight A’s in school,” the mother adds. Should the nurse be worried about Cheyenne?**

## **BULIMIA NERVOSA**

*Bulimia* refers to recurrent and episodic binge eating and purging by vomiting, accompanied by awareness that the eating pattern is abnormal yet the individual is not able to stop the pattern (Lock, 2013). Eating is considered “**binge eating**” when large amounts of food are consumed in a relatively short period of time, followed by inappropriate compensatory measures to prevent weight gain, typically within 2 hours. These actions can include self-induced vomiting; misuse of laxatives, diuretics, or other medications; fasting; or excessive exercise (APA, 2013). A period of depression or guilt usually follows the period of bingeing. Like anorexia nervosa, bulimia typically is seen in adolescence or early adult life and predominantly in girls. Individuals with bulimia are often a normal weight or slightly overweight, and therefore, the problem may escape notice from friends and family. The teen may frequently worry or complain about being fat, may not want to eat in public or in front of others, and may go to the bathroom during a meal or immediately afterward. The disorder may last for months or years with periods of normal eating interspersed between bulimic ones, and the risk of death is significant. Some teenagers with the disorder rely on laxatives and diuretics and excessive exercise in place of vomiting to maintain their weight (a non-purging type) (Sigel, 2012). With either type, the combination of frequent vomiting and use of laxative or diuretics can result in such serious physical complications, notably electrolyte abnormalities, which can ultimately lead to effects as severe as cardiac arrest. Adolescents with purging may develop severe erosion of their teeth because of the constant exposure to acidic gastrointestinal juices from vomiting. Russell’s sign, scars or calluses on the dorsal side of the hand from repeated contact of the teeth while inducing vomiting, might be present in those who engage in purging behavior. Esophageal tears may also result from forceful vomiting.

Factors associated with the development of bulimia include being female, age (late teen to early adulthood), and having a first-degree relative with a history of an eating disorder.

Psychological and emotional problems such as anxiety, depression, and low self-esteem may increase the risk of bulimia. There are also societal pressures, including the media and activities that stress physical appearance, such as modeling.

Treatment focused on restoring nutritional balance and keeping a structured nutritional intake is key for successful mental health counseling. CBT concentrates on improving the person's distorted self-image, uncontrollable and excessive eating, and guilt and embarrassment associated with bingeing and purging.

Family counseling can address concerns about how the bulimia is affecting the teen's development and family functioning. The use of medications usually includes antidepressants or other medications to address the obsessive thinking and compulsive behaviors. The antidepressant, anti-obsessive-compulsive, and antiemetic actions of fluoxetine are linked to the inhibition of neuronal reuptake of serotonin in the central nervous system (CNS). Fluoxetine (Prozac) is the only SSRI that has the FDA indication for treatment of bulimia, and the failure of a patient to respond to treatment is evident in approximately 3 weeks (Sysko, Sha, Wang, et al., 2010).

### *QSEN Checkpoint Question 54.4*

#### **EVIDENCE-BASED PRACTICE**

Eating disorders have a high incidence in adolescents. To see if this also exists in teenage athletes, researchers asked 966 first-year high school students to complete a questionnaire and then sit for an interview as to whether they have or ever had an eating disorder. Results of the study showed that the prevalence of eating disorders was higher in athletes compared to nonathletes (6.9% versus 2.3%). It was also higher in female than male athletes (13.5% versus 3.2%) (Martinsen & Sundgot-Borgen, 2013).

Based on the previous study, which statement by Cheyenne, Todd's adolescent sister, would make her at highest risk for developing an eating disorder?

- a. "I hate sports. Nothing more athletic than poker interests me."
- b. "I've played basketball for 2 years; I like the way I look in uniform."
- c. "I don't play a whole lot of sports, but I love watching football games."
- d. "I don't know why girls play sports like tennis; they all look so skinny."

*Look in Appendix A for the best answer and rationale.*

## **Tic Disorders**

A tic is a sudden, rapid, recurrent, nonrhythmic motor movement or vocalization (APA, 2013). Four diagnostic categories are used, based on the presence of motor and/or vocal tics, duration of symptoms, and age at onset when other medical causes have been excluded. The hierarchical ranking of tic disorders is described as provisional tic disorder, persistent (chronic) motor or vocal tic disorder, and Tourette disorder. The pathophysiology of tic disorder involves a complex pathway involving the basal ganglia and neurotransmitters and interaction with motor, sensory, limbic, and executive networks (Yael, Vinner, & Bar-Gad, 2015). The neurotransmitters may be misfiring or not communicating correctly causing tics. They may be motor (such as rapid eye

blinking or facial twitching) or vocal (throat clearing or twitching) and can be described as transient/provisional or chronic.

Provisional tic disorder describes single or multiple motor and/or vocal tics, onset before age 18 years, and duration of symptoms less than 1 year. Chronic tics are diagnosed when certain criteria are met, including an occurrence of symptoms almost every day for more than a year, no “tic-free” period longer than 3 months, and a diagnosis before the age of 18 years (APA, 2013). They usually become more pronounced during periods of stress and diminish during sleep. Tics can further be described as “**simple motor tics**,” which have a short duration (milliseconds). **Simple vocal tics** include coughing, throat clearing, snorting, and barking. **Complex motor tics** have a longer duration and often include a combination of simple tics, such as head turning and shoulder shrugging. They may appear purposeful and include facial gestures, grooming behaviors, jumping, touching, and smelling objects. Children are most prone to these disorders before the onset of puberty, with peak severity between 10 and 12 years of age. They occur more frequently in boys than in girls and more frequently in children who demonstrate obsessive-compulsive behavior or ADHD. Some instances tend to be familial, possibly because of dopamine receptor inhibition. They occur so frequently that as many as 15% of children experience some form of transient tic disorder (Plessen, 2013).

Because transient tics are associated with high stress, treatment usually focuses on reducing areas of stress in the child’s life. Pointing out the mannerism to the child is not usually helpful and may intensify the frequency of the manifestation if it increases stress. Behavior modification may be successful in eliminating a particular tic. If the stress is not removed, however, the child may substitute another compulsive mechanism for the original tic. Treatment of persistent/chronic tic disorder depends on the severity of symptoms as the degree of socially disruptive behavior and is similar to the treatment of Tourette syndrome.

## TOURETTE SYNDROME

Although persistent/chronic tic disorder is either vocal or motor tics, Tourette syndrome is an inherited syndrome of motor and one or more phonic vocal tics (Wu & Gilbert, 2013). It occurs three times more frequently in boys than in girls, and because it is inherited, often, there is some other form of movement disorder in another family member. Typically, the age at onset is between 4 and 6 years, peaking in severity around the ages of 10 to 12 years, with motor tics usually occurring before vocal tics. **Complex vocal tics** include the repeated use of words or phrases out of context—specifically, **coprolalia** (use of socially unacceptable words, usually obscenities), **palilalia** (repeating one’s own words), and **echolalia** (repeating others’ words). Some children with this syndrome have nonspecific electroencephalographic abnormalities and soft neurologic signs that aid in diagnosis. Although most children can suppress their tics for short periods, giving into a tic brings a sense of relief. Children with Tourette syndrome can develop low self-esteem because of their uncontrollable actions

before the syndrome is fully diagnosed. Treatment for Tourette syndrome, including comprehensive behavioral intervention for tics (CBIT), is associated with an improvement in symptoms. In CBIT, children and teens are taught to recognize the urge to tic and to use a replacement response instead of the tic (Piacentini, Woods, Scahill, et al., 2010). This syndrome responds to medications that alter the effects of dopamine, such as haloperidol (Haldol), pimozide (Orap), or risperidone (Risperdal).

### *QSEN Checkpoint Question 54.5*

#### **QUALITY IMPROVEMENT**

Cheyenne tells the nurse she had a transient tic disorder when she was in grade school. The nurse would rate Cheyenne's subsequent care as most adequate if it included assessment for which of the following?

- a. Signs she has developed a convulsive disorder
- b. Lack of sensitivity to pain from autistic disorder
- c. Gastrointestinal symptoms because she likely has pica
- d. Depression because she has a loss of self-esteem

*Look in Appendix A for the best answer and rationale.*

## **Depression, Psychiatric, and Bipolar and Related Disorders Affecting Children**

Three mental health illnesses typically thought of as occurring in adults—depression, bipolar disorder, and schizophrenia—have their roots in childhood.

### **CHILDHOOD DEPRESSIVE EPISODES**

Children and adolescents can experience depressive episodes similar to those experienced by adults (Hagerty, 2012). A significant way depression can be differentiated from “usual” sadness is when children report they cannot remember the last time they felt happy or had a good time (**anhedonia**) (Fig. 54.4). The incidence ranges from 1% to 3% before puberty and 3% to 6% among adolescents, as likelihood of onset increases with puberty. A child is considered to have a major depressive disorder when symptoms such as loss of interest or pleasure, significant weight loss or gain, depressed mood, insomnia, psychomotor agitation, feelings of worthlessness or excessive or inappropriate guilt, diminished concentration, recurrent thoughts of death, and suicidal ideation exist for 2 weeks or longer. A family history of depression is the number 1 risk factor for a major depressive disorder. Persistent depression disorder has a reported prevalence of 1.6% to 8%. Persistent depression disorder differs from a major depressive disorder in the length of time; the child/teen must have symptoms for 1 year. Underlying factors that lead to extended depression in children are marital discord or violence, paternal anxiety, and lack of family or social support (Fatori, Bordin, Curto, et

al., 2013). Because these symptoms are easily missed, a history should be taken from the child as well as from the parents at well-child healthcare visits. The AACAP has issued practice parameters for the assessment and treatment of depressive disorders in children and adolescents because early identification and treatment of depression has a significant impact on the child/teen and family functioning (AACAP, 2007a). Several evidence-based screening tools can easily be administered to youth and adult guardians and take only a few minutes to complete, such as the Children's Depression Inventory, or CDI-2. Children diagnosed with depression need CBT or psychotherapy, such as individual or family counseling, to help children regain self-esteem and to help the family to understand the level of depression that has occurred. Those with mild symptoms of depression can benefit from psychoeducation, active support, and exercise therapy. In addition to counseling, some children require antidepressant therapy with an SSRI to relieve the symptoms. Observe carefully any child who is prescribed an antidepressant to detect deepening depression or emerging suicidal behavior because this is associated with antidepressant use in children. Adolescent self-injury as a result of depression is discussed in [Chapter 33](#) with concerns of the adolescent.

**Figure 54.4** Symptoms of depression are easily missed in school-age children unless history taking is thorough. (© Caroline Brown, RNC, MS, DEd.)

*What If... 54.3*

**The parents of Cheyenne, Todd's sister, tell the nurse that Cheyenne seems increasingly tired, so much so that she sleeps almost all day every weekend. Is**

**this usual teenage behavior, or does Cheyenne need a referral to detect whether she is depressed?**

## **BIPOLAR AND RELATED DISORDERS**

Bipolar and related disorders serve as the bridge between depression and schizophrenia in terms of symptomology, history, and genetics and include bipolar I, bipolar II, and cyclothymia (APA, 2013). Although children and adolescents are unlikely to be diagnosed with bipolar disorder, they may experience bipolar-like symptoms. Bipolar I disorder requires at least one manic episode, which is an elevated, expansive, or irritable mood, such as grandiose behavior, little need for sleep, increased goal-directed activity, distractibility, or a flight of ideas (APA, 2013). Although the mean age at onset is typically 18 years, children who experience a manic episode may present with repeated episodes of extreme silliness or happiness in an inappropriate setting, beyond what is developmentally expected of the child; children can also present with an overestimation of skills or ability, such as being the very best, or unstoppable (APA, 2013). The same is true for bipolar II disorder, although there is no presence of mania, but rather hypomania, a less severe, shorter period of increased energy, mood, and activity. Cyclothymic disorder is the presence of hypomanic and depressive periods that do not meet full criteria for bipolar I or II and persist for at least 1 year in children or adolescents (APA, 2013). Nurses should consider family history of bipolar disorder, as genetic predisposition is the most consistent and strongest risk factor for the diagnosis, and monitor for suicidal ideation in children with family history and/or suspected bipolar disorder due to the increased risk of suicide in individuals with bipolar.

## **CHILDHOOD SCHIZOPHRENIA**

Schizophrenia is actually a group of disorders of thought processes characterized by the gradual disintegration of mental functioning; it occurs in about 2 of every 10,000 children (Miller & Buckley, 2013). It is a devastating mental illness that most commonly strikes in adolescence or young adulthood, and onset prior to adolescence is rare (APA, 2013). Symptoms until that time may be undifferentiated or ill defined. Despite years of investigation, the cause of schizophrenia is unknown. Current evidence suggests there may be both genetic and environmental foundations for the disorder. Magnetic resonance imaging (MRI) has shown that cerebral involvement, such as enlarged ventricles, decreased blood to the frontal lobe, or cortical cell loss, may begin the disorder. Neurochemical mediators may influence or prolong the disorder. The use of functional brain imaging, including positron emission tomography (PET) and single-photon emission computerized tomography (SPECT), may lead scientists to be able to classify and diagnose various psychiatric disorders and possibly predict therapeutic effect. (Drug Addiction & Alcoholism Treatment Centers, 2013). Children with schizophrenia experience hallucinations (hear or see people or objects that other people cannot) and may display rambling or illogical speech patterns. They may not be

responsive (have a **flat affect**), may withdraw into themselves so completely they are stuporous (**catatonia**), or be so extremely suspicious that others want to harm them (paranoia) that it is difficult for them to function. Although schizophrenic manifestations may occur suddenly after a major stress in a child's life (such as rejection by a boyfriend or girlfriend), subtle signs of mental illness have usually been present for some time.

The diagnosis of a psychotic disorder of this extent is often a shock to parents. Fortunately, therapy with modern antipsychotic drugs such as clozapine is effective in reducing children's hallucinations and bizarre thought processes. Many children who are diagnosed as having schizophrenia in childhood continue to have mental illness as adults, making continuing support and long-term follow-up essential (Malone-Cole, 2012).

### **QSEN Checkpoint Question 54.6**

#### **TEAMWORK & COLLABORATION**

Symptoms of schizophrenia often begin in adolescence, so the nurse reviews Cheyenne's history with a psychiatric-mental health nurse. Which statement by Cheyenne would signal to the nurses she is developing symptoms of schizophrenia?

- "I absolutely hate babysitting for my younger brother on week nights."
- "Both my English and math teachers gave me bad marks last quarter. I got so mad."
- "My father seems more worried about his health than he does about mine."
- "At night, I can hear my friends plotting against me through the water pipes."

Look in [Appendix A](#) for the best answer and rationale.

## **Elimination Disorders**

Elimination disorders include functional enuresis (involuntary loss of urine) and encopresis (involuntary loss of feces). Developmental enuresis is discussed in [Chapter 31](#) with the development of the preschooler.

### **ENCOPRESIS**

In children ages 4 years and older, loss of feces is *encopresis* if there is repeated passage of feces at least once a month for at least 3 months in places not culturally appropriate for that purpose. It is more common in boys than in girls and considered primary if the child was never fully toilet trained and secondary if the problem began after effective training (Coehlo, 2011). It is diagnosed only after medical causes such as lactase deficiency, thyroid disease, hypercalcemia, Hirschsprung disease, and infectious diarrhea have been ruled out. Between 1.5% and 7.5% of children ages 6 to 12 years old have encopresis, and it is 6 times as common in boys as in girls (Ortiz & Stratis, 2013).

Isolated occurrences of encopresis may happen when a sibling is born (as part of an

overall regression reaction) or when a child is visiting at a strange house and is too shy to ask for the bathroom. It can occur in a new school because a child is unable to locate the bathroom in time or cannot use a bathroom because it is “owned” by a school gang.

In a few instances, encopresis occurs because hard bowel movements cause anal fissures. Because it then hurts to move the bowels, children avoid bowel movements, leading to chronically distended rectums. They are then no longer able to sense when they need to defecate, so involuntary or overflow defecation occurs.

### Assessment

To document encopresis, take a careful history of usual bowel evacuation habits, the number of bowel accidents, and the times at which they occur. Additionally, a dietary history including fiber and fluid intake is important. Investigate any recent changes or stress factors in the child’s environment. A physical examination that includes a rectal examination should be done to establish whether there is proper anal sphincter control. If anal fissures are present, the possibility of child maltreatment needs to be investigated, although encopresis alone does not substantiate sexual abuse.

### Therapeutic Management

Once diagnosed, the treatment of encopresis begins with a therapeutic regimen to empty the bowels of impacted stool, most often with laxatives, enemas, or a combination of both (Mosca & Schatz, 2013). Behavior interventions are centered on habit relearning. Reserving time in a busy household for children to evacuate their bowels about two times daily (in the morning and after dinner) may create new “habit” periods for them. It is especially advantageous if they are able to evacuate their bowels before they leave for school in the morning because then they are less likely to experience encopresis and embarrassment in school. The administration of a stool softener such as lactulose, a high-fiber diet, or 1 to 6 tablespoons of mineral oil daily for 2 or 3 months often softens stools so bowel movements are not painful. Remind parents that children receiving long-term mineral oil therapy also need to take water-soluble forms of vitamins A, D, and K because these vitamins tend to be removed from the gastrointestinal tract with the mineral oil. Emphasize to parents that children should not be punished for encopresis. Encourage them to pay as little attention as possible to bowel accidents and to give praise for days when encopresis does not occur.

### ENURESIS

*Enuresis* is defined as repeated involuntary or intentional urination during the day or at night after an age at which a child has attained or should have attained control over bladder function, when no organic cause for the problem can be found (Deshpande, Caldwell, & Sureshkumar, 2012). Chronologic age (or developmental level) is at least 5 years (APA, 2013), and there is a positive family history in many instances. Although stress may be a factor in occurrences of enuresis, its primary cause is unknown. Most

children outgrow the problem by adolescence. It is important to treat enuresis to minimize embarrassment and anxiety of the child and frustration experienced by parents and/or caregivers. The most serious result of enuresis is related to the child's feelings of failure with each occurrence and associated rejection by peers. All this contributes to a lowered sense of self-esteem. The problem and associated nursing diagnoses are described in more detail in [Chapter 46](#). Treatment focuses on behavioral management and positive reinforcement ([Walle, Rittig, Tekgül, et al., 2017](#)). Enuresis alarms can be beneficial in the short and long term; however, their use can be labor intensive and time-consuming. Success is more likely with strong family support and a positive attitude. A medication such as desmopressin (DDAVP), a synthetic analogue of antidiuretic hormone (ADH), is a first-line pharmacologic agent used in children over the age of 5 years. It can be used for short-term treatment for children hesitant to be away from home overnight, for example, at a slumber party or overnight camp.

#### *What If... 54.4*

**The nurse is particularly interested in exploring one of the 2020 National Health Goals related to mental illness in children (see [Box 54.1](#)). What would be a possible research topic pertinent to this goal that would be applicable to Todd and Cheyenne's family and also advance evidence-based practice?**

### **KEY POINTS FOR REVIEW**

- Both intellectual and mental health disorders pose long-term care concerns for children and their families.
- For children with intellectual disability, a stigma still may be present in many communities, although less so than previously. Help parents to gain the insight that intellectual disabilities occur in a proportion of infants in every population and that having a child with this problem merely reflects a chance occurrence not a reflection of their family's capabilities.
- Mental health disorders often begin subtly in children and are often first manifested as behavior problems in school or with personal relationships. Assess thoroughly any child who is referred for disruptive behavior or interpersonal distress in a school class for the possibility the child has a serious mental health problem in order to not only meet QSEN competencies but also best meet the family's total needs.
- Autism spectrum disorder is a pervasive developmental disorder that has a range of behaviors, including fascination with movement, impairment of communication skills, and insensitivity to pain.
- Attention deficit and disruptive behavior disorders, such as oppositional defiant and conduct disorders, may occur in childhood. Children with ADHD may be treated with stimulant or nonstimulant medication to reduce the hyperactivity and allow them to achieve better in school and interact successfully at home.

- Eating disorders seen in childhood include pica, rumination, anorexia nervosa, and bulimia. All of these disorders can lead to loss of weight and electrolyte imbalances if left unrecognized and untreated.
- Tic disorders such as Tourette syndrome are abnormalities of semi-involuntary movement that are thought to result from dysfunction of the basal ganglia or distorted dopamine reception.
- Children with depressed mood are at high risk for self-injury. They need thorough assessment and close observation to be certain that this does not happen. Monitor children carefully who are prescribed antidepressants to relieve depression because these may actually increase self-injury attempts.
- Schizophrenia often begins in adolescence. It usually presents as disorganized behavior. Long-term therapy with antipsychotic drugs is necessary.
- Encopresis is the repeated passage of feces in places not culturally appropriate for that purpose. Therapy is both physiologic and psychological.

### CRITICAL THINKING CARE STUDY

Leonette is an 8-year-old child you see at an ambulatory clinic. She began loud lip smacking and shouting, “Hey! Hey! Hey!” almost constantly when she was 4 years old. The timing coincided with her parents’ divorce, so her mother thought for a long time that her behavior was a reaction to the divorce. A childcare teacher suggested that it might be something more significant, and Leonette was diagnosed with Tourette syndrome. Today, she takes haloperidol and still has those mannerisms, but they only occur when she is in a new or stressful situation. Leonette lives with her mother; a new stepfather; two stepbrothers, ages 12 and 14 years; and a new baby sister, age 2 months. Because the house is small, Leonette and her two brothers share a bedroom and bathroom. “Not a good arrangement,” Mrs. Firestone tells you, “but workable.” Mrs. Firestone works as a teller at a local bank; she has just returned to work after a 10-week maternity leave; her husband sells real estate.

1. “Take Your Daughter to Work Day” is next week, so you ask Leonette’s mother if she is going to take Leonette to the bank with her. Mrs. Leonette looks uncomfortable at your question and replies quickly, “No. It’s not allowed, because we handle money and everything.” Leonette looks disappointed. Would you suggest that Mrs. Firestone take Leonette, or would the visit be too upsetting to suggest?
2. Leonette’s mother brought her to the clinic today because she’s had two episodes in the past month where the school called her to take Leonette home because of encopresis. When you ask the mother when was the last time Leonette moved her bowels at home, her mother answers, “No idea. I don’t have time to keep track of who’s going to the bathroom or not.” How could you help this family?
3. You notice that Leonette is afraid to leave her mother’s side to come into an examining room so you can take her blood pressure. Her mother tells you she has

had to stay home from work for the past 3 days because Leonette refused to go to school and even refuses to leave her side, following her from room to room in the house and sleeping on the floor at the foot of her bed. “Her teacher said it’s separation anxiety from the new marriage and will pass,” the mother tells you. Would you be concerned that this is not as simple a problem as the mother suggests?

## Nursing Care of a Family in Crisis: Maltreatment and Violence in the Family

*Hillary Landstrum is a 3-year-old you see in an emergency department. Her mother, who is the city mayor, tells you Hillary fell off a swing in the backyard. Hillary has a broken forearm, a broken rib, and multiple bruises on her chest and back. You notice in her electronic record that Hillary was seen in the same emergency room a month ago for a burn on her hand. When you mention to her mother that Hillary's injuries seem extreme for a simple fall, her mother says, "She isn't very pretty. I guess she's also clumsy."*

*Previous chapters described the normal growth and development of children and care of children with disorders of specific body systems. This chapter adds information about the effect on children when child maltreatment or intimate partner violence occurs in a family. Such information can build a base for care and for putting into place ways to prevent further maltreatment or violence.*

**You suspect Hillary is a victim of child maltreatment. What additional questions would you want to ask her mother to help determine whether this is so? What should you do if you feel certain Hillary has been maltreated?**

### KEY TERMS

**abusive head trauma**

**factitious disorder**

**failure to thrive**

**hebephile**

**incest**

**intimate partner violence**

**learned helplessness**

**maltreatment**

**mandatory reporters**

**molestation**

**pedophile**

**permissive reporters**

**rape trauma syndrome**  
**sexual maltreatment**

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Discuss the types of child maltreatment or intimate partner violence seen in families and the theories explaining their occurrence.
2. Identify 2020 National Health Goals related to child maltreatment or intimate partner violence that nurses can help the nation achieve.
3. Assess a family that has experienced physical or emotional child maltreatment or intimate partner violence.
4. Formulate nursing diagnoses related to a family in which child maltreatment or intimate partner violence is present.
5. Develop expected outcomes for a family that has experienced child maltreatment or intimate partner violence to help them manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care for a family in which child maltreatment or intimate partner violence has occurred, such as ways to role model developmentally age appropriate parenting.
8. Evaluate expected outcomes for effectiveness and achievement of care.
9. Integrate knowledge of family child maltreatment or intimate partner violence with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

Child protective services in the United States receive 3.4 million reports of children being maltreated or neglected per year, with about 683,000 of those children determined to have been maltreated ([U.S. Department of Health and Human Services, Administration for Children and Families, Administration on Children, Youth and Families, Children's Bureau, 2017](#)). A nationally representative sample determined that 10.2% of U.S. children are maltreated in some way, and the lifetime cost in medical bills and lost productivity is over \$210,000 per child, making the total economic cost of maltreatment as much as \$585 billion a year nationally ([Fang, Brown, Florence, et al., 2012](#)).

Child maltreatment is associated with stress and has been linked with the inability of a family to handle external and internal stressors. Accordingly, maltreatment or violence in a family is rarely an isolated event but rather an indication of many other factors that

require intervention (McCloskey, 2013).

**Maltreatment**, formerly termed *abuse*, is defined as the “willful injury by one person of another” (Helfer & Kempe, 1987) and takes many forms: physical or emotional maltreatment, neglect or sexual maltreatment, intimate partner violence, and maltreatment or violence of the elderly. Maternity, child health, and family care nurses need to be especially observant for signs of possible maltreatment or violence in a family because these increase during pregnancy and possibly during the care of an ill child. In all instances, the victim’s safety is paramount, but ensuring this safety must be done with sensitivity to the importance of maintaining and improving overall family functioning.

Child maltreatment has long-term consequences; as many as 30% of children from families where there is child maltreatment become maltreating parents themselves (A. J. Lang, Gartstein, Rodgers, et al., 2010; Valentino, Nuttall, Comas, et al., 2012). It also predisposes victims to numerous psychological problems and induces a persistent sensitization of the stress-response system (Heim, Shugart, Craighead, et al., 2010). Box 55.1 shows 2020 National Health Goals related to child maltreatment and intimate partner violence.

#### BOX 55.1

#### Nursing Care Planning Based on 2020 National Health Goals

The mark of a developed nation is the ability to protect the health of its most vulnerable members. This makes both child maltreatment and intimate partner violence national health concerns. Examples of 2020 National Health Goals that specifically address these issues are:

- Reduce the rate of maltreatment of children younger than 18 years of age from a baseline of 9.4 per 1,000 to a target level of 8.5 per 1,000.
- Reduce the rate of child maltreatment fatalities from a baseline of 2.4 per 100,000 to a target level of 2.2 per 100,000.
- Reduce the rate of physical, sexual, and psychological violence by current or former intimate partners.
- Reduce stalking by former or present intimate partners.
- Reduce abusive sexual conduct and rape (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by educating parents about how to parent more effectively and by identifying children or adults in school or healthcare agency settings who have been maltreated, neglected, or victim of violence.

#### *Nursing Process Overview*

FOR CARE OF A FAMILY THAT HAS EXPERIENCED CHILD  
MALTREATMENT OR INTIMATE PARTNER VIOLENCE

## ASSESSMENT

Nurses are often the first individuals to identify symptoms of possible child maltreatment or intimate partner violence in a family because they are often the first to take a health history or see a child or woman undressed at a healthcare visit and recognize significant bruising; they are also often the person to whom a pregnant woman or child confides the problem. If maltreatment or violence in any form is suspected, it is essential to get as full a picture as possible. If child maltreatment is suspected, talk with the parents first, without the child, and then interview the child separately to help uncover any inconsistencies in the parents' explanations. Remember, however, you are *not* investigating the concern—you are doing an initial screening to assess the need for referral and reporting. Your agency's patient protective services department will do the actual investigation.

## NURSING DIAGNOSIS

Nursing diagnoses associated with child maltreatment or family violence should address both the physical and the emotional results of the concern. Some examples are:

- Pain related to burn on hand from documented child maltreatment
- Risk for injury related to previous intimate partner violence
- Risk for other-directed violence related to admitted poor self-control
- Impaired parenting related to high level of stress
- Compromised family coping as manifested by child maltreatment related to alcohol use by father
- Disturbed self-esteem related to stalking and sexual maltreatment

## OUTCOME IDENTIFICATION AND PLANNING

Planning must center first on ensuring the safety of the maltreated family member and minimizing the effects of trauma. Second comes reporting the discovery to authorities as nurses are mandated by law to report child maltreatment. Long-term planning includes helping a maltreated family member find safe refuge and re-establishing self-esteem through a self-help or advocacy program. Teaching empowerment, or the ability to take charge of one's life, is particularly important for older children and women in families where there is maltreatment or violence. In addition, the person who maltreated a child or woman needs a program of therapy to help prevent future offenses.

The following organizations can be helpful for referral: Parents Anonymous ([www.parentsanonymous.org](http://www.parentsanonymous.org)), the Child Abuse Prevention Network ([www.child-abuse.com](http://www.child-abuse.com)), the National Coalition Against Domestic Violence ([www.ncadv.org](http://www.ncadv.org)), and Women Organized Against Rape ([www.WOAR.org](http://www.WOAR.org)).

## IMPLEMENTATION

The most important intervention related to family child maltreatment or intimate partner violence is prevention. Nurses can do much in all settings to be particularly observant for families who seem to be at risk for maltreatment or violence and role

model optimal ways to handle family stress. Further education is an intervention that can help parents who may not recognize their children's needs or normal child behavior to learn healthy patterns of childrearing.

### **OUTCOME EVALUATION**

Expected outcomes should focus on specific examples of improved family interaction, such as:

- The parent holds baby in a caring manner and maintains good eye contact.
- The parent attends full series of counseling sessions on learning better parenting.
- The parent states she has the Crisis Center telephone number on her cell phone and will call for help if she feels under threat by her partner.
- The adolescent states she can still think of herself with high self-esteem despite rape by stepbrother.
- The parent attends monthly meetings of Parents Anonymous.

## **Health Promotion and Risk Management**

Prevention must be the goal of healthcare providers to reduce the incidence of child maltreatment (Box 55.2). Because many adults who maltreat children were maltreated themselves, stopping the cycle of abuse will help prevent maltreatment in generations to come.

### **BOX 55.2**

#### **Measures to Prevent Child Maltreatment or Intimate Partner Violence**

1. Advocate for high school or college courses on parenting and growth and development of children so young parents are familiar with typical growth and development of children.
2. Help children learn problem-solving techniques so they are not overwhelmed by mounting problems when they become adults.
3. Foster high self-esteem in children and women so they are not dependent on others but are assertive (to prevent them from becoming passive observers to maltreatment or violence).
4. Help parents with responsible reproductive planning, so children are intended and desired.
5. Help parents locate support people in their community, such as crisis centers or Parents Anonymous or religious or social contacts, so they have ready support people to help them manage stress.
6. Role model caring behaviors with children for parents.
7. Identify children who may be viewed as special in some way by parents, such as those who were separated from the family at birth, were premature, or are

physically or cognitively challenged, because these children are at high risk to be victims of maltreatment.

