For the first 3 days after birth, a lochia discharge consists almost entirely of blood, with only small particles of decidua and mucus. Because of its mainly red color, it is termed *lochia rubra*. As the amount of blood involved in the cast-off tissue decreases (about the fourth day) and leukocytes begin to invade the area, as they do with any healing surface, the flow becomes pink or brownish (*lochia serosa*). On about the 10th day, the amount of the flow decreases and becomes colorless or white with streaks of brownish mucus (*lochia alba*). Lochia alba is present in most women until the third week after birth, although it is not unusual for a lochia flow to last the entire 6 weeks of the puerperium. Characteristics of lochia are summarized in Table 17.1. Several rules for judging whether lochia flow is normal are summarized in Box 17.6.

**TABLE 17.1 CHARACTERISTICS OF LOCHIA**

Type of Lochia	Color	Postpartal Day	Composition
Lochia rubra	Red	1–3	Blood, fragments of decidua, and

Lochia serosa	Pink	3–10	mucus Blood, mucus, and invading leukocytes
Lochia alba	White	10–14 (may last 6 weeks)	Largely mucus; leukocyte count high

## BOX 17.6

### Nursing Care Planning Based on Family Teaching

#### EVALUATING LOCHIA FLOW

**Q.** Leana Cooper asks you, “How do I know if my lochia is normal?”

**A.** Several guidelines are helpful for evaluating lochia flow:

*Amount:* Lochia amount varies greatly from woman to woman. Mothers who breastfeed tend to have less lochial discharge than those who do not because the natural release of the hormone oxytocin during breastfeeding strengthens uterine contractions. Lochial flow increases on exertion, especially the first few times a woman is out of bed but decreases again with rest. Saturating a perineal pad in less than 1 hour is considered an abnormally heavy flow and should be reported. Don’t use tampons to halt the flow or this could lead to infection.

*Consistency:* Lochia should contain no exceedingly large clots as these may indicate a portion of the placenta has been retained and is preventing closure of the maternal uterine blood sinuses. In any event, large clots denote poor uterine contraction, which needs to be corrected.

*Pattern:* Lochia is red for the first 1 to 3 days (lochia rubra), pinkish-brown from days 4 to 10 (lochia serosa), and then white (lochia alba) for as long as 6 weeks after birth. The pattern of lochia (rubra to serosa to alba) should not reverse as this suggests a placental fragment has been retained or uterine contraction is decreasing and new bleeding is beginning.

*Odor:* Lochia should not have an offensive odor as this suggests the uterus has become infected. Immediate intervention is needed to halt postpartal infection.

*Absence:* Lochia should never be absent during the first 1 to 3 weeks as absence of lochia, like presence of an offensive odor, may indicate postpartal infection. Lochia may be scant in amount after cesarean delivery, but it is never altogether absent.

## The Cervix

Immediately after birth, a uterine cervix feels soft and malleable to palpation. Both the internal and external os are open. Like contraction of the uterus, contraction of the cervix toward its prepregnant state begins at once. By the end of 7 days, the external os has narrowed to the size of a pencil opening; the cervix feels firm and nongravid again.

In contrast to the process of uterine involution, in which the changes consist

primarily of old cells being returned to their former position by contraction, the process in the cervix does involve the formation of new muscle cells. Because of this, the cervix does not return exactly to its prepregnancy state. The internal os closes as before, but after a vaginal birth, the external os usually remains slightly open and appears slit-like or stellate (star shaped), whereas previously, it was round. Finding this pattern on pelvic examination suggests that childbearing has taken place.

## The Vagina

After a vaginal birth, the vagina feels soft, with few rugae, and its diameter is considerably greater than normal. The hymen is permanently torn and heals with small, separate tags of tissue. It takes the entire postpartal period for the vagina to involute (by contraction, as with the uterus) until it gradually returns to its approximate prepregnancy state. Thickening of the walls appears to depend on renewed estrogen stimulation from the ovaries. Because a woman who is breastfeeding may have delayed ovulation, she may continue to have thin-walled or fragile vaginal cells that cause slight vaginal bleeding during sexual intercourse until about 6 weeks' time. If a woman practices Kegel exercises, the strength and tone of the vagina will increase more rapidly (see [Chapter 12](#)). This may be important for the sexual enjoyment of both a woman and her partner.

### *QSEN Checkpoint Question 17.3*

#### **SAFETY**

The nurse wants to prepare Leana to assess her own health after discharge. Which statement by her would make the nurse worry that she needs added information?

- “I know about lochia; I’ll use tampons just like I do for my periods.”
- “I admit I don’t like having lochia, but I understand its purpose.”
- “I know to wash my hands after I change perineal pads and before handling the baby.”
- “I’ll look for the color of my lochia to change from red to pink.”

*Look in [Appendix A](#) for the best answer and rationale.*

## The Perineum

Because of the great amount of pressure experienced during birth, the perineum is edematous and tender immediately after birth. Ecchymosis patches from ruptured capillaries may show on the surface. The labia majora and labia minora typically remain atrophic and softened after birth, never returning to their prepregnancy state. Mothers may experience various levels of tenderness in the perineum area. Suggesting nonpharmacologic comfort measures such as ice or warm packs or a gentle pillow or doughnut pad to sit on will be much appreciated by the mother. Nurses should discuss with the mother’s provider available pharmacologic pain relievers, such as

acetaminophen or ibuprofen, and administer according to the prescription orders when deemed necessary or by maternal request.

## SYSTEMIC CHANGES

The same body systems that were involved in pregnancy are also involved in postpartal changes as the body returns to its prepregnancy state.

### The Hormonal System

Pregnancy hormones begin to decrease as soon as the placenta is no longer present. Levels of human chorionic gonadotropin (hCG) and human placental lactogen (hPL) are almost negligible by 24 hours. By week 1, progesterone, estrogen, and estradiol are all at prepregnancy levels (estriol may take an additional week before it reaches prepregnancy levels). Follicle-stimulating hormone (FSH) remains low for about 12 days and then begins to rise as a new menstrual cycle is initiated.

### The Urinary System

During pregnancy, as much as 2,000 to 3,000 ml of excess fluid accumulates in the body so extensive diaphoresis (excessive sweating) and diuresis (excess urine production) begin almost immediately after birth to rid the body of this fluid. This easily increases the daily urine output of a postpartal woman from a normal level of 1,500 ml to as much as 3,000 ml/day during the second to fifth day after birth. This marked increase in urine production causes the bladder to fill rapidly. Reassure the mother that this is normal and she still needs to continue drinking a healthy amount of fluids daily, especially if she is breastfeeding.

Because during a vaginal birth, the fetal head exerts a great deal of pressure on the bladder and urethra as it passes on the bladder's underside, this may leave the bladder with a transient loss of tone that, together with the edema surrounding the urethra, decreases a woman's ability to sense when she has to void. A woman who has had epidural anesthesia can feel no sensation in the bladder area until the anesthetic has worn off.

To prevent permanent damage to the bladder from overdistention, assess a woman's abdomen frequently in the immediate postpartal period. On palpation, a full bladder is felt as a hard or firm area just above the symphysis pubis. On percussion (placing one finger flat on the woman's abdomen over the bladder and tapping it with the middle finger of the other hand), a full bladder sounds resonant, in contrast to the dull, thudding sound of non-fluid-filled tissue. Pressure on this area may make a woman feel as if she has to void, but she is then unable to do so. As the bladder fills, it displaces the uterus; uterine position and lack of contraction are therefore a second good gauge of whether a bladder is full or empty (Mulder, Schoffemeer, Hakvoort, et al., 2012).

The hydronephrosis or increased size of ureters that occurred during pregnancy remains present for about 4 weeks after birth. The increased size of these structures, in

conjunction with reduced bladder sensitivity, increases the possibility of urinary stasis and urinary tract infection in the postpartal period.

## The Circulatory System

The diuresis that is evident between the second and fifth days after birth, as well as the blood loss at birth, acts to reduce the added blood volume a woman accumulated during pregnancy. This reduction occurs so rapidly, in fact, that the blood volume returns to its normal prepregnancy level by the first or second week after birth.

The usual blood loss with a vaginal birth is 300 to 500 ml. With a cesarean delivery, it is 500 to 1,000 ml. A 4-point decrease in hematocrit (proportion of red blood cells to circulating plasma) and a 1-g decrease in hemoglobin value occur with each 250 ml of blood lost. For example, if an average woman enters labor with a hematocrit of 37%, it will be about 33% on the first postpartal day, and hemoglobin will fall from 11 to 10 g/dl. If the woman was anemic during pregnancy, she can expect to continue to be anemic afterward. As excess fluid is excreted, the hematocrit gradually rises (because of hemoconcentration), reaching prepregnancy levels by 6 weeks after birth.