8. Identify parents who were maltreated as children and offer specific help to them to break the chain of child maltreatment.
9. Advocate and support laws that implement the “No Hit Zone” in public places such as hospitals and school settings.

Identifying parents who may be at risk for maltreating their child is a necessary step in prevention. Listen carefully to the way pregnant women or their partners talk about the child they are expecting. A parent who is overly concerned about the physical appearance or sex of the child (“This had better be a girl” or “He’d better not have his father’s nose” or “She better have good hair”) may have difficulty accepting a child who does not meet these expectations. Listen for a parent who is concerned about “not letting children get the upper hand” or who says a child “had better be good.” Such parents may be conveying worry about how they will act when a child is “bad.”

During the postpartum period, be aware of parents who do not touch their infant within 24 hours and those who make disparaging remarks about the child’s appearance, as this lack of contact could signal risk. Remember, though, not all parents immediately bond or react warmly to their newborns. Many may only tentatively touch or pick up their infant immediately.

Parents may also be identified as being able to maltreat children during health maintenance visits. By the time a baby is brought to a healthcare agency for the initial health maintenance visit, you should be able to see that positive parent–child interaction has begun. Listen for parents who say the baby is “nothing but trouble,” “cries all the time,” or “is bad.” Ask new parents how it feels to be a new parent. “I’m exhausted but enjoying it” is a different answer from “It takes too much time” or “It’s not much fun.” Specific observations to make during postpartum and pediatric healthcare checkups are summarized in [Box 55.3](#).

### BOX 55.3

#### Questions to Ask to Detect the Potential for Child Maltreatment in New Parents

1. Is the parent enjoying this new role?
2. Does the parent establish eye contact with the baby?
3. How does the parent talk to the baby? Is everything expressed as a demand?
4. Are most of the parent’s verbalizations about the child negative?
5. Does the parent remain disappointed about the child’s sex or appearance?
6. Are the parent’s expectations for the child’s development far beyond the child’s capabilities?
7. Is the parent very bothered by the baby’s crying? Does he or she ignore the baby’s demands to be fed? When the baby cries, is the parent able to comfort the

child?

8. What is the parent's reaction to the task of changing diapers? Is the parent repulsed by the messiness?
9. Can the parents name a support person they can turn to for advice or assurance?
10. Is sibling rivalry a problem? Is the husband jealous of the baby's claim on the mother's time and affection?
11. When a parent brings the child for health care, does the parent become involved with the baby's needs during the examination and while in the waiting room? Or does the parent relinquish control to the healthcare provider or nurse such as undressing the child, holding the child, or allowing the child to express fears?
12. Can attention be focused on the child in the parent's presence? Can the parent see something positive in that focus?
13. Does the parent report nonexistent symptoms in the baby? Describe the child in terms that you do not recognize at all? Call with strange stories, such as the child has stopped breathing, changed color, or is doing something "on purpose" to aggravate the parent?

Helping parents to seek assistance from support people is another necessary step in prevention. Home visits, family counseling and therapy, and referral to organizations for parents who maltreat children, such as Parents Anonymous, can be highly effective in encouraging parents to reach out for help in times of crisis.

Another nursing responsibility aimed at preventing child maltreatment is helping young parents learn about normal growth and development of children and how to better respond to the child's behavior (Fig. 55.1). Courses in high school or college that describe sound parenting and review normal growth and development and the responsibilities involved in parenting are additional measures in preventing child maltreatment. Parenting classes conducted in high-risk prenatal settings might also have an impact.

**Figure 55.1** Teaching that all children have unique characteristics helps to prevent child maltreatment. Here, new parents explore the already noticeable unique aspects of their newborn.

## Child Maltreatment

Because parenting is not an easy task and good parenting is not an automatic or truly instinctive ability, children in every community are injured because of maltreatment. This may be physical (the child is beaten or burned), it may be neglect (the child is not fed, clothed, supervised properly, or offered medical care or educational opportunities), or it also could be psychological or emotional (a child is made to feel unintelligent or inadequate). In some instances, women who threatened the health of their fetus by abusing drugs during pregnancy have been viewed by some courts as being guilty of child maltreatment (Goodwin, 2011).

Maltreatment not only places a child at immediate risk for harm but can also lead to long-term effects. For example, physically maltreated children are found to be more angry, noncompliant, and hyperactive than others; they may demonstrate poor self-control and low self-esteem. Children whose parents do not interact with them (emotional maltreatment) are apt to be more withdrawn and to have a flatter affect than others. Because a family where maltreatment occurs is a disrupted one, children often have undiagnosed medical problems, such as anemia, otitis media, or lead poisoning. Children who suffer sexual maltreatment can develop sexually transmitted infections or have long-term effects of depression, guilt, and difficulty enjoying sexual relations (Honor, 2010).

In addition, when children reach adulthood and begin parenting, they tend to rear their children in basically the same way as they were reared. Parents who themselves

received little love or were maltreated as children may never form a basic sense of trust and so may not be able to form a sense of intimacy or the ability to care for others as late adolescents.

## **THEORIES OF CHILD MALTREATMENT**

The most commonly accepted theory regarding why child maltreatment occurs is that a special triad of circumstances develops (Helfer & Kempe, 1987):

- A parent has the potential to maltreat a child (special parent).
- A child is viewed as “different” in some way by the parent (special child).
- An event or circumstance brings about the maltreatment (special circumstance).

Some health practices or illnesses can be confused with child maltreatment and thus are important to remember in assessment. For example, coin-rolling, a type of massage to draw illness out of the body used by some Asian cultures (a coin is heated and then vigorously rubbed over the body), leaves red welts on the back similar to those that would appear on a child who has been struck repeatedly.

Some infants may bump their head while learning to walk; most toddlers have some ecchymotic spots on their legs from bumping into tables or chairs during normal toddler activities, and preschoolers who actively play may have bruises on multiple bony spots (shin, elbows, knees, etc.). Some childhood diseases, such as leukemia or purpura, begin with easy bruising, which can mimic marks from maltreatment. Children with osteogenesis imperfecta have frequent broken bones as a natural consequence of their disease. Because of inadequate fact finding in these instances, false reports do occur. When this happens, it can lead to severe stress on the family that has been falsely accused and can interfere with the relationship between the parents of an ill child and the healthcare personnel who will then give care to the child. Being aware of a practice such as coin-rolling and usual symptoms of illnesses aids understanding of the meaning of illness to parents and helps prevent false reports of child maltreatment.

There are, however, classic “red flags” of nonaccidental trauma that are important to keep in mind, such as spiral fractures of bones (from a twisting force—envision an adult twisting a child’s arm, hard) and skull fractures. There are times when these injuries are unintentional injuries, such as a spiral fracture of the leg because the child slipped when climbing down the bunk-bed ladder and the leg was caught while the body twisted and fell, but these injuries always need to be reviewed carefully with an increased index of suspicion. Any fracture in a nonmobile infant is suspicious, especially long bone fractures (Sullivan, 2011). Always assess for injuries that do not match a child’s developmental level or abilities or injuries that do not match the explanation of how the injury occurred.

### **Special Parent: Parents Who Maltreat**

Risk factors for parents who maltreat children include substance abuse, mental health issues, young age, low education and income, single parent status, and having multiple

dependent children (Fortson, Klevens, Merrick, et al., 2016). Many of these parents were maltreated as children. They may be unfamiliar with the normal growth and development of children and so have unrealistic expectations of a child. They also may be socially isolated, with no support readily available, and can become overwhelmed by childrearing. The isolation may be by distance (a parent separated from other people in a farmhouse miles from neighbors) or it may be the type that exists in communities or apartment houses where neighbors do not routinely speak to one another. Maltreatment is strongly associated with excessive parental use of drugs such as alcohol, substances that remove inhibitions and self-control. Studies have found that areas with an increased amount of bars per square mile have increased amounts of child neglect, whereas areas with more off-premises alcohol outlets/liquor stores have increased amounts of child maltreatment, possibly because some parents who drink in bars leave children home alone, whereas some parents who drink at home are more likely to maltreat when the child “misbehaves” (Freisthler, 2011).

### **Special Child: Children Who Are Maltreated**

Maltreated children tend to be viewed by parents as somehow “different.” They may be more or less intelligent than other children in the family; they may have been unplanned, or they just may not live up to their parents’ expectations in some way. Studies suggest that lesbian, gay, and bisexual (LGB) children and adolescents are also at greater risk of child maltreatment compared to non-LGB kids. These children and adolescents are 3.8 times more likely to experience sexual abuse and 1.2 times more likely to be physically abused compared to their heterosexual peers (Friedman, Marshal, Guadamuz, et al., 2011). Additionally, children with gender nonconformity are at increased risk of child maltreatment during childhood (Roberts, Rosario, Corliss, et al., 2012).

Children younger than 4 years of age are at greater risk for child abuse than older children as are those who require an increased caregiver burden such as children with disabilities, mental retardation, mental health issues, and chronic illness (Fortson et al., 2016). Without an effective relationship, when a child is injured, parents who are unable to deal with stress may not show the usual degree of compassion for their child’s pain or offer comfort. They may appear more concerned with how the injury affects them than how it affects the child, saying, “Don’t cry. You’ll make me look like a bad parent,” rather than, “It’s okay to cry. I know that hurts.” They may not seek treatment for an injury in an expected amount of time.

To prevent maltreatment, a child may assume a role reversal with the parent or become the comforting, solacing person. They recognize very early in life that when a parent is upset, they will be hurt. They learn to comfort the parent and reduce the parent’s stress and anxiety, thereby avoiding the hurt. For this reason, it is important to assess who is comforting whom when a childhood injury occurs.

### **Special Circumstance: Stress**

The third factor in child maltreatment is stress, which may be a response to an event that would not necessarily be stressful for an average parent. It might be something as common as a blocked toilet, an illness in the family, a lost job, a landlord asking for the rent, or a rainstorm that cancels a picnic. Child maltreatment crosses all socioeconomic levels because stress of this nature occurs at all levels. Stress generally has a greater impact on individuals who do not have strong support people around them. Families whose internal support system is faulty or who have not formed outside support systems are apt to have a higher incidence of maltreatment.

## REPORTING SUSPECTED CHILD MALTREATMENT

State laws typically identify two levels of responsibility for reporting child maltreatment: mandatory reporters and permissive reporters. **Permissive reporters** are encouraged to report suspected child abuse but are not required by law. **Mandatory reporters** are professionals who are mandated by law to report child maltreatment. Nurses are included in the mandatory category in most states; this means they *must* report suspected child maltreatment when they identify it. Failure to do so can result in a fine, jail time, or loss of nursing licensure. The fact that the information was given in a confidential interview does not free a nurse from this responsibility (it is an exception under the confidentiality rules of the Health Insurance Portability and Accountability Act [HIPAA]) (Fraser, Mathews, Walsh, et al., 2010).

All healthcare institutions and agencies have protocols on how the reporting of child maltreatment should be managed. It is important to learn the protocol required by your particular agency, community, and state. After an official report of child maltreatment has been made to a child protection agency, a hospital has the right, in most instances, to hold the child for 72 hours for protection to give an appointed caseworker time to investigate whether maltreatment has occurred. After the 72 hours, a court proceeding will determine whether the child should be returned to the parents' care or kept in a safer location. Because child maltreatment is a crime, the healthcare record of the child can be subpoenaed and displayed in court. Be certain, therefore, when charting information related to child maltreatment that you make specific and factual notes (observations, not interpretations), such as "Parent spoke loudly and slurred his words," rather than "Parent was intoxicated," or "Mother stated, 'This child is nothing but trouble,'" not "I think this mother dislikes this child." Photographs of physical maltreatment enhance the strength of the testimony of maltreatment, so these are usually taken.

A second provision in state laws is protection from having a lawsuit brought against a healthcare provider for reporting suspected maltreatment "in good faith" that is then proved false. In other words, the laws are written to make it better to err on the side of reporting suspected maltreatment rather than not reporting it, from both a child safety standpoint and a legal perspective. When maltreatment is officially reported, parents need to be told child maltreatment is suspected because open lines of communication with parents are important to both protect the child and to arrange counseling for the

parent who has maltreated the child. Remember when taking history that maltreatment is not always done by parents, so a parent could really not know how an injury occurred. Alternate caregivers such as daycare workers, a babysitter, or a nonbiologic parental figure (the new spouse) could be the person at fault.

## PHYSICAL MALTREATMENT

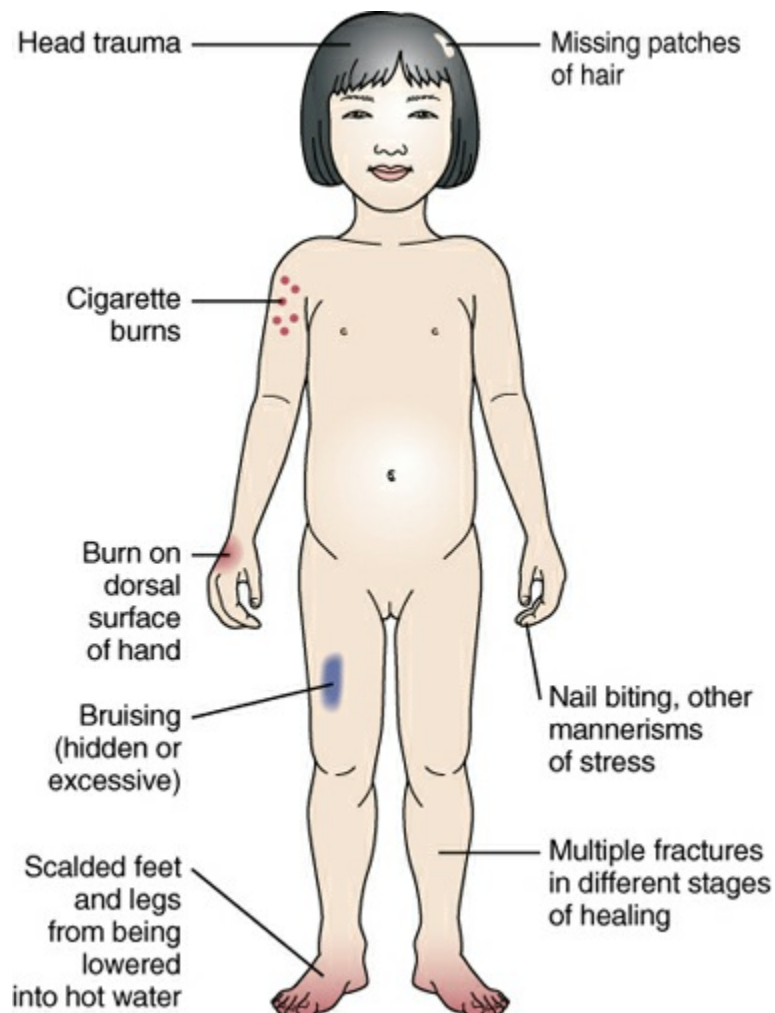

Physical maltreatment is the action of a caregiver that causes physical injury to a child. It is commonly revealed by burns or by injuries to the head or hands (Box 55.4).

BOX 55.4

### Nursing Care Planning Using Assessment

#### ASSESSING A CHILD FOR SIGNS OF MALTREATMENT

### Assessment

When taking history, always ask caregivers to account for any injury to a child's body. Remember, however, that most childhood injuries are the result of unintentional injuries

caused by the child's inability to distinguish safe situations from dangerous ones or by parents' overestimating their child's ability to do such things as lighting a fire to burn trash or using a saw for a wood project.

An important mark of maltreatment in contrast to an unintentional injury is that the injury is out of proportion to the history given by the parent or caregiver (Fig. 55.2). The parent or caregiver, for example, may report that the child was playing underneath the coffee table when he reared up quickly and hit his head to explain the large hematoma and temporary loss of consciousness the child is experiencing or that the infant "rolled off the couch" but now has two broken arms. In other instances, the parents may give conflicting stories (the mother says the child fell, but the father says the child broke his arm while throwing a baseball) or they may give no reason for the injury ("He woke up from his nap and couldn't move his arm; I have no idea what could have happened.").

**Figure 55.2** (A) Cigarette burn on child's foot. (B) Branding injury showing imprint of radiator cover. (C) Rope burn with edema and skin breakdown from being tied to crib rails. (D) Imprint marks from beating with a looped electrical cord. (From Zitelli, B. J., & Davis, H. W. [1997]. *Atlas of pediatric physical diagnosis* [3rd ed.]. St. Louis, MO: Mosby-Year Book, Inc.)

Ask children about the injury as well as the parents because if they did not hear the

parent's explanation of the injury, they may say something that is inconsistent with the parent's explanation. They also may cry little in response to a painful procedure, such as an injection, because they are not used to receiving comfort for pain. They may draw back from an examiner more than the average child because they are afraid of adults. These are very subjective observations, however, because children react in different ways to the fear produced by a recent injury or a health examination.

It is often difficult to remain objective when talking to the parents of a child who has been maltreated when you believe the parent is the one who is guilty of the maltreatment. Emotional involvement is not constructive, however; it rarely helps the parents to change, and it may cause them to avoid seeking health care in the future, leaving the child totally unprotected, especially if they were not the one who hurt the child.

To remain objective, always assume the parents have done the best they could under the circumstances in which they found themselves. The fact they have brought the child for care means they are seeking help; it may be their way of saying, "Help me; I don't want this to happen again." In many instances, child maltreatment is not an isolated phenomenon or a parent is also a victim and needs as much help and protection as the child.

## Physical Examination

When children are examined at a well-child visit or because of illness, be certain they are fully undressed (including removing all bandages and adhesive bandage) so their entire body can be observed. Plot height and weight on a standard growth chart. Delays in growth may suggest neglect.

Several injuries in children clearly signal probable child maltreatment. Most parents protect their children's hands carefully; in contrast, children who are maltreated have a higher incidence of hand injury. Children who are beaten with electrical cords, belts, or clotheslines have peculiar circular and linear lesions (see [Fig. 55.2](#)). Children who are beaten with a belt buckle may have additional curved lacerations from the imprint of the buckle; few other objects produce such contusions. Abrasions or ecchymotic areas on the wrists or ankles may be present if the child was tied to a bed or against a wall.

Burns or scalds are frequent injuries in maltreated children. The peak age at which children unintentionally burn themselves is 2 years; the peak age of burns related to maltreatment is closer to 3 years. When children burn their hand by accident, they usually burn the palm; burns from maltreatment are often on the dorsal surface. Scalding with hot water can occur from a child pulling a hot cup of coffee or a coffee maker off a table. This can, however, be child maltreatment (an adult deliberately scalded the child). Young children do unintentionally step into bathtubs containing water that is hot enough to burn. When this happens, however, the child usually falls forward and so also has burns on the hands and splash marks on the chest or face. If a child is lowered into scalding water as punishment, only the feet and the skin up to the knees are scalded. A child who is placed in a tub of hot water buttocks first by an angry

parent usually has no burn in the center of the buttocks because the buttocks touched the bottom of the tub creating a ring of burns or a “doughnut-hole” effect.

Cigarette burns are another common finding on the bodies of physically maltreated children. A fresh cigarette burn causes a blister that resembles the scab of impetigo; differentiation at this stage is often difficult. Impetigo lesions, however, heal without scarring. Cigarette burns heal with a definite circular scar.

Human bites or chunks of hair pulled off the scalp are other signs of maltreatment. Head injuries and broken bones are also frequent findings. Children who are preschool age and younger usually do not fall far enough under normal circumstances to break bones; a broken bone at this age, therefore, suggests the child was thrown or struck so hard the bone broke. Other common findings include multiple fractures in different stages of healing, rib or occipital fractures, and metaphyseal–epiphyseal injuries. Bones are not always broken if a child is shaken roughly, but the periosteum may be torn so that an X-ray reveals a strange haziness along both sides of the bone shaft. Tibial torsion (twisting) is also often seen (Fig. 55.3).

**Figure 55.3** A spiral fracture around the bone is caused by a wrenching force and is frequently associated with child maltreatment.

Deliberate poisoning is yet another form of child maltreatment; this usually occurs in a child younger than 2.5 years of age. Bruises on a child who is too young to walk also are highly suspicious because those bruises only come from outside sources. Remembering the 3 Bs, a light-hearted although meaningful phrase for such an important situation, may help with assessment: **B**ruises on **B**abies are nearly always **B**ad (Lazoritz,

Rossiter, & Whiteaker, 2010) (Fig. 55.4).

**Figure 55.4** Large bruises on a child's body. With this type of injury, carefully assessing the history of the traumatic event would be essential. (© Biophoto Associates/Photograph Researchers.)

**QSEN Checkpoint Question 55.1**

**TEAMWORK & COLLABORATION**

Which finding in Hillary's history would cause the nurse to alert Child Protective Services because the nurse suspects child maltreatment?

- a. Hillary's mother described her as "not pretty."
- b. Hillary has a previous health visit for "multiple bruises."
- c. Hillary's mother is under severe stress because of her job.
- d. Hillary's mother described her as "clumsy."

Look in *Appendix A* for the best answer and rationale.

**Nursing Diagnoses and Related Interventions**

**Nursing Diagnosis:** Risk for injury related to documented maltreatment by parent

**Outcome Evaluation:** Child has no further physical injuries identifiable as being inflicted by parent.

*Prevent Further Maltreatment.* When child maltreatment is discovered, it would be ideal if the person responsible for the maltreatment could change behavior, and thus, the relationship could be kept intact. In most cases, however, once child maltreatment

has been discovered, either the child or the abuser usually must be removed from the home to keep the child safe from being maltreated again. Even so, it may be impossible to reverse the damage that has been done to the child's sense of trust and self-esteem.

*Provide Consistent Care and Support for the Maltreated Child.* A major nursing role is providing a consistent, caring adult presence for a maltreated child where the child can feel safe. [Box 55.5](#) shows an interprofessional care map illustrating both nursing and team planning for a child who has been maltreated.

Use a primary or case management type of nursing care assignment to offer consistency and the security of a one-to-one relationship. Many maltreated children are used to playing by themselves, not with an adult, and only to the point at which a parent wants them to continue; this means they may watch you carefully for signs that you approve of their behavior. They may not be used to activities such as quietly rocking or talking. When taking history, be careful not to imply that any one answer to your question will be the correct one. Otherwise, maltreated children may supply what they think you want to hear rather than the truth. (A question such as "That feels better, doesn't it?" may be followed by an instant "yes" even though the child feels no improvement in symptoms.)

*Evaluate and Promote Family Health.* An important factor to help evaluate is whether a child will be safe remaining in the parents' care. When parents who are suspected child abusers visit the healthcare facility, be certain they are given the same welcome and orientation to the facility and procedures as other parents. When caring for a child, point out positive characteristics about the child, as well as growth and development markers and realistic expectations of the child's age, because lack of knowledge of normal growth and development may have contributed to the maltreatment. Take some time as well to talk to the parents away from the child so that your total attention is focused on them. Praise them for the things they have done well to lay a foundation for them to accept counseling and hopefully change.

For many parents, the response to a charge of child maltreatment is anger. For others, it is relief; now, an unwanted child will be taken away from them. In some instances, the diagnosis of maltreatment will force a passive partner to make some important decisions about whether to continue a marriage or relationship with the abusive partner. These are not easy decisions to make; if decision making of any kind were easy for this parent, the circumstances probably would never have reached the point at which child maltreatment occurred.

In some instances, a maltreated child will be removed temporarily from a home and only returned to the home after the person responsible for the maltreatment has been removed or after the stress that led to the maltreatment has been resolved. Such children need careful follow-up because an offending parent may return to the home while waiting trial and, if stress occurs again, revert to a maltreatment pattern.

If a child was injured seriously enough to be hospitalized and has had to be

removed permanently from the parents' care, urge the foster family to visit before discharge to make the transition less frightening for the child. Children who are being removed from their parents in this way can feel an acute sense of loss and may grieve for the non-abusing parent or siblings very much. You may also find maltreated children grieving for an abusing parent, especially if they are convinced that they were the one responsible for the maltreatment or that the parent was not to blame.

Outcome evaluation for maltreated children must include not only whether they are physically safe but also whether they are developing emotional well-being. Children who are maltreated oftentimes suffer from posttraumatic stress disorder that can affect them throughout adulthood if not addressed earlier.

BOX 55.5

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR A CHILD WHO HAS BEEN MALTREATED

Hillary is a 3-year-old you see in the emergency department. She has a broken forearm, a broken rib, and multiple bruises on her chest and back. She was seen in the same emergency room a month ago for a burn on the palm of her hand. When you mention to her mother that Hillary's injuries seem extreme for a simple fall, her mother says, "Hillary isn't very pretty. I guess she's also clumsy." You suspect Hillary may be a victim of child maltreatment.

**Family Assessment:** Hillary is an only child. Mother works long hours as city mayor; father (computer consultant) provides child care most evenings. Finances rated as "good." When primary healthcare provider suggested the child may have been beaten and maltreated, she stated, "Neither of us would ever do that. Not with me running for reelection."

**Patient Assessment:** A 3-year-old girl dressed in wool coat and cap even though outside temperature is 80°F. Father protested removal of the child's clothing for examination. Child's right forearm is misaligned and swollen; 3 × 4-in. bruise on right side of anterior ribs, four ½-in. diameter circular lesions on right arm; large 4-cm ecchymotic area on both buttocks and anterior left thigh. Sharp, pointed, triangular blistering and inflamed area noted on back of left hand mother states are "mosquito bites"; mark on hand is a "birthmark." Child remained passive while being examined but drew back when mother approached.

**Nursing Diagnosis:** Fear related to repeated episodes of maltreatment

**Outcome Criteria:** Child expresses fears verbally and through play; interacts with caregivers appropriately; demonstrates positive age-appropriate coping behaviors.

Team Member

Expected

Responsible	Assessment	Intervention	Rationale	Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess what self-care activities child is able to complete after right arm is casted.	Assist child as necessary with self-care.	Maltreated children may lack self-esteem; allowing them to do as much self-care as able can help improve self-esteem.	Child names tasks she thinks she can do herself; asks for appropriate help for others.
<i>Teamwork and Collaboration</i>				
Nurse/primary healthcare provider	Assess physical and history findings to establish suspicion of maltreatment.	Contact hospital child maltreatment team and alert them to suspicious findings.	Child healthcare providers have an obligation to report maltreatment to proper authorities.	Child maltreatment team meets with parents; documents or rules out maltreatment.
<i>Procedures/Medications for Quality Improvement</i>				
Nurse/nurse practitioner	Assess whether child has ever had a full physical examination and full-body photographs before.	Perform or assist with a complete physical exam and photographs to document child's injuries.	Physical examinations can refresh memories of maltreatment; photographs document extent and type of injuries.	Child cooperates with physical exam and photographer. Photographs are obtained.
<i>Nutrition</i>				
Nurse	Assess whether child is able to manage fork and spoon with cast in place.	Offer help with eating as necessary.	Eating is a self-care activity that can increase self-esteem.	Child demonstrates ability to eat satisfactorily with cast in place.
<i>Patient-Centered Care</i>				

Nurse/primary healthcare provider	Assess whether parent understands the seriousness of the diagnosis of child maltreatment and need for hospitalization.	Explain the reporting procedures and actions that accompany a child maltreatment report.	The parent's cooperation is essential for a successful outcome.	Mother states she will cooperate with procedures. Child understands she will remain in hospital overnight.
-----------------------------------	--	--	---	--

---

*Psychosocial/Spiritual/Emotional Needs*

---

Nurse	Assess which the best primary nurse provider for the child.	Arrange for a primary nurse provider; assure child she is now in safe hands.	Removing the child from the threatening environment and providing a consistent caretaker can help reduce fear.	Child states she feels safe in the hospital; participates in therapeutic play.
-------	---	--	--	--

---

*Informatics for Seamless Healthcare Planning*

---

Nurse/child maltreatment team	Assess whether parent would like a referral to Parents Anonymous.	Make a referral as appropriate for support group for family. Explain why a restraining order may be issued to prevent one or both parents from visiting child.	Family needs continued follow-up and support because investigation of child maltreatment can be lengthy. Passive parent needs counseling as well as potential maltreating parent.	Parents are cooperative with maltreatment investigation; will attend at least one parents' group meeting.
-------------------------------	---	--	---	---

*What If . . . 55.1*

**A nurse overhears Hillary keep repeating to her mother that she knows the**

**fall was her own fault and her mother shouldn't be mad because everything will be all right. Is this a typical sign of maltreatment?**

---

## **ABUSIVE HEAD TRAUMA**

**Abusive head trauma**, previously known as shaken baby syndrome, is the repetitive, violent shaking of a small infant by the arms or shoulders, causing a whiplash injury to the neck, edema to the brainstem, possibly subdural hemorrhage, and distinctive hemorrhages to the retinas ([Hitchcock, 2012](#)). A controversial diagnosis, and one difficult to prove, it is a particularly insidious form of child maltreatment because the damage inflicted on the infant is not readily apparent. Increased use of computed tomography (CT) scans and magnetic resonance imaging is helping to detect children with these internal symptoms. Parents may bring a child for care because they have used a covert camcorder (“a Nanny cam”) to reveal that a caregiver shook their baby this way.

## **RITUAL MALTREATMENT**

Ritual maltreatment is cult-based or religiously, spiritually, or satanically motivated and typically involves physical, sexual, or psychological maltreatment with bizarre or ceremonial activities. With this type of maltreatment, multiple perpetrators may maltreat multiple victims over an extended period ([Schwecke, 2011](#)).

## **PHYSICAL NEGLECT**

Physical neglect is a more subtle form of maltreatment than physical maltreatment, but it can be just as damaging to a child's welfare. A neglected child may appear unwashed, thin, and malnourished or be dressed inappropriately, such as without mittens, a coat, or shoes in cold weather. In some families, no one has a warm coat to wear or receives enough food because there is no money for these things; that is, different from the family in which parents do have these things, but the children or one particular child does not.

Failing to bring a child for medical attention or failing to seek early medical care for an infection are other signs of neglect. Not requiring a child to attend school, deliberately keeping a child out of school without setting up a home school program, or allowing a child to go unsupervised after school may also be interpreted as neglect. Such actions may be willful or they may occur if parents simply do not realize the developmental needs of a child. Use of electronic records allowing a child's total healthcare history to be examined has made identifying neglected children easier ([Tonmyr, Jack, Brooks, et al., 2012](#)). Many parents need anticipatory guidance from healthcare personnel to better understand their child's needs and developmentally appropriate parenting skills.

## PSYCHOLOGICAL MALTREATMENT

Psychological maltreatment includes constant belittling or threatening, rejecting, isolating, or exploiting a child or is the absence of positive parenting. Children who are psychologically maltreated this way are likely to have difficulty becoming emotionally confident adults. This type of maltreatment is the most difficult form of maltreatment to detect because it may occur only in the home, and its effects, although severe, may be subtle. It can result, however, in the same type of inability to achieve that occurs in children who are physically maltreated.

Be sure to include enough growth and development questions during a health assessment to assess for it; observe the parent–child interaction to determine whether it is positive and healthy or negative and potentially unhealthy. Some indicators of emotional abuse include:

- Developmental delays
- Bed-wetting without medical cause
- Frequent psychosomatic complaints
- Severe depression
- Anxiety or aggression
- Self-destructive behaviors such as self-harming
- Overly compliant child

Children who are emotionally abused may model negative behaviors and language from their parent, which can be witnessed when they are playing with other children.