Women usually continue to have the same high level of plasma fibrinogen during the first postpartal weeks as they did during pregnancy. This is a protective measure against hemorrhage. However, this high level also increases the risk of thrombus formation. There is also an increase in the number of leukocytes in the blood. The white blood cell count may be as high as 30,000 cells/mm<sup>3</sup> (mainly granulocytes) compared to a normal level of 5,000 to 10,000 cells/mm<sup>3</sup>, particularly if labor was long or difficult. This, too, is part of the body's defense system, a defense against infection and an aid to healing.

Any varicosities that are present from pregnancy will recede, but they rarely return to a completely prepregnant appearance. Although vascular blemishes, such as spider angiomas, fade slightly, they may not disappear completely either. Bilateral ankle edema is not uncommon but should not progress above the knees. This decreases over time as fluid shifts and returns to the circulatory system.

## The Gastrointestinal System

Digestion and absorption begin to be active again soon after birth unless a woman has had a cesarean delivery. Almost immediately, the woman feels hungry and thirsty, and she can eat without difficulty from nausea or vomiting during this time.

Hemorrhoids (distended rectal veins) that have been pushed out of the rectum because of the effort of pelvic-stage pushing often are present. Bowel sounds are active, but passage of stool through the bowel may be slow because of the still-present effect of **relaxin** (a hormone which softens and lengthens the cervix and pubic symphysis for preparation of the infant's birth during pregnancy) on the bowel. Bowel evacuation may be difficult because of pain if a woman has episiotomy sutures or from hemorrhoids. Encouraging the mother to eat produce and soluble fiber foods, especially fruits, will

help keep her stools naturally soft and ease in her bowel movements.

### The Integumentary System

After birth, the stretch marks on a woman's abdomen (**striae gravidarum**) still appear reddened and may be even more prominent than during pregnancy, when they were tightly stretched. Typically, in a White woman, these will fade to a pale white over the next 3 to 6 months; in a Black woman, they may remain as areas of slightly darker pigment. Excessive pigment on the face and neck (**chloasma**) and on the abdomen (**linea nigra**) will become barely detectable by 6 weeks' time. If **diastasis recti** (overstretching and separation of the abdominal musculature) occurred, the area will appear as a slightly indented bluish streak in the abdominal midline. Modified sit-ups help to strengthen abdominal muscles and return abdominal support to its prepregnant level. Diastasis recti, however, may require surgery to correct (Hickey, Finch, & Khanna, 2011).

## RETROGRESSIVE CHANGES OF THE PUERPERIUM

The overall effects of postpartal retrogressive changes are exhaustion and weight loss.

### Exhaustion

As soon as birth is completed, a woman experiences total exhaustion. For the last several months of pregnancy, she probably experienced some difficulty sleeping. All during labor, she worked hard with little or no sleep. Now, she has "sleep hunger," which may make it difficult for her to cope with new experiences and stressful situations until she has enjoyed a sustained period of sleep.

### Weight Loss

The rapid diuresis and diaphoresis during the second to fifth days after birth usually result in a weight loss of 5 lb (2 to 4 kg), in addition to the approximately 12 lb (5.8 kg) lost at birth. Lochia flow causes an additional 2- to 3-lb (1-kg) loss, for a total weight loss of about 19 lb. Additional weight loss is dependent on the amount of pregnancy weight gain and on whether a woman continues active measures to lose weight (Cahill, Freeland-Graves, Shah, et al., 2012). It is also influenced by nutrition, exercise, and breastfeeding. The weight a woman reaches at 6 weeks after birth becomes her baseline postpartal weight unless she continues active measures to lose the weight. In many women, this baseline is higher than their prepregnancy weight and one of the reasons that obesity has become a national health concern (Lipsky, Strawderman, & Olson, 2012). Balancing a newborn, eating healthy foods, and finding the time to exercise becomes a challenge to many mothers. Discussing strategies with her will help to organize her efforts to find balance, such as helpful babysitters, family members, and/or her partner to come and give her needed breaks.

## Vital Sign Changes

Vital sign changes in the postpartum period reflect the internal adjustments that occur as a woman's body returns to its prepregnant state.

### Temperature

Temperature is always taken orally or tympanically (never rectally) during the puerperium because of the danger of vaginal contamination and the discomfort involved in rectal intrusion.

A woman may show a slight increase in temperature during the first 24 hours after birth because of dehydration that occurred during labor. If she takes in adequate fluid during the first 24 hours, this temperature elevation will return to normal. Most women are thirsty immediately after birth and are eager to take in fluid, so drinking a large quantity of fluid is not a problem unless the woman is nauseated from a birth analgesic.

Any woman whose oral temperature rises above 100.4°F (38°C), excluding the first 24-hour period, is considered by criteria of the Joint Commission on Maternal Welfare to be febrile, and such a high temperature may indicate that a postpartal infection is present (Johnson, Thakar, & Sultan, 2012). Occasionally, when a woman's breasts fill with milk on the third or fourth postpartum day during lactogenesis II, her temperature will rise for a period of hours because of the increased vascular activity involved; this process is termed **engorgement**. If the elevation in temperature lasts longer than a few hours, however, infection may be the reason. An infection of the breast during lactation is termed *mastitis*. Mothers may or may not feel breast pain or experience redness of the breast, but they will often have a high temperature and feel flu-like symptoms such as malaise and fatigue. Mastitis can interfere with lactation, and sometimes, an infant will refuse to nurse on the affected side. The woman's medical provider must be notified to initiate antibiotic treatment (congruent with breastfeeding). Mothers should be instructed to continue breastfeeding if the infant will breastfeed from the affected side. If the infant refuses, instruct the mother to pump her breasts to maintain flow (and to avoid clogged ducts) and then offer the affected breast after 12 to 24 hours. Once the mastitis is treated, infants often will resume breastfeeding after 12 to 24 hours. Unless specifically directed otherwise, infants are safe to continue to breastfeed while a mother is being treated for mastitis; there is no reason to provide alternative feeding methods or to wean because of maternal mastitis. Because infection is a major cause of postpartal mortality and morbidity, nurses have the important role of being the healthcare providers who may first detect the problem.

### Pulse

A woman's pulse rate during the postpartal period is usually slightly slower than usual. During pregnancy, the distended uterus obstructed the amount of venous blood returning to the heart; after birth, to accommodate the increased blood volume returning to the heart, stroke volume increases. This increased stroke volume reduces the pulse

rate to between 60 and 70 beats/min. As diuresis diminishes the blood volume and causes blood pressure to fall, the pulse rate increases accordingly. By the end of the first week, the pulse rate will have returned to normal.

Evaluate pulse rate conscientiously in the postpartal period because a rapid and thready pulse during this time could be a sign of hemorrhage.

## Blood Pressure

Blood pressure should also be monitored carefully during the postpartal period because a decrease in this can also indicate bleeding. In contrast, an elevation above 140 mmHg systolic or 90 mmHg diastolic may indicate the development of postpartal hypertension of pregnancy, an unusual but serious complication of the puerperium (Chhabra, Tyagi, Bhavani, et al., 2012) (see Chapter 21).

To evaluate blood pressure, compare a woman's pressure with her prepregnancy level if possible rather than with standard blood pressure ranges; otherwise, if her blood pressure rose during pregnancy, a significant postpartal decrease in pressure could be missed.

Oxytocics, drugs frequently administered during the postpartal period to achieve uterine contraction, cause contraction of all smooth muscle, including blood vessels (Karch, 2013). Consequently, these drugs can increase blood pressure. Always measure blood pressure before administering one of these agents; if blood pressure is greater than 140/90 mmHg, withhold the agent and notify the woman's primary care provider to prevent hypertension and, possibly, a cerebrovascular accident.

A major complication in women who have lost an appreciable amount of blood with birth is orthostatic hypotension, or dizziness that occurs on standing because of the lack of adequate blood volume to maintain nourishment of brain cells. To test whether a woman will be susceptible to this, assess her blood pressure and pulse while she is lying supine. Next, raise the head of the bed fully upright, wait 2 or 3 minutes, and reassess these values. If the pulse rate is increased by more than 20 beats/min and blood pressure is 15 to 20 mmHg lower than formerly, the woman might be susceptible to dizziness and fainting when she ambulates. Inform the woman's primary care provider of these findings. Advise her to always sit up slowly and "dangle" on the side of her bed before attempting to walk. If she notices obvious dizziness on sitting upright, support her during ambulation to avoid the possibility of a fall. Caution her not to attempt to walk carrying her newborn until her cardiovascular status adjusts to her blood loss.

### *What If... 17.1*

**Leana Cooper, now 12 hours postpartum, has an oral temperature of 99°F (37.2°C) and is uncomfortable from profuse diaphoresis and extreme fatigue. What actions would the nurse take?**

## PROGRESSIVE CHANGES OF THE PUERPERIUM

Two physiologic changes that occur during the puerperium involve progressive changes, or the building of new tissue. Because this requires good nutrition, caution women against strict dieting that would limit cell-building ability during the first 6 weeks after childbirth (Whitney & Rolfes, 2012).