## FACTITIOUS DISORDER

**Factitious disorder**, formally known as Munchausen syndrome by proxy, refers to a parent who repeatedly brings a child to a healthcare facility and reports symptoms of illness when, in fact, the child is well (Kucuker, Demir, & Oral, 2010). For example, a parent might report symptoms such as seizures, excessive sleepiness, or abdominal pain in a child. Because of these symptoms, the child is submitted to needless diagnostic procedures or therapeutic regimens. Another parent might go so far as to deliberately inflict injury on a child, such as giving a laxative to induce diarrhea or slowly poisoning the child with a prescription drug. Two classic findings of the syndrome are usually present: First, the symptoms are not easily detected by physical examination, only by history; and second, the symptoms are present only when the person initiating the symptoms is providing care (they disappear when care is provided by another person). The parent usually has some degree of medical or childcare knowledge obtained through formal education, reading, or Internet browsing. In the hospital, the parent tends to stay with the child constantly, offering to give the majority of care. This makes a difficult to detect form of maltreatment because wanting to stay and give care is also the hallmark of a very conscientious and caring parent.

To diagnose this disorder, covert video surveillance may be necessary. Because this syndrome reveals distorted perceptions on the part of the parent, it is almost always

necessary to remove the child from the home to protect the child, even if the parent receives counseling.

### *QSEN Checkpoint Question 55.2*

#### **SAFETY**

If Hillary had been maltreated as an infant, she might have experienced abusive head trauma (shaken baby syndrome). Which finding is common with this syndrome and would indicate a baby should be evaluated for medical and safety reasons?

- a. A baby is fearful of strangers.
- b. Retinal hemorrhages develop.
- c. A baby develops Crohn disease.
- d. A major bone has been broken.

*Look in [Appendix A](#) for the best answer and rationale.*

### **FAILURE TO THRIVE (REACTIVE ATTACHMENT DISORDER)**

**Failure to thrive** is a unique syndrome in which an infant falls below the 5th percentile for weight and height on a standard growth chart or is falling in percentiles on a growth chart. The condition is usually divided into two categories: One where severe loss of weight can be explained because of organic causes, such as cardiac disease, and a second that occurs because of a disturbance in the parent–child relationship, resulting in maternal role insufficiency (a nonorganic cause). Sometimes, both forms combine to play a role in failure to thrive (Jaffe, 2011).

The nonorganic type is considered a form of child neglect, although this represents a very complex interplay between parent and child. In many instances, the parent feels little emotional attachment to the child and often has a history of frequent moves and little family support. The parent may not be offering enough food because of the lack of attachment, he or she is not aware of the hunger cues the infant is offering, or the parent does not have enough concern for the child to offer food regularly. A child may contribute to the poor parenting interaction by being an irritable, fussy, colicky, or “difficult” child. Some infants are offered sufficient food, but the emotional deprivation they sense makes them so lethargic they do not eat enough. In other instances, the child has a minimal neurologic dysfunction and thus does not respond in a way that is developmentally appropriate for the child’s age. The mother may interpret this lethargic behavior as lack of response to her and thus does not interact or nurture the infant adequately.

Failure to thrive begins with subtle signs that need to be identified and taken seriously because the syndrome can lead to cognitive impairment in the child and even death if allowed to continue.

### **Assessment**

Take a detailed pregnancy history of children at routine health assessments because in many instances, a breakdown in the development of parenting began in the prenatal period because of such factors as a pregnancy that was unintended or not accepted, a partner who left during the pregnancy, an economic catastrophe such as loss of a job, or a long-distance move that left support people behind.

Always weigh children at routine assessments and plot and compare their weight with standard growth curves so children who are failing to thrive can be identified at the earliest point possible. On physical examination, these infants usually demonstrate typical characteristics such as:

- Lethargy with poor muscle tone, a loss of subcutaneous fat, or skin breakdown (Fig. 55.5)
- Lack of resistance to the examiner's manipulation, unlike the response of the average infant
- Rocking on all fours excessively, as if seeking stimulation
- Possibly a greater reluctance to reach for toys or initiate human contact than is demonstrated by the average infant; diminished or nonexistent crying
- Staring hungrily at people who approach them as if they are starved for human contact
- Little cuddling or conforming to being held
- Delays in sitting, pulling to a standing position, crawling, and walking because the child spends so much time alone
- Markedly delayed or absent speech because of the lack of interaction

**Figure 55.5** The child with failure to thrive experiences a loss of subcutaneous fat, muscle wasting, and skin breakdown. (From Zitelli, B. J., & Davis, H. W. [1997]. *Atlas of pediatric physical diagnosis* [3rd ed.]. St. Louis, MO: Mosby–Year Book, Inc.)

With advanced failure to thrive, the child's nutritional status may be so extremely poor that the infant is near acidosis from starvation. If an upper respiratory tract infection should develop, the child's resistance to infection may be so low that it could result in death from secondary infections such as pneumonia.

### **Therapeutic Management**

With rare exceptions, children with failure to thrive need to be removed from the parents' care and hospitalized for evaluation and therapy. Otherwise, the syndrome may lead to permanent neurologic damage or leave a child cognitively challenged because of protein deficits and interference with brain metabolism. If an infant is admitted to a hospital, studies other than routine admission blood work and urinalysis are usually delayed to avoid submitting such an understimulated child to pain or unnecessary manipulation.

Infants are immediately placed on a diet appropriate for their ideal weight (the weight they would have been normally for their age). Rapid weight gain on this diet is diagnostic that their presenting illness was nonorganic failure to thrive.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Imbalanced nutrition, less than body requirements, related to inadequate intake secondary to emotional deprivation

**Outcome Evaluation.** Child shows interest in bottle feedings; child is able to establish a regular eating pattern; child begins to gain weight.

Be certain the plan of care designed for the family of a child who is failing to thrive is realistic because parents cannot be made to form a bond with a child instantly, particularly if lack of bonding has gone on for some time. Don't give up hope, however, that this will happen. With the proper support and guidance over time, and when obstacles to bonding are removed, a healthy child–parent relationship could still develop.

*Ensure Adequate Nutrition.* Keep a careful record of intake and output so the number of calories being consumed every day can be effectively calculated. Assess stools for pH and reducing substances (glucose) to be certain the infant is absorbing nutrients. If a stool tests positive for glucose or has an acid pH (less than 7.0), it suggests that carbohydrates, the easiest food to absorb, are being processed.

Evaluate how well the infant sucks or is able to take food from a spoon and swallow to be certain these reflexes are intact. Record any symptoms, such as pulling up the legs or crying after eating, that suggest gastrointestinal discomfort.

*Nurture the Child.* Because infants with failure to thrive are suffering from emotional deprivation, they need effective nurturing from the nurses who care for them. This does not mean everyone who passes the crib should stop and play with the child for a few minutes; it means one member of the nursing team should be chosen to care for the child during the hospital stay (a primary nursing or case management pattern of assignment). It is important this nurse reserves time for providing active interactions with the child such as rocking and talking, giving a leisurely bath, offering toys, and “parenting” as passive rocking without talking to the child may be no different than the parents' care.

*Support and Encourage the Parents.* Encourage the parents of children with failure to thrive to visit as much as possible while the child is hospitalized or in foster care because without encouragement, these parents may visit little or not at all. When they do visit, encourage them to feed and interact with the infant. Parents cannot change their feelings about a child overnight, however, so telling them they ought to pick up the baby more or hold the infant while feeding may only increase the parents' feelings of inadequacy. Giving some suggestions about how the baby tries to communicate with them may be more effective; for example. “Do you know what I think he's trying to say when he stops sucking like that? I think he's saying he's

ready to be burped.” and “Look how he turns his head at the sound of your voice. He recognizes you.”

Occasionally, parents are so distraught by such factors as the illness or death of an older child or relative they simply have become unaware of how much energy is being drained from them by these events. These parents quickly can become good parents to a deprived child as soon as they realize what has been happening. More often, however, the disturbance in a parent–child interaction began long before or is so great that a parenting bond cannot be established. If the infant is discharged from the hospital to the parents’ care, the parents will need effective follow-up in the months to come to see that they maintain parenting skills that will keep the infant thriving and safe. There is a very thin line between the child who fails to thrive and one who is maltreated causing some of these children to be placed in foster homes for their own safety and to ensure that they receive adequate care.

*Help Prevent Poor Parenting.* Parents who may be at risk for lacking adequate parenting skills and support systems need to be identified during pregnancy, so they can receive counseling and close follow-up in the postnatal period. Some parents who are overwhelmed by the task of parenting may need respite care for their children and extended counseling to prevent future parenting breakdown.

### *What If . . . 55.2*

**A nurse weighs Hillary’s baby cousin at a well-child visit and discovers that the infant’s weight has fallen below the 2nd percentile on a standardized growth chart. What questions should the nurse ask the mother? What particular areas would the nurse assess on a physical examination?**

## **Sexual Maltreatment**

**Sexual maltreatment** is broadly defined as any sexual contact between a child and an adult (Neutze, Grundmann, Scherner, et al., 2012). Child sexual abuse is evident when the activity is intended to gratify or satisfy the needs of the other person. Such a scenario can include an adult or another child who is in a relationship of trust or power due to age. This type of relationships includes but is not limited to the coercion of a child to engage in any unlawful sexual activity or the exploitation of a child in prostitution or pornographic performances and materials (Legano, McHugh, & Palusci, 2009). It involves the coercion of dependent, developmentally immature children or adolescents in sexual activities that they do not fully comprehend, to which they are unable to give informed consent, or that violate the social taboos of society.

Sexual abuse is a problem of epidemic proportions with 25% of girls and 16% of boys in the United States sexually abused before the age of 18 years (Hornor, 2011).

Adolescents have a higher rate of rape or sexual maltreatment than any other age group (8% to 10%) (Delacroix, Brown, Kadenhe-Chiweshe, et al., 2011). It's important to remember that boys, as well as girls, can be sexually maltreated. Although their abusers may be seemingly trustworthy coaches or teachers, they also may be people inside the family such as an older sibling, a parent, or a stepparent (Carlson, 2011). Abusers may contact children online through chat rooms, making the monitoring of websites an important preventive measure for parents (Briggs, Simon, & Simonsen, 2011). Health professionals who care for children with cognitive disabilities must be especially watchful to protect these vulnerable children from sexual maltreatment (Koetting, Fitzpatrick, Lewin, et al., 2012).

Sexual maltreatment is physically and emotionally destructive because it leaves children unable to trust others and may result in a sense of ambivalence toward intimacy and an overall sense of worthlessness. Remind parents to teach children by preschool age that their bodies are their own and to report anyone who tries to touch them in their private parts (Fig. 55.6). Children who have been sexually maltreated may be identified because they have a sexual vocabulary beyond that expected of a child their age. On physical exam, girls will have tears or inflammation of the vagina or perineum; both sexes may have rectal tears or symptoms of a sexually transmitted disease. Nurses need to keep in mind that less than 5% of children who are sexually abused will have a physical finding upon examination. This is due to the noninvasive forms of abuse, the elasticity of the hymen and other ano-genital structures, and the rapid healing of ano-genital injuries without residual injury (Hornor, 2011).

**Figure 55.6** Teach children their bodies are their own and they have to give permission before anyone can touch them.

*Megan's Law* is a federal law that requires law enforcement authorities to report to neighbors when a sexual abuser moves into a neighborhood. Parents need to be aware of this law and insist that it should be enforced so they can take appropriate precautions to protect their children's safety (Neutze et al., 2012). Sexual predators are also listed on websites and thus can be tracked by parents. Additional laws parents need to be aware of to keep their children safe are child pornography laws. In some states, for example, "sexting" (texting sexually explicit photos) to friends may violate such laws—even though a minor is doing the texting. Their child could forever be classified as a sexual abuser and listed under Megan's Law (Wastler, 2010).

## **TYPES OF SEXUAL MALTREATMENT**

Sexual maltreatment involves a wide range of diagnoses from molestation to vaginal penetration.

### **Molestation**

**Molestation** is a vague term that includes “indecent liberties” such as oral–genital contact, genital fondling and viewing, or masturbation. A **pedophile** is an adult who seeks out prepubescent children (Tanner stage 0 to 1, usually younger than 12 years of age) for sexual gratification, whereas a **hebephile** seeks out pubescent children (Tanner stage 1 to 4, usually age 11 to 15 years) (Neutze et al., 2012). In contrast to a rapist, whose crime is violent, both pedophiles and hebephiles may be very gentle and limit the involvement to molestation. Such persons are usually male, but sometimes female; they may have suffered sexual maltreatment as a child and thus repeatedly select children or young adolescents who are of the same age at which the maltreatment occurred. The relationship may involve people with either homosexual or heterosexual orientations. Many pedophiles or hebephiles take photos or videos of their activities with children to use for sexual gratification at a later date.

Rehabilitation of pedophiles/hebephiles is difficult because they are fixated emotionally at a childhood level (seeing themselves as children, they do not perceive relationships with children as wrong). Listen carefully to children who report that someone enjoys photographing them; ask children to describe what they mean by someone “touching” or “feeling” them to detect this type of maltreatment.

### **Pornography and Prostitution**

Child pornography involves photographing or describing sexual acts by any medium involving children or distributing such material in person or by mail, fax, cell phone, or over the Internet. Child prostitution involves arranging or participating in sexual acts with children. Both of these phenomena are demeaning to children and are illegal. Child prostitution carries the additional risks of sexually transmitted infection and violence, the same as adult prostitution.

### **Incest**

**Incest** is sexual activity between family members. It often involves an older man and a young girl, although it may involve an older woman and a younger boy, a brother and sister, or a same-sex partner. It may involve foster, adopted, and stepchildren. Incest is a deviation from the norm and is so strongly viewed as such by most people that incest taboos are common to most cultures (Carlson, 2011). Incest results in a destructive relationship because it causes a great deal of guilt and loss of self-esteem in both the abusing and the maltreated person. The abuser is aware that this act is not culturally approved but still is unable to end the relationship; the victim recognizes this act as wrong but is unable to resist the advances. Other members of the family are likely to suspect the maltreatment is occurring but are helpless to do anything about it; this leads to guilt and feelings of worthlessness on their part for not being able to protect the victim.

Children do not typically report incest because they have been told by the abuser to keep the activity a secret. In some cases, it is first revealed on a routine health

examination by either history or physical findings of vaginal or rectal lesions.

### **QSEN Checkpoint Question 55.3**

#### **EVIDENCE-BASED PRACTICE**

It is difficult to know the true incidence of sexual maltreatment in adolescents because it is suspected that many adolescents never report the abusive incident. To investigate whether adolescents who are sexually maltreated confide in their parents, researchers interviewed 800 male and female adolescents ages 13 to 16 years to identify if they had been the victim of sexual maltreatment. One hundred and seventy-seven adolescents in the study revealed they had been sexually maltreated. Of that number, 81% of the participants disclosed the maltreatment to a friend and 70% disclosed to a friend within a month of the incident. Sixty-three percent disclosed to more than one person (Lam, 2014).

Mrs. Landstrum's adolescent sister, Andrea, is examined in the emergency room because she has pain and a vaginal discharge. Based on the previous study, the nurse determines which person (aside from Andrea herself) as most likely to be the most reliable reporter as to whether Andrea has been sexually maltreated?

- a. Andrea's mother, because Andrea says she respects her
- b. Megan, a soccer teammate and close friend of Andrea
- c. Andrea's father, because he is the patriarch of the family
- d. Andrea's soccer coach, because she sees Andrea daily

*Look in Appendix A for the best answer and rationale.*

#### **ASSESSMENT**

Signs of sexual maltreatment are shown in Box 55.6. In addition to physical signs, a suspicion of sexual maltreatment may first be revealed by a young girl worrying she is pregnant or a child's abnormal anxiety about a parent returning home from a hospital stay or being left with or cared for by a particular individual in the family (Box 55.7). Young children who are the victims of this type of relationship typically have extremely low self-esteem and may believe they are so inadequate they deserve to be treated this way.

**BOX 55.6**

**Nursing Care Planning Based on Family Teaching**

#### **IDENTIFYING SIGNS OF SEXUAL MALTREATMENT**

**Q.** Hillary's mother asks you, "What signs should I look for if I suspect my daughter is being sexually maltreated?"

**A.** Here are some general indications that a child is being sexually maltreated:

- The child reports she has had sexual activity with an adult.

- The child demonstrates an awareness of sex or a sexual vocabulary beyond her age expectations.
- The child participates in sexual expression with dolls.
- A girl younger than 15 years of age is pregnant.
- A perineal, vaginal, or anal exam reveals inflammation or vaginal tears or anal fissures.
- A child younger than 15 years of age has a sexually transmitted infection.
- A child has a history of symptoms of increased anxiety such as a sleep disturbance, development of nervous tics, nail biting, or stuttering.
- There is a change in school performance, school phobia, or truancy.
- The child voices a fear of being left alone with a certain adult.
- A child reports vague abdominal pain or demonstrates acting-out behavior.

### BOX 55.7

#### Nursing Care Planning Tips for Effective Communication

You notice during history taking that Hillary uses several swear words to describe where she hurts.

*Tip:* Help parents identify signs of potential child maltreatment. Remain nonjudgmental and encourage parents to ask questions or to discuss any concerns they may have.

**Nurse:** Mrs. Lindstrum, your daughter seems to know some words that are unusual for a 3-year-old.

**Mrs. Lindstrum:** She gets that from watching cartoons on TV.

**Nurse:** Cartoon characters don't usually say the words she uses.

**Mrs. Lindstrum:** We're proud she's advanced for her age.

**Nurse:** Using words with sexual connotations doesn't necessarily mean her vocabulary is advanced. It means she most likely keeps company with an adult who speaks that way.

**Mrs. Lindstrum:** That's probably her uncle. He babysits once a week.

**Nurse:** Does she mind staying with him?

**Mrs. Lindstrum:** Does it matter? A free babysitter doesn't happen every day.

**Nurse:** Let's talk some more about her vocabulary, especially in light of her infection.

Allowing young children to play with anatomically correct dolls is a common method for determining whether sexual maltreatment is occurring (Hlavka, Olinger, & Lashley, 2010). The average reaction of a preschooler or young school-age child who has not been maltreated, for example, is to undress the dolls, giggle for a moment or two about how they look, and then redress or put them aside. The child who is involved in

an incestuous relationship may make the dolls perform a sexual act, such as placing the male doll's penis into the female doll's mouth. The use of such dolls is controversial because there is a concern that without a common protocol for their use, the child's actions could be misinterpreted. Asking the child to draw a picture of what happened may also be an effective way of revealing sexual maltreatment.

## THERAPEUTIC MANAGEMENT

Sexual maltreatment, like physical maltreatment, must be reported because this is a criminal offense. It's important, as with all child maltreatment, that information about the maltreatment is collected objectively so the adult's rights are respected and the testimony is therefore admissible in court.

Both the adult and the child involved in a sexual maltreatment relationship need psychological counseling—the child to improve self-esteem and the adult to channel sexual expression to less destructive outlets. To improve the child's self-esteem, the adult in the relationship needs to admit the fault was the adult's, not the child's. Follow-up care is best done by one of the providers who sees the child initially, so that the child does not have to recount the incident to strangers again and again. Treatment for sexually transmitted infections or protection against pregnancy should be provided as needed.

Parents may need as much counseling as the child when their child has been sexually maltreated, so they can help the child work through feelings about the situation. In many instances, because the offender is a family member or a trusted outsider and the relationship has been occurring for some time before it is reported, parents may feel guilty they allowed the family member to have access to the child or did not listen to a child's protestations that being alone with this family member was uncomfortable for the child. If incest involves a parent or marriage or relationship partner, it may be extremely difficult for parents or partners to continue to relate to each other effectively enough to help the child. Review with parents and encourage parents to teach children simple rules to help children avoid sexual maltreatment (see [Chapter 32, Box 32.4](#)).

### *QSEN Checkpoint Question 55.4*

#### QUALITY IMPROVEMENT

A member of the child maltreatment team offers Hillary anatomically correct male and female dolls for her to play with. When Hillary begins playing, she places the male doll's penis in the female doll's mouth. How should the nurse best respond?

- a. "Do you think it's wrong that the dolls do that?"
- b. "I bet you're playing a game you've seen on TV."
- c. "Are the dolls playing a game? Tell me about it."
- d. "Okay, can you please put the dolls down now?"

*Look in [Appendix A](#) for the best answer and rationale.*

## Rape

Rape is sexual activity such as intercourse or penetration of a body orifice by a penis or other object under actual or threatened force. *Statutory rape* is sexual activity with a person under the age of consent (in most states, younger than 18 years of age) and is considered to have occurred regardless of the apparent willingness of the underage person. *Sexual assault* is typically used to refer to other forced sexual acts, such as oral–genital or anal–genital acts (Hornor, 2011).

Rape is a crime of violence, not of passion, and includes “date rape,” a situation in which an individual forces a date or casual friend into having coitus despite a voiced unwillingness or inability to consent (D. L. Lang, Sales, Salazer, et al., 2011). The increasing misuse of flunitrazepam (Rohypnol), a drug easily dissolved in a drink, has led to an increase in the incidence of date rape because it leaves a victim with little or no memory of the event (see Chapter 33). It may be very difficult for the victim of date rape to find a sympathetic ear if her companion insists he meant no harm; he simply didn’t believe her. Urge adolescents to be aware of the danger of the drug and to say “no” convincingly (Makin-Byrd & Bierman, 2013).

Both rape and sexual assault represent deviant behavior. They lack privacy and mutual consent, which are the elements of “normal” or usual sexual behavior, and include violence, causing them to be degrading and dehumanizing and leaving the victim feeling helpless and victimized. Review with teenagers of both sexes ways to prevent rape at routine health visits (Box 55.8).

### BOX 55.8

#### Nursing Care Planning to Empower a Family

#### GUIDELINES FOR THE PREVENTION OF RAPE IN ADOLESCENTS

**Q.** Hillary’s mother is concerned about the incidence of rape in her community. She asks you, “What should I teach my adolescent sister to help her avoid rape?”

**A.** A number of suggestions are:

##### Home

1. Do not advertise that you stay home alone while a parent works or is on vacation.
2. Do not allow anyone to your house when you are home alone, even meter readers or repairmen who produce identification.
3. Insist on adequate lighting for hallways in an apartment building or streetlights around your home.
4. Have your house key in your hand when you approach your door; do not stand fumbling for it by the doorway.
5. Keep your doors and windows locked when you are alone at home.

##### Car

1. Avoid isolated parking places; park near a building or in a lot with a parking attendant.
2. Lock your car when waiting in it and after parking it.
3. Look in the backseat before unlocking and entering your car to be sure no one is there.
4. Have your car key ready when you approach your car; do not stand fumbling for it.

**Work or School**

1. Do not enter an elevator with a stranger.
2. Lock the outside door and do not admit people you do not know when working alone in an office or classroom at night.
3. Ask for security protection to walk out to your car after hours.
4. When going to and from school or work after dark, walk in the street rather than next to shrubs or dark buildings.

**Social Settings**

1. Be clear with your date that when you say no, you mean no.
2. Limit alcohol use because it can lead to risk-taking behavior.
3. Make it clear you consider date rape the same as any rape and you will press charges.
4. Flunitrazepam (Rohypnol) is a sedative, known as a “date rape” drug. Do not date any individual who brags that he knows how to obtain it or use it.

**Personal Actions**

1. Do not wear chains around your neck that could be used to strangle you.
2. Learn self-defense; scratch the attacker to obtain skin and blood specimens under fingernails.
3. Be aware that an attacker could take any weapon you hold away and use it on you; use caution carrying a weapon or mace.
4. If an attack occurs, observe the attacker’s appearance as carefully as possible. Note identifying characteristics, such as a birthmark, scar, tattoo, words, or manner of speech, to be able to identify the individual later.
5. Press charges in court to make rape a crime of extreme magnitude and as an opportunity to fight back.
6. Work to provide rape prevention information and a united front against rape in your community.

Determining the actual incidence of rape is difficult; it seems to be more prevalent than formerly but that may be because more people report it. Many adolescents want to avoid the secondary, but no less severe, trauma associated with reporting rape and therefore do not report it. This leaves them, unfortunately, without the immediate treatment and follow-up care that are so important to a complete recovery.

Although victims can be of any age and either male or female, the average rape victim is an adolescent girl. The rapist may be a relative or family friend, and rapists

frequently commit the act in the neighborhood where they live. Up to 75% of girls know their attacker. Based on arrest data, the average rapist is a late adolescent man with a background of aggressive behavior. His motivation usually relates to expressions of power or anger; sexual satisfaction does not appear to be a dominant motive. An excessive amount of alcohol intake often precedes rape (Thompson, McGee, & Mays, 2012). Rape tends to be a repetitive, planned activity on the part of the attacker rather than an isolated event.

## ASSESSMENT

Many rape victims demonstrate immediate physical and emotional symptoms that can last for weeks. These symptoms constitute what has been termed **rape trauma syndrome**, a form of posttraumatic stress syndrome, and they usually occur in two stages: disorganization and reorganization. In the immediate *disorganization phase*, victims feel a combination of humiliation, shame and guilt, embarrassment, anger, and vengefulness. They feel that their lives have been completely disrupted by the crisis because they were unable to protect themselves from the assault. They may tremble from fear or be in great pain from perineal lacerations and are apt to startle visibly at the sound of anyone approaching or touching them. They need gentle, sympathetic support in the days after the event to allow them to feel safe. They may have nightmares of the attack occurring again. This immediate stage of disruption and disorganization usually lasts about 3 days.

The second stage of rape trauma syndrome, termed the *reorganization phase*, may last for months or years. Many rape victims report recurring nightmares, perhaps sexual dysfunction, and continuing inability to relate to the opposite sex or to face new and surprising situations. They may continue to have a great deal of difficulty discussing the rape. Many rape victims, trying to escape, change their residence at great sacrifice to finances and lifestyle. If not offered constructive counseling, victims may still feel guilt or shame when thinking about the rape as long as 20 to 30 years later.

## EMERGENCY CARE

Although most large-city police forces have special officers assigned to investigate rape charges, victims can be confused and further traumatized by police officers who imply they provoked the attack because of their manner of dress or could have done more to resist or prevent the event. This increases a victim's feelings of shame and degradation. It may be especially harmful to adolescents because people they have been taught to respect have no concept of the degree of fright they have experienced or the strength of their attacker. Healthcare providers usually are the second group of people victims see after an attack. It is vital that healthcare providers are extremely cautious to not show this same type of callous behavior.

Most healthcare agencies where many rape victims are seen have a rape trauma team, including specially educated counselors to talk to victims immediately after a rape

and to offer long-term counseling as needed. Nurses serve as important members of such teams and may provide primary care after a rape. Any nurse should be able to offer emergency support because it might be a long time before a specifically designated staff member arrives, and such services are not available in every community.

Because rape is a crime, the electronic record of a rape victim is often displayed as part of a court procedure. For the victim to bring charges against the attacker, information concerning the victim’s appearance and history needs to be detailed in the record. For that reason, a sexual assault nurse examiner (SANE nurse) should be called if available. Pediatric nurses trained as sexual assault examiners are called P-SANE nurses and are a crucial part of properly examining a child assault victim. Make sure to involve child advocacy centers (CACs) if available in your area to consult with and examine child maltreatment and child sexual assault victims. If available, *stop* after the initial basic exam and call the CAC team so they can properly interview and examine the victim, observing local laws and evidence requirements.

Table 55.1 summarizes common tests and procedures for emergency care of rape victims. If no CAC team is available, be certain statements you make in a record are accurate and unbiased. Quote the victim’s exact words whenever possible. Describe the victim’s physical appearance in unbiased detail, including the presence and location of injuries, such as bruises, lacerations, teeth marks, or abrasions, and the condition of clothing. Be certain to ask whether the victim bathed or washed before coming for care because this can obscure evidence and obliterate the presence of sperm or DNA material. Ask whether the woman was menstruating or using a tampon as the force of penis penetration with rape can cause a tampon to tear through the posterior vaginal wall into the abdominal cavity, causing an extreme loss of blood internally.

**TABLE 55.1 Common Specimen Procedures After Rape**

<b>Procedure</b>	<b>Purpose</b>
Oral washing	Help patient rinse mouth with 5 ml sterile water, which is then collected in test tube, analyzed for blood group antigens, or sperm or DNA of attacker.
Fingernail scraping	Scrape under all of patient’s fingernails so scrapings can be analyzed for blood, skin, DNA, and clothing fibers of attacker.
Blood Venereal Disease Research Laboratory (VDRL), HIV, and hepatitis B surface antigen (HBsAg)	Draw blood for antibody titer for syphilis, HIV, and hepatitis B and typing to differentiate it from attacker’s type.
Pregnancy test	Obtain blood for analysis; complete vaginal examination before woman voids.

Hair samples	Remove both scalp and pubic hairs of patient (about 10) to be compared with attacker's.
Vaginal smear for sperm and DNA	Swab vagina with a dry applicator and smear onto slide so sperm and DNA analysis can be performed.
<i>Gonococcus</i> smear	Culture the patient's cervix, vagina, and rectum (also throat if oral coitus was attempted).
Vaginal washing	Place 5 ml of sterile saline into patient's vagina and aspirate again to detect sperm, DNA, and acid phosphate.
Skin washings	Touch any dried stains of blood or semen on the patient's skin or clothing with a moistened cotton swab to be analyzed for attacker's blood, semen, or DNA.
Clothing	Save any clothing stained or torn as evidence of violent attack.

Label all specimens carefully, indicating where they were obtained, to aid medical therapy and provide legal evidence.

After preliminary observations, a gynecologic or anal examination will be done to evaluate the physical condition of the victim and to document that rape occurred by the presence of any vaginal or perineal lacerations or sperm or DNA left behind by the assailant on the perineum or in the vagina or rectum. Acid phosphate, a component of prostatic fluid, is a substance that is not normally present in vaginal or rectal secretions but is present in semen. Determining the presence of acid phosphate can be extremely important, therefore, if the attacker is infertile or sterile, making DNA analysis difficult. Its presence may be the best evidence that rape occurred. Vaginal and anal cultures are taken for gonorrhea, and a Pap test is also performed. Blood is drawn for a pregnancy test and a Venereal Disease Research Laboratory (VDRL) test for syphilis if appropriate. Prophylactic administration of antibiotics against gonorrhea and syphilis may be necessary. If the woman is not menstruating, she may be given "morning after" therapy to avoid pregnancy. The victim may have a baseline blood sample drawn to diagnose HIV and hepatitis B status.

Be certain during emergency care to provide privacy. Many people may want to ask the victim questions, including police officers or detectives, the victim's family, a rape trauma team, and an examining primary healthcare provider. Describing the experience is good, but lack of privacy during a perineal examination demonstrates little concern for the victim's self-esteem. Many female victims are uncomfortable with a male examiner after rape because they are temporarily fearful of men. Having a female nurse remain with the victim during this time may be helpful. A male nurse can be equally supportive, however, because it is not the male-female contrast that a victim is seeking

so much as a contrast between aggression and caring.

### *What If... 55.3*

**Hillary’s physical examination reveals she has purulent vulvovaginitis, and a culture reveals this is caused by gonorrhea. What questions should the nurse ask Hillary to determine how she contracted the infection? Would the fact that Hillary’s mother is influential in the city influence what questions the nurse asks?**

## LEGAL CONSIDERATIONS

Nurses working in emergency departments may be asked to testify in court about a rape victim’s appearance after the assault, although the documentation in the record is usually all that is necessary. Many victims, especially adolescents, do not press charges against their assailants because they were too frightened or unable at the time to observe the assailant’s appearance and therefore cannot identify him later. They may fear that if they name him in court, he will return and kill them. Whether victims follow through with a legal action or not is their choice, but the incidence of rape might be reduced if rapists were aware they are not apt to escape without a penalty for their crime. For that reason, some states have prosecutors press charges even if the victim declines, as with domestic violence charges. Taking the rapist to court may be an opportunity and appropriate time for victims to “fight back” and therefore not be as helpless as they were forced to be during the attack.

### *QSEN Checkpoint Question 55.5*

#### INFORMATICS

Hillary’s mother reveals that she was raped when she was a teenager. What is the most important question to ask before beginning a physical assessment for an adolescent who has been raped?

- “Have you bathed or showered since the attack?”
- “Did the rape feel more sexual or more violent?”
- “Was anything stolen from you during the attack?”
- “Can you think of a way you could have prevented this?”

*Look in [Appendix A](#) for the best answer and rationale.*

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Anxiety related to recent rape

**Outcome Evaluation:** Victim is able to discuss what happened and voice intense feelings about the crime; victim states ability to move forward with life.

One of the major needs of any victim after a violent act is to talk about what happened because a person who can describe an incident can also begin to “put a fence around” the event or bring the event down from “something terrible has happened,” a situation that leaves the person with a continuing high anxiety level, to “this specific thing has happened,” a situation that allows the traumatic event to be examined and managed (something that is concrete and describable is rarely as frightening as “something out there”).

Ask the victim to describe the incident to you with an introduction such as “Most people find it helps to talk about what happened to them.” Be certain victims have a support person to accompany them home. Be sure they know that, if their distress becomes acute, they can return as needed to the healthcare facility for additional care or counseling. Be certain as well that they have the telephone number of a counseling service.

Because genital bruising may not be apparent until 24 hours after the rape, victims may be asked to return for a re-examination the next day so this can be documented. Syphilis will not be apparent for up to 6 weeks in serum, so they should return for a repeat VDRL at that time. They may be advised to return in 6 weeks and again in 6 months for HIV testing.

**Nursing Diagnosis:** Disabled family coping related to recent rape of family member

**Outcome Evaluation:** Partner or other family members express feelings about the rape to healthcare provider; family members state confidence in ability to support rape victim.

In many instances, the victim’s usual sexual partner has difficulty being a support person after a rape because this person has as much difficulty dealing with the rape as the victim. Not infrequently, a relationship that was meaningful before the rape deteriorates because the partner mistakenly believes the victim was somehow responsible for the trauma or actually enjoyed the experience. In other instances, the partner may become so overprotective (not allowing the victim to go out alone; checking on her constantly) that she is not free to maintain her identity. Parents of a young adolescent may feel the same way. Counseling for the victim’s partner or family may be necessary to help them to be truly supportive ([Box 55.9](#)).

#### BOX 55.9

#### Goals of Crisis Intervention for Families of Rape Victims

- Help the family be supportive of and reassuring to the victim to help initiate problem-solving techniques.
- Explain the possibility of future psychological and somatic symptoms that

characterize a rape trauma syndrome and what the family can do to minimize these symptoms.

- Eliminate the family's sense of guilt for not protecting the victim by assuring them they could not have anticipated or prevented the rape.
- Educate the family about rape as a *violent crime*, not a sexually motivated act, to eliminate a focus on the victim's guilt or responsibility.
- Discourage violent, destructive, or irrational retribution toward the rapist (under the guise of being on the victim's behalf) by encouraging sharing of feelings of helplessness, sadness, hurt, and anger.
- Encourage discussion of the sexual relationship between partners; suggest that the victim's partner let her know (a) that his or her feelings have not changed (if this is true) and that she is still sexually desirable, (b) that the partner will wait for her to approach, and (c) that sex therapy is available if they have persistent difficulties and want assistance in reestablishing usual sexual relations.
- Explain the possibility of sexually transmitted disease and pregnancy that may result from a rape, the preventive care necessary for the victim and spouse or sexual partner, and the follow-up care indicated.
- Refer the family for counseling if members' shared responses to the crisis interfere with their ability to cope adaptively.
- Identify how the family has handled crises in the past and encourage members to use adaptive coping mechanisms for this crisis. Encourage contact with persons identified as supportive to the family and offer to contact such persons.

## Intimate Partner Violence

**Intimate partner violence** is maltreatment by a family member against another adult living in the household, such as a spouse or significant other. Spouse or partner maltreatment and child maltreatment may both exist in a family. It is vital for nurses to provide family-centered care to help identify and intervene with these situations. As many as 20% to 30% of women seen in emergency departments are there because they have been maltreated by their intimate partner. Common injuries suffered include burns, lacerations, bruises, and head injuries. Asking all women at physical examinations to account for any bruise they have helps detect physical maltreatment. Asking them whether they are ever concerned about their safety or well-being during well visits helps detect and prevent this type of maltreatment.

Like child maltreatment, intimate partner violence affects all ethnic and social groups. If it appears to be more prevalent in lower socioeconomic neighborhoods, it is because these families are more visible to service organizations and law enforcement officials. When it occurs in middle or upper class houses, wives are often too embarrassed to let people know and tend to keep the violence hidden longer.

It occurs at a higher rate during pregnancy than other times, so including questions about this in pregnancy health histories is especially important (Hellmuth, Gordon,

Stuart, et al., 2013). The rate of intimate partner violence is so high during pregnancy that homicide from intimate partner violence is the number one cause of death in pregnant women, a finding that probably occurs because stress (from pregnancy) can be a trigger to violence.

Maltreated women may have an unintended and unwanted pregnancy because they were unable to fight off sexual advances from their abusive partner. Other women may desire the pregnancy because they believe having a child will change the partner and make him a better person or having an infant will offer her someone who loves her.

The reason why intimate partner violence occurs is perplexing, but violent family situations can be divided into two groups: those in which violence preceded the relationship or children and those in which the violence developed after the relationship was established or children were born.

In the first situation, which is more common, violence is usually brought into the family by a man with a history of violence (although women may also be offenders). His violence-prone characteristics usually erupt early in the courtship and grow progressively worse as he uses violence to handle even small conflicts, which instills a pervasive feeling of powerlessness in the people around him. Such men usually have a history of early and prolonged exposure to family violence as children; alcohol is frequently associated with the expression of violence (Gómez, 2011).

A cycle of violence often follows three phases: tension-building, acute violence, and a “honeymoon” or tranquil, loving phase. During the first phase, the offender displays actions such as anger, arguing, and blaming the victim for external problems or for provoking the violence. The acute violence phase can be triggered by a response from the intimate partner or by an external crisis and can result in extreme physical harm to the victim. The tranquil, loving phase, characterized by kind and contrite behavior, follows the violence, lulling the victim into forgiveness and a wish to continue the relationship. Without intervention, however, this phase ends at some point, and the cycle of violence repeats (Kuijpers, van der Knaap, & Winkel, 2012).

Partners react to the situation in three phases (Table 55.2). During the impact phase (stage I), or the light level of violence, the victim uses denial as a defense mechanism. By not stopping or facing what is happening, however, she is indirectly giving the offender permission to continue. During the second stage, the victim can no longer deny the violence is occurring. At the same time, she cannot stop it because she does not provoke the violence; she is only a convenient recipient of poorly controlled extreme behavior. She is forced to use coping mechanisms such as becoming very obedient and cooperative and doing everything her partner asks in a desperate effort to reduce the violence. The woman is forced to become isolated; she sinks into hopelessness and depression. This phase is often referred to as psychological infantilism or **learned helplessness**. To stop the cycle from repeating after a period of calm, she needs healthcare personnel to recognize her circumstances and offer her help.

**TABLE 55.2** Typical Levels of Intimate Partner Violence

---

## Level Description

I	Maltreatment is occasional; consists of slapping, punching, kicking, verbal maltreatment. Contusions occur.
II	Maltreatment is becoming more frequent; beatings are sustained and cause fractures, such as a broken jaw or rib fracture.
III	Maltreatment is even more frequent, perhaps daily. A weapon, such as a gun, baseball bat, or broom handle, may be used. Permanent disability or death from injuries, such as intracranial hemorrhage or concussion, may occur.

Although it is impossible to predict how any individual woman will respond, pregnant maltreated women may demonstrate typical behaviors that reveal violence. A woman may come for care late in pregnancy or not at all, for example, because her partner controls her transportation or money; she may have been pretending the pregnancy did not exist to reduce stress in her home. She may be noticeable in a prenatal setting because she has purchased no maternity clothing (she has no funds for herself and asking for money may incite violence). For the same reason, she may decline laboratory tests if they involve additional transportation or money.

A maltreated woman may have difficulty following recommended pregnancy nutrition (she must cook what her partner wants or she will be beaten). She may grow anxious if her appointment is running late (she must be home to cook dinner or risk a beating). She may call and cancel appointments frequently (or simply not keep appointments) because she has an obvious black eye or a bleeding facial laceration she does not want to reveal. She may dress inappropriately for warm weather, wearing long-sleeved, tight-necked blouses to cover up bruises on her neck or arms. When undressed for a physical examination, there may be bruises or lacerations on her breasts, abdomen, or back she cannot explain. Her neck may reveal linear bruises from strangulation. Give thoughtful consideration as to whether the explanation the woman gives for a bruise or laceration correlates with the extent and placement of the injury.

A woman who has experienced recent violence may be anxious to listen to the baby's heartbeat or have fundal height measured at prenatal visits because she is worried the fetus may have been hurt. If abdominal trauma is present, an ultrasound may be prescribed to further assess fetal health. If an ultrasound reveals minimal placental infarcts from blunt abdominal trauma, this can lead to poor placental perfusion, low birth weight, or pregnancy loss.

### *QSEN Checkpoint Question 55.6*

#### **PATIENT-CENTERED CARE**

Through history taking, the nurse discovers that Hillary's mother is a victim of intimate partner violence. When addressing this issue, what typical characteristic of an intimate partner who is violent toward a female partner should the nurse be aware

of?

- a. A man has been raised in a family where the father was violent.
- b. A man wants to earn more money but has no education.
- c. A man is under severe psychological stress.
- d. A man has more than three children younger than 10 years old.

Look in *Appendix A* for the best answer and rationale.

## Nursing Diagnoses and Related Interventions

Nursing diagnoses for a woman who has experienced intimate partner violence may pertain to physical injuries sustained, but they should also address the emotional manifestations of violence. Some examples include:

- Powerlessness related to perception that it is impossible to break away from abusing partner
- Fear related to constant threat of violence
- Social isolation related to patient's need to hide evidence of intimate partner violence
- Ineffective denial related to inability to face the fact that partner is sexually violent
- Compromised family coping related to dysfunctional relationship between patient and abusive partner

Expected outcomes should address specific tasks a woman could accomplish to keep herself safe from further intimate partner violence, such as:

- Patient carries with her telephone numbers of emergency services and a shelter for women who have experienced intimate partner violence.
- Patient and abusive partner continue to attend counseling sessions.
- Patient states she has filed a restraining order against abusive partner.
- Patient states she feels secure living at a safe house.

It may be difficult to understand why a woman elects to stay in a violent intimate partner relationship. A common finding is that a woman is unable to leave because the guilt and low self-esteem she feels have led her to believe she deserves to be treated this way or because of fear the abusive person will find her and kill her. To free herself from this emotional paralysis, she needs outside help. Unfortunately, she doesn't seek this because her low self-esteem and depression lead her to believe that no one would be interested in helping her.

Until she can develop better self-esteem, a woman may need support to make even simple decisions. Any ability she has to make constructive decisions should be supported and reinforced. Be familiar with shelters for women who have experienced intimate partner violence in your community; discuss with her how she can call the police at any time and they will take her to the shelter. Help her to file charges or

obtain a restraining order to keep the abusive person from coming near her again if this is necessary.

Be careful not to blame the victim or leave a woman who has found the courage to leave her abuser without a support system because without effective support, she may decide that self-injury or returning to the intimate partner is her best recourse. If a woman does return to live with an abusive partner, both she and the infant need frequent healthcare visits scheduled so their health and welfare can be monitored. A child raised in a home where a member is violent will learn that this is acceptable conduct, and the violence may extend to yet another generation.

Children who have a parent who is violent may be identified because of behavior problems, noncompliance, and aggression in school. They may develop low levels of empathy or they may display distress behaviors such as clinging, crying, abdominal pain, or sleeping disorders. Effects may be long term if the violence causes teenage girls to shy away from relationships with boys, afraid they will be exposed to the same level of violence as their mother.

#### *What If . . . 55.4*

**A nurse is interested in exploring one of the 2020 National Health Goals regarding violence toward or maltreatment of children and families (see Box 55.1). Most government-sponsored funding for nursing research is allotted based on these goals. What would be a possible research topic pertinent to these goals that would be applicable to Hillary's family and also advance evidence-based practice?**

### Unfolding Patient Stories: Charlie Snow • Part 2

Recall **Charlie Snow**, a 6-year-old boy with a known hypersensitivity to dyes, perfumes, and peanuts, whom you first met in **Chapter 42**. Since living with his aunt and uncle while his parents are in the military, he has been treated for a skin reaction and is now hospitalized with an anaphylactic reaction from peanut ingestion. How would the nurse determine if Charlie is at risk for maltreatment or neglect? What measures can the nurse take to assure his safety at home?

Care for Charlie and other patients in a realistic virtual environment: ([thepoint.lww.com/vSimMaternityPed](http://thepoint.lww.com/vSimMaternityPed)). Practice documenting these patients' care in DocuCare ([thepoint.lww.com/DocuCareEHR](http://thepoint.lww.com/DocuCareEHR)).

### KEY POINTS FOR REVIEW

- Child maltreatment can exist in many forms. It may be physical, emotional, or sexual

and may encompass neglect.

- A high suspicion for child maltreatment should be present if burns, head injury, or rib fractures are present or if the history of the accident seems out of proportion to the injury.
- Abusive head trauma, previously known as shaken baby syndrome, involves repetitive, violent shaking of a small infant by the arms or shoulders, causing a whiplash injury to the neck, edema to the brainstem, and distinct retinal hemorrhages.
- A triad of “special parent, special child, special circumstance” is characteristic of the family in which child maltreatment occurs.
- Failure to thrive is a syndrome in which an infant falls below the 5th percentile for weight and height on a standard growth chart. It may be associated with a disturbance in the parent–child relationship.
- Children who comfort parents in emergency settings may just be sensitive children or they may be demonstrating role reversal, a behavior characteristic of maltreated children.
- In families in which a child is maltreated, a parent may also be a victim of maltreatment. Ask about safety in the home at healthcare visits to be certain that this problem does not exist as well as help plan nursing care that not only meets Quality & Safety Education for Nurses (QSEN) competencies but also best meets the family’s total needs.
- Child maltreatment is reportable by law. Nurses can initiate reporting as an independent action or through their health agency’s referral network.
- Methods to prevent maltreatment in which nurses can actively participate include teaching about the expected growth and development of children, educating parents for parenting roles, and teaching empowerment or a sense that children and adults have control of their own lives.
- Sexual maltreatment of children can be prevented by teaching children to recognize abnormal advances and to empower the child to speak out if touched in private parts or forced to perform any inappropriate acts.
- Maltreatment is a family problem, not an individual problem. Therapy must include all family members to be effective.
- Rape is a crime of violence, not of sexual intent. Rape victims need both short- and long-term counseling.
- Pregnant women with traumatic injuries need to be carefully assessed to determine whether intimate partner violence was the cause of the trauma.

### CRITICAL THINKING CARE STUDY

Nick is 6 years old; his brother Sam is 13 months old. Emergency medical technicians (EMTs) brought them into your emergency room by ambulance after a minor automobile accident involving their family car. They are alert, were in child

booster seats with seat belts, and appear uninjured. However, when examined at the accident scene, the EMTs found bruises in various stages of healing on the children. Some were in expected areas, but others indicated potential child maltreatment.

1. Sites of “expected bruising” change with developmental level. How would they differ between Nick, a 6-year-old, and his 13-month-old brother?
2. When the boys’ father arrives, you hear him tell the boys, “Don’t say a word about the accident.” Is this a clue the boys have been maltreated? If these two boys are being maltreated, would they have been so carefully protected by seat belts in the car?
3. Should you alert your agency’s child protection team based on the stated findings that you suspect child abuse or wait until you talk to the mother to see if there is another side of this story?

## 56

# Nursing Care of a Family When a Child Has a Long-Term or Terminal Illness

*Charlie is a 3-year-old who has had a relapse after 18 months of chemotherapy for leukemia. You meet him in the emergency department because he has developed a severe cough and high fever. He is diagnosed as having pneumonia. “We’re all so tired,” her mother tells you. “And he’s been sick for so long. How could he develop something else?”*

*Previous chapters described the growth and development of well children and the care of children with specific disorders. This chapter adds information about the care of chronically and terminally ill children. This is important information because it builds a base for care and health teaching and support for the parents and child.*

**How could you best help this parent? What would be important topics to talk to her about?**

## KEY TERMS

**anticipatory grief**  
**complicated grief**  
**death**  
**grief process**  
**vulnerable children**

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe common concerns of parents of children with a long-term or terminal illness.
2. Identify nursing contributions in achieving 2020 National Health Goals related to children with long-term or terminal illnesses.

3. Assess the adjustment of a child or family to a long-term or terminal illness.
  4. Formulate nursing diagnoses for a child with a long-term or terminal illness to help him or her manage seamless transitions across differing healthcare settings.
  5. Identify expected outcomes for a child with a long-term or terminal illness.
  6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
  7. Implement nursing care for a child with a long-term or terminal illness, such as helping parents with time management and identification of resources.
  8. Evaluate effectiveness and achievement of expected outcomes for a child with a long-term or terminal illness and their families.
  9. Integrate knowledge of long-term or terminal illness with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.
- 

When children have an acute illness, both they and their parents become frightened by the sudden onset and severity of symptoms. Because human beings have a great capacity for coping with stress, however, as long as they are given adequate support, they can usually adjust to the strain of disrupted daily routines, hospital visits, and home care.

When a child's illness becomes long term or is one that is projected to have a terminal outcome, a family's capacity to cope can become stretched beyond its limits. Support is essential for such a family if it is to survive under this level of pressure and stress (Nikkola, Kaunonen, & Aho, 2013).

People cope with situations depending on their perception of the event, the type and kind of support they receive from people around them, and the ways they have found to be successful in coping with stressful situations in the past. When working with parents of a child with a long-term or terminal illness, discovering how the parents perceive the problem, what resources they have available, and how they plan to use these resources are crucial in planning effective nursing care.

Whether the medical diagnosis involves a permanent disability or impending death, parents' first response may be grief. The parents have either lost the "perfect" child imagined during pregnancy or the well child they had up to the time of diagnosis. Depending on their age and maturity, children may also experience a grief response. Quality of life in children with long-term or terminal conditions is important to the overall health of children; therefore, the related 2020 National Health Goals are shown in [Box 56.1](#).

#### BOX 56.1

Long-term illness or early death in children is a major cost to the nation and individual families because it has the potential to reduce the earning power and contribution of future citizens. Examples of 2020 National Health Goals that address this include:

- Increase the proportion of youth with special healthcare needs whose healthcare provider has discussed transition planning from pediatric to adult health care from a baseline of 41.2% to a target level of 45.3%.
- Increase the proportion of children with disabilities from birth through age 2 years who receive early intervention services in home or in community-based settings from 91% to 95%.
- Reduce the rate of infant deaths from a baseline of 6.7 per 1,000 live births to a target rate of 6.0 per 1,000.
- Reduce the death rate for children 1 to 4 years of age from a baseline of 28.6 per 100,000 to no more than 25.7 per 100,000 children and for children aged 5 to 9 years from a baseline of 13.7 per 100,000 to 12.3 per 100,000.
- Reduce the death rate for children 10 to 14 years of age from a baseline of 16.9 per 100,000 to no more than 15.2 per 100,000 and the death rate for adolescents 15 to 19 years of age from a baseline of 61.9 per 100,000 to 55.7 per 100,000 (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by educating women to seek care during pregnancy so that congenital anomalies, a common cause of infant morbidity and mortality, are less frequent and to teach unintentional injury prevention and the importance of immunizations so unintentional injuries and infectious diseases that can lead to long-term illness, such as rubeola and meningitis, can be reduced.

### *Nursing Process Overview*

#### FOR CARE OF A FAMILY WITH A CHILD WHO HAS A LONG-TERM OR TERMINAL ILLNESS

##### **ASSESSMENT**

Because a family's coping abilities are best assessed gradually and over a period of many contacts, nurses' assessments of the degree of a family's coping are often the most thorough and meaningful of all healthcare providers.

Observing children at home, where they are most comfortable, or at school in a familiar atmosphere often reveals a great deal more about a child's present disease status or coping potential than does a formal test situation. Children with a long-term illness, on the whole, have been through multiple tests and procedures in the process of diagnosis; they may have come to think of healthcare providers as people who hurt them, not people from whom they wish to receive care. Changing their perception

may require maintaining a reassuring, gentle manner during assessment and subsequent care procedures.

### **NURSING DIAGNOSIS**

A long-term illness can take many forms. A condition that requires daily attention, such as diabetes mellitus (e.g., managing an insulin pump), but is relatively stable may not be as stressful to parents as an illness, such as muscular dystrophy, that may require many adjustments in care due to its slow progression. In the former, although the child and family must adjust their lifestyle to incorporate the child's daily needs, they feel more in control of the illness and the child's overall health. In the latter, the child and family feel powerless because they lack the ability to alter the course of the disease; they must simply be prepared for the next acute crisis to develop. Nursing diagnoses for children with long-term or terminal illnesses need to address both the child and the family and the stage of illness. Some examples of nursing diagnoses when a long-term illness is present include:

- Interrupted family processes related to recent diagnosis of chronic illness in the child
- Compromised family coping related to the child's disability
- Disabling family coping related to the parents' inability to accept the child's long-term illness
- Anticipatory grieving related to chronicity of the child's illness
- Risk for delayed growth and development due to decreased mobility because of disability

New issues develop when the child's disorder becomes terminal. The family must learn to accept not only the child's illness but also its eventual outcome. Some examples of nursing diagnoses when a terminal illness is present include:

- Hopelessness related to steady progression of the child's disease
- Anticipatory grieving related to the child's terminal illness
- Powerlessness related to inability to change the course of the child's illness
- Decisional conflict related to treatment options and choice of setting for the child's final care

### **OUTCOME IDENTIFICATION AND PLANNING**

Be certain when planning care for children with a chronic or fatal illness that the outcomes established are realistic. You probably cannot alter the course of a child's illness, but you can help parents cope with signs and symptoms of the illness or the impending death.

Parents who have not yet accepted the seriousness of their child's illness—who hold on to the hope that their child will eventually be cured or restored to full health—may make plans that the child cannot accomplish. Sometimes, this level of denial is necessary for the development of coping strategies to deal with the child's daily needs and the needs of the rest of the family. If parents believe they must shield the child or other family members from the truth, it can be hard for them to plan effective

outcomes. Focusing on hopeful but realistic outcomes, such as the desire the child will not experience pain or the child will learn how to move about independently in a wheelchair, can help a family move forward toward acceptance of the seriousness of the child's illness.

Referrals can be made to helpful organizations such as the Candlelighters for Children With Cancer ([www.4kidswithcancer.org](http://www.4kidswithcancer.org)), The Compassionate Friends ([www.compassionatefriends.org](http://www.compassionatefriends.org)), and the National Association of School Psychologists ([www.nasponline.org](http://www.nasponline.org)).

## **IMPLEMENTATION**

Parents can become overprotective of children who have a long-term or terminal illness, which may discourage their development. Helping parents recognize their child's capabilities and arrange appropriate activities for the child are ways in which nurses can facilitate parents' acceptance of the diagnosis and the road ahead. Suggestions for helping children achieve developmental milestones are discussed for each age group in [Chapters 29](#) through [33](#).

Helping parents develop coping strategies and establish effective ways to manage the complex medical needs of the child, maintain quality care despite the burdens of care, and maintain a balanced life that includes self-care are other important measures.

## **OUTCOME EVALUATION**

Children with a long-term or terminal illness need periodic follow-up care because children's needs across the life span changes. Plans made in the early school years may need to be modified by the time the child is 12 years of age, and they must change again with adolescence. You may need to remind parents that in addition to health care by a specialty clinic, children also need routine health maintenance care. Otherwise, children will be well protected from the complications of their special illness but unprotected from common childhood illnesses.

An evaluation of whether expected outcomes for the family and child are achieved will identify discrepancies between what families hope for and what is realistic given the child's condition. When discordance is identified, and outcomes are not achieved, healthcare providers have an opportunity to strengthen their understanding of the effect of chronic illness or the death of a child on families.

Some examples suggesting achievement of outcomes include:

- Parents state realistic plans for their child regarding school placement.
- Parents state they have been able to deal with their grief over their child's diagnosis to maintain near-normal family functioning.
- Parents state they are able to cope with present stressors and can specify coping strategies they utilize.
- The child states he is aware his illness is chronic (long term) but thinks of himself as a person who will be able to accomplish many things in life.

## The Child With a Long-Term Illness

Families have different resources, and everyone reacts to situations differently. Each child with a long-term illness and the family need to be assessed individually for their potential to cope with the illness and to provide necessary care. Through such an assessment, appropriate interventions to help the family adapt can be started early in the course of the illness (Longden, 2011).

### THE PARENTS' ADJUSTMENT

Children need support in adjusting to stressful events and parents can serve as role models while providing the emotional and instrumental support the child needs. Therefore, an assessment begins with an examination of the parents' response to the stress of a long-term illness. Responses from caregivers can vary based on the relationship and dynamics between the caregiver and the child. This relationship can be based on family structure and emotional stability of the family and on differences in the typical behavior of mothers, fathers, sons, and daughters. Questions by the nurse should seek to elicit responses by each family member and identify the different relationships that exist in the family.

Chronic health conditions affect the entire family. The nurse should support each family member as their reactions and needs may vary because each person's response is individualized. The nurse should seek to:

- Answer the family's questions or seek assistance from the medical team in answering their questions.
- Identify and address the needs of the family and child.
- Assist the family in meeting the physical needs of the child, including pain relief and symptom management.
- Assist the family with advanced care planning, including the inevitable effect on the physical and mental health of parents, siblings, and extended family.
- Identify and assist with psychological and spiritual support.
- Assist with care coordination.

### The Grief Response

Parents can be expected to experience a **grief process**, or the regulated steps in grieving, after diagnosis of a terminal illness and physical or cognitive challenges their child will experience. The most commonly accepted steps or stages of grief are those outlined by Kübler-Ross (1969). Table 56.1 summarizes these stages. Many parents with a child who is physically or cognitively challenged never arrive at the final stage of acceptance or they spend years with chronic sorrow (also called **complicated grief**) (Whittingham, Wee, Sanders, et al., 2013). Reaching a final stage may be particularly difficult when parents grieve in different ways or at different paces (Wender, 2012).

#### TABLE 56.1 THE STAGES OF GRIEF

---

Stage	Parents' Reaction	Description
1	Denial	Parents have difficulty realizing what has occurred. They ask, "How could this have happened?"
2	Anger	Parents react to the injustice of being singled out this way. They say, "It isn't fair this is happening."
3	Bargaining	Parents attempt to work out a "deal" to buy their way out of the situation. They say, "If my child gets well, I'll devote the rest of my life to doing good."
4	Depression	Parents begin to face what is happening. They feel sad and unprotected.
5	Acceptance	Acceptance is being able to say, "Yes, this is happening, and it is all right it is happening." With a child who has a long-term illness, parents may never reach this stage but will always remain in the chronic sorrow of the depression stage.

Based on Kübler-Ross, E. (1969). *On death and dying*. New York, NY: Macmillan.

During the first stage of grief (shock or denial), parents are usually unable to plan past immediate or short-term actions (e.g., learning to change a dressing, what pills to give each day). Trying to establish long-term outcomes at this point (e.g., what type of school the child will attend, future surgery that will be needed) is rarely productive because this must all be done again when parents are truly ready to look this far ahead. During the second stage (anger), parents may be unwilling to concentrate on goals (e.g., the whole thing is so unfair; planning is asking too much of them; besides, if you were really helpful, you would cure their child and not talk about ways they have to adjust). Therefore, this may also be a time of waiting. During the bargaining stage of grief, parents are still not ready to plan. They believe that if their bargain is fulfilled (e.g., if their child is able to walk, and they promise to spend the rest of their life doing good), they do not have to make plans such as purchasing a wheelchair because these will be unnecessary after their wish is granted and the child's condition improves.

During the next stage of grief (depression), parents are ready to make plans but need a great deal of support because they feel sad and fatigued. During this phase, it is critical to make plans *with* them not *for* them. Many parents of children who are physically or cognitively challenged develop low self-esteem as well as depression. Their low confidence in their parenting abilities may make them believe your suggestions are superior to their own. Upon their return home, they are the ones who must implement these plans and mitigate challenges they will experience so they need to participate in the planning process.

Even after parents reach the final stage of grief (acceptance), some parents need guidance in making plans to avoid ignoring the needs and wishes of other family members. For example, parents may spend every waking moment with their ill child.

Talking to them about the importance of self-care and the burdens of caregiving are helpful. Help them approach their child's care with moderation and allow time for all family members as well. Helping them to plan a respite from the care of a sick child, such as an evening out while a babysitter cares for the child, could be part of this approach (Thomas & Price, 2012).

If parents had a chronically ill child late in life, by the time the child is school age, parents need to face one more step in their development as parents of a chronically ill child: to begin to make some concrete plans as to who will care for the child in the event of their death. Like the steps that came before it, this is very difficult for parents; it asks them to contemplate not only their child's vulnerability but also their own. They might consult with family members about guardianship and with a lawyer to help them write a will that will provide future caretaking and economic support for the chronically ill child when they are no longer able to do so.

### Factors Influencing Parental Adjustment

Certain circumstances, such as the degree and timing of their child's illness, the experience of the parents, the availability of support, and the ability to make long-term plans, appear to increase parents' ease or difficulty in adjusting to their child's disabling or long-term illness.

#### The Degree of Illness

The seriousness of an illness affects the ability of parents to adjust (Whittingham et al., 2013). A child who needs total care, for example, requires a much more radical readjustment of the parents' lives than a child who only needs additional speech therapy for an hour a day. In most instances, the parents' perception of the child's illness is as important as the child's condition itself (Fig. 56.1). For example, a parent who envisioned a son as someday becoming an Olympic runner may perceive a son with developmental hip dysplasia as having a serious physical challenge; a parent whose mental image of the child was that of a lawyer mainly doing desk work may not view the hip problem as a serious illness.

**Figure 56.1** A parent's perception of a child's disability is important to how well the family adjusts. Often, it is easier to accept a disability that allows for greater functioning in everyday activities. (© Bill Bachman/Science Source/Photo Researchers.)

Many parents have hopes and dreams for their child, once women realize they are pregnant. Hidden desires are often revealed if you ask parents, "If things could have been different, what kind of person would you have liked your child to be?" A parent who answers "A kind person" can still have that wish fulfilled no matter what the degree of illness. A parent who says "I always assumed my child would take over the family business someday" may have some major mental readjustments to make.