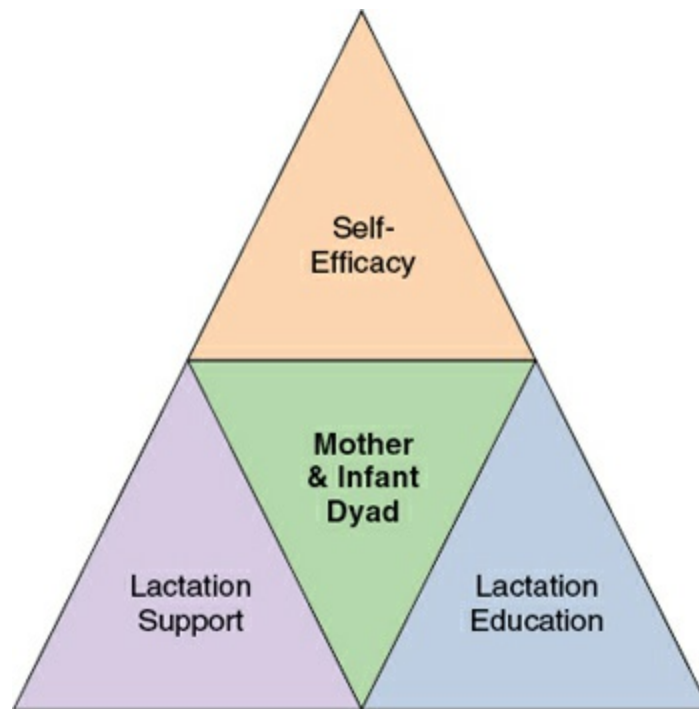

### Lactation

The early lactation process, which is driven by hormones from the hypothalamus to the pituitary gland in order to secrete the lactation hormones, is identified by four phases of **lactogenesis** (human milk production). Prolactin hormone is responsible for milk production, and oxytocin is responsible for the let-down reflex arch. A retained placenta can inhibit this process by causing continual circulation of progesterone, which inhibits prolactin and thus milk production. The lactogenesis I (milk synthesis) process begins around 16 weeks gestation as the glandular luminal cells in the breast begin secreting **colostrum**, a thin, watery prelactation secretion (Wambach & Riordan, 2016). Lactogenesis II is triggered at birth by the delivery of the placenta, when the progesterone hormone (prolactin is no longer inhibited) and other circulating pregnancy hormones suddenly decrease and oxytocin sharply increases as a result of the infant suckling. Oxytocin helps the uterus to shrink to its prepregnancy size; some mothers will feel uterine cramps initially when breastfeeding until the uterus fully involutes. Lactogenesis II is often when mothers feel that their “milk has come in” (engorgement) and occurs from birth to 5 to 10 days postpartum; this is often termed “transitional milk.” Lactogenesis III can occur from day 10 until weaning postpartum, when the “mature milk” supply is now driven by the circulating lactation hormones oxytocin and progesterone. Lactogenesis IV occurs after complete weaning and the breasts involute to their prelactation state. Other hormones are associated with breastfeeding, such as endorphins and oxytocin, and may help to mitigate and reduce the risk of developing postpartum depression (Ahn & Corwin, 2015).

The formation of breast milk (lactation) begins in a postpartal woman whether or not she plans to breastfeed (Stuebe, 2012). Early in pregnancy, the increased estrogen level produced by the placenta stimulated the growth of milk glands; breasts increased in size because of these larger glands, accumulated fluid, and some extra adipose tissue. For the first 2 days after birth, an average woman notices little change in her breasts from the way they were during pregnancy because, since midway through pregnancy, she has been secreting colostrum. On the third day after birth, her breasts become full and feel tense or tender as milk forms within breast ducts and replaces colostrum. If a mother reports she experienced little or no changes in her breasts during pregnancy, alert her provider and call for a lactation consultation. This may indicate a complication in her breast anatomy and her ability to secrete enough milk. Generally, breastfeeding complications are rare and typically initially stem from a painful latch, a problem that can be addressed quickly. Most American women are able to successfully breastfeed

their newborn and even twins or triplets.

Breast milk forms in response to the decrease in estrogen and progesterone levels that follows delivery of the placenta (which stimulates prolactin production and, consequently, milk production) and an increase in prolactin and oxytocin. A woman's breasts become fuller, larger, and firmer as blood and lymph enter the area to contribute fluid to the formation of milk. In many women, breast distention/engorgement is accompanied by a feeling of heat or tenderness. During the engorgement phase, the breast tissue may appear reddened as if an acute inflammatory or infectious process were present and some moms experience increased tenderness or throbbing. This feeling of tension in the breasts on the third or fourth day after birth is termed *primary engorgement*. It fades as the infant begins effective latching and begins transferring colostrum initially followed by milk from the breasts. Whether milk production (lactogenesis) continues will depend on an infant's successful latch, ability to suck, and transfer milk effectively, as this releases oxytocin and prolactin which promotes the lactogenesis process. Mothers who are primigravida tend to have a longer initial lactogenesis phase and may not have an abundance of milk until the fourth to sixth day postpartum. This is normal and does not indicate that a mother cannot breastfeed. Multigravida mothers' breast milk often "arrives" quickly within the first few days and their milk volume tends to be fuller earlier. First-time mothers may need additional breastfeeding support and lots of encouragement and assurance to continue efforts to breastfeed. Whether women continue to breastfeed after hospital discharge is influenced by such factors as lactation support, latch, milk supply, employment, personal habits, and how important they view breastfeeding to be for themselves and their newborn (Busch, Nassar, & Silbert-Flagg, 2015; Gage, Williams, Von Rosen-Von Hoewel, et al., 2012; McCarter-Spaulding, Lucas, & Gore, 2011). The tri-core lactation model is an evidenced-based practice model that can help guide nurses in providing early postpartum lactation promotion (Fig. 17.5); incorporating breastfeeding support, education, and maternal self-efficacy (confidence) strategies to improve a mother's chances of a successful breastfeeding relationship with her infant (Busch, Logan, & Wilkinson, 2014; Busch et al., 2015). Primary care offices that also incorporate the American Academy of Pediatrics (2014) *Ten Steps for Supporting Parents' Choice to Breastfeed Their Baby* have shown to improve the long-term rates and durations of breastfeeding beyond the initial early postpartum period (Box 17.7).

**Figure 17.5** The tri-core breastfeeding model. (Reprinted with permission from Busch, D. W., Logan, K., & Wilkinson, A. [2014]. Clinical practice breastfeeding recommendations for primary care: Applying a tri-core breastfeeding conceptual model. *Journal of Pediatric Health Care*, 28[6], 486–496.)

#### BOX 17.7

### American Academy of Pediatrics Ten Steps to Support Parents' Choice to Breastfeed

1. Make a commitment to the importance of breastfeeding.
2. Train all staff in skills necessary to support breastfeeding.
3. Inform women and families about the benefits and management of breastfeeding.
4. Assess infants during early follow-up visits.
5. Encourage mothers to breastfeed on demand.
6. Show mothers how to breastfeed and how to maintain lactation when they will be away from their babies.
7. Use appropriate anticipatory guidance that supports exclusive breastfeeding until infants are about 6 months old.
8. Support breastfeeding by providing accurate information about maternal issues.
9. Communicate support for breastfeeding in the office environment.
10. Expand the network of support for breastfeeding.

Reprinted with permission from American Academy of Pediatrics. (2014). *Ten steps to support parents' choice to breastfeed their baby*. Elk Grove Village, IL: Author.

While breastfeeding, women must be certain to drink adequate fluid daily, eat a varied nutritious diet, and check with their healthcare provider before ingesting medicine or alternative therapies such as herbs because most of these can be found in breast milk and their use may not be evidence-based (Schaffir & Czapla, 2012). Breastfeeding techniques are discussed in [Chapter 19](#).

## RETURN OF MENSTRUAL FLOW

With the delivery of the placenta, the production of placental estrogen and progesterone ends. The resulting decrease in hormone concentrations causes a rise in production of FSH by the pituitary, which leads, with only a slight delay, to the return of ovulation. This initiates the return of normal menstrual cycles.

A woman who is not breastfeeding can expect her menstrual flow to return in 6 to 10 weeks after birth. If she is breastfeeding, a menstrual flow may not return for 3 or 4 months (*lactational amenorrhea*) or, in some women, for the entire lactation period. However, the absence of a menstrual flow does not guarantee that a woman will not conceive during this time because she may ovulate well before menstruation returns (Kramer & Kakuma, 2012).

## Nursing Care of a Woman and Family During the First 24 Hours After Birth

A woman remains in a birthing room for at least the first hour after birth so she has time to become acquainted with her newborn and to provide for careful healthcare team observation. Skin-to-skin cuddling with the newborn should be encouraged as well as offering the newborn the breast to try to suckle. She then remains in the room as a postpartal patient or is transferred to a separate postpartal room. With this, the most dangerous hour in childbearing—the first hour after birth—has passed.

Hemorrhage is still a possibility for the first 2 or 3 days after birth, until the myometrial vessels have sclerosed. One of the worries for a woman giving birth at home is that she will not appreciate how dangerous a time this is. With attention focused more on the newborn than on her, postpartal hemorrhage could occur. In the hospital, various healthcare personnel may be involved in caring for a woman: Be certain all members of your healthcare team are knowledgeable about this danger.

Women may have cultural preferences such as the temperature of the room and the fluids they drink. A warm room and drink may be preferred over a cooler room and ice water. Some women may choose not to shower or bathe their newborn immediately for fear that the cool water will cause illness.

## ASSESSMENT

Assessment of a postpartal woman includes history, physical examination, and analysis of laboratory findings.

## Health History

The technical aspects of a woman's pregnancy, labor, and birth can be learned from her electronic record. Most of this information is best obtained from a woman herself, however, because this supplies not only information on the events of her pregnancy and labor but also her emotions and impressions about them.

## Family Profile

Information for a family profile includes age, partner and/or newborn's father, support persons, other children, type of housing and community setting, occupation, education and socioeconomic level, or that information necessary to evaluate the impact a new child will have on the woman and her family. This information also lays a foundation for teaching self-care and child care specific to the woman's knowledge level and needs.

## Pregnancy History

Information for a pregnancy history includes para and gravida status (and the reason for any discrepancy), expected date of birth, whether the pregnancy was intended, and any problems or complications such as spotting or gestational hypertension that occurred during pregnancy. This information helps you gauge a woman's potential for bonding because an unplanned pregnancy or complications arising during pregnancy can interfere greatly with bonding.

## Labor and Birth History

It's important to gather information on the length of labor, position of the fetus, type of birth, any analgesia or anesthesia used, problems during labor such as fetal distress, supine hypotension syndrome, and the presence of perineal sutures because this information helps in planning necessary procedures. In addition, explore the mother's thoughts and feelings about labor and birth and whether this was a positive experience for her.

## Infant Data

The sex and weight of the infant, Apgar scores, any difficulty at birth such as the need for resuscitation, plans to breastfeed or formula feed, and any congenital anomalies present are the major facts to obtain because, again, this information helps in planning care for the infant and promoting bonding with the parents.

## Postpartal Course

To assess a woman's postpartal course and plan anticipatory guidance needed, ask about her general health; her activity level since the birth; a description of lochia; the presence of perineal, abdominal, or breast pain; difficulty with elimination; success with infant feeding; and response of her support person to parenting.

## Laboratory Data

Women who had a cesarean delivery, prenatal anemia, or an excessive blood loss will routinely have their hemoglobin and hematocrit levels measured 12 to 24 hours after birth to determine whether blood loss at birth has left them anemic. If the hemoglobin finding is lower than 10.5 g/100 ml, supplemental iron is usually prescribed. It's important that postpartal anemia be detected because the responsibilities of being a new mother, coupled with the additional burden of an undetected low hemoglobin level, can severely tax a woman's energy levels and increase her risk for postpartum depression (East, 2012).

## Physical Assessment

During early labor, a woman is given a fairly complete physical examination. During the immediate postpartal period, therefore, repetition of a complete examination is not usually necessary. However, crucial assessments examining particular aspects of health, such as an estimation of nutrition and fluid state, energy level, presence or absence of pain, breast health, fundal height and consistency, lochia amount and character, perineal integrity, and circulatory adequacy, are required.

### General Appearance

A woman's general appearance in the postpartal period reveals a great deal about her energy level, her self-esteem, and whether she is moving into a taking-hold phase. Before beginning assessment, ask a woman to void so she has an empty bladder. Observe how much energy she uses when reaching for her robe or walking to the bathroom—does she struggle or move listlessly, or does she accomplish this task quickly? Observe for a cringing expression or hand pressure against her abdomen that suggests pain on movement. Observe whether she has combed her hair and put on her own clothing. Many women choose to sleep in an agency gown to prevent lochia stains on their own clothing, but a woman who is pleased with herself, her pregnancy, and her birth experience is usually anxious to wear her own clothing and “fuss” with her appearance within an hour after birth. The mother may be chatty and enjoy talking with the nurse and inquire about the baby's disposition. In contrast, a woman who is extremely exhausted or depressed probably will not bother with her appearance this way. An overspent mother will often not have the energy to chat and may want to avoid extra conversations. Keep in mind, however, a woman whose labor progressed so rapidly she came to a healthcare agency as an emergency admission may not have had time to pack a comb and brush or her own clothing. Cultural variations also affect appearance and actions.

### Hair

Palpate the woman's hair to determine its firmness and strength; whenever a diet is full of nutrients, hair is firm and crisp, whereas if a woman's intake during pregnancy was

deficient in nutrients, her hair feels listless and “stringy.” Many women begin to lose a quantity of hair in the postpartal period because, during pregnancy, their increased metabolism caused hair to grow rapidly and many hairs to reach maturity at the same time. As the woman’s body returns to a normal metabolism level following birth, this rapid-growth hair will be lost, especially around 6 to 12 weeks postpartum. You may need to reassure a woman that hair loss is not a sign of illness but just another aspect of return to her prepregnant state.

## Face

Assess the woman’s face for evidence of edema such as puffy eyelids or a prominent fold of tissue inferior to the lower eyelid. Normally, this should be negligible. However, in a woman who had gestational hypertension and thus accumulated excessive fluid, it will be evident. It also will become evident in a woman who is developing postpartal hypertension (although this condition is rare). Facial edema is most apparent early in the morning because the woman has been lying flat with her head level during the night.

## Eyes

Inspect the color and texture of the inner conjunctiva. If a woman is dehydrated, the area appears dry. The conjunctiva of a woman who is anemic from poor pregnancy nutrition or excessive blood loss is pale. Be alert to possible variations because of skin color, however, as dark-skinned women may have a ruddy conjunctiva appearance even with anemia. Check the electronic record of any woman with paler than usual conjunctivae to determine whether anemia (revealed by a low hemoglobin level) is present.

## Breasts

Breast tissue increases in size as breast milk forms. To assess breasts, ask a woman to remove her bra and cover her breasts with a towel or folded sheet to protect modesty. Ask her to raise her hands and tuck them under her head because this stretches and thins breast tissue. Inspect and then palpate for breast size, shape, and color.

Breast tissue should feel soft on palpation on the first and second postpartal day. On the third day, it should begin to feel firm and warm (described as *filling*). On the third or fourth day, breasts appear large and reddened, with taut, shiny skin (engorgement) and, on palpation, feel hard and tense and painful. Because, normally, engorgement causes the entire breast to feel warm or appear reddened, if only one portion of a breast appears this way, inflammation or, possibly, infection of glands or milk ducts (mastitis) is suggested (Katz, 2012). It is also normal for the breast to swell into the axillary area due to lymph node swelling and/or breast tissue engorgement. This is called the tail of Spence area; reassure the mother that this finding is normal.

Occasionally, a firm nodule is detected on palpation. Usually, this is only a temporarily blocked milk duct preventing milk from flowing forward to the nipple.

Often, hand massages and warm compresses will help to soften the nodule area. One of the best interventions for engorgement is an effective latch and to have the newborn breastfeed often from both sides initially while the milk is coming in (lactogenesis I and II). If the nodule remains troublesome, note the location of the nodule and report its presence to the woman's primary care provider so that it can be thoroughly reassessed to ascertain whether a fibrocystic or malignant growth unrelated to the pregnancy is present.

Note also whether the breast nipples are normally erect and not inverted. Assess for any cracks, fissures, or the presence of caked milk. Avoid squeezing the nipples because this can be painful. Unnecessary nipple manipulation also may increase the risk of mastitis by providing a portal for infection. If the mother is experiencing a painful latch or the newborn is having difficulty latching and transferring milk, a call to the hospital lactation consultant is warranted immediately.

## Uterus

For uterine assessment, position the woman supine so the height of the uterus is not influenced by an elevated position. Observe her abdomen for contour, to detect distention, and for the appearance of striae or a diastasis. If a diastasis is present (a slightly indented, possibly bluish-tinged groove in the midline of the abdomen), measure the width and length by fingerbreadths.

Palpate the fundus of the uterus by placing one hand on the base of the uterus, just above the symphysis pubis, and the other at the umbilicus. Press in and downward with the hand at the umbilicus until you "bump" against a firm globular mass in the abdomen: the uterine fundus (Fig. 17.6). Assess consistency (firm, soft, or boggy), location (midline), and height. For the first hour after birth, the height of the fundus is at the umbilicus or even slightly above it; it then decreases one fingerbreadth in size daily. Measure the distance under the umbilicus in fingerbreadths, such as "2 F↓" or 2 cm beneath the umbilicus. Although this measurement seems less scientific than a measurement of the height of the uterus from the pubis, it is a more certain measurement and demonstrates the gradual decline in size of the uterus.