Whether an illness is noticeable (cerebral palsy) or not noticeable (controlled seizures) also can make a difference in how parents adjust to the illness. A mother who takes her child with cerebral palsy shopping, during which the child walks unsteadily and knocks over a display, may hear other shoppers say, "Wouldn't you think a mother would watch her child more carefully?" On days that her child uses a wheelchair, however, shoppers' comments are more apt to be, "Poor little thing. Isn't it wonderful his mother brings him shopping with her?" She is happy to have a signal (the wheelchair) that announces that her child is different and cannot be held to the same standards as other children. Other parents might be more grateful that a child's illness is not a visible one: It makes the illness seem lesser in extent and therefore easier for them to accept.

### The Relationship With Own Parents

When adults are able to relate well to their parents, it suggests they were raised in an atmosphere of love or were able to develop a sense of trust (Erikson, 1993). People with a sense of trust are able to form a firm sense of intimacy as adults and so be better able to give love to children even when the children have challenges in some way.

### The Onset of the Illness

Whether a condition is apparent at birth (such as a myelomeningocele) or occurs at a later time (a child is struck by a car at school age or who develops autism spectrum disorder) is another factor that may make a difference in parents' ability to adjust. In either situation, the long-term care of a child will totally change the parents' lifestyle. As an example, when a child has a physical handicap, parents may have to change their living arrangements to accommodate for the needs of the child. These changes may impact housing, transportation, and work schedules and cause financial constraints due to the cost of care of a chronically ill child.

### The Effect of Parental Experience

First-time parents may have more difficulty caring for a child with a long-term illness

than older, more experienced parents because all phases of parenting are new and unique for them. On the other hand, first-time parents may have no preconceived opinions and so may be more flexible than other parents or able to adjust more readily to a change in routine. A young parent who has just this one child may have more time to spend in a daily exercise program than does a parent with four other children.

### The Availability of Support People

Adjusting to illness in a child for a family with few close friends and relatives at a distance may be more difficult than a family that has close support system. People who can locate secondary support systems in their community, such as an organization for parents of children who are physically or cognitively challenged or a local church or synagogue, or who can depend on healthcare resources usually do better than parents who are without these resources. Whether a family can depend on healthcare resources is related to:

- The availability of transportation (e.g., it is difficult to take a child in a 50-lb cast on a bus)
- A language barrier (e.g., it is frustrating to go for care and be unable to make your needs known)
- Finances and insurance coverage (e.g., it is disturbing for parents to be told their child needs to see a specialist when they have no money or health coverage to pay for one)
- Past experience with healthcare providers can set the stage for a distrustful relationship between the provider and parent.

### Life Events

A child's illness usually appears to be more acute at times when the child would normally reach developmental milestones than when the child reaches traditional milestones such as obtaining their driver's license or participating in a bar mitzvah. When the child does not reach these traditional milestones, it reminds parents about their child's illness in a particularly painful way. Factors that indicate a family will probably be able to adjust to caring for a child with a long-term illness are summarized in [Table 56.2](#).

**TABLE 56.2 FACTORS THAT EASE PARENTAL ADJUSTMENT TO A CHILD'S LONG-TERM ILLNESS**

<b>Factor</b>	<b>Rationale</b>
Support people are available.	Caring for a child is a series of crises during which support people become very important.
A strong marital bond exists between the parents.	A marriage partner can serve as the strongest support person.

A good relationship exists between the child's parents and their parents.	The parents have a firm sense of trust and the ability to give care to another and child has the support of the extended family.
The child is other than the first born.	The parents have had practice parenting.
The family lives close to shopping, schools, and transportation.	The family is not isolated.
The family has a strong spiritual faith or community contacts.	Secondary support systems are important in times of stress.
The parents are told of the child's disability as soon as possible.	A handicap may be easier to accept if the parents never thought of the child as totally well.

***QSEN Checkpoint Question 56.1***

**INFORMATICS**

A nurse is reviewing the electronic notes of the social worker who has been involved with the family's care of Charlie, 3 years of age. What noted factor is most apt to help Charlie's parents cope with the stress of his long-term illness?

- a. The parents believe in alternative therapies and consequently have many options.
- b. Both parents have a good relationship with their own parents.
- c. The parents are wealthy, so are not distressed by the cost of his care.
- d. The family is private, so they cannot compare Charlie's condition to other ill children.

*Look in [Appendix A](#) for the best answer and rationale.*

**THE CHILD'S ADJUSTMENT**

A child's reaction to being physically or cognitively challenged or to having a long-term illness is strongly influenced by the family's reaction to the illness. This may range from overprotectiveness to rejection and from denial to acceptance. The child's adjustment may also be influenced by peers and other support people, such as school personnel or healthcare providers. Social exclusion, discrimination, and physical barriers at school or in the community make it difficult for a child to adjust to a physical challenge or a long-term illness. Inclusion in school and social activities, acceptance by peers and support people, and the ability to function as normally as possible help the child adjust ([Crosland & Dunlap, 2012](#)).

A child's ability to cope is further influenced by personal attitude and temperament,

self-concept, age and development, understanding of the condition, and degree of the disorder. As the child grows and life situations change, the ability to cope may improve or worsen. For example, an adolescent who is physically challenged may have a more positive outlook on life with a chronic illness because she is successfully working at her first job; another adolescent may become angered by his deteriorating condition because he is suddenly confined to a wheelchair.

The degree of fatigue that a child experiences is also instrumental in how well they adjust to a chronic illness because chronic fatigue can play a large role in making even simple tasks seem monumental (Fisher & Crawley, 2013).

Nursing interventions to help a child better adjust to a chronic condition include encouraging optimal growth and development (see Chapters 29 to 33), promoting self-care activities, enhancing self-esteem, preventing social isolation, providing health education, preventing fatigue, and supporting the child and family to identify strategies to adapt to living with the child's condition.

## **SIBLINGS' ADJUSTMENT**

Siblings' reactions to a child with a long-term or terminal illness are influenced by individual circumstances; however, their chief reaction is most profoundly affected by the reactions and perceptions of the parents. Without counseling, siblings may react with jealousy, anger, hostility, resentment, competition, guilt, or withdrawal. They may feel they take second place to the sibling who needs more care. These reactions are common when parents focus most of their attention on the ill child, allow the health problem and its treatment to disrupt family life significantly, or grant the ill child special privileges and minimal discipline.

With counseling and support, however, siblings can develop acceptance, care, concern, and cooperation (Vermaes, van Susante, & van Bakel, 2012). Such reactions are common when parents make it a point to set aside time each day for special activities with the well siblings such as playing a table game, walking in the park, teaching a child to swim, carefully explaining the condition and the necessity for their sibling's special care, including them in the care of the ill child, providing them with respite from care if needed, and establishing realistic rules for all family members.

At any one time, the siblings may experience a mixture of feelings. For example, if a boy's parents must take his sister for chemotherapy during his swim meet, the boy may feel both resentment that his parents missed the meet and sadness that his sister could not compete in that meet or in any others.

## **THE NURSE AND THE ILL CHILD**

Caring for children with long-term illnesses can be a stressful role for nurses (St. Ledger, Begley, Reid, et al., 2012). Nurses help the parents and child with a long-term illness review specific aspects of the child's condition and the possible complications that could occur. Over a period of years, parents become experts in the care of a child

with a particular condition (Box 56.2). This can make them grow impatient with healthcare providers who appear to be unaware of things they know well. When young children are seen at an ambulatory care setting or are admitted to a hospital for care, review with the parents their routines and techniques so that you can continue to care for their child in the same way. As the child grows older and more independent in managing their care, include the child in these discussions. Be available, however, to show a parent or a child an easier way to do something if it seems appropriate. Frankly admitting to parents “You’re more familiar with Jennifer’s care than I am; you’ll have to teach me some things” is a refreshing approach; it not only allows parents to feel confidence in you, but your honesty also increases their self-esteem.

### BOX 56.2

#### Nursing Care Planning Tips for Effective Communication

Charlie is admitted to the hospital, and intravenous therapy is begun. You notice his skin is unusually reddened where the adhesive tape was removed. He cries when you touch the irritated site.

*Tip:* It is easy to believe that a fellow nurse who has spent a great deal of time caring for a child has become an expert in that child’s care. It is often more difficult to remember that a parent can become this type of expert also. Remember to ask parents of children with a long-term illness for their input. This can not only simplify care but also add to the parents’ feeling of self-esteem, thus improving their parenting.

**Nurse:** Look at Charlie’s skin. It looks so red and sore.

**Mrs. Circuso:** That’s from the adhesive tape.

**Nurse:** Has Charlie had this type of reaction before?

**Mrs. Circuso:** It has happened before.

**Nurse:** I should have been more specific when I asked about allergies. I’ll make a note in his patient record.

Familiarize yourself as well with the community resources that are available for children with long-term illnesses. Advising parents to see a dentist who specializes in caring for children with autism spectrum disorder when there is no one of that description less than 200 miles away, for example, is not only helpful but it can also be destructive because it raises expectations in parents that cannot be met, thus accentuating a problem.

Most parents of a chronically ill child adhere well to instructions and keep healthcare appointments consistently. Sometimes, however, you will find parents who do not follow this pattern. This inability to adhere usually is related to their stage of adjustment to the illness. As long as denial, anger, bargaining, or depression is present, coming in for health care or an evaluation is viewed as a major demand. Each visit is

more of a reminder of the child's illness than a time of reassuring health assessment.

### Developmental Tasks

Children with long-term illnesses often do not meet developmental milestones on schedule because achieving developmental tasks takes practice. When you are helping parents teach a child who is physically or cognitively challenged a new skill, such as toilet training or using a spoon, help them break the task down into its component parts (e.g., reach for the spoon, grasp it, push it under the chosen food, lift it toward the mouth). Breaking a task down into steps in this way allows parents to appreciate that they are asking their child to learn a task that, although it looks easy, actually encompasses 20 or more coordinated motions. Helping them learn this technique enables them to be patient in teaching additional tasks in future years.

The unique concerns of children who are physically or cognitively challenged and ways to help them achieve developmental tasks are discussed in [Chapters 29 to 33](#). For healthcare providers, exposing them to usual events during a hospital stay or an ambulatory healthcare visit can help expand their world ([Fig. 56.2](#)).

**Figure 56.2** Therapy dogs can be helpful to keep children with a long-

term illness active and in touch with usual events. (© Marmaduke St. John/Alamy.)

## Education

Children with a long-term illness often need special education programs or at least separate hours of individualized instruction to succeed in school. Most children benefit from preschool programs because these programs offer them a head start. Children with a long-term illness tend to miss school more often than do their healthier classmates because of healthcare visits and exacerbations of their illness. This can cause them to fall behind in school unless individualized plans to keep them with their school group are made. By federal law (Public Law No. 99-457, Education of the Handicapped Amendment), a school system must provide educational opportunities in the least structured setting possible for physically and cognitively challenged children, beginning with preschool. You may have to be a strong child advocate to see that the best educational program available is being provided for an individual child (Kirk, Beatty, Callery, et al., 2012).

## Home Care

Most children with a long-term illness may be hospitalized for a short term but then receive the bulk of their care at home (Newton & Lamarche, 2012).

Planning for home care is discussed in Chapter 4. Important aspects to consider include the best school setting (home or traditional school), ways to involve the family in community activities, ways to include the child in a play group if possible, how much self-care the child can achieve, and future plans, such as preparing a child for puberty or enrolling in college. Home care or community health nurses can be instrumental in identifying goals for self-care and planning school or community activities (Peacock & Stanik-Hutt, 2013).

Many parents today seek complementary or alternative therapies for children with long-term illnesses in home care. Always ask what therapies and medications they are using to document the full extent of treatment that a child is receiving (Braga & Almgren, 2013).

### *What If . . . 56.1*

**A nurse arranges for Charlie's mother to spend an afternoon shopping so she can have some respite time away from her ill child, but she spends the time cleaning her kitchen cupboards instead. How might the nurse advise Charlie's mother?**

Think back to **Brittany Long**, whom you met in **Chapter 38**. Brittany is a Black girl diagnosed with sickle cell anemia who lives with her mother, 7-year-old sister, and grandmother. Her pain crises are mostly managed at home, and she has been hospitalized three times. How can the nurse help Brittany and her family cope with a long-term illness and the management of acute crises? How can the reactions of family members influence Brittany's adjustment to sickle cell disease? What effect can a long-term illness have on the sister and what actions can support her understanding and cooperation?

Care for Brittany and other patients in a realistic virtual environment: ([thepoint.lww.com/vSimMaternityPed](http://thepoint.lww.com/vSimMaternityPed)). Practice documenting these patients' care in DocuCare ([thepoint.lww.com/DocuCareEHR](http://thepoint.lww.com/DocuCareEHR)).

## The Child Who Is Terminally Ill

Death can come suddenly to some families, such as when adolescents choose to harm themselves or take their own life or when a child is killed in an automobile accident or random shooting, providing no time for parents to prepare for the death (**Bogle & Go, 2015**). Parents of terminally ill children need to make end-of-life preparations for their child. Nurses can be an integral part of this planning. This can be one of the hardest tasks in nursing because most people are raised to accept the fact that elderly people die, but such people have also lived a long life. Most people can accept the death of middle-aged people with the same philosophy—they experienced at least a portion of their life. It is often more difficult to accept the death of children because they have had so little opportunity to live. It is imperative for nurses to work through their own feelings about a child's dying so they can find the strength to care for the child and support the parents.

### PARENTAL GRIEF RESPONSES

Although the reaction to learning that a child has a terminal illness can be culturally influenced, each family reacts in a unique way. Being aware of the usual grief response that occurs in anticipation of a child's death helps in recognizing such a response as grief and supporting a family through this very difficult period (**Box 56.3**).

#### BOX 56.3

#### Nursing Care Planning to Respect Cultural Diversity

The way death is viewed and the manner in which people express grief differ greatly across cultures. Some people express grief very loudly and openly, whereas others are very restrained. The way a child's body is handled after death also differs. Some religions, for example, forbid organ donations or transplants. Autopsies are not approved because it is important that a child be buried quickly. Cremation may or may not be permitted. Being aware that people have different expectations for final

care and that grief is expressed differently by different cultures enables better understanding of parents' concerns and reactions during a child's terminal illness and when death occurs. Don't depend on stereotypical descriptions of how parents should react; ask them if they need help resolving a cultural conflict or if there is a care measure based on their cultural beliefs that they would like you to include in care.

### **Stage 1: Denial**

A parent's usual response to the diagnosis of a terminal illness in a child is denial, the same as with long-term illness (see [Table 56.1](#)). Although people are aware that children die, most proceed through life thinking and hoping for a cure or minimal challenges. When they realize they might lose their child, they respond with disbelief. The likelihood of this response is enhanced by the fact that many terminal illnesses, such as a brain tumor or leukemia, begin insidiously allowing little opportunity for parents to be mentally prepared (e.g., "How can a few black-and-blue marks be the symptoms of a potentially terminal disease?").

How the parents handle this initial disbelief has a great deal to do with their relationship with healthcare personnel. If they have a trusting relationship with healthcare providers from past experiences, they are more likely to seek information and support from the providers. If they lack trust in the providers, they may not believe the diagnosis and feel the need to obtain a second opinion. Although this often involves considerable expense, for many parents, it is a necessary step in moving past this first reaction. Parents who feel a need for a third, fourth, or fifth opinion may be having an unusually difficult time resolving a "surely not me" response. Be certain they have received factual explanations and evidence of the diagnosis such as through a copy of the blood or the pathologist's biopsy report. Urge them to talk about how they feel and ask questions. Facts regarding the illness, the challenges it may present and also the terminal nature of it will assist parents to accept the diagnosis and identify strategies to adapt.

During this stage of denial, you may find the parents' downplaying their child's illness. It is easy to view such denial as a step that should be hurried because parents cannot begin to deal with the problem as long as they deny there is a problem. Denial is a temporary pain-relief measure and a necessary step on the way to acceptance, and individuals will move through this stage at different speeds.

### **Stage 2: Anger**

Parents can be expected to enter a stage of anger soon—a change from "Surely not me" to "It's not right this is happening to me." When parents are angry about a diagnosis, they may be unable to direct their anger appropriately. One parent may be angry with the other (e.g., criticizing the other for reckless driving or for eating a fattening food for lunch). They may be angry with you (e.g., for not answering the child's call light immediately). They may be angry with the medical, X-ray, laboratory, and dietary staff

or with the entire healthcare system. It can be difficult to react to this kind of anger because it seems unjustified. Be certain your first reaction is not to be angry in response.

A more therapeutic reaction is to accept the parents' explicit emotions and anger and respond with empathy and acceptance.

Some parents may seek out another healthcare provider during this stage, although their reaction will depend to a great extent on their experience with death in the past.

When you ask grieving parents to talk, therefore, they may talk not about the child but about how they felt when a parent died, how hard their job is for them, or how they worry that their marriage is failing. This is part of grief: gathering resources, reworking stress from the past, and arming themselves to face present stress and what to expect in the future. Parents often receive support from other parents in the hospital whose children are also terminally ill. Interacting with parents of other children and learning about ways they have adjusted to the effects of a terminal illness will be helpful.

### *What If... 56.2*

**Charlie's parents, who are both 50 years old and live on a ranch, tell the nurse their two grown children have expressed resentment at the amount of time and money they have spent trying to find a cure for Charlie. Charlie's parents have no health insurance, so finances are always tight. How should the nurse respond to Charlie's parents?**

### **Stage 3: Bargaining**

Although not everyone progresses through a grief response in a linear fashion, and instead vacillates between stages, bargaining often follows anger. This is a time when parents try to correct or change the course of illness by bargaining. They vow to be better people or to function in a different way in exchange for their child's life. When parents realize that bargaining is ineffective, it brings them to a very low point because they are let down not only by healthcare providers but also by the superior power with whom they tried to bargain. They may need more support after bargaining fails than at any other point.

### **Stage 4: Depression**

When parents have passed through the stages of denial, anger, and bargaining, developing awareness of the reality of this diagnosis will usher them into the stage of depression. This is a change from "I can keep it from happening" to "It is happening." Frequent crying or projecting an overall sad countenance is the most common sign that this stage has been reached. Parents may ask more questions about care, procedures, or medications than they did before. Be careful you do not interpret this questioning as criticism. Parents' questions stem from the full awareness of the serious implication of the chronic illness.

At this stage, parents may work through the expected challenges that lie ahead by talking about their plans for the child. They may suddenly shower the child with expensive gifts or trips and have difficulty leaving a hospitalized child to go home to care for other children or to report for work. On the surface, all the questions and demands may imply they are taking a step backward. Actually, this reflects their appreciation of the diagnosis and its magnitude and should be seen as a step forward.

At about this stage, parents need to think about preparing other children in the family for the challenges the ill child will face. If the ill child is hospitalized and siblings have not been allowed to visit, siblings may misinterpret the hospital experiences of the ill child and also the reasons why visitation may be restricted. You may need to advocate for sibling visitation to overcome this misinterpretation and to allow the sibling to observe the hospital setting first hand.

Some siblings feel responsible for the death of the ill child. All children wish at one time or another that a sibling were dead (or would simply disappear) so they could have a bedroom all to themselves or so they could have the other child's bicycle. Maybe they were told not to wrestle with the ill sibling, but they did anyway. These children need reassurance that the sibling's death is not a result of their musings but an expected result of the child's illness. Assure them that they need not feel guilty.

### Stage 5: Acceptance

The acceptance stage of the grief process is resolution that the child has an illness that may be fatal. Some parents do not reach this stage until the time of the child's death; working through grief will need to continue for years after the child has died.

#### *QSEN Checkpoint Question 56.2*

#### **PATIENT-CENTERED CARE**

Charlie's parents are grieving because they fear he will not survive this recurrence of his illness. The nurse is planning Charlie's care with the knowledge that the family is experiencing intense sadness. During which stage of grief do parents usually feel the most intense depression?

- The first stage, because everything is such a shock
- The last stage, because they fully accept the death
- The fourth stage, as they realize death is happening
- The stage at which the child begins to talk about death

*Look in Appendix A for the best answer and rationale.*

### **PARENTAL COPING RESPONSES**

Throughout the stages of grieving, parents develop important coping mechanisms to help them through this crisis in their life. Even if they have already learned to cope positively with their child's illness and treatment measures, the determination that the

illness is now terminal requires yet another step. Promoting the development of positive coping strategies while being sensitive to the unique needs of each family member is an important nursing responsibility. It may be difficult to determine when a coping strategy is truly helpful and when it has become maladaptive. For instance, seeking information, such as surfing the Internet and asking to have medical library access, is generally a very useful strategy for parents with ill children. Knowing what to expect reduces anxiety. Some parents, however, continue these seeking procedures past the point at which information is helpful to them, believing if they only look hard enough or long enough, they will discover a way to cure their child (prolonged denial), or they may “overintellectualize” their child’s illness and impending death to block out their feelings of sadness.

Problem solving is always an effective coping strategy as long as the parents are realistic about which problems they can solve. Seeking the support of others, including healthcare providers and families with similar needs, is encouraged. Providing the names of support groups or individual families (with their permission) who have gone through similar experiences can also be helpful. You may also need to help parents who are not comfortable accepting the help of others to learn how to do so or to simply learn how to feel comfortable expressing their feelings to others.

Many parents are able to cope by searching for the meaning of life or death in philosophical, spiritual, or religious terms. For these parents, body organ donation may be a meaningful way to give themselves some solace that their child will in some way continue to live and contribute to others. Assuring parents that their child will be kept comfortable and will not suffer at the end of life can be extremely comforting.

### Anticipatory Grief

Parents who have been warned that their child’s death should be expected from the time the child’s illness is diagnosed may begin a preparatory or **anticipatory grief** phase in which they gradually incorporate the reality of their child’s fate into their thoughts (Yang, Mu, & Wang, 2016). Anticipatory mourning in this way can prepare parents for their child’s death and spare them the abrupt, devastating, and intolerable grief reaction that comes to parents whose child dies suddenly from trauma, such as in a car accident or sudden infant death syndrome (see [Box 56.4](#), an interprofessional care map on nursing and team responsibility for care of children when illness has become terminal).

BOX 56.4

#### Nursing Care Planning

##### AN INTERPROFESSIONAL CARE MAP FOR THE FAMILY OF A CHILD WITH A POTENTIALLY FATAL ILLNESS

Charlie is a 3-year-old who has had a relapse after 18 months of chemotherapy for leukemia. His parents have arranged for hospice care for him at home. They state,

“He’s been through so much already. It’s very hard on us but we want him to die at home, close to us.”

**Family Assessment:** Child lives with parents on their llama ranch. Two older siblings (brother, age 20 years, and sister, age 26 years) have left home. Parents report finances as “tight.” Family has no health insurance because they are self-employed.

**Patient Assessment:** Child is cachexic. Skin cool, damp, and mottled. Pulse rate, 62 beats/min and weak; respirations, 8 breaths/min. Rattling sounds noted from chest. Responsive only to deep pain stimuli. Parents at bedside; older siblings absent.

**Nursing Diagnosis:** Anticipatory grieving related to impending death of child

**Outcome Criteria:** Parents express feelings about anticipated death; demonstrate positive coping mechanisms.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess whether the parents have any concerns or special wishes about child’s final days of care.	Stay with the family and sit with them quietly if they prefer not to talk and allow them to cry.	Your presence demonstrates caring and concern for their well-being and wishes and offers support.	Parents discuss any concerns or wishes they have with care.
<i>Teamwork and Collaboration</i>				
Nurse/hospice care staff	Assess whether the parents would like a final visit from their clergy or other support person.	Arrange for visit by the support person if desired.	A visit by the family’s support people can provide the family with final needed support.	Parents state whether a support person’s visit would be helpful to them. Help plan arrangements.
<i>Procedures/Medications for Quality Improvement</i>				
Nurse	Assess whether the child appears comfortable.	Provide for the child’s comfort, including positioning, turning, changing linen,	Providing comfort to the child is comforting to the family as well as the	Parents state they feel the child is comfortable.

		applying lotion, and alleviating pain.	child.	
Nurse	Ask whether the parents would like to provide final care.	Allow family members to provide care as desired without forcing them.	Allowing family participation in care provides them with some sense of control over the situation, decreasing their feelings of powerlessness.	Parents state they feel they have had a voice in and are satisfied with child's care.
<i>Nutrition</i>				
Nurse	Assess the child's appetite and whether he could be hungry.	The child's mental state is not appropriate for oral feeding; intravenous (IV) fluid prescribed only as maintenance.	Hunger is an uncomfortable sensation and feeding is a basic need per Maslow's hierarchy of needs	Parents agree they feel the child is comfortable and no food is needed.
<i>Patient-Centered Care</i>				
Nurse	Assess whether parents have any questions about what actions they should take at the time of death.	Inform the family about what to expect, and explore their expectations and clarify any misconceptions.	Providing information helps to ease the family's fears and anxiety about the unknown.	Parents state they feel comfortable caring for child in final minutes and immediately afterward.
<i>Psychosocial/Spiritual/Emotional Needs</i>				
Nurse	Assess whether parents need any type of additional emotional	Explore as far as parents are willing whether support from their other	Close family members can supply the most meaningful type of emotional	Parents state that although they are disappointed in older siblings' reactions, they

	support and if appropriate question why older siblings are not present.	children would be helpful.	support.	understand everyone grieves differently and are managing well.
Nurse	Ask whether parents have begun “grief work” such as reviewing and preserving memories of the child.	Provide the family with opportunities to review special memories or experiences with the child.	Reviewing memories and special experiences provides a positive method for coping with grief.	Parents report they have begun a scrapbook of favorite photos they anticipate will give them solace in years to come.

*Informatics for Seamless Healthcare Planning*

Nurse	Assess whether parents have made final arrangements for the child’s burial and responsibility for reporting death to hospice group.	Assist the family with making arrangements for what to do when the child dies.	Assistance with planning provides support and aids in grieving, allowing time to be spent with the child rather than on arrangements.	Parents state that they understand obligations for reporting death and have good relationship with the hospice group to answer questions.
Nurse	Assess whether parents have contacted a community support group other than hospice group.	If parents feel they need this, initiate referral to a community organization for additional support.	Community organizations can supply long-term support after the child dies.	Parents state they have the name of a community support group and will contact group if they feel a need in the future.

Although anticipatory grief does not shield parents from experiencing renewed grief at the time of their child’s death, it can be a useful process for them. A danger of anticipatory grief is that a parent may reach the acceptance stage of the grief process too far in advance of the child’s death. If this happens, parents may begin to treat the child as if the child has already died. They stop visiting, or when they do visit, they spend most of their time visiting other children on the unit or sitting in the waiting room

talking to other parents. Once they spent time comforting their child; now, they may fail to rock or touch the child as much. They may clean out the child's room and throw out or give away toys. They are gradually drawing back from emotional attachment to shield themselves from the abrupt, stabbing pain that death will bring.

Children need a great deal of support if anticipatory grieving blocks out communication this way, just as they did during the initial denial stage. Parents cannot help that the grief process did not coincide with the child's death. Extend understanding and do not provide criticism for this reaction.

For some parents, because of anticipatory grief, the event seems anticlimactic when the child actually dies. They have anticipated death so long that when it does occur, they cannot believe it has actually happened. They may be so used to thinking constantly about their child's needs and having their child dependent on them that they feel lost or feel as if there is a hole in their thoughts and life. Some parents are reluctant to leave the hospital this final time because leaving with the child's possessions is the step that will make the death real.

### **Vulnerable or Fragile Child Syndrome**

When anticipatory grief proceeds so effectively that parents begin to think of a youngster as already dead but then the child does not die, parents may find their grief reaction was so complete that they are unable to reverse it and they cannot view the child in the same way as they did before. Instead, they begin to treat the child in a cold and unfeeling way, as if the child were not really there but had actually died. Such children are termed **vulnerable children**, or fragile children (Green & Solnit, 1964). They may develop behavior problems as they grow older (e.g., acting out behavior, such as temper tantrums; stealing in school; shoplifting as adolescents) as if to say, "Notice me! I'm not dead!" They may require skilled counseling so they can feel secure that they are still loved and can learn to react effectively with others.

## **CHILDREN'S REACTIONS TO IMPENDING DEATH**

Children's reactions to death are strongly influenced by the previous experiences and the family's attitude toward death. For instance, death can be a new or frightening phenomenon if a child has never had a pet die, was forbidden from visiting a dying relative, or was discouraged from discussing the death of a loved one. Children's reactions to death are also influenced by their stage of development and cognitive ability.

### **Infants and Toddlers**

Infants and toddlers are certainly too young to appreciate that their death is imminent. If the person who cared for them dies, they experience a deep loss and a void in their life. If such a loss interferes with the development of a sense of trust, its implications for the child's ability to achieve warm, close relationships could last a lifetime.

## Preschoolers

Preschoolers cannot always differentiate what is real from what is make-believe play. This is a normal part of development and extends to abstract concepts such as illness and death. They envision death as temporary and therefore may not have the same fears adults may have about death.

This view of death is sometimes interpreted as unfeeling. For example, the first response of a child who is told his brother has just been killed in an automobile accident might be to ask if he can have his brother's cell phone. This happens because he thinks of his brother as being gone for only a short time, making this a chance to take advantage of his property. The understanding of death as temporary may be strengthened by fictional depictions of death in children's animation or stories in which sometimes characters that are killed come back to life.

The separation anxiety preschoolers experience can complicate their response to death. When confronted with their own death, their main concern may be separation from their parents. Constant reassurances and having a caregiver present with the child helps mitigate these fears.

## School-Age Children

School-age children begin to have additional experiences with death, so their knowledge of its finality increases. They may think of it, however, as something that happens only to adults. Children's books tend to deal only superficially with the subject, although many books that deal specifically with death are available for children (Box 56.5). As children near 8 or 9 years of age, they begin to appreciate that death is permanent. They may experience the same feeling of loneliness experienced when they went away to camp or just for a weekend, but this time, the separation will be permanent.

### BOX 56.5

#### Books About Death for Children

- Brown, L. K., & Brown, M. (1996). *When dinosaurs die: A guide to understanding death*. Boston, MA: Little, Brown.

- Farrant, N. (2013). *After Iris*. New York, NY: Dial Press.
- Isherwood, S., & Isherwood, K. (2000). *Remembering Granddad*. London, United Kingdom: Oxford Press.
- Koppens, J., & van Lindenhuisen, E. (2013). *Goodbye, fish*. New York, NY: Clavis.
- Millis, J. C. (2003). *Gentle Willow: A story for children about dying*. Warminster, PA: Marco.
- Spergel, H., & Stylou, G. (2013). *Cloud City: A child's journey through bereavement*. Upper Montclair, NJ: Turn the Page.
- Tott-Rizzuti, K. (1992). *Mommy, what does dying mean?* Pittsburgh, PA: Dorrance.

Weitzman, E. (1996). *Let's talk about when a parent dies*. New York, NY: Rosen Group.

Most school-age children are aware of what is happening to them when their disorder has a fatal prognosis. Unfortunately, they may learn of this prognosis from other children on the unit or at school, from their parents' unusual responses to questions, or from overhearing conversations about reports or physical findings. Children are accustomed to adapting to new situations (e.g., starting school, visiting a museum for the first time, boarding an airplane for the first time), and they are able to effectively cope with these experiences as long as they know someone they care about will be there to support them. Dying can be viewed as another new experience, which they are able to cope with as long as they know they will have someone with them. If the parents are unable to relate to a child because of their grief, a nurse may need to step in and fill the gap (Fig. 56.3).