**Figure 17.6** To palpate a uterus, be certain to place one hand at the base of the uterus. This fundus measures about two fingerbreadths below the umbilicus.

Never palpate a uterus without supporting the lower segment because the uterus potentially could invert (turn inside out) if not stabilized, resulting in a massive hemorrhage.

Palpation of a fundus should not cause pain as long as the action is done gently. If the uterus is not firm on palpation, massage it gently with the examining hand; this usually causes the fundus to contract and immediately become firm. Use a gentle rotating motion, never a hard or forceful touch, so that you do not cause pain or cause the uterus to expend excess energy in contracting. If the uterine fundus does not grow firm with massage, extreme atony, possibly retained placenta fragments, or an excess amount of blood loss may be occurring. Notify the woman's primary care provider. Administer oxytocin as prescribed. In addition, placing the woman's infant at her breast will cause endogenous release of oxytocin and achieve the same effect as oxytocin administration.

If massage appears ineffective, the cause of this may be a clot present in the cavity

of the uterus. This may be expressed from the uterus by gentle pressure on the fundus but only after the uterus has been massaged and is fairly firm. As mentioned earlier, if fundal pressure is applied with the uterus totally relaxed, fundal pressure could cause inversion of the uterus, an extremely serious complication that leads to rapid hemorrhage. Another reason the uterus may not be well contracted is that a rapidly filling bladder is preventing contraction. If contraction remains inadequate, a lower abdominal ultrasound may be prescribed to help detect an abnormality.

A woman who received no oxytocin after birth to help her uterus contract is at greater risk for poor uterine contraction than is a woman who did receive oxytocin and thus needs frequent uterine assessment (about every 10 to 15 minutes for the first hour).

Once this first hour has passed, height and consistency can be assessed less frequently, depending on institutional policy. By the 9th or 10th day after delivery, the uterus will have become so small that it is no longer palpable above the symphysis pubis.

### *QSEN Checkpoint Question 17.4*

#### **TEAMWORK & COLLABORATION**

The nurse is performing massage of Leana's fundus 2 days postpartum. What assessment finding should prompt the nurse to contact Leana's primary care provider immediately?

- a. Leana's fundal height is two fingerbreadths below her umbilicus.
- b. Leana's uterus does not become firm when massaged.
- c. Firm massage of Leana's fundus results in pain.
- d. The fundus is located midline on Leana's abdomen.

*Look in [Appendix A](#) for the best answer and rationale.*

## Lochia

A woman can expect to have lochia for 2 to 6 weeks. Characteristics of normal lochia and the change in pattern from red to pink to white were described in [Table 17.1](#).

During the first hour after birth, when the fundus is checked every 15 minutes, also remove the mother's perineal pad and evaluate lochia character, amount, color (rubra, serosa, or alba), odor, and the presence of any clots. If the woman has perineal stitches, be certain the pad is not adhering to those before removing it.

Ask the woman to turn, so you can inspect under her buttocks to be certain blood is not pooling beneath her. If you observe a constant trickle of vaginal flow or a woman is soaking through a pad every 60 minutes, she is losing more than the average amount of blood. It is concerning if the woman appears disoriented and/or her vital signs are abnormal. She needs to be examined by her primary care provider to be certain there is no cervical or vaginal tear or that poor uterine contraction is not causing excessive bleeding.

While a woman is at the healthcare facility, inspect her lochia discharge once every 15 minutes for the first hour and then according to the institution's policy (usually hourly for the next 4 hours and then every 8 hours after that). Make certain a woman understands that she should wash her hands after handling pads and must use only her own personal care equipment so that she does not contract or spread infection. Demonstrate good role modeling for hand washing and nonsharing of equipment. Encourage a woman to change perineal pads frequently as she begins self-care because lochia is an excellent medium for bacterial growth that could spread through the vagina to the uterus. The presence of constantly wet pads against an episiotomy suture line also slows healing. Be certain she knows not to use tampons until after she returns for her postpartal checkup to diminish the risk of infection and possibly toxic shock syndrome (see [Chapter 47](#)) and to contact her provider if she develops a fever upon returning home. Ensure women are familiar with the criteria for judging the amount and type of normal lochia (see [Box 17.6](#)), so they can do this accurately when they return home.

## Perineum

While asking a woman to turn on her side to evaluate whether lochia is pooling, also inspect her perineum. If a woman has no episiotomy or a midline one, which side she turns to does not matter. If she has a mediolateral incision, ask her to turn so the incision is on the bottom buttock because this tends to cause less pain and offers better visibility. Gently lift the upper buttock and inspect for ecchymosis, a hematoma, erythema, edema, intactness, and presence of drainage or bleeding from any episiotomy stitches.

Episiotomies are rarely done today because they may increase the risk of extended perineal lacerations. If stitches are present, the suture line is 1 or 2 in. long. If a laceration extends beyond the episiotomy incision, stitches may extend from the vagina back to the rectum or go into the muscle and tissues surrounding the perineal area. The incision line is usually fused (edges sealed) by 24 hours after birth; if it is a midline incision, it may be almost invisible to see because the perineal fold obscures it. If there is clotted lochia along the incision line, review postpartal perineal care so that this does not continue to occur. Before discharge, teach a woman who has stitches how to lie on her back and view her perineum with a handheld mirror, so that, once a day while at home, she can inspect her perineum for redness, sloughing of sutures, pus formation, drainage at the suture line, or development of a hematoma. A hematoma is a collection of blood in the subcutaneous space from bleeding from the episiotomy incision that can become so extensive it causes intense pain and disrupts the suture line (see [Chapter 25](#)).

Following perineal assessment, assess the rectal area for the presence of hemorrhoids. If any are present, document their number, appearance, and size in centimeters. Because postpartum women are not on bed rest unless they have a serious complication, assess risk of skin breakdown as per facility protocol using an assessment scale such as the Braden Assessment Scale ([Teschler, Branda, Byrne, et al., 2012](#)).

### What If... 17.2

**Leana Cooper, at 18 hours postpartum, tells the nurse she has had to change her perineal pads twice in the last 30 minutes because they were saturated. In addition, the nurse noticed two large clots on her last pad. To guard her safety, what should be the nurse's first action?**

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for fluid volume deficit related to uterine atony

**Outcome Evaluation:** Patient maintains vital signs within normal range; fundus is firm to palpation; lochia discharge is small to moderate with a minimum of clot formation.

In order to assess if uterine atony is present, frequently assess vital signs, lochia amount, and fundal height. Teach patient the usual involution process and how to check her fundus and evaluate lochia so she can do this after she returns home.

**Nursing Diagnosis:** Pain related to perineal discomfort, uterine cramping (afterpains), or muscular aches

**Outcome Evaluation:** Patient states that degree of pain is tolerable; patient demonstrates knowledge of measures for adequate pain relief.

Women experience pain postpartally as a result of uterine contraction as well as from the aftereffects of pushing during labor.

*Provide Pain Relief for Afterpains.* Pain from uterine contractions is similar to pain from menstrual cramps and can be intense. It's usually helpful to assure a woman that this type of discomfort, although painful, is normal and rarely lasts longer than 3 days. If necessary, either ibuprofen (such as Motrin), which has anti-inflammatory and antiprostaglandin properties, or a common analgesic such as acetaminophen (such as Tylenol) is effective for pain relief. As with any abdominal pain, heat to the abdomen should be avoided because it could cause relaxation of the uterus and subsequent uterine bleeding. Remind the woman that the total 24-hour dose for acetaminophen is 3,000 mg so she does not take an excessive amount after returning home (Karch, 2013).

*Relieve Muscular Aches.* Many women feel so sore and achy after labor and birth that they describe feeling as if they have "run for miles." A backrub is usually effective

for relieving an aching back or shoulders, but some woman may appreciate a mild analgesic such as acetaminophen for the pain. Carefully assess a woman who states she has intense warmth or pain in the calf of her leg on standing because pain in the calf on standing (a position that dorsiflexes the foot) is **Homans sign** and could indicate that thrombophlebitis is present (see later discussion).

*Administer Cold and Hot Therapy.* Applying an ice or cold pack to the perineum during the first 24 hours reduces perineal edema and the possibility of hematoma formation and also reduces pain and promotes healing and comfort. Be certain not to place ice or plastic directly on the woman's perineum. Use a commercial cold pack, or wrap an ice bag first in a towel or disposable pad, to decrease the chance of a thermal burn (risk of injury increases because the perineum has decreased sensation from edema after birth).

Ice to the perineum after the first 24 hours is no longer therapeutic because, after this time, healing increases best if circulation to the area is encouraged by the use of heat. Dry heat in the form of a perineal hot pack or moist heat with a sitz bath are both effective ways to increase circulation to the perineum, provide comfort, reduce edema, and promote healing.

Commercial hot packs grow warm after they are “cracked” and the chemicals in them combine. Caution women to use a washcloth or gauze square between the pack and their skin, to prevent a possible burn.