**Figure 56.3** A one-to-one nursing relationship helps children with terminal illnesses to not feel deserted.

Many children associate death with sleep, so they may be afraid to fall asleep without someone near them and will need to have you sit with them while they fall asleep. They may need the light left on at night because they associate death with darkness. Considering how busy a unit nurses' station can be, a child who is dying may be moved to the end of the hallway, away from the nurses' station. However, this further isolates both a child who needs support and the child's parents, who also need your support and your presence nearby. Advocate as necessary for both the child and the parents so they can have continued interaction not just with each other but also with outside sources.

### Adolescents

During adolescence, the capacity to think in abstract terms grows and an adolescent has a realistic perspective on death. However, adolescents have an unrealistic view of their

own mortality and see themselves as invincible. Risky activities such as driving at high speeds reflect this judgment. They may deny symptoms that reveal their condition is worsening for longer than you'd expect because they believe it is impossible that anything serious could be happening to them. They appreciate time provided for discussion of how they have contributed to their family or community while their own death is imminent. Continuing to participate in favorite activities helps them maintain a sense of control.

### **QSEN Checkpoint Question 56.3**

#### **QUALITY IMPROVEMENT**

Charlie, 3 years old, asks the nurse what it feels like to die. Keeping in mind the goal to improve the way sensitive topics are discussed with children, which response by the nurse is best?

- a. "I think it's like going into a long white tunnel."
- b. "It doesn't hurt if you're worrying about that."
- c. "Everything probably goes black like it does at night."
- d. "Why are you asking a question about dying?"

*Look in [Appendix A](#) for the best answer and rationale.*

## **ENVIRONMENT FOR DEATH**

The environment in which children die can influence their and their family's acceptance of death.

### **The Hospital**

A number of children die each year in emergency departments from unintentional injuries such as automobile accidents or from severe infections (Allareddy, Anderson, Lee, et al., 2015). Children with a terminal illness have many medical needs (e.g., a new tracheotomy, lung ventilation), and their complex medical care may necessitate they remain in an acute care setting. Their family may not have the skills or resources to manage the complex medical needs at home. In a hospital setting, be certain that visiting hours are adequately extended for parents and other family members so that children are not left alone when they need people around the most. Be certain also that children have opportunities to maintain contact with peers.

### **The Home**

Today, most children with terminal illnesses are not kept in the hospital when it is determined that therapy is no longer effective. Many families prefer that their child die at home, surrounded by family and familiar possessions rather than in a hospital. Time spent discussing arrangements—such as who the parents should contact if the child suddenly decompensates, how they will manage periodic checkups, or how they will

purchase medicine or supplies—is important preparation for home care. Assess how the family will schedule leisure time so they can balance the care of the ill child and their self-care.

Including safeguards in the home plan of care will involve interventions for caregivers' emotional and physical health (discussed further in [Chapter 4](#)).

## The Hospice

In 1967, St. Christopher's Hospice in London opened as a facility for people who wanted to die in a homelike setting while still receiving skilled professional health care. Most large communities today have hospice settings, although places specifically for children, and especially infants, are still not available in many communities ([Price, Dornan, & Quail, 2012](#)).

In a hospice, friends, family, and even younger children and pets are allowed unlimited visiting. Children are invited to bring possessions with them that are important to them. They are given choices regarding the degree of pain relief they want. Strong analgesia is often used to make a child pain free.

The philosophy of hospice care is that death is an extension or part of life, not a separate entity; therefore, it can be accepted not with separate or awkward rituals but with the same warm concern as other situations in everyday life. For many children, hospice care is furnished as part of home care so that they are not separated from their families ([Robert, Zhukovsky, Mauricio, et al., 2012](#)).

### *QSEN Checkpoint Question 56.4*

#### **TEAMWORK & COLLABORATION**

Charlie's parents were told by his medical care team that he was going to die, but he doesn't. What is an unexpected consequence of anticipatory grieving a nurse would want their nursing colleagues to know when planning subsequent care for the family?

- It will have minimal effect because he did not die.
- It could disrupt the parents' relationship with Charlie.
- It teaches the child that healthcare providers can be wrong.
- It breaks the parents' confidence in healthcare procedures.

*Look in [Appendix A](#) for the best answer and rationale.*

## **PREPARATION FOR A NURSING ROLE WITH DYING CHILDREN AND THEIR FAMILIES**

End-of-life care for children can be an emotionally distressing experience for healthcare providers as well as family members ([Forster & Hafiz, 2015](#)). Although it is best that nursing assignments be consistent so a child has meaningful support, there is a point at which a healthcare provider may need a respite from caring for the child or providing support for the parents.

## Self-Awareness

Before you can offer support to children in any circumstance, be aware of your own reactions and feelings. To offer support to a child who is dying, one must recognize their own feelings, values, and beliefs about death of children.

### Fear

Fear is a natural response to death, and to overcome this fear, it should be put into perspective. In nursing, you care for many people who have illnesses and experiences you will never have, so caring for people with experiences beyond your own is not really strange but almost routine.

People who have never seen someone die may fear the moment of death and how they will respond to it. People who were declared dead and then resuscitated by heroic measures report that death was not at all frightening but actually involved a feeling of exceptional calm and comfort; people have reported afterward they wished they had been allowed to die rather than being called back to their body because death seemed so appealing (Facco & Agrillo, 2012).

### Failure

Some healthcare professionals find themselves drawing back from caring for dying children because death symbolizes failure to them. Remind yourself that death is the ultimate outcome for everyone. At the point that death becomes unpreventable, the only failure that can exist is the failure of healthcare professionals to help a child die with dignity and consideration and free of pain.

## Grief

Nursing care is so intense that the relationship formed between a nurse and a child may be closer than you realize until a child is diagnosed as having a terminal illness or dies and only then do you experience the depth of the relationship. Because nurses develop such close bonds with terminally ill children, they may experience profound grief when a child dies or no longer requires their care. The grief that accompanies caring for dying children can be broken down into the same stages of grief experienced by the children themselves when they learn they are dying.

### Denial

There is a danger that a nurse who is in a stage of denial may care for children without mentioning they have more than a simple illness. This includes omitting the use of such common expressions as “How are you this morning?” to avoid having to hear the answer. Denial may be so extensive that you avoid going into a child’s room unless an important procedure must be done. This is unfortunate because it can be confusing and lonely for children because they miss the normal exchange of conversation and contact.

The moral distress felt by nurses after the death of a child to whom they felt close may result in them reevaluating the profession and whether they want to continue this career.

## Anger

Anger may be intense when a young child dies because the death seems so unfair. Feelings of anger cause difficulty in offering effective care. Anger also clouds nursing judgment, such as to which analgesic would be best to administer or whether a change in vital signs is important. It is disappointing from a child's perspective because dying children may not fully grasp the anger in caregivers and identify its origin. They may feel lonely and perhaps feel guilty that they caused this anger.

## Bargaining

Caregivers begin to bargain for life, just as children do. A statement such as "If Tommy just makes it through the weekend while I'm off, I'll spend all my extra time with him next week" is a bargaining statement. Bargains of this kind are easy to overlook in your coworkers or yourself. Listening for them helps you to evaluate when a fellow worker is having difficulty caring for a particular child and perhaps needs a change in assignments. Hearing yourself express these sentiments should alert you that you may be more involved with a child than you perhaps have realized. It's a warning that you need to talk to someone about your feelings or ask for help. Remember that when bargaining fails, people reach their lowest point in grief. Recognizing bargaining statements in yourself, therefore, helps you prepare for the sadness that may follow.

## Depression

Nurses who enter this phase may be ineffective caregivers because depression may cloud judgment and result in inadequate problem-solving skills. It's easy for nurses to make unwise decisions in their personal lives as a result of the ineffective problem solving.

Depression is twice as destructive because when you are depressed, your reasoning processes are so distorted that you lose the ability to recognize that depression is the problem. When caring for a child who is expected to die, monitor your behavior to see if you are following your usual pattern. If irregularities occur (e.g., changes in sleeping pattern or loss of appetite), assess whether depression may be the underlying cause. If you feel you are depressed, try to make no major decisions for at least a week or you may find later you have made an unwise, irreversible decision.

## Acceptance

The average person can reach a stage of acceptance in grief because people are subjected to few true losses in a lifetime. A nurse on a unit, where many terminally ill children come for care, may find him or herself facing loss or death repeatedly. Therefore, a stage of acceptance may not be reached fully. A caregiver who cannot

reach a stage of acceptance is left in a stage of distress and may have difficulty functioning.

To achieve a stage of acceptance, you may need to modify your perspective. You may not be able to accept the unfairness of death in children, but you can accept your ability to offer care that facilitates death with dignity and compassion and maintains quality of life. It is important for parents to take care of their own emotional health, and they will improve their ability to care for others as they nurture themselves and their child.

### *What If... 56.3*

**A nurse has been caring for Charlie for an extended period. Would the nurse feel grief over Charlie's condition? How might this grief be expressed?**

## **Caring for the Dying Child**

A child may live for days, weeks, or even months at the end-of-life stage. Attentive physical and emotional care is essential for a child to maintain a sense of security and positive self-esteem during this time. It is also essential to assess if parents are coping well if this period is prolonged. Frequent and substantive communication is a major part of providing this care. Children, like their parents, need the opportunity to talk about their fears and feelings about death. Practicing good communication skills when providing any care such as when administering pain medication, starting intravenous lines, or providing basic comfort measures such as a bath help to establish a trusting relationship with the child, hopefully making the child feel more comfortable about openly sharing their feelings with you (Fig. 56.4). Box 56.6 provides some specific guidelines about communicating with a child who is dying.

**Figure 56.4** Good communication skills help build a trusting relationship, allowing a child to share feelings about being terminally ill. (iStock.com/FatCamera)

**MEASURES TO HELP COMMUNICATION WITH CHILDREN WHO ARE TERMINALLY ILL**

1. *Continue active conversation.* Children who are dying need to be stimulated and kept engaged.
2. *Use moments of silence therapeutically.* Such moments occur normally. Do not feel obligated to chatter to fill quiet intervals. Silence allows for processing and reflection.
3. *Use the words “death” and “dying” as appropriate in conversation.* Trying to avoid a word makes interchanges awkward. The word “death” or “dying” can be mentioned without hesitation in sentences as appropriate.
4. *Preserve dying children’s defenses.* If they are using denial or bargaining, do not try to push them to the next step of grieving by confrontation. Children will move on to the next step when they are psychologically ready.
5. *Terminally ill children may feel more vulnerable at night.* They may be comforted by having someone sit beside them until they fall asleep.
6. *Be supportive, not trite.* A statement such as “All of us are dying” is true but not helpful. A supportive statement such as “This must be hard for you” is more appropriate.
7. *Be aware that not all people’s beliefs are the same as yours.* Statement such as “God works in mysterious ways,” which may explain death for the person saying it, may evoke an angry response from you. People grieve and react to grief in many different ways.

**The Child’s Family**

For many children, terminal illness involves a series of hospital admissions interspersed with ambulatory care or home visits. Parents need time during these visits to talk about the problems they are having, not only with physical care (e.g., Should the child attend regular school? Could he come on vacation? How many times a day are we supposed to give the immunosuppressant?) but also about how it feels to live with a child who is dying (e.g., How should they answer the child’s or siblings’ questions about death?). Although many parents are reluctant to tell a child that he is dying, this is probably the soundest course once the child can see that his or her condition is deteriorating because there is often less anxiety in knowing what is happening than in hearing people whispering or spelling out words.

If a child with a chronic illness experiences an exacerbation of the disease, parents may again begin an anticipatory grief reaction: anger, bargaining, depression, and acceptance. The process will be cut short by improvement, only to begin again at the next exacerbation. For this reason, the parents of a child who is being admitted to the hospital for the 12th time for a fatal illness may be in the same stage of grief as the

parents of a child with a newly diagnosed fatal illness.

During health supervision visits, ask parents how other children in the family are managing. The parents may need to be reminded that, although the dying child does need a lot of their time, other children find this illness in a sibling just as baffling as the parents. When the ill child dies, siblings need the same active support to help them grieve (Siegel, Alpert, & Goldstein, 2011).

### **QSEN Checkpoint Question 56.5**

#### **EVIDENCE-BASED PRACTICE**

Helping parents survive the death of a child can be a challenging experience in nursing. Two hundred parents were studied to investigate what parents believe their role is when caring for seriously ill children. The study concluded that parents saw their role as ensuring their child felt loved, followed by focusing on the child's health, making informed medical care decisions, and advocating for their child with medical staff (Feudtner, Walter, Faerber, et al., 2015).

Based on this study, which action would probably give Charlie's mother the most satisfaction with his end-of-life care?

- a. Participating in keeping him clean and comfortable
- b. Being allowed to inspect his health record on a regular basis
- c. Interacting with the nursing staff on a personal or friendly level
- d. Providing counseling to other parents on the unit

*Look in Appendix A for the best answer and rationale.*

### **The Onset of Death**

As death nears in children, physiologic changes, such as slowed metabolism, decreased cell oxygenation, and cell dysfunction, begin to occur, thus changing children's appearance.

Stroke volume of the heart decreases, so the power to circulate blood is reduced. The child's skin feels cool and may appear mottled or cyanotic because blood can no longer be pushed to distal sites. Just before death, blood begins to pool in dependent body parts, making them appear purple. As circulation fails, absorption of a drug from a muscle becomes virtually impossible; if emergency drugs need to be administered, they need to be injected intravenously or often don't have an effect.

As peripheral circulation fails, less heat is lost from the body and the internal temperature rises. The child's body compensates for this by increased perspiration to increase heat loss through evaporation. This makes the child's skin feel cool and damp. You may need to change linens frequently because of the increased moisture on the skin. Because perfusion of distal body parts is impaired, turn the child slowly to allow the circulatory system to accommodate to the change in position.

Slowed respirations lead to increased secretions in the lungs and the appearance of

rales, the sound of air being pulled through fluid in the alveoli. To compensate for a few minutes of very slow respirations, a child may take several quick or extremely deep inhalations periodically. Be certain the child's chest is not compressed so that the child has optimal lung expansion to do this.

A decrease in muscular function leads to severe weakness and fatigue. More and more, children maintain the exact position into which they were placed. As the throat muscles become lax, the possibility of aspiration increases. Offer only a small amount of oral fluid until you're certain the child's swallowing reflex is intact before offering a full glass. If the gag or swallowing reflex is impaired, position the child on the side to allow saliva to drain from the mouth to prevent aspiration.

A loss of consciousness occurs as children grow closer and closer to death, although they may remain perfectly alert until seconds before death. Vision apparently blurs because children tend to turn their head toward a light. Touch seems to remain intact as they often quiet to a gentle stroking of the arm or shoulder, and they will grasp your hand meaningfully, as if touch is appreciated and felt. Because hearing is one of the last senses lost, you may need to remind family members and, on occasion, other healthcare personnel, that the child may not be able to respond but may be able to hear. Continue to explain procedures to unconscious children as if they were conscious because they undoubtedly do hear you. Never make any comment in their presence that you would not make if they were alert. Continue to use the same gentle touch and nonverbal communication motions, such as holding a hand or brushing hair from the forehead as if children were fully conscious because they may be fully aware of your actions even though they can give no indication of it.

Another body function that slows is digestion as total body metabolism slows. Constipation because of poor bowel tone and decreased peristaltic action will occur. The abdomen may become distended from intestinal flatus. Dehydration with dry mucous membranes and conjunctivae will occur unless intravenous fluid replacement is initiated. Mouth dryness will lead to cracking, secondary infection, and pain; prevent this by frequently cleaning the mucous membrane with clear water and with the application of an ointment to the lips. If the conjunctivae appear dry, ask for a prescription of moistening eye drops, and keep any crusting at the eyelids washed away so that optimal vision is possible.

Be certain to keep skin surfaces from rubbing against one another by using supportive pillows and good positioning. Keep the skin free of urine or feces from incontinence to prevent painful ulcers. These are concerns in that are due to the decreased peripheral blood perfusion. Assess for indications of pain (e.g., thrashing, moaning) and provide relief with appropriate comfort measures.

### *QSEN Checkpoint Question 56.6*

#### **SAFETY**

Children's body functions grow increasingly weaker as death approaches. What

safety precaution would the nurse want to remember when caring for Charlie?

- a. Children may aspirate easily as their gag reflex begins to fade.
- b. Children who are unconscious cannot hear and so like the room quiet.
- c. Turning and repositioning children can cause more harm than good.
- d. To help them cope, you should avoid asking parents to give any final care.

---

*Look in [Appendix A](#) for the best answer and rationale.*

---

## Documentation of Death

Defining when death occurs is controversial and involves both legal and ethical issues. As a child nears death, ethical committees may be used to assist families in decision making. Signs of death in a child not receiving ventilatory or mechanical assistance are the same as in adults:

- Absence of respirations
- No audible heart sounds by stethoscope
- No pulse by palpation
- No apparent blood pressure
- Absence of body movement or reflexes
- Dilated, fixed pupils

**Death** is officially determined by a lack of receptivity and responsivity, no spontaneous muscular movement or breath, no reflex response, and a flat electroencephalogram—again, the same as in adults.

## Organ Donation

Parents may be asked by their primary healthcare provider or by a specifically designated transplantation team before a child's death to grant permission for body organs to be transplanted into other children after death occurs ([Weiss, Hornby, Witteman, et al., 2016](#)).

This is particularly important for liver and kidney transplants because it is difficult to transplant adult-size organs into children. If parents decide to allow organ donation, document this information on the child's electronic record and alert the primary care provider about the decision. When death does occur, the child's body will be maintained on life support to ensure that the organ remains perfused until it can be removed. The donation of body organs is not something that all parents can agree to, but it can help parents who choose the option to accept their child's death more easily because it allows them to feel that their child has helped another person live. Donating their child's organs is not a practice for everyone ([Siebelink, Albers, Roodbol, et al., 2012](#)).

## Aftercare

Before beginning any aftercare for a child who has died in a healthcare facility or at home, check with family members to see if they want to spend a few minutes with the child or if there are any religious rites they want to complete before the body is

transported to the morgue or funeral parlor. Some parents need this time for closure. Some people have special prayers or traditions and rituals they need to follow; others want to say a final, private goodbye. Check that the child's bed and room is orderly before you ask a family whether they would like to spend some time in the room, particularly if the death was following an unsuccessful resuscitation attempt.

Remain in the room with the family in case they need your support, but be unobtrusive. Some parents fear touching a child's body after death, but touch is a strong and intimate gesture that a family member may need to be encouraged to make. Some parents may seem unable to leave the room or to let go of the child's hand. It may be necessary for you to gradually separate their hands while showing empathy for what they are experiencing. This helps parents begin to accept the fact that, in more than a physical sense, it is time to let go.

Crying is helpful for parents. You may need to reassure them that crying is not a sign of weakness but a normal response to a loved one's death. Do not, however, interpret a lack of tears as a lack of feeling because crying is not everyone's response to death. It is not unprofessional for nurses to cry when a child dies. A parent's warmest memory of a hospital experience may be that a nurse cried as she said goodbye to their child—the implication being the child made an important impact on people other than the family.

### Autopsy Permission

State laws vary, but generally, if a child's death is a result of homicide, suicide, death within 24 hours after a hospital admission, suspected harmful death, or death in an institution or home where the child was not under the care of a primary healthcare provider, an autopsy is required by law and parents have no input regarding whether this is done or not. In other instances, it would be helpful to medical progress or to research if an autopsy could be done. In these instances, parents must give permission for this. Parents may refuse to allow an autopsy for a child, believing that doing so will protect the child from any more hurt or because of spiritual convictions. Autopsies advance medical science, so they should be done if at all possible; however, parents have every right to refuse permission without being made to feel guilty for their actions, so you may need to advocate for them.

#### *What If . . . 56.4*

**A nurse is particularly interested in exploring one of the 2020 National Health Goals related to chronic or terminal illness in children (see [Box 56.1](#)). What would be a possible research topic pertinent to this goal that would be applicable to Charlie's family and that would also advance evidence-based practice?**

## KEY POINTS FOR REVIEW

- Children with long-term illnesses need continual reassessment because, like all children, their needs change as they grow older. Larger doses of medicine may become necessary or additional muscle-strengthening exercises may be necessary.
- Factors that make it easier for parents to accept a long-term illness in a child include having support people present and being told about the child's condition as early as possible.
- Long-term illness in a child is often most difficult for parents to accept at times when the child would have been achieving specific milestones of development such as a time that would have been the first day of school for the child. Extra support for both the parents and the child may be necessary during these challenging times not only because it meets QSEN competencies but also because it meets a family's needs.
- Help children with a long-term disorder to do as much care for themselves as possible within the limits of their illness. Self-care empowers them to be as independent as possible.
- Children are about 9 years old before they are able to understand the meaning of death and that it is permanent. A child and parents can be expected to move through the stages of grief (denial, anger, bargaining, depression, and acceptance) on learning about a potentially fatal diagnosis.
- Children and parents are apt to need help to face a terminal diagnosis in a child. Urge the parents and the child to ask for help to see them through this very difficult time in their lives.

## CRITICAL THINKING CARE STUDY

“Skater” is a 16-year-old gang member you meet in the emergency room. He is unconscious from a gunshot wound to his head, which was suffered while he was robbing a convenience store. The police officer who accompanied the ambulance tells you Skater was shot by the store owner. A fellow gang member tells you Skater shot himself to keep from being arrested.

1. Skater was diagnosed with autism spectrum disorder when he was 4 years old. He dropped out of school last year because “he didn’t like being told what to do.” If you were assigned to accompany him to the X-ray department for a cranial magnetic resonance imaging (MRI), would you need to explain to him what is happening (he doesn’t like instructions and he’s unconscious)?
2. Skater’s mother rushes into the emergency room and describes her son as “a precious child” whom she wants to live. His older brother describes him as “nothing but trouble his whole life” and adds that the family would be better off if Skater died. Would these conflicting opinions affect your care? Would the dispute over whether he was shot or shot himself influence care?
3. Skater’s mother and sibling seem to have totally different opinions about the effect Skater has had on his family, probably based on actions related to him

being autistic. Why do you suppose these two people have formed such different opinions of Skater?

## CHAPTER 1

### A Framework for Maternal and Child Health Nursing

- 1.1 C. The nurse should inform the team members that a Magnet hospital is one that stresses exemplary nursing care. It does not necessarily denote care for acute patients. This designation is not conferred by the American Medical Association.
- 1.2 C. The nurse explains that the perinatal period is the time between 20 weeks of pregnancy and 4 to 6 weeks following birth.
- 1.3 C. The trend toward quality improvement through technology can become overwhelming for families if nursing support is not included in care. Premature infants require extensive care, and there are no immunizations for all childhood diseases. Nursing is predicted to maintain an important role in health care.
- 1.4 A. The nurse should assess if Mr. Chung is open to trying skin-to-skin contact with his newborn. Skin-to-skin contact is important for newborns and may help fathers bond with their infants. It would be incorrect to withhold this until after discharge.
- 1.5 B. The nurse should acknowledge the patient's concerns while affirming her efforts rather than downplaying her concerns or providing false assurance.
- 1.6 D. The nurse should explain that consent is required for all patients regardless of age and the amount of pain involved in the procedure and can be given by telephone or e-mail for long distance consultation.

## CHAPTER 2

### Diversity and Maternal Child Nursing

- 2.1 B. The nurse assessing a family's structure and decision-making norms is a component of culturally competent care. These patterns of behavior differ significantly between cultures. Nurses should avoid assumptions that may border on being stereotypes, such as equating a preference for tacos with a patient who is Hispanic.
- 2.2 A. The nurse should encourage the care provider to communicate as naturally and clearly as possible; imitating Maria's accent is inappropriate. There is no

- particular need to avoid pop culture references if these are contextually appropriate.
- 2.3 **D.** It is important for the nurse to avoid interactions between home remedies and prescribed medicine. For the nurse to use the words “you people” is a term of disrespect.
  - 2.4 **B.** It would be discriminatory for the nurse to presume that Maria will not “fit in” by virtue of her ethnicity.
  - 2.5 **D.** The nurse respecting food choices is a way of respecting cultural diversity. The nurse addressing the taste of the food does not focus on Maria’s concerns.
  - 2.6 **B.** The nurse should reinforce the results of the study and state that “Children raised in same-sex parent houses do just as well as children raised with different sex parents.” Questioning whether Sofia will be a good parent based on sexual orientation, defining the situation as a challenge to raising a child, or assuming the child needs a male figure is disrespectful to the family structure.

## **CHAPTER 3**

### **The Childbearing and Childrearing Family in the Community**

- 3.1 **B.** The nurse should address that fact that because women earn less than men and single-parent families are usually headed by women, finances are a common concern. Communication, emotional engagement, and education are not necessarily lacking as often.
- 3.2 **B.** The nurse should be aware that the person who allows information in or out of a family is the gatekeeper.
- 3.3 **D.** The nurse knows that the oldest child marks a family stage; because the Hanovans’ oldest child is 17 years of age, they are at a family with an adolescent stage.
- 3.4 **D.** The nurse should teach parents that automobile accidents are a major cause of death in adolescents. Rates of such accidents exceed those among younger children.
- 3.5 **B.** The nurse should ensure the parents are aware that teenagers need responsible adult supervision in both custodial settings. It would be inappropriate for the nurse to suggest shared custody, to suggest quitting work, or to assume that the situation will be independently resolved.
- 3.6 **C.** The nurse should teach parents that the AAP recommends television viewing be restricted until a child is 2 years of age to reduce exposure to violence and stimulate language development.

## **CHAPTER 4**

### **Home Care and the Childbearing and Childrearing Family**

- 4.1 **C.** The nurse could suggest that Lisa needs a sedentary activity to interact with friends. Shouting for basketball teams or joining in with cheerleading would

contradict bed rest. She is unable to safely go on outings due to her activity restriction. Journaling does not meet her socialization needs.

- 4.2 **A.** The nurse's first visit will involve gathering a health history, so having a parent present would be helpful. The nurse should not dictate a time because this is not an effective way to empower or involve a patient in planning care.
- 4.3 **D.** The nurse should always call for help if he or she feels in danger. Leaving the home would leave the patient still in danger. Changing the locks would not solve the immediate problem. It is difficult and often unsafe to reason with angry people.
- 4.4 **A.** The nurse should assure Lisa that privacy rules apply to home care as well as hospital care; health records are not copyrighted.
- 4.5 **C.** The nurse should suggest drinking more fluid as an adequate fluid intake helps prevent constipation. Walking is contraindicated as Lisa is on bed rest. The size of meals or calcium intake shouldn't make a difference.
- 4.6 **A.** Lisa's community is probably safe enough for her to stay alone. The nurse should worry about the mother "trying to quit smoking" because it is not enough to prevent exposure to secondary smoke and toxic tobacco contaminants because smoke particles cling to clothing. If the mother "usually" smokes outside, then this implies that she is sometimes smoking in the home.

## CHAPTER 5

### The Nursing Role in Reproductive and Sexual Health

- 5.1 **C.** The nurse should teach the client that thelarche refers to breast development. Adrenarche is development of other secondary sex characteristics; menarche is the first menstrual period.
- 5.2 **C.** The nurse should state that because the vas deferens is easy to locate, it is the organ blocked/ligated for a vasectomy.
- 5.3 **D.** The nurse should explain that cystocele is herniation of the bladder into the vagina and can lead to urinary tract infection.
- 5.4 **D.** The nurse could help the patient calculate the ovulation date by teaching that ovulation usually occurs on the 14th day from the end of the menstrual cycle, or in this instance, 14 from 34 or on the 20th day.

## CHAPTER 6

### Nursing Care for the Family in Need of Reproductive Life Planning

- 6.1 **B.** The nurse should teach Dana that cervical mucus is thin and watery at ovulation. Subjective sensations of warmth, breast tenderness, and emotional lability are not safe and reliable indicators.
- 6.2 **B.** The nursing care plan for Dana should include teaching her that female condoms should be inserted before any sexual contact, they should not be reused, and they already contain a spermicide.

- 6.3 **D.** The nurse should have Dana report severe migraine headaches because they are a contraindication to COCs.
- 6.4 **B.** Intramuscular injections (DMPA) are associated with osteoporosis, so recommending a high calcium intake is important.
- 6.5 **A.** The nurse should teach Dana that tubal ligation is a minor surgical procedure in which the fallopian tubes are occluded by cautery, crushed, clamped, or blocked, thereby preventing passage of both sperm and ova.
- 6.6 **C.** Having access to multiple methods, reliable methods, and highly effective methods of birth control caused a 36% decrease in the pregnancy rate among adolescents from 2007 to 2012. Teens were not likely to decrease sexual activity or more likely to use abortion. Although community influence may play a role in the rates of adolescent pregnancy, that was not measured in this study.

## CHAPTER 7

### Nursing Care of the Family Having Difficulty Conceiving a Child

- 7.1 **C.** The nurse should state that a year is the typical time to wait as, after trying to conceive unsuccessfully for 1 year, a couple is said to be subfertile. Acknowledging the reality of regretting a decision does not directly address her concerns.
- 7.2 **C.** The nurse should remind couples with reduced fertility that just because they are no longer using a contraceptive method, they still need to follow safer sex precautions.
- 7.3 **A.** Patient teaching should include the fact that mild cramping may occur during the procedure. X-ray is not used; no bleeding should result.
- 7.4 **D.** The nurse should document endometriosis on the health record because this condition can affect fertility by blocking fallopian tubes and interfering with sperm or ovum transport.
- 7.5 **C.** The nurse should state that patients who are to undergo intrauterine insemination receive an injection of clomiphene (Clomid) or FSH 1 month prior to the procedure. Estrogen, bedrest, and genetic testing are not indicated.
- 7.6 **C.** The nurse should tell Cheryl that women begin breastfeeding effectively but may need additional support to continue it long term. Telling someone to not worry is not effective counseling. IVF does not preclude normal breastfeeding.

## CHAPTER 8

### The Nursing Role in Genetic Assessment and Counseling

- 8.1 **D.** The nurse providing health information in a relevant and appropriate manner is an important component of high-quality care. False hope must be avoided. Journals and websites are not substitutes for health education provided by nurses and may not meet Amy's learning needs.
- 8.2 **D.** The nurse should recommend that in order for Mrs. Alvarez to make an

informed choice about her future, talking to other parents might be helpful. False hope should be avoided, and the nurse's own personal views are not relevant.

- 8.3 **B.** The nurse should inform team members that infants with Down syndrome have one palm crease instead of the usual three. Babies tend to be hypotonic, not hypertonic. Sole creases are an indication of any mature fetus.

## CHAPTER 9

### Nursing Care During Normal Pregnancy and Care of the Developing Fetus

- 9.1 **D.** The nurse should state to team members that the baby is an embryo during the period between implantation and 5 to 8 weeks. After that, it is a fetus.
- 9.2 **B.** The nurse's assessment findings of a normal umbilical cord would be one vein and two arteries. Other patterns are associated with cardiac or chromosomal disorders.
- 9.3 **A.** The nurse should explain that surfactant, a phospholipid substance, is formed and excreted by the alveolar cells of the lungs beginning at approximately the 24th week of pregnancy. This decreases alveolar surface tension on expiration, preventing alveolar collapse and improving the infant's ability to maintain respirations in the outside environment at birth.
- 9.4 **A.** The study reveals alcohol consumption, low socioeconomic status, and depression contribute to smoking. The nurse should counsel the client regarding the effects of smoking and alcohol on the fetus.
- 9.5 **C.** The nurse should teach that a full bladder improves the accuracy of the scan. There is no pain involved.
- 9.6 **A.** If the client is having the amniocentesis after week 20 of pregnancy, the nurse should ensure the client voids prior to the amniocentesis to prevent puncturing the bladder.