*Promote Perineal Exercises.* Some women find that carrying out perineal exercises three or four times a day can greatly relieve perineal edema. The most effective exercise consists of contracting and relaxing the muscles of the perineum 5 to 10 times in succession, as if trying to stop voiding (**Kegel exercises**). This aids comfort by improving circulation to the area and decreasing edema. When repeated frequently, Kegel exercises can also help a woman regain her prepregnant muscle tone and help prevent urinary incontinence (Boyle, Hay-Smith, Cody, et al., 2012).

*Give Suture Line Care for Women With An Episiotomy.* Although relatively small in size, episiotomy sutures can cause considerable discomfort because the perineum is an extremely sensitive area and the muscles of the perineum are involved in so many activities such as sitting, walking, stooping, squatting, bending, urinating, and defecating.

Because the perineal area heals rapidly, you can assure a woman that discomfort is normal and does not usually last longer than 5 or 6 days. Most primary care providers prescribe a soothing anesthetic cream or spray to be applied to the suture line to reduce discomfort. A cortisone-based cream or warm sitz bath helps to decrease inflammation and relieve tension in the area. Because of their cooling effect, witch hazel-impregnated pads (Tucks) are a mainstay for relief of both perineal and hemorrhoidal discomfort.

In addition to local perineum creams or sprays, a woman may require an oral analgesic such as hydrocodone for the first 24 hours and then a milder one such as

acetaminophen for the remainder of the first week. Caution a woman not to use aspirin for pain relief during the postpartal period because it interferes with blood clotting and may increase her risk for hemorrhage from the denuded placental site (Karch, 2013). If a woman is worried she will experience additional discomfort when her episiotomy sutures are removed, you can assure her these sutures will dissolve within 10 days and thus do not need to be removed.

**Nursing Diagnosis:** Risk for infection (uterine) related to presence of lochia and denuded uterine surface

**Outcome Evaluation:** Patient's temperature remains below 100.4°F; lochia is present and without foul odor.

Measures to decrease the risk of infection are concerned with not allowing organisms to spread from the perineum into the uterus.

*Provide Perineal Care.* Postpartal women are particularly prone to a uterine infection because lochia, if allowed to dry and harden on the vulva and perineum, furnishes a rich bed for bacterial growth, which then can spread to the uterus. Because the vagina lies in close proximity to the rectum, there is also always the danger bacteria will spread from the rectum to the vagina. Interruption in skin integrity from an episiotomy also increases a woman's risk for infection.

To reduce these risks, teach a woman to include perineal care as part of her daily bath or shower and after every voiding or bowel movement. For the woman on bed rest during the first hour after birth, you will need to provide this care for her.

Before beginning perineal care, be certain to wash your hands well and pull on clean gloves. This nursing action requires universal precautions. Place a plastic-covered pad under the woman's buttocks to protect the bed from lochia or water. With the woman lying supine, remove her perineal pad from front to back (the direction is important to prevent the portion of the pad that was over her rectal area from sliding forward to contaminate the vaginal opening).

Agencies differ as to the type of cleansing that is done and the articles and solutions used to wash away accumulating lochia. If actual washing is to be done, use a clean gauze square or a clean portion of a washcloth with the designated solution for each stroke, always washing from front to back or from the pubis toward the rectum. Rinse the area in the same manner and pat it dry.

A second common method of cleaning is to spray the perineum with clear tap water from a spray bottle. When doing this, direct the spray toward the front of the perineum and allow it to flow from front to back, from the vaginal to the rectal area to reduce cross-bacterial transmission into the vagina. The labia have a tendency to close and cover the vaginal opening. Do not separate the labia; instead, allow them to perform this protective function. Spray gently to avoid splashing any blood-tinged solution on yourself.

*Promote Perineal Self-Care.* As soon as a woman is allowed to be out of bed and use

a bathroom (if she gave birth without an anesthetic, this is within the first hour after birth), teach her how to carry out her own perineal care.

A postpartum bathroom should have an area close to the toilet where she can place the equipment she needs for care: a spray bottle, sponges to dry, clean pads, and so forth. Remind her of the importance of applying any cream or medication that has been prescribed. Caution her not to flush the toilet until she is standing upright so the flushing water doesn't spray her perineum and increase the risk of infection.

If women are given a clear explanation as to why perineal care is important, they perform it well. Self-care does not eliminate a nurse's responsibility, however, for checking a woman's perineum to assess its condition and the amount and type of lochia flow present. By continuing with these assessments, you remain a woman's first line of defense against both infection and hemorrhage.

**Nursing Diagnosis:** Disturbed sleep pattern related to exhaustion from and excitement of childbirth

**Outcome Evaluation:** Patient states she is able to sleep and feels rested during postpartal period.

After birth, a woman is a paradox. She wants to hold and be with the new person in her life. She wants to talk to her support person about the experience, their child, and their future. At the same time, she is so exhausted she falls asleep easily.

*Promote Rest in the Early Postpartal Period.* Few women are prepared for the degree of fatigue they experience after childbirth. When giving care, try to consolidate procedures to allow as much time for sleep as possible. If a woman has discomfort from hemorrhoids, perineal stitches, or afterpains, be certain to supply adequate pain relief so she can rest comfortably or sleep. Caution her to return her infant to a bassinette if she grows sleepy while feeding or holding the infant as a newborn in a narrow bed could easily fall and be injured.

Some women experience shaking chills immediately or within a half hour after birth. This is caused in part by the pressure changes in the abdomen that occur with reduction in the bulk of the uterus and temperature readjustment in response to the diaphoresis of labor. It also may result from the exhilaration the woman is feeling, combined with exhaustion. In any event, you can assure a woman that shaking chills at this point are very common, so she will not attribute them to developing a cold or other infection. Covering her with a warm blanket and offering a warm drink are usually enough to cause the chill to be transient and allow the woman to fall into a sound, much-needed sleep of about an hour. Although a woman may choose any position to sleep, she may enjoy being able to sleep on her stomach, something she was not able to do during the latter part of pregnancy.

*Promote Rest Throughout the Puerperium.* You cannot stress too much to women the importance of rest throughout the entire puerperium. Offer suggestions for getting adequate rest after a woman returns home such as sleeping while her baby naps or

asking for respite time from baby care so she can nap.

A woman without this type of support can have difficulty balancing the many demands of her new role—being a mother instead of a daughter; a mother as well as a wife; or a mother of three, not two. Overcome by sleep hunger, her judgment and sense of balance can blur. Although it is not the only contributing factor, extreme fatigue is also associated with the development of postpartal depression (Meadows-Oliver, 2012). Learning to breastfeed her infant can also be an overwhelming experience; provide reassurance to the women that this is a normal feeling and suggest that her partner or support person relieve her so she may nap after she breastfeeds.

**Nursing Diagnosis:** Risk for bathing/hygiene self-care deficit related to exhaustion from childbirth

**Outcome Evaluation:** Patient takes full daily responsibility for own hygiene.

After childbirth, women often report that their hospital or birthing center room feels too warm; to prove it, they point out how heavily they are perspiring. Postpartal rooms often are kept warm so newborns will be comfortable, but the profuse perspiration a woman is experiencing most likely comes from her body's attempt to regulate fluid, not from the heat of the environment.

You can assure a woman that sweating is a normal postpartal event that is helping to bring her body back to its pre-pregnant state. If she has profuse diaphoresis, particularly at night, suggest she wear a hospital gown rather than one of her own. She may need frequent gown changes during the day to be comfortable and not become chilled.

Before a woman walks to a shower room on her first postpartal day, perform a fall-risk assessment as identified by your facility protocol. Accompany her in the hallway because she may be more fatigued than she realizes. Encourage her to not make the shower excessively warm and to keep the call light in reach because standing under warm water may make her feel so dizzy that she may need help to walk safely back to bed.

Formerly, women were not allowed to take tub baths after birth, for fear bacteria from the bath water would enter the vagina and cause infection. There appears to be little evidence this is a real danger, however, so if a woman wants to bathe instead of shower after she returns home, she may do so.

**Nursing Diagnosis:** Imbalanced nutrition, less than body requirements, related to lack of knowledge about postpartal needs

**Outcome Evaluation:** Patient ingests a 2,200- to 2,700-kcal diet and drinks six to eight glasses of fluid daily.

Postpartal menu planning should include a diet of between 2,200 and 2,300 calories daily including foods high in protein and the vitamins and minerals needed for good tissue repair. An adequate supply of roughage is also important to help restore

peristaltic action of the bowel. Women who are breastfeeding need an additional 500 calories (a 2,700-kcal diet) and an additional 500 ml of fluid (these may be from the same source) each day to encourage the production of high-quality breast milk. Most mothers are hungry during the immediate postpartal period and consume an adequate diet without urging.

After hospital discharge, a woman needs to continue to eat a nutritious diet. It's important to stress this because women can become so fatigued during their first weeks at home they are unable to prepare anything but fast-food meals. Neglecting to eat properly leads to more fatigue and, ultimately, to an even less nutritious diet. Encourage the mother to eat and drink frequently, such as every 2 to 3 hours while awake; these can be simple snacks such as an apple and peanut butter (if no allergy) or yogurt and granola.

If a woman has any prenatal vitamins or supplementary iron preparations left over from pregnancy, she should, as a rule, continue to take them until her supply is used. Breastfeeding patients are strongly encouraged to continue taking their prenatal vitamins until they stop nursing their infant. If a woman needs further supplements, her primary care provider will prescribe them for her either on discharge from her birth setting or when she returns for her postpartum checkup (Milman, 2012).

*Promote Adequate Fluid Intake.* The rapid diuresis and diaphoresis that occur during the second to fifth postpartal days ordinarily result in a weight loss of 5 lb in addition to the approximately 12 lb lost at childbirth.

Women often feel thirsty during this period of rapid fluid loss because they also may have had a limited liquid intake during labor, and so they readily drink a large amount of fluid. You may need to encourage an individual woman to drink more fluid because she is restricting fluid in the hope of preventing her breasts from becoming engorged or is beginning to diet in the hope of bringing her body more quickly back to its nonpregnant slim state. Fluid restriction, however, does little to affect engorgement or weight loss and thus should be discouraged. Instead, encourage a woman to drink at least three to four 8-oz glasses of fluid each day (six to eight glasses if breastfeeding).

**Nursing Diagnosis:** Risk for impaired urinary elimination or constipation related to loss of bladder and bowel sensation after childbirth

**Outcome Evaluation:** Patient voids more than 30 ml/hr without urinary retention, beginning 1 hour after birth and has a bowel movement by postpartum day 4. No urinary incontinence is noted.

Because the fetal head pressed on the posterior surface of the bladder during birth, a woman's bladder may have so much edema that the sensation of a full bladder is hard to sense. Bowel peristalsis may also be reduced because a woman's abdominal wall is so lax.

*Promote Urinary Elimination.* Because the diuresis of the postpartal period begins

almost immediately after birth, a woman's bladder begins filling almost immediately. This is potentially serious because a full bladder puts pressure on the uterus and so can interfere with uterine contraction. An overdistended bladder may also damage bladder function. Women who have had epidural anesthesia are particularly prone to inability to sense a full bladder and so can develop urinary retention (Mulder et al., 2012).

Encourage a woman to walk to the bathroom and void at the end of the first hour after birth to help prevent bladder distention; however, some women have too much perineal edema to be able to void this early. A woman with an episiotomy may be reluctant to void because she knows acid urine against her sutures will sting. Most women who have had epidural anesthesia have enough residual effect, however, that even with perineal stitches, voiding at this time is painless. Assist by providing privacy (but remain in close proximity in case a woman feels faint), running water at the sink, or offering the woman a drink of water. Pouring warm tap water over the vulva, if consistent with the agency's policy for perineal care, also may help.

If the woman still has not been able to void by 4 to 8 hours after birth, and bladder distention is present, she will need to be catheterized to relieve bladder pressure. It can be difficult to locate the urethra in a woman after birth because the perineum is edematous. Be certain that, during catheterization, you do not invade the vagina by mistake and thereby carry contamination to the denuded uterus. Occasionally, because of poor tone, the bladder appears to be emptying but actually is retaining large amounts of residual urine that harbors bacteria and can lead to bladder infection.

To detect whether urinary retention is occurring, be certain to measure a first voiding after birth. Whether the bladder is emptying also may be judged by measuring whether the fundal height is decreasing or by palpating or percussing bladder prominence in the lower abdomen. If a woman is voiding less than 100 ml at a time or has a displaced uterus or a palpable bladder, her primary care provider may prescribe catheterization for residual urine after a voiding. As a rule, if the residual urine removed is more than 100 to 150 ml, the catheter is left in place for 12 to 24 hours to give the bladder time to regain its normal tone and to begin to function efficiently.

Fortunately for most women who must be catheterized, the procedure needs to be done only once after birth. After another 6 to 8 hours have passed and the bladder has filled again, some of the perineal edema has subsided, the bladder has achieved better tone, and the woman is able to void by herself if helped to the bathroom.

Because catheterization can lead to urinary infection, it should not be used indiscriminately. However, it should be done before the woman's bladder is injured or the uterus is displaced and uncontracted, resulting in bleeding.

Some women experience urinary incontinence during the postpartal period, probably resulting from poor perineal tone and sensation. Suggest Kegel exercises to strengthen perineal muscles and eliminate incontinence in the future.

**Prevent Constipation.** Many women have difficulty moving their bowels during the first week of the puerperium, a condition that can be both worrisome and uncomfortable. Constipation occurs because of relaxation of the abdominal wall and the intestine, now that they are no longer compressed by the bulky uterus. Also, if hemorrhoids or perineal stitches are present, a woman may decline to try to move her bowels for fear of pain.

To prevent constipation, early ambulation, a diet with adequate roughage, and an adequate fluid intake are all helpful measures. Many women are prescribed a stool softener such as docusate sodium (Colace) beginning with the first day after birth (Box 17.8). If a woman has not moved her bowels by the third postpartum day, a mild laxative or cathartic may be prescribed. There is danger in giving cathartics before the third day because the resulting increase in intestinal activity could cause uterine irritation and lead to insufficient contraction.

#### BOX 17.8

### Nursing Care Planning Based on Responsibility for Pharmacology

#### **DOCUSATE SODIUM (COLACE, SURFAK)**

**Classification:** Docusate sodium is a stool softener.

**Action:** Used in the postpartal period to prevent constipation. It works by lowering the surface tension of feces, allowing water and lipids to penetrate the stool and soften it (Karch, 2013).

**Pregnancy Risk Category:** C

**Dosage:** 50–100 mg PO daily.

**Possible Adverse Effects:** Occasional abdominal pain and diarrhea

#### **Nursing Implications**

- Encourage a woman to swallow the medication with a full glass of water or juice.
- Instruct a woman to consume high-fiber foods to encourage elimination.
- Encourage activity to promote intestinal motility.

**Prevent Development of Hemorrhoids.** The pressure of the fetal head on the rectal veins during birth tends to aggravate or produce hemorrhoids (swollen rectal veins) to such an extent that some women find hemorrhoidal discomfort to be their chief discomfort in the first few days after birth (Avsar & Keskin, 2010). This discomfort can be relieved by sitz baths, anesthetic sprays, witch hazel or astringent preparations, or preparations such as hydrocortisone acetate (Proctofoam). Gentle manual replacement of hemorrhoidal tissue may also give relief. Assuming a Sims position several times a day aids in good venous return to the rectal area and also reduces discomfort. Increased fluid and the administration of a stool softener can prevent the

development of hardened stool, which can irritate hemorrhoids.

**Nursing Diagnosis:** Risk for ineffective peripheral tissue perfusion related to immobility and increased estrogen level

**Outcome Evaluation:** Patient demonstrates negative Homans sign and absence of erythema or pain in calves of legs.

Because estrogen, which aids blood clotting, is still elevated following birth, women are at high risk for thrombophlebitis of the leg unless they ambulate quickly after birth.

**Assess Peripheral Circulation.** As a rule, women who ambulate quickly feel stronger and healthier by the end of their first week and have fewer bowel, bladder, and circulatory complications than those who do not (Fig. 17.7). To determine if peripheral circulation is adequate, assess a woman's thigh for skin turgor. Assess for edema at the ankle and over the tibia on the lower leg. Although this technique is not totally reliable, assess for thrombophlebitis by dorsiflexing a woman's ankle and asking her if she notices pain in her calf on that motion (Homans sign). Assess also for redness in the calf area because thrombophlebitis can be present even with a negative Homans sign. Continue to assess for adequate peripheral circulation once every 8 hours during the woman's stay in a healthcare facility. If you suspect thrombophlebitis, do not massage the area—doing so could cause the thrombophlebitis to become an embolus.

**Figure 17.7** Ambulating postpartum is not always easy but helps to prevent complications.

**Nursing Diagnosis:** Pain related to primary breast engorgement

**Outcome Evaluation:** Patient states pain from breast engorgement is at a tolerable level.

**Prevent/Alleviate Breast Engorgement.** If a woman is breastfeeding, encouraging her

newborn to attempt to latch at the breast is the main treatment for relief of the tenderness and soreness of primary breast engorgement (breastfeeding techniques are discussed in [Chapter 19](#)).

Many women find the application of warm compresses or standing under a warm shower beneficial to relieve the discomfort of engorgement. Instructing a mother how to perform manual expression helps to relieve milk engorgement as well. Good support from a bra also offers relief because it prevents unnecessary strain on the supporting muscles of the breasts and positions the breasts in good alignment. Assess the woman for any intense nipple discomfort or pain. If nipple pain is occurring within the first few days postpartum it is often due to an infant's ineffective latch. Nipple damage from a mislatch can result in a bacterial or yeast infection of the nipple. Nipple pain must be assessed by a lactation consultant and the women's provider prior to discharge and preferably as soon as possible.