## CHAPTER 10

### Nursing Care Related to Psychological and Physiologic Changes of Pregnancy

- 10.1 **A.** The nurse is aware that women in the study reacted both positively and negatively at the thought of a second pregnancy. Lauren's paradoxical response represents this.
- 10.2 **B.** The nurse counsels Lauren that ensuring safe passage for the fetus consists of accepting the pregnancy (first trimester), accepting the coming baby (second trimester), and preparing for parenthood (third trimester).
- 10.3 **C.** The nurse would tell the unlicensed care provider that narcissism refers to interest in yourself in contrast to interest in others.
- 10.4 **D.** The nurse should teach that the three positive signs of pregnancy are fetal

heartbeat heard by examiner or seen on sonogram and fetal movement felt by examiner.

- 10.5 D. The nurse should explain that Chadwick's sign is a color change in the vagina from pink to purple because of increased formation of blood vessels and blood flow.
- 10.6 A. The nurse should state that with insulin becoming ineffective, glucose levels rise, serving to safeguard the fetus from hypoglycemia. Maternal insulin does not cross the placenta.

## CHAPTER 11

### Nursing Care Related to Assessment of a Pregnant Family

- 11.1 C. The nurse should explain that the odds of experiencing a medication-free birth are far higher when a nurse-midwife leads care. It is inaccurate to characterize nurse-midwives as always being more "patient-friendly," and it is not appropriate to wholly defer teaching or advice when the patient initiates.
- 11.2 C. The nurse should state that prenatal care is a prime time for health education; during this time, nurses play an important role in effective prenatal care. Ultimately, this promotes safe pregnancy, labor, and delivery. This is more important than collecting statistical data or promoting social interaction. Allergies are not correlated with preterm labor. Despite the patient's wishes, regular prenatal care should be strongly encouraged.
- 11.3 B. The nurse should ask Sandra about past surgery because surgery such as for appendicitis can leave adhesions, which then might interfere with uterine growth. Risks of uterine rupture and preterm labor are not higher in women with a surgical history.
- 11.4 D. The nurse should teach that palmar erythema commonly occurs from increasing estrogen levels. It is not a result of Rh incompatibility, edema, or anxiety.
- 11.5 D. The nurse should know that relaxation is important to reduce pain with a pelvic examination and teach her to breathe slowly and evenly when being examined. Holding the breath or pushing down on the diaphragm does not relax abdominal muscles.
- 11.6 C. The nurse should have Sandra report a weight gain more than 3 lb a week during the second trimester as this would be a potential sign of gestational hypertension. The other listed changes do not constitute safety risks.

## CHAPTER 12

### Nursing Care to Promote Fetal and Maternal Health

- 12.1 C. The nurse should teach Julberry that she can still contract a sexually transmitted infection, so she still needs to use precautions. However, a condom would not tear the membranes. Julberry's other responses reflect a sound understanding or self-

care during pregnancy.

- 12.2 **A.** The nurse should recognize that jogging is not recommended during pregnancy because the extra weight of the pregnancy can cause knee injuries. The other health promotion statements are accurate.
- 12.3 **C.** The nurse assesses that all of the things Julberry describes are concerns, but it is the accumulation of symptoms that apparently leads to depression.
- 12.4 **D.** The nurse should counsel Julberry to use witch hazel as it feels cool and may shrink hemorrhoids. Mineral oil is contraindicated because it prevents absorption of vitamin A; eating fiber should not be omitted because it is helpful in preventing constipation; she can't lie on her stomach because she is pregnant.
- 12.5 **C.** The nurse would recognize that Julberry has read the correct information on ankle edema. Ankle edema is a common occurrence in pregnancy and occurs from increased pressure on lower extremity veins. It can be relieved by resting with feet elevated.
- 12.6 **C.** The nurse should teach that pregnant women should check with their healthcare provider before taking medicine during pregnancy. All over-the-counter medicine is not safe; measles vaccine contains a live virus so is contraindicated during pregnancy.

## CHAPTER 13

### The Nursing Role in Promoting Nutritional Health During Pregnancy

- 13.1 **B.** The team should recommend that Tori gain 15 to 25 lb during her pregnancy because she is slightly overweight.
- 13.2 **D.** The nurse should confirm that iron is absorbed best from an acid medium. Crushing the pills or taking them with milk or carbonated beverages is not advised.
- 13.3 **C.** The nurse should recommend leafy green vegetables to eat during pregnancy. Leafy green vegetables are rich in many of the dietary components that are lacking women's diets. Protein, fiber, and iron are all important during pregnancy so should be encouraged. Dieting should normally be discouraged.
- 13.4 **C.** The assessment document should specify a 24-hour recall history to secure the most accurate nutrition pattern.
- 13.5 **A.** The nurse identifies eating erasers as a sign of pica. Some women report a craving for foods such as oranges or chocolate. Women with pica, however, crave a nonfood substance, in this case, an eraser. Typically, these cravings include clay, dirt, cornstarch, or ice cubes.
- 13.6 **D.** The nurse would note that vitamin B<sub>12</sub> is found only in animal sources and would be omitted in a vegetarian diet.

## CHAPTER 14

### Preparing a Family for Childbirth and Parenting

- 14.1 **D.** The nurse recognizes that the statement that best assures a workable birth plan is keeping the plan “flexible.” Rigid expectations can lead to disappointment and anxiety. The partner’s wishes are indeed secondary, but they should not be wholly rejected. Interventions such as opioids should not be included solely on the recommendation of a parent.
- 14.2 **B.** The nurse should suggest squatting or tailor sitting to tighten perineal muscles. Tightening and relaxing them (Kegel exercises) would also strengthen them. The nurse should not recommend vigorous exercise and bearing down forcefully as these actions carry safety risks.
- 14.3 **C.** The nurse should make Elena aware that women who give birth in upright positions have fewer obstetric and anal sphincter injuries. Voicing the fact that she is willing to try different positions should achieve this. Media presentations of labor are not always realistic.
- 14.4 **A.** The Lamaze philosophy is based on the gate control theory of pain perception, which states that pain sensations can be interrupted. This philosophy does not deny the reality of pain or the inevitability of pain during labor.
- 14.5 **D.** The nurse should teach that slow breathing is adequate for early contractions; a cleansing breath is always important. Hypoventilation is relieved by breathing into a paper bag. Rapid breathing is contraindicated.
- 14.6 **C.** The nurse should emphasize that emergency care is more readily available in a hospital setting than in other birth settings. Childbirth is not pain-free, and the cost of present-day hospital stays is typically high. Hospitals, like all birth settings, are not sterile environments.

## CHAPTER 15

### Nursing Care of a Family During Labor and Birth

- 15.1 **A.** The nurse is aware that an occipitoanterior position means the lie is cephalic—the back of the baby’s head is facing the right anterior quadrant of the mother’s pelvis. Full flexion means the smallest diameter of the fetal head is presenting to the cervix. This position is considered to be ideal and is most conducive to a healthy delivery that requires fewer interventions.
- 15.2 **D.** An important teaching point for Celeste would have been that cervical dilation is a mark of true labor. For the mucus plug to be loosened, cervical dilatation must be occurring.
- 15.3 **A.** The nurse should be most concerned that Celeste is “losing a grasp on things.” In the study, a feeling of loss of control severely affected women’s impressions of whether labor was traumatic or not.
- 15.4 **D.** The nurse should assure her that a placenta loosens quickly so waiting time will not be long. Pulling on the cord, pushing on the uterine fundus, or hard pushing could all cause additional bleeding. The placenta must normally be delivered spontaneously.

- 15.5 **B.** The nurse should report a contraction 70 seconds long as it is long enough to compromise fetal oxygenation. In the context of labor, pain is not necessarily indicative of pathophysiology.
- 15.6 **B.** The nurse would document FHR decreasing in rate 30 seconds after the start of a contraction as a late deceleration. A late deceleration means the FHR decreases as a contraction ends, rather than at the beginning of a contraction, as is usual.

## CHAPTER 16

### The Nursing Role in Providing Comfort During Labor and Birth

- 16.1 **C.** The nurse's best answer would be that a doula is a second support person in labor. She doesn't replace a woman's partner and does much more than time contractions. The use of a doula is an individual choice.
- 16.2 **D.** Based on the study, the nurse could confirm that music is best used in early labor to help a woman relax.
- 16.3 **C.** The nurse should recommend slow breathing. Slow breathing calls for concentration. Consequently, it can be used as a distraction technique. Women should not lie on their back during labor in order to prevent hypotension. Women should not hold their breath as long as possible, and rapid breathing should not be encouraged.
- 16.4 **B.** The nurse should state that warm water is comforting during labor; it may be contraindicated if membranes are ruptured because of the increased risk of infection.
- 16.5 **A.** The nurse should inform Jonny that peripheral relaxation can lead to systemic hypotension with epidural anesthesia. A slowed second stage of labor also may occur.
- 16.6 **C.** The nurse should have a drug to speed gastric emptying on hand in case of general anesthesia use. A drug to increase gastric emptying helps to avoid vomiting. The other listed drugs do not have this therapeutic effect.

## CHAPTER 17

### Nursing Care of a Postpartal Family

- 17.1 **C.** The taking-hold phase means a woman is interested in actively caring for her baby. The nurse should encourage her to participate in the care of her baby by bathing the baby. Telling her she did well or encouraging the naming of the baby does not help to usher in the taking-hold phase.
- 17.2 **A.** The nurse assesses that an "en face" position suggests she is interested in becoming acquainted with the newborn.
- 17.3 **A.** The nurse should teach Leana that tampons should not be used postpartum to help prevent infection.
- 17.4 **B.** If the uterine fundus does not grow firm with massage, extreme atony, possibly retained placenta fragments, or an excess amount of blood loss may be occurring;

the nurse should notify the woman's primary care provider. A uterine fundus decreases in size at a rate of one fingerbreadth a day. The fundus should be located midline. Firm massage will result in pain, but this is not acceptable nursing practice.

- 17.5 **D.** The nurse worries about Leana's comment that the baby will sleep fine. This statement may suggest that Leana is unprepared for the fact that her infant may spend more time crying than sleeping. Her expectations for her own levels of rest may be unrealistic.
- 17.6 **B.** The nurse records that Leana's uterine fundus sinks below the symphysis pubis at about 10 days after birth. This is a normal finding.

## CHAPTER 18

### Nursing Care of a Family With a Newborn

- 18.1 **D.** The nurse is aware that conduction is the transfer of body heat to a cold object that touches the infant. Each of the other factors can result in heat loss, but none involves heat loss by conduction.
- 18.2 **C.** The nurse should lift the baby's head and allow it to fall back 1 in. to elicit a Moro reflex. This action best initiates a Moro reflex. Making a noise or shaking a crib is less effective way to test the reflex.
- 18.3 **A.** Using the apgar test, the nurse assesses heart rate, respiratory effort, muscle tone, reflex irritability, and color.
- 18.4 **A.** The nurse should advise Beth that milia spots will disappear on their own, so she doesn't need to take any action.
- 18.5 **C.** The nurse would confirm that a week is an average time for a dried cord to detach.
- 18.6 **C.** Shaking infants is potentially dangerous because it can cause head injury; the nurse educating about newborn abilities helps parents better understand a newborn reacts the way he or she does. This approach is likely more effective than the nurse immediately addressing shaken baby syndrome, which may be a premature and "heavy-handed" approach. A sedative is contraindicated with breastfeeding.

## CHAPTER 19

### Nutritional Needs of a Newborn

- 19.1 **A.** Nursing assessment of infant nutrition begins during pregnancy with assessment of the mother's and her partner's attitudes and choices about infant feeding. This is an important aspect of patient-centered care and should normally precede other assessments.
- 19.2 **A.** The nurse sees having prenatal care as an indication that Linda will successfully breastfeed. Prenatal care is associated with success at exclusive breastfeeding. Smoking, young age, and low income are negatively associated.

- 19.3 **B.** The nurse should teach Linda that breast milk provides not only nutrition but also aspects of immunity. Breastfeeding may reduce the risk of obesity but does not ensure the infant will never become obese. It does not necessarily prevent cancer.
- 19.4 **C.** The nurse determines that Linda stating that she should drink 12 glasses of fluid a day warrants further teaching. Drinking 12 glasses of fluid a day is extreme; 6 to 8 is a better recommendation.
- 19.5 **A, B, D.** The nurse should teach that breastfeeding exclusively for 6 months can reduce the risk of obesity later in life and decrease the risk of breast and ovarian cancer for the mother, and a pacifier can be used to decrease the risk of sudden infant death syndrome once breastfeeding is established. Formula feeding does not increase calcium density of the spine.
- 19.6 **D.** Educational literature should include the fact that discarding leftover milk discourages the growth of pathogens. The presence of yellowish stools is consistent with breast milk. A microwave should not be used to warm breast milk, and propping a bottle risks for aspiration.

## CHAPTER 20

### Nursing Care of a Family Experiencing a Pregnancy Complication From a Preexisting or Newly Acquired Illness

- 20.1 **C.** An appropriate nursing action for Angelina is allowing her to choose a subcutaneous site for the injection. Heparin is administered subcutaneously. Hemoglobin levels and WBC do not need to be monitored during therapy.
- 20.2 **C.** The nurse is alerted to the fact that the woman is taking an iron pill every day. Women with sickle-cell anemia are not prescribed iron pills during pregnancy because sickle cells are unable to incorporate as much iron in their structure as normal red cells. The woman's other statements reflect a sound understanding of sickle cell disease.
- 20.3 **C.** Nurses should emphasize that good perineal care, a generous fluid intake, wearing cotton underwear, and avoiding bath salts are common ways to avoid urinary tract infections so should be followed during pregnancy.
- 20.4 **A.** The nurse should alert care team members that because the fetus requires calcium to build bones, calcium-surrounded tuberculosis lesions can be activated if a woman doesn't ingest adequate calcium.
- 20.5 **B.** The nurse should explain that continuous insulin administration with no food intake can lead to hypoglycemia. Women should typically eat a high-protein/complex carbohydrate snack such as peanut butter and celery before bedtime to prevent fetal hypoglycemia from ingesting little food during the night.
- 20.6 **A.** The nurse should be concerned about Angelina wanting to "shed some pounds." Concerns about gaining weight and having to have a cesarean birth were the two factors most associated with depression following pregnancy with

gestational diabetes. Wanting to “shed some pounds” is suggestive of earlier weight gain that is perceived as being excessive.

## CHAPTER 21

### Nursing Care of a Family Experiencing a Sudden Pregnancy Complication

- 21.1 C. The nurse should advise saving any clots or material passed to help the healthcare provider assess the amount of bleeding and whether the miscarriage process is incomplete or complete and allows them to be assessed for the possibility of gestational trophoblastic disease. A woman should not use a tampon, so the amount of bleeding she is having can be evaluated. Vaginal bleeding always needs to be investigated during pregnancy.
- 21.2 B. The nurse should check if Beverly received Rh immune globulin (RhIG or RhoGAM) because it is the medication used to minimize the risk of isoimmunization.
- 21.3 C. It is important for the nurse to assess for vaginal bleeding and clear fluid leakage every shift. Vaginal examinations are contraindicated as this procedure may cause bleeding. If the previa is not total, a cesarean birth may not be necessary.
- 21.4 B. The nurse identifies assessing FHR and whether she is having contractions as the best first actions. Walking stimulates contractions. Hydration, not dehydration, may reduce contractions.
- 21.5 D. The nurse recognizes that edema is often a first symptom of gestational hypertension a woman notes. The edema associated with gestational hypertension can be separated from the typical ankle edema of pregnancy because it begins to accumulate in the upper part of the body as well. Beverly’s other statements are not necessarily indicative of gestational hypertension.
- 21.6 B. The nurse is aware that activities at work were not associated with development of hypertension of pregnancy. Not taking time to eat regularly could lead to fetal hypoglycemia and would be a significant concern that the nurse should address.

## CHAPTER 22

### Nursing Care of a Pregnant Family With Special Needs

- 22.1 C. The nurse should support Mindy in her attempts to take responsibility for her own care. Pregnant adolescents are emancipated minors so are capable of and appreciate support for making healthcare decisions. It would be unwise for the nurse to create a climate that would alienate the mother as, although an emancipated minor, Mindy will still need the support and help of her mother.
- 22.2 C. The nurse should check Mindy’s lab results. Reticulocytes are immature red blood cells that will start to grow rapidly if sufficient iron is available. Mindy’s

oral report may or may not be reliable. Urine testing and assessment of her nail beds are not reliable indicators.

- 22.3 **D.** Nurses should be aware that gestational hypertension is caused by marked vasospasm and monitor women over the age of 40 years. Hypertension becomes even more acute if blood vessels have limited elasticity, as in older individuals.
- 22.4 **C.** It is imperative for the nurse to provide information that is appropriate to the patient's cognitive level. The patient herself must not be excluded from education. Written material is unlikely to be ideal.
- 22.5 **D.** The nurse should refer Mindy to addictions support services. Substance dependence is such an all-encompassing phenomenon, and such women need support from an interprofessional team because pregnancy is a long time to remain drug free. Toxicology testing will confirm the type of substance being abused but will not give Mindy support to quit. The nurse telling her to quit without providing support would be futile.
- 22.6 **B.** The nurse should halt bleeding by putting pressure on the edges of the laceration as the priority nursing action. This may be difficult to achieve in the lower extremities because venous pressure is so greatly increased in the legs during pregnancy. After cleansing and applying lidocaine, the area can be sutured through each layer of tissue involved to approximate the edges.

## CHAPTER 23

### Nursing Care of a Family Experiencing a Complication of Labor or Birth

- 23.1 **D.** It would be important for the nurse to document the characteristics of Rosann's contractions to see if they are irregular; even though ineffective, they are still painful so she needs pain relief.
- 23.2 **C.** The nurse would question her labor augmentation with oxytocin because with a large fetus cephalopelvic disproportion may be present. Amniocentesis, elevated blood pressure, and ruptured membranes do not contraindicate the use of oxytocin.
- 23.3 **C.** Discontinuing the oxytocin infusion would be the nurse's first step in the management of Rosann's change in labor progress. Turning to the left side and increasing fluid are second and third steps.
- 23.4 **D.** Although not evidence based, the nurse would want team members to know a hands-and-knees position appears to aid fetal occipital rotation more than the other listed positions.
- 23.5 **C.** The research results revealed an increase in shoulder dystocia, which can result in diaphragmatic paralysis. Because this affects breathing, it is the nurse's primary assessment taken after the birth.

## CHAPTER 24

### Nursing Care of a Family During a Surgical Intervention for Birth

- 24.1 C. A danger of amniotomy is that the fetal cord can prolapse which will interfere with fetal circulation. This makes the nurse's immediate assessment of the fetal heart rate important.
- 24.2 A. The urinary catheter inserted by the nurse will keep the bladder empty. Oxytocin contracts the uterus, not the bladder. Restricting fluid and administering a diuretic could lead to fluid volume deficit.
- 24.3 C. Moja will want her dominant hand free to hold her baby after birth, so the nurse needs to identify this. The nurse giving Moja this choice exemplifies patient-centered care.
- 24.4 A. The nurse's priority in this situation is to protect confidential health information. Leaving or minimizing the record until the nurse who left it open returns may expose Moja's health information. Reporting this error to the nurse-manager is not the immediate priority.
- 24.5 C. Women rated spontaneous vaginal birth as the most satisfying type. Nurses should be knowledgeable about best evidence and use this knowledge to guide their practice. A coworker's personal experience might not be a reliable opinion. Instrumental vaginal births were rated lower than cesarean sections, so it would be inaccurate to describe all vaginal births as being more satisfying than all cesarean births.
- 24.6 D. Moja needs reassurance from the nurse that incisional pain only lasts about 7 days following surgery. Although women need to be comfortable while breastfeeding, many medications are contraindicated. Referral to a lactation consultant may or may not be necessary, and the nurse should not insist on this action.

## CHAPTER 25

### Nursing Care of a Family Experiencing a Postpartum Complication

- 25.1 D. The nurse should assess uterine tone and height for the potential to prevent uterine hemorrhage. Collection of this assessment datum is a priority over assessing the patient's perineal care, oxygen saturation, or skin integrity.
- 25.2 C. The nurse would expect a human chorionic gonadotropin test to reveal a retained fragment is present. Human chorionic gonadotropin hormone is produced by the placenta. As a result, it will be present as long as any placenta is present. Estrogen, progesterone, and oxytocin levels are not assessed for this purpose.
- 25.3 A. The nurse should advise that an upright position prevents pooling of infected lochia. Supine, prone, and Trendelenburg positions should be avoided.
- 25.4 D. The nurse should promote early ambulation as a safeguard against the development of blood stasis, which could lead to a blood clot. None of the other listed measures is a prevention against venous thromboembolism.
- 25.5 B. The nurse is aware that according to the study, a depressed person would be more likely to be withdrawn in behavior with the infant. In this case, the father is

not talking to the baby yet. Misunderstanding an explanation does not necessarily suggest a lapse in memory. The other statements are not suggestive of depressed mood.

- 25.6 C. The nurse is aware that postpartum psychosis means a woman has separated from reality, such as stating “I’m happy not to have any children.” Each of the other statements can be linked to Bailey’s current reality.

## CHAPTER 26

### Nursing Care of a Family With a High-Risk Newborn

- 26.1 C. It is critical to guard against hypothermia in low-birth-weight infants because they are unable to increase their metabolic rate to warm themselves. The study revealed that stockinette caps alone are not adequate to do this. The nurse should provide teaching to Mrs. Atkins regarding precautions to prevent hypothermia.
- 26.2 C. Developmental care is aimed at instilling a sense of safety and security into the child by reducing stimuli such as loud noise or bright lights. The nurse recommending a homemade blanket could give him a feeling of being sheltered. None of the other listed actions would have this beneficial effect.
- 26.3 B. The nurse should teach Mrs. Atkins that surfactant is not a relaxant, and it does not influence respiratory rate. It acts on the surface of the alveoli to help them not to stick together upon expiration. Without surfactant, the sticky alveoli collapse, the sides stick together, and are very difficult to inflate.
- 26.4 B. The nurse should flick the foot gently to stimulate the infant to remember to breathe. Theophylline would not be an initial intervention. Both rectal temperature assessment and vigorous suctioning can produce a vagal stimulation causing bradycardia. In addition, the infant should only be suctioned as needed, not every 2 hours.
- 26.5 B. Nurses should urge all mothers to breastfeed early. Early feeding enhances bilirubin clearance. Infants should be in a well-lit environment to enhance binding of bilirubin. Phototherapy is not initiated until the infant’s total serum bilirubin level rises to a specific age- and gestational age-dependent level. An older therapy, phenobarbital is rarely used today to combat neonatal jaundice.
- 26.6 A. The nurse should explain that if a woman with diabetes has hyperglycemia during pregnancy; her baby is apt to be born large and lethargic—facts that are a potential source of stress. The infant will not necessarily have diabetes, impaired respiratory function, or cognitive deficits.

## CHAPTER 27

### Nursing Care of the Child Born With a Physical or Developmental Challenge

- 27.1 A. The nurse should teach Maia to perform baby neck stretching exercises. Simple neck stretching should relieve torticollis in infants. Giving aspirin with

- each feeding would result in an overdose and would not alleviate the problem. Application of a warm towel is insufficient.
- 27.2 **C.** Pavlik harnesses seem simple, but because they hold the hip in adduction, they are very effective. The nurse should state that they should be worn constantly except for bathing. Looking at blog sites for specific care advice could supply misinformation.
- 27.3 **B.** The nurse should role-model better interaction with the infant to demonstrate warmer parent–child interactions. Although the mother may not realize she is not reacting warmly to her child, people do not usually change behavior simply by being told to change it.
- 27.4 **D.** The nurse should keep the herniated intestines moist to keep them from drying. Warmth is important but not by a radiant heater because this would dry the bowel. Resting on the abdomen could cause intestine to twist.
- 27.5 **C.** The nurse sitting the infant in an infant chair encourages the herniated bowel to sink against the diaphragm, freeing up lung space. Lying on the left side allows better respirations in the unaffected lung.
- 27.6 **C.** The nurse should report changes in vital signs. Changes in vital signs with increased cranial pressure are easy to remember because they move in opposite directions: Temperature and blood pressure increase, and pulse and respiratory rate decrease.

## CHAPTER 28

### Principles of Growth and Development

- 28.1 **B.** The nurse should explain that the lymphatic system reaches such a peak in early school-age children; their throats appear to be “all tonsils.”
- 28.2 **B.** Young children in the study recognized what overweight was but were unable to apply the concept to themselves. The nurse recognizes John’s inability to connect his own appearance with the pictures is consistent with this tendency.
- 28.3 **C.** The interprofessional team should recognize that Freud stressed that school age is a latent stage and that it is not a stage of great advancement.
- 28.4 **D.** The nurse should choose health promotions activities for John based on Erikson’s theory that the developmental task of the school-age child is to learn industry or to do things well.
- 28.5 **A.** The nurse recognizes that ascribing human properties to inanimate objects is indicative of magical thinking.
- 28.6 **C.** The nurse understands that conservation is learning that two different shapes can actually be equal in mass or volume, and John has not yet learned this concept.

## CHAPTER 29

### Nursing Care of a Family With an Infant

- 29.1 C. Infants sit steadily at 8 months of age.
- 29.2 A. Children at 12 months usually say two words beside “ma-ma” and “da-da.” They are not incapable of understanding, but they cannot express their needs verbally.
- 29.3 A. Infants understand permanence when they look for someone or something out of sight.
- 29.4 D. A mother who “always has a hot cup of coffee in her hand” could easily spill that on the infant while giving care or holding the infant.
- 29.5 D. Aspiration and falls are the most frequent unintentional injuries in infants.
- 29.6 D. Focusing on abilities rather than disabilities promotes efficacy and well-being among the family members of a child with unique needs. This practice exemplifies patient-centered care. Lowering the family’s expectations is normally inappropriate and unnecessary.

## CHAPTER 30

### Nursing Care of a Family With a Toddler

- 30.1 B. The nurse should reaffirm with Jason’s father that toddlers typically walk with a wide-based gait. Strong arch support would not make a difference.
- 30.2 B. The nurse would expect 2-year-olds to speak with two-word, noun–verb sentences.
- 30.3 D. The nurse should teach that television viewing for toddlers should be carefully limited; they need supervision to prevent pulling a television onto themselves.
- 30.4 D. The nurse should teach that locking medicine or placing it out of reach is the best safeguard. Young children can occasionally open childproof caps.
- 30.5 A. The nurse enforces the rule that a child should sit still in time-out for as many minutes as his age. This seems like a short time, but for a 2-year-old, sitting still for 2 minutes is a long time.
- 30.6 C. The nurse should advise that reducing the number of questions asked reduces the number of times a toddler can say no. Reasoning with toddlers or mimicking behavior is rarely effective.

## CHAPTER 31

### Nursing Care of a Family With a Preschool Child

- 31.1 C. Although this is variable, the nurse should point out that preschoolers typically ask 300 to 400 questions a day.
- 31.2 B. The nurse should suggest that watching chosen DVDs could improve the quality of video material to which Cathy is exposed. Cartoons are often violent. TV should be carefully limited but does not necessarily need to be withheld until age 5 years.
- 31.3 C. Allowing a child to use a night-light, inspecting the child’s room for objects that look particularly scary after dark, and limiting the child’s television viewing

to programs not as frightening are recommendations that the nurse can make to help decrease a child's fears.

- 31.4 **D.** The nurse should advise the parents to instruct their child not to leave daycare with anyone but them or a designated person. If the parents wish, it is acceptable to have a child's fingerprints taken and recorded. It is not likely necessary to limit Cathy to her own home. Describing kidnapping is likely to elicit fear.
- 31.5 **A.** It is important for the nurse to encourage women to maintain contact with their preschooler during the short time they are hospitalized for the new birth. This fosters family cohesion. Each of the other teaching points may be necessary, but none so clearly promotes family bonding.
- 31.6 **C.** The nurse should state that sexual education should be approached in a clear but age-appropriate manner. At this age, it is not normally necessary to address sexual intercourse and its consensual nature.

## **CHAPTER 32**

### **Nursing Care of a Family With a School-Age Child**

- 32.1 **D.** The nurse can establish a sense of industry in Shelly by encouraging her to complete small projects or tasks that offer a reward when completed.
- 32.2 **C.** The school nurse could state that clubs can potentially foster social interaction between children whose interests are similar. Clubs are frequently single-gender, and they do not always have formal rules and regulations.
- 32.3 **A.** The nurse should advise that heavy backpacks can put unnecessary strain on the back of school-age children. School-age children still need assistance with evaluating illness. Eating healthy to avoid being overweight should start before 18 years of age. Booster seats are usually unnecessary at this age.
- 32.4 **D.** The study documents the fact that injuries occur in cheerleading activities. However, the nurse should state that taking part is likely of benefit, provided Shelly is cognizant of some of the risks. No mention is made of weight or calcium intake.
- 32.5 **B.** The nurse should teach that candy that dissolves rapidly remains in contact with teeth for the shortest time. This may be associated with a reduced risk of dental caries.
- 32.6 **C.** The nurse should acknowledge that smoking is viewed as an adult activity; therefore, adopting the habit can be considered a giant step on the road to adulthood. Antismoking interventions must acknowledge this reality. The media are not known to have exaggerated the risks of smoking.

## **CHAPTER 33**

### **Nursing Care of a Family With an Adolescent**

- 33.1 **B.** The nurse should teach that apocrine glands, found predominantly in the axilla and groin, are responsible for body odor. This problem does not result from

- sebaceous activity or ethnicity, and hygiene is not the major contributing factor.
- 33.2 **A, B, C, D.** The nurse recognizes that all the options represent tasks adolescents must complete to achieve a sense of identity: emancipation, body image, values, and career choice.
- 33.3 **B.** The nurse should counsel that medications should not be shared with other people. The nurse should also teach the warnings and precautions involved with the administration of this drug, including the fact that it is a teratogen.
- 33.4 **C.** The nurse would note that whether stalking is done in person or by the Internet, continuous, unwelcome actions are stalking.
- 33.5 **C.** The nurse is aware that alcohol is identified as the gateway drug or is the one which is most apt to lead to further substance use disorders, especially if parents condone early use.
- 33.6 **D.** The nurse is aware that sniffing cocaine can cause loss of nasal hair. Upon assessment, the absence of nasal hair would suggest more extensive cocaine use.

## **CHAPTER 34**

### **Child Health Assessment**

- 34.1 **C.** The nurse should teach the father that household products were swallowed most commonly by young children. These are often stored below sinks in bathrooms or kitchens. The nurse should question if these cabinets are locked if they contain household products.
- 34.2 **B.** Parents may be unwilling to discuss a chief concern until they feel comfortable with an interviewer. The nurse should provide an open-ended invitation to address any outstanding issues that can sometimes reveal important data.
- 34.3 **B.** Blood pressure is routinely assessed beginning at 3 years of age; therefore, the nurse can exclude this assessment in this case.
- 34.4 **B.** The nurse should be aware that gagging a child who has a swollen epiglottis can cause the epiglottis to obstruct breathing.
- 34.5 **D.** The nurse identifies the fourth or fifth left intercostal space at the nipple line as the best place to assess mitral heart valve closing, although this is not its anatomical position.
- 34.6 **D.** The nurse teaches the father that human papillomavirus virus (HPV) vaccine is typically administered at 11 to 12 years of age.

## **CHAPTER 35**

### **Communication and Teaching With Children and Families**

- 35.1 **D.** The nurse should perform teaching in personal space, which is a distance of about 18 in. to 4 ft, or conversational space. It is most appropriate for face-to-face teaching.
- 35.2 **C.** The nurse should be guided by the principle that technology has the potential to enhance learning and communication, but it cannot wholly substitute for the

- nurse's sophisticated and thoughtful interpersonal communication skills.
- 35.3 **B.** The nurse is teaching using cognitive learning, which is learning facts or increasing knowledge. A and D are affective learning; C is psychomotor or skill learning.
- 35.4 **A.** Video resources must be vetted by the nurse to ensure that the material presented is evidence-based, safe, and age-appropriate.
- 35.5 **C.** Neither the Web-based/DVD program nor the face-to-face instruction was demonstrably superior; therefore, the nurse could allow the child to choose which delivery method he or she preferred.
- 35.6 **C.** When teaching a 3-year-old, the nurse would probably do best by playing a game. Lecture, group discussion, and reading a pamphlet are all more advanced than this child's age level.

## CHAPTER 36

### Nursing Care of a Family With an Ill Child

- 36.1 **A.** The nurse confirms that Becky's symptoms of anxiety may indicate separation anxiety. Protest, the first stage of separation anxiety, is marked by loud, intense crying.
- 36.2 **D.** The most significant outcome of teaching patients and their families about the perioperative process was a reduction in their anxiety. As an outcome of education, this is more important than being able to adhere to instructions, describe asepsis, or explain the rationale for surgery. While providing teaching, the nurse should also focus on reducing anxiety for the child and caregivers.
- 36.3 **B.** School children do best with small tasks and a feeling of reward. The nurse should use a collaborative approach with the caregivers to encourage Becky to drink more water in small glasses, which is also more likely to prevent nausea and vomiting. Warning her of negative consequences is less likely to result in positive outcomes.
- 36.4 **D.** A children's hospital playroom is designated as a "pain-free" zone to help the child cope with the stressors of hospitalization. Reducing the ill effects of separation and hospitalization to the extent possible should be a high priority for the nurse. The nurse should encourage parents to stay whenever possible and tell the child if they need to be separated from them for a time. The nurse should ensure all procedures are performed in the treatment room, not at bedside, so the child feels comfortable in the hospital room.
- 36.5 **D.** The nurse is aware that blocks that are 1-in. square are the smallest items that can fit in a toddler's mouth easily. The nurse should teach the parents that any item smaller than the internal roll on toilet paper is a dangerous size to be aspirated. The other listed toys do not pose a serious risk of aspiration.
- 36.6 **B.** The nurse could have Becky handle a bandage to address specifically what is happening to Becky. She can apply it to the foot and become more comfortable

with the concept of a bandage. Therapeutic play materials are best if they are most relevant to a child's condition or procedures.

## CHAPTER 37

### Nursing Care of a Family When a Child Needs Diagnostic or Therapeutic Modalities

- 37.1 C. The nurse should provide support during procedures using the least amount of restraint possible. In this case, the help of another nurse to hold the hand steady is the best choice. The mother may not be capable of restraining the child during the procedure in a safe manner.
- 37.2 D. Most parents are anxious to have diagnostic tests done so their child's illness can be identified. The nurse should ask her why she feels the way she does, which might reveal that she needs a better understanding of what an MRI involves.
- 37.3 C. The commercial device reduced pain by serving as a distraction. The nurse should collaborate with the mother to select a distraction technique that would be effective with Felipe because his mother may know what will work most best. Pre- and postprocedure assessment will not necessarily reduce his anxiety and pain. The nurse telling him that he or she will try to distract him may be counterproductive.
- 37.4 B. The nurse giving Felipe a choice of fingers to use can interest him in the procedure. Comparing him to other children his age or threatening the withholding of privileges or treats is inappropriate nursing responses.
- 37.5 A. The nurse should start the 24-hour urine collections from the discard of the first urine to ensure it is truly a 24-hour specimen.
- 37.6 A. Measuring the amount a child vomits (emesis) can be challenging if it spills onto clothing or bed linen. When this happens, the nurse should estimate the amount in relation to the amount of food or fluid the child recently ate and include the number of episodes and a description of the vomitus. The nurse should not delegate estimating the quantity of the vomitus to Felipe's mother.

## CHAPTER 38

### Nursing Care of a Family When a Child Needs Medication Administration or Intravenous Therapy

- 38.1 C. Any drugs are transported attached to plasma proteins; a deficit of these can interfere with medication distribution. ABGs, gallbladder function, and renal function are important assessments, but none directly gauges drug distribution.
- 38.2 C. In the absence of an ID band, the nurse should ask a parent to identify her. Children may lie about their name or give a false name out of fear or being playful.
- 38.3 C. The nurse should recommend that using something that dissolves easily, like

ice, can allow children to practice swallowing in a safe and effective way. Drawing a picture or tipping the child's head forward is not effective. The nurse should never refer to medicine as candy.

- 38.4 **D.** The nurse should keep the child's head turned to the side to allow the medication to stay in the ear longer and increase absorption. Self-administration is unsafe and impractical. For a child older than age 2 years, the nurse should pull the ear pinna up and back.
- 38.5 **D.** The nurse is aware that the point of watching television is to create a distraction. If Terry is absorbed in her watching her present program, changing the channel could exacerbate her pain by removing the distraction.
- 38.6 **A.** Reading a story to Terry is an appropriate distraction. To help guard the stability of the intravenous site while still meeting her psychosocial needs, Terry needs the nurse to initiate an activity which is quiet and which does not include use of her hands.

## CHAPTER 39

### Pain Management in Children

- 39.1 **B.** The nurse would document somatic pain. Bone pain is somatic pain. Cutaneous pain is skin pain; visceral is pain from body organs.
- 39.2 **B.** The nurse ensuring that the doses are correct is a priority; drug doses are based on weight, not age. Site compatibility is irrelevant because the two drugs have two different routes.
- 39.3 **A.** The nurse knows that the advantage of a patient-controlled pump is that it offers the child a sense of control and rapid analgesia. Nursing care is not reduced, and there is still a chance of adverse effects.
- 39.4 **D.** The nurse should instruct colleagues to tell the child she will be sleepy but able to talk. This is a comforting and accurate explanation. It is inappropriate to tell a child that he or she will be "knocked out." A description of analgesia and anesthetic is too technical for a 3-year-old.
- 39.5 **C.** Distraction techniques need to be individualized; therefore, that nurse should ask the mother what technique is apt to be most successful. Reassuring the parents before the procedure so they do not radiate extensive fear would be a better action than asking them to leave or not talk.
- 39.6 **C.** Imagery requires a child to be able to replace a painful image with a nonpainful one. This requires a working imagination, which is a characteristic of childhood.

## CHAPTER 40

### Nursing Care of a Family When a Child Has a Respiratory Disorder

- 40.1 **A.** The nurse should advise the parent to pinch the lower part of the nose (alae nasi) for 10 minutes without releasing pressure. The nurse should also advise the

- parent to keep the child in an upright position with his head tilted slightly forward to minimize the amount of blood pressure in nasal vessels and to keep blood moving forward, not back into the nasopharynx.
- 40.2 **B.** Choanal atresia is blockage of the posterior nares in newborns. The nurse may assess this health problem by holding the newborn's mouth closed, then gently compressing first one nostril, and then the other. If atresia is present, infants will struggle as they experience air hunger when their mouth is closed.
- 40.3 **C.** The nurse should teach the parents a full course of prescribed antibiotics is necessary to prevent glomerulonephritis or rheumatic fever.
- 40.4 **D.** Cold decreases edema and promotes healing. Foods that are salty, have sharp edges, or tarts are difficult to swallow and should be avoided.
- 40.5 **D.** Because initiating gagging may cause further airway closure, the nurse should never elicit a gag reflex on children with a high fever, barky cough, and sore throat. Instead, the nurse should assess his throat with simple inspection.
- 40.6 **C.** The nurse should instruct the child who is undergoing peak flow testing to place the meter in his or her mouth and blow out as hard and fast as possible.

## CHAPTER 41

### Nursing Care of a Family When a Child Has a Cardiovascular Disorder

- 41.1 **D.** The nurse would be alerted to the mother's comment that nausea and vomiting are expected side effects for the first few weeks of treatment. Although nausea and vomiting are side effects of digoxin (and many medications), the child would not automatically experience these symptoms after initiation of the medication. If the child does experience these symptoms, the provider should be contacted immediately and the family should not wait several weeks. All of the other statements are true.
- 41.2 **B.** Henry's surgery to repair his VSD is open-heart surgery, performed through the breastbone, and he does require cardiopulmonary bypass. But overall, children who have a VSD repaired do very well. There was a recent study in 2017 where the researchers noted that VSD surgeries overall go very well and infrequently have significant complications. They did note that children with genetic syndromes and low weight for age at the time of surgery do tend to have prolonged ICU stays with longer mechanical ventilation times, but they ultimately did well. Therefore, Henry may need his breathing tube in the ICU for a few days, but he should recover without major complications.
- 41.3 **D.** The nurse should emphasize that after heart surgery requiring a median sternotomy approach, infants and children will require 6 weeks for the sternum to heal. Limiting participation in physical activities and heavy lifting (including heavy backpacks for school) will ensure strong healing of the bone and minimal pain for the child. During this time, children should not be lifted under their arms or pulled by the arms as this will cause significant pain for the child. Infants

- should be scooped behind the neck and under their bottoms. Children should be assisted by supporting behind the back. Surgeries that required a lateral thoracotomy approach are also very painful, and maintaining these same guidelines is appropriate. Regardless of the surgical approach, all children should use car seat belts, booster seats, or car seats as recommended. Appropriate placement and fit of these safety restraints will not harm the child after surgery.
- 41.4 **B.** The nurse notes that this heart rate is exceptionally high for a child of this age. This rate and rhythm meet all of the criteria for SVT: The rate is greater than 160 bpm, it is a narrow complex that does not change with activity level, and the P waves are not visible. Sinus tachycardia would most likely not have a rate this high, and the P waves would be visible. Torsades de pointes is a chaotic and pulseless rhythm so the child would not have other vital signs that were life sustaining. Ventricular tachycardia in children is typically a very wide complex rhythm; it may or may not have associated vital signs that are near normal. This child has presented with classic symptoms, ECG, and onset pattern of SVT.
- 41.5 **D.** The nurse knows that regardless of the child's underlying medical disorder or etiology of a pediatric arrest, ensuring a patent airway and providing appropriate respirations is paramount. Children more frequently experience a pure respiratory decompensation or arrest prior to any cardiac involvement, even in children with underlying cardiac disorders. Positioning the child in a sniffing position to ensure an optimal airway and providing respiratory support through bag/mask ventilation will likely reverse the bradycardia. Regardless, the nurse should begin with respiratory support and provide cardiac support with compressions once the nurse is able or when help arrives. The nurse should never leave a child who is decompensating to retrieve equipment or personnel. As more personnel arrive, they will fill the other necessary roles of CPR provider, documentation, medications, and medical support.
- 41.6 **C.** It is important for the nurse to include the child when discussing management strategies. Adolescents (and many school-age children) are quite capable of participating in conversations about their health and wellness, and any treatment plan will be better followed if the child was included in its development or has an understanding of the importance of such a plan. Charlene needs to address not only her diet but also her weight and most likely her activity level. By working with both Charlene and her mother, the nurse's treatment strategies are more likely to be effective.

## CHAPTER 42

### Nursing Care of a Family When a Child Has an Immune Disorder

- 42.1 **D.** The nurse is aware that repeated exposures to latex can create allergies in sensitive children. Distraction does not help protect his safety, and the use of a new blood pressure cuff does not prevent allergic reactions.

- 42.2 **A, C.** A complete blood count with differential is always the best starting point to evaluate a child like Dexter. Allergic children generally have a higher number or proportion of eosinophils in the blood. Children with immunodeficiencies may have elevated neutrophil counts if they have an active bacterial infection. At baseline, a reduced lymphocyte count or percentage may be a “red flag” for an immunodeficiency. Allergic children generally have elevated IgE levels, both the overall serum IgE as well as allergen-specific IgE.
- 42.3 **C.** The nurse should teach that hyposensitization increases the number of IgG immunoglobulins, which then block the action of IgE immunoglobulins that are involved in an allergic response. Immunotherapy does not improve the broader function of the immune system or protect against infection.
- 42.4 **C.** Epinephrine is the drug of choice for an anaphylactic reaction because it quickly causes bronchodilation, immediately enlarging a constricted airway. The nurse would administer 0.3 mg of the drug.
- 42.5 **A.** The nurse would deem treatment successful if the child is able to maintain age-appropriate activities despite having allergies. “Curing” allergies is not always a possibility.
- 42.6 **B.** The nurse knows that many accidental ingestions occur because food was offered by another person. A willingness to share may include sharing food and a consequent allergic reaction that would best be treated by an EpiPen.

## CHAPTER 43

### Nursing Care of a Family When a Child Has an Infectious Disorder

- 43.1 **B.** The nurse should stress handwashing and the role parents have in setting a good example with this practice. Parents’ hand-washing practices were noted to influence handwashing in their children. Frequent reminders, teaching children about bacteria, and characterizing hand hygiene as “grown up” were not specifically noted to be effective interventions.
- 43.2 **C.** The nurse knows that coughing and sneezing requires droplet precautions (gloves, mask, and gown). If Jack wears a mask, there may be contaminated surfaces in the room so the nurse needs to guard against these surfaces.
- 43.3 **B.** Although rating his pain would be informative, to stop the itching, administration of an antihistamine by the nurse would be most effective. Children need their hands free to facilitate self-care.
- 43.4 **B.** The nurse would assess for mono by evaluating the spleen by nontouching maneuvers using the scratch test. The spleen enlarges to destroy the affected cells, so the spleen could rupture easily on pressure. Petechiae should not be massaged; percussion and the use of a Doppler are unnecessary during assessment.
- 43.5 **C.** Mumps cause a parotid gland enlargement without skin erythema in the majority of patients. This enlargement will obscure the angle of jaw and therefore is helpful from differentiating it from submaxillary adenitis (inflammation of

lymph nodes). The best method of differentiation is to place a hand along the jaw line. If the major amount of swelling is above the hand, it is probably mumps.

- 43.6 **D.** The nurse would inform the school nurse that scarlet fever is contagious for 1 to 7 days after the appearance of disease symptoms, so Jack will no longer be infectious after a week. A faster return to school may result in the infection of other children.

## CHAPTER 44

### Nursing Care of a Family When a Child Has a Hematologic Disorder

- 44.1 **B.** The nurse reassuring Lana's mother that the consequent risks of infection will be addressed acknowledges potential risks while still providing reassurance. It would be inappropriate for the nurse to have the child's mother restrain her during a painful procedure. It would also be inaccurate to reassure her that this is a one-time event.
- 44.2 **A.** The nurse knows the mother understands iron chelation therapy when she states that the drug acts to remove excess iron from her child. Iron chelation therapy removes excess iron from the body to prevent hemosiderosis. The mother needs to assess voiding, not pulse, before administration.
- 44.3 **B.** The nurse could suggest that swimming would be a healthy and low-risk activity. To protect the father, playing football would be inadvisable. Sedentary activities are not an advantage for either father or son.
- 44.4 **B.** Pain control is paramount during sickle-cell crises. As a result, evidence of adequate pain control is a nursing priority over positive expressions about his time in hospital, even though these are certainly desirable. The nurse should perform health education also, but pain control is the priority.
- 44.5 **D.** The nurse should inform the team members that autoimmune acquired hemolytic anemia affects red blood cell counts and a CBC should be performed promptly.
- 44.6 **A.** Idiopathic thrombocytopenia purpura (ITP) is a deficiency of platelets so the nurse should caution Lana and her mother that Lana will bruise easily. Assessments related to blood glucose levels, headache, and proteinuria are not priorities.

## CHAPTER 45

### Nursing Care of a Family When a Child Has a Gastrointestinal Disorder

- 45.1 **C.** The nurse would expect metabolic alkalosis, which occurs because of the loss of gastric acid that occurs with emesis.
- 45.2 **C.** The nurse should teach that raw chicken is a potential source of *Salmonella*. None of the other listed actions prevents this foodborne illness.
- 45.3 **A.** The nurse should assess the baby for vomiting immediately after feeding because that is a symptom of pyloric stenosis. The vomiting occurs due to the

- thickened pylorus muscle causing a delay in gastric emptying.
- 45.4 **B.** The nurse recognizes that hepatitis A can be transmitted via fecally contaminated shellfish. The nurse should advise parents to carefully consider the origin of sushi or shellfish served to their family.
- 45.5 **A.** The nurse should keep the parents informed by encouraging daily interaction with the medical team.
- 45.6 **C.** Kwashiorkor results from a deficiency of protein in the diet; therefore, the nurse would anticipate the dietitian to prioritize quality protein in the diet.

## **CHAPTER 46**

### **Nursing Care of a Family When a Child Has a Renal or Urinary Tract Disorder**

- 46.1 **C.** The nurse should keep in mind that because preschoolers have recently been taught that voiding is a private activity, voiding while an X-ray is taken may feel uncomfortable. Dye capsules are not used, and the test does not occur in a metal tube.
- 46.2 **C.** The nurse realizes that the grandmother received adequate education on the prevention of UTIs when she says she will be certain to administer all the antibiotic pills prescribed. Taking the full antibiotic prescription helps prevent recurrence of infection. Avoidance of dairy and exercise is unnecessary. The use of bath salts is not recommended.
- 46.3 **B.** The nurse recognizes that the first symptom of poststreptococcal glomerulonephritis is often bright red hematuria. Abdominal pain and joint pain are atypical.
- 46.4 **C.** The nurse teaches the grandmother that testing for urine protein is important with nephrotic syndrome because a large amount of protein is lost in urine. The other listed actions do not directly address this health problem.
- 46.5 **A, B, C, E.** The following findings suggest to the nurse that Carey's kidneys are failing: Anemia develops from a lack of erythropoietin and vitamin D cannot be synthesized, phosphorus cannot be excreted, and fluid overload causes hypertension. Creatinine levels increase, not decrease, in cases of renal failure.
- 46.6 **A.** Parents thought support from healthcare professionals was important; therefore, it was an appropriate action for the nurse to assure the grandmother that she can call the clinic any time with questions. Asking the grandmother to keep a journal or ignore family members could make her time management even more stressful.

## **CHAPTER 47**

### **Nursing Care of a Family When a Child Has a Reproductive Disorder**

- 47.1 **C.** The nurse would teach the parents that although children with precocious puberty appear older, they function at their chronologic age. Both sexes can be

- fertile even at such a young age. Dietary and activity restrictions are unnecessary.
- 47.2 **C.** The nurse would recommend that Navi participate in an exercise program. Yoga may be an effective measure to reduce symptoms of dysmenorrhea. Increased exercise intensity is not a guarantee of a proportionate reduction in pain. The benefits of yoga were not limited to improved coping.
- 47.3 **B.** The nurse should teach Navi that polycystic ovary syndrome leads to obesity, hirsutism, irregular menstrual cycles, and subfertility. It is not easy to reverse the syndrome.
- 47.4 **C.** The nurse should counsel Navi that if having small breasts interferes with self-esteem, a girl can have surgical augmentation, but this needs careful consideration regarding whether it is necessary at this young age. There is no increase in disease risk, and breastfeeding is unaffected.
- 47.5 **C.** The nurse would refer the adolescent for further treatment if she had a white, cheese-like vaginal discharge. Candidal vaginal infections usually cause a thick, pruritic, white vaginal discharge. All of the listed complaints warrant follow-up, but they are not indicative of candidiasis.
- 47.6 **A.** The nurse needs to teach Navi that gonorrhea may be spread by singular sexual contact. The disease has a bacterial etiology. All forms of sexual contact carry risks, and saliva is not bactericidal.

## CHAPTER 48

### Nursing Care of a Family When a Child Has an Endocrine or a Metabolic Disorder

- 48.1 **A, B.** The nurse should teach that growth hormone is an injectable and can be discontinued in adolescence when full growth is achieved. It is not recommended to take in the oral form.
- 48.2 **C.** The school nurse should be aware that hyperthyroidism increases metabolism, so it leads to rapid, jittery movements.
- 48.3 **C.** A function of aldosterone is to retain sodium in the body.
- 48.4 **D.** The nurse understands that when children with diabetes first begin injections of insulin, it “reminds” their pancreas to produce insulin, so for a short period, the child may not need exogenous insulin administered or may need minimal amounts.
- 48.5 **B.** The total amount of carbohydrates included in this lunch is 75 g. At a ratio of 1:10, he would inject 7.5 units of regular insulin.
- 48.6 **A.** Based on the study, the nurse would believe LaRoya’s family situation is not ideal because she has lost friends. The study found that loss of friends had a negative effect on quality of life. The other statements do not reflect an influence on quality of life.

## CHAPTER 49

## **Nursing Care of a Family When a Child Has a Neurologic Disorder**

- 49.1 **B.** Neurologic examinations are lengthy so it's difficult to keep children's attention unless the nurse presents the examination as being interesting. There is no "pass" or "fail." Alluding to the possibility of tumors or an "unhealthy brain" will likely cause undue anxiety.
- 49.2 **A.** The nurse should inform Tasha that before a lumbar puncture is performed, the lumbar region is cleansed with a solution that creates a temporary sensation of cold. The procedure is not necessarily painless, and EMLA should be applied approximately 1 hour beforehand. A side-lying position is used to perform a lumbar puncture.
- 49.3 **D.** The nurse should teach the parents that as the child needs fine motor control to achieve at writing or ambulating, the loss of function may seem more acute. Cognitive and physical effects of the disease do not necessarily exist in the same degree. Vaccinations do not cause cerebral palsy.
- 49.4 **B.** The nursing team should maintain respiratory precautions for at least 24 hours following the beginning of antibiotic therapy.
- 49.5 **B.** The nurse should suspect depression when Tasha's mother expresses sadness. None of the other listed statements is as clearly suggestive of depression.
- 49.6 **A, C, D.** It is not likely a child would require a tracheostomy. The nurse should have the call bell, suction, and supplementary oxygen available to maintain safety and the integrity of the child's airway.

## **CHAPTER 50**

### **Nursing Care of a Family When a Child Has a Vision or Hearing Disorder**

- 50.1 **B.** The nurse notes that the mother covering the stronger eye will encourage central vision to develop in the weaker eye. Each of the other actions is counterproductive.
- 50.2 **C.** The nurse teaches that wiping infectious discharge away from the other eye prevents infection from spreading to the second eye. The other listed actions are not indicated.
- 50.3 **C.** The nurse should prevent vomiting because increased intraocular pressure from vomiting could disrupt a suture line.
- 50.4 **C.** The nurse is aware that the hallmark of glaucoma is increased intraocular pressure.
- 50.5 **D.** The nurse would be concerned that he listens to music with earbuds. The study showed that long exposure to loud noise may be responsible for lowering hearing level in teenagers. An individual is more likely to listen at high volume when using earphones (as when on a bus or in a subway car). Listening to computer speakers may not be as loud.
- 50.6 **B.** The nurse recognizes that otitis media is an infection of the middle ear; otitis externa is infection of the ear canal. Both diagnoses can be painful.

## CHAPTER 51

### Nursing Care of a Family When a Child Has a Musculoskeletal Disorder

- 51.1 C. The nurse should teach Jeffrey that it's important to bear weight on his arms, not his axillae, so nerves and blood vessels that cross at the axilla are not injured. If crutches are properly fitted, there should be a space of 1 to 1½ in. between the axilla crutch pad and the child's axilla. The nurse should ensure that when Jeffrey stands upright and places his hands on the hand rests of the crutches, the elbows flex about 20 degrees. Stairs present a fall risk.
- 51.2 A. Osteomyelitis is a severe bone infection that needs IV antibiotic therapy to ensure that microorganisms do not cause chronic infection and deformity. The nurse's vigilant administration of antibiotics is thus a priority over health education, even though this should be performed. ADLs should be encouraged within his current limitations. Fluid restriction is not indicated.
- 51.3 D. Application of heat and administration of a nonsteroidal anti-inflammatory agent are first-line therapies for children with juvenile arthritis.
- 51.4 B. The nurse should prioritize preventing weight gain and encouraging the child to be as mobile as possible to prolong function in muscular dystrophy as muscles weaken. Purines and calcium are not focuses of dietary modifications.
- 51.5 B. The team members should be aware that an elbow cast that is too tight can lead to compartment syndrome and result in permanent nerve damage. Frequent neurovascular assessment is necessary, and this could be safely performed by the LPN. Sepsis is not likely, and cleanliness of cast is not a priority over neurovascular assessment.
- 51.6 A. The nurse should advise Jeffrey not to swing his sister by the arms. Holding preschoolers by the arm and swinging them is the most common cause of a traction injury. The other listed activities are not considered to be high risk.

## CHAPTER 52

### Nursing Care of a Family When a Child Has an Unintentional Injury

- 52.1 A. Based on Damashek and Corlis (2017) study, visual and proximity in combination are predictive in preventing injuries
- 52.2 D. The nurse is aware that increasing temperature and blood pressure are marks of increasing intracranial pressure. Amnesia is frequently seen with a head concussion.
- 52.3 B. The appropriate nursing action is to administer acetylcysteine or activated charcoal. Acetylcysteine is the specific antidote for acetaminophen poisoning; activated charcoal may be given if no acetylcysteine is immediately available. Educating the parents is important but is not the immediate priority.
- 52.4 D. The nurse would assess for paint chips in the home. Paint chips taste sweet so children enjoy their taste; they are the most common source of lead poisoning in children.

- 52.5 C. The nurse would recommend applying cool water to reduce the water temperature and stop the burning as well as reduce the pain.
- 52.6 D. The nurse would instruct the care team to allow Sage to speak of the incident. Being burned is such a frightening event, children need “debriefing” afterward, so they are assured they are now safe and healing. The other listed actions are appropriate.

## CHAPTER 53

### Nursing Care of a Family When a Child Has a Malignancy

- 53.1 D. The nurse confirms that hand hygiene prevents the mother from spreading microorganisms to her son, but it does not protect her from the possible effect of handling toxic drugs. The nurse needs to tell her to wear gloves to handle oral chemotherapy agents. The other listed actions are appropriate.
- 53.2 C. The nurse would confirm the early signs of ALL are fatigue and leg bruises. Because so many white blood cells are produced in cases of ALL, red blood cell and platelet production falls leading to fatigue and bleeding disorders.
- 53.3 A. The nurse would confirm Hodgkin disease usually presents with a single isolated lymph node and suspect its development. The other listed signs and symptoms are not closely associated with this disease.
- 53.4 B. The nurse explains that straining to pass stool causes increased ICP. A Trendelenburg position would rarely be used because this would increase ICP.
- 53.5 C. The nurse should inform Gerri’s mother that osteosarcoma is often discovered when a sports injury causes an athlete to report pain or a swelling at the injury site for some time, but sports injury is not the cause of osteosarcoma. Calcium intake is unrelated.
- 53.6 C. The nurse should keep the child’s immediate surroundings free of plants, flowers, and goldfish, all of which could harbor mold spores. If the child comes in contact with the flowers at the nurse’s desk, it could still be an infection risk.

## CHAPTER 54

### Nursing Care of a Family When a Child Has an Intellectual or Mental Health Disorder

- 54.1 C. The nurse understands that chronic sorrow is apt to be most acute at the time of developmental milestones such as beginning first grade or high school graduation.
- 54.2 C. The nurse recognizes that repetitive movements such as whirling, rocking, or watching a spinning top are common symptoms of autistic spectrum disorder. The other listed symptoms are not consistent with this health problem.
- 54.3 C. The nurses know that the most common side effects of methylphenidate hydrochloride (Ritalin) are insomnia and lack of appetite. Weight gain and iron-deficiency anemia are atypical.

- 54.4 **B.** Eating disorders in the study occurred more often in female athletes than in nonathletes.
- 54.5 **D.** The nurse would check if Cheyenne received an assessment for depression. Because tics are poorly understood, children who have them can be the victim of bullying or teasing and develop low self-esteem.
- 54.6 **D.** The nurse would suspect schizophrenia after Cheyenne says she hears her friends plotting against her at night. Hearing voices, or hallucinations, is a prominent symptom of schizophrenia. The other listed statements are not consistent with this disorder.

## CHAPTER 55

### Nursing Care of a Family in Crisis: Maltreatment and Violence in the Family

- 55.1 **A.** The average parent describes their child in a positive manner. Stating that a child is “not pretty” would alert the nurse to assess for child maltreatment because it is considered to be more negative than describing her as “clumsy.”
- 55.2 **B.** The nurse would be alerted to shaken baby syndrome if retinal hemorrhages develop. Shaking a baby causes small hemorrhages in the retina of the eye as well as possibly more serious injuries such as subdural hematoma. Broken bones are associated with maltreatment but not specifically with shaking.
- 55.3 **B.** According to this study, most adolescents reveal sexual maltreatment to a trusted peer.
- 55.4 **C.** Children who have been physically maltreated may reveal the maltreatment through having dolls simulate a sex act. The nurse should want to learn more about their reaction, not stop the play.
- 55.5 **A.** The nurse should counsel that it is important to preserve any DNA evidence that could reveal the identity of the rapist so a woman should not bath or shower until after an internal examination. Property loss is comparatively insignificant, and it would be highly inappropriate to address prevention at this time.
- 55.6 **A.** The nurse should be aware of the fact that intimate partner violent offenders are often men who were raised in a household with violence.

## CHAPTER 56

### Nursing Care of a Family When a Child Has a Long-Term or Terminal Illness

- 56.1 **B.** The nurse is aware that as with any crisis, support people can offer help and guidance. Privacy and a belief in alternative therapies may not necessarily enhance their coping skills. Wealth can be an asset during treatment but does not necessarily help the family cope with the child’s illness.
- 56.2 **C.** The nurse assesses that the parents are in the fourth stage of grief or

- depression. This is the stage when parents start to realize death will happen.
- 56.3 D.** The nurse notes that this is a mature question for a 3-year-old. Before answering, it would be important to know why the child is asking the question. Has he heard he is dying or just interested in what happened to a favorite cartoon character he just saw “die” on television?
- 56.4 B.** The nurse should inform nursing colleagues that anticipatory grieving can make it hard for parents to relate to their child because they have already grieved as if the child were dead.
- 56.5 A.** The study revealed parents wanted most to just continue to be effective parents. The nurse should promote enhancing his comfort by keeping him neat and clean as the sort of activity that might meet that need. None of the other listed actions would be normally appropriate.
- 56.6 A.** The nurse should be aware that if a gag reflex is not intact, children can aspirate easily. Hearing may not be lost; parents usually appreciate giving final care.