A woman who is not breastfeeding may experience strong discomfort for the first few days. When little or no milk is removed from the breasts, however, the accumulation of milk inhibits further milk formation, and engorgement subsides by the third day. An oral analgesic, wearing a snug-fitting bra, avoiding nipple stimulation, or applying cold compresses three or four times a day can all provide relief. Restricting fluid and pumping milk from the breasts are not effective.

***Promote Breast Hygiene.*** Breast care during the postpartal period includes cleanliness and support and is the same whether or not a woman is breastfeeding.

Teach a woman to wash her breasts daily with clear water and gentle soap at the time of her bath or shower and then dry them with a soft towel. It is not necessary for women to wash their breasts more often than daily or use a vast amount of soap because excessive washing means unnecessary skin manipulation.

A woman who has a considerable discharge of colostrum or milk from her breasts (whether breastfeeding or not) should insert clean gauze squares or commercial nursing pads into her bra to absorb the moisture, changing them as often as necessary to keep the nipples dry because if the nipples remain wet for any length of time, fissures may form and lead to infection.

***Nursing Diagnosis:*** Health-seeking behaviors related to future breast health

***Outcome Evaluation:*** Patient states the importance of once-yearly breast examination by a healthcare provider and a yearly to biyearly mammography, if appropriate for her age and risk factors, and her intention to schedule this examination yearly ([Oelffinger, Fontham, Etzioni, et al., 2015](#)).

Because breast cancer is a major type of neoplasm in women, all women of childbearing age should know the importance of yearly breast assessment ([Granek & Fergus, 2012](#); [Oelffinger et al., 2015](#)). Many women are not interested in hearing about cancer prevention measures during pregnancy because the possibility of developing cancer seems too far removed from what they are doing—creating life. In

the postpartal period, they become conscious of the need to remain well to raise this new child to maturity. This makes them more receptive to a review of the importance of a yearly breast exam at healthcare visits.

A breastfeeding woman may occasionally discover a distended milk gland that feels very much like a cyst or tumor, especially in the axillary area (tail of Spence). You can assure her she need not report such distended glands unless they persist beyond two breastfeedings.

**Nursing Diagnosis:** Health-seeking behaviors related to patient’s desire to return to prepregnant weight and appearance

**Outcome Evaluation:** Patient states realistic goals for return to former appearance; patient is able to demonstrate appropriate exercises.

After childbirth, the abdominal wall and the uterine ligaments remain stretched. The abdomen tends to pouch forward. Wearing a girdle may help a woman feel more comfortable during the first few weeks after birth, but it does not aid, and may actually hinder, strengthening the tone of the abdominal wall. She can best help her abdominal wall return to good tone by using proper body mechanics and posture, getting adequate rest, and performing prescribed exercises such as those described in [Table 17.2](#).

**TABLE 17.2 MUSCLE-STRENGTHENING EXERCISES**

Exercise	Description
Abdominal breathing	Abdominal breathing may be started on the first day after birth because it is a relatively easy exercise. Lying flat on her back or sitting, a woman should breathe slowly and deeply in and out five times, using her abdominal muscles. Check by watching her abdominal wall rise that she is actually using these muscles.
Chin-to-chest	The chin-to-chest exercise is excellent for the second day. Lying on her back with no pillow, a woman raises her head and bends her chin forward on her chest without moving any other part of her body while exhaling. She should start this gradually, repeating it no more than 5 times the first time and then increasing it to 10–15 times in succession. The exercise can be done 3 or 4 times a day. She will feel her abdominal muscles pull and tighten if she is doing it correctly.
Perineal contraction	If a woman is not already using this exercise as a means of alleviating perineal discomfort, it is a good one to add on the third day. She should tighten and relax her perineal muscles 10–25 times in succession as if she were trying to stop voiding (Kegel exercises). She will feel her perineal muscles working if she is doing it

correctly.

Arm raising	Arm raising helps both the breasts and the abdomen return to good tone and is a good exercise to add on the fourth day. Lying on her back, arms at her sides, a woman moves her arms out from her sides until they are perpendicular to her body. She then raises them over her body until her hands touch and lowers them slowly to her sides. She should rest a moment and then repeat the exercise five times.
Abdominal crunches	It is advisable to wait until the 10th or 12th day after birth before attempting abdominal crunches. Lying flat on her back with knees bent, a woman folds her arms across her chest and raises herself to a sitting position. This exercise expends a great deal of effort and tires a postpartal woman easily. Caution her to begin very gradually and work up slowly to doing it 10 times in a row.

**Teach Methods to Promote Uterine Involution.** All during the postpartal period, lying on the abdomen gives support to abdominal muscles and may aid involution because it tips the uterus into its natural forward position. If this puts too much pressure on sore breasts, placement of a small pillow under the abdomen usually solves the problem.

*It may be dangerous for a woman to assume a knee–chest position until at least the third week after birth* because, in a knee–chest position, the vagina tends to open. Because the cervical os is open to some extent until the third week, there is a danger air could enter the vagina and the open cervix, penetrate the open blood sinuses inside the uterus, enter the circulatory system, and cause an air embolism.

Although this would be a rare occurrence, it is good practice for a woman to avoid this position until she returns for a postpartal examination and is assured her cervix has closed. Women who have used a knee–chest position during pregnancy to relieve the pressure of hemorrhoids need to be cautioned that a modified Sims position, such as they used for a rest position during pregnancy, is better for them now.

**Nursing Diagnosis:** Risk for ineffective sexuality patterns related to physiologic changes of postpartal period

**Outcome Evaluation:** Patient states she has a satisfactory sexual relationship with her partner; patient demonstrates understanding of both coital and noncoital methods of sexual expression.

At one time, women were cautioned not to resume sexual relations after the birth of a baby until after their medical checkup at 6 weeks. However, there is no apparent physiologic reason to delay sexual relations this long. For most couples, gentle coitus may be resumed as soon as lochia serosa has stopped—about 1 to 2 weeks after birth.

Caution women, however, that sex may be somewhat uncomfortable if it is begun

this early because vaginal epithelium is still thin and tender. A woman who is breastfeeding may also notice that breast milk is released from her nipples with sexual arousal. Use of a lubricant will help any mucosal dryness. A female-superior position may be most comfortable because it allows the woman to control the depth of penile penetration. Be sure women receive adequate reproductive planning information, if desired, before they resume sexual relations to prevent another pregnancy so soon (see [Chapter 6](#)). If a woman experiences intense pain during intercourse, instruct her to consult her gynecologist for further evaluation.

**Nursing Diagnosis:** Risk for impaired parenting related to inadequate bonding behavior after childbirth

**Outcome Evaluation:** Parents hold and comfort their infant appropriately and voice positive characteristics of child.

To assess whether bonding is occurring, listen to what parents say about their newborn in the immediate postpartal period. Do they make positive statements, such as “I’m glad he’s a boy” or “She’s cute,” or negative ones, such as “I really hoped it would be a girl” or “She looks like a circus clown with no hair”? First impressions may not be lasting ones; however, negative comments need to be identified, so that extra discussion about issues such as what it feels like to have four boys or not to have the prettiest child in the nursery can take place. Although brief hospital stays are advantageous in many ways, if limited time prevents such discussions from occurring, a family may be discharged from the healthcare agency with not only physical but also educational and emotional needs unmet ([Gross, Resnik, Nanda, et al., 2011](#)). Typical signs of good parent–child adaptation are shown in [Box 17.9](#).

### BOX 17.9

#### Signs of Positive Parent–Child Adaptation

Good parent–child adaptation is demonstrated when a parent:

- Speaks of infant as desirable and attractive
- Is not upset by vomiting, drooling, and the like
- Holds the baby warmly
- Makes eye contact with the infant
- Plays with and soothes the infant
- Talks or sings to the baby
- Expresses confidence that the infant is well
- Finds physical or psychological attributes to admire about the baby
- Is able to discriminate between the baby’s signs of hunger or need for sleep

#### *QSEN Checkpoint Question 17.5*

#### EVIDENCE-BASED PRACTICE

Many new mothers are not prepared for how much time newborns spend crying (as many as 16 of 24 hours); trying to quiet a newborn can lead to extreme fatigue in a postpartal parent. To investigate the effect of newborn crying on new mothers' ability to rest, researchers conducted a systematic review of studies concerned with newborn crying. Results of the literature review revealed that infant crying during the first 3 months postpartum is responsible for disrupting new mothers' circadian rhythms, reducing opportunities to rest, and exacerbating tiredness. Incremental exhaustion from infant crying diminishes a parent's ability to concentrate, raises the fear of harming the children, triggers depressive symptoms, and burdens parent–child interaction (Nugent, 2013).

The Neonatal Behavioral Assessment Scale (NBAS) focuses on the dynamic relationship of a newborn with its parents, rather than a passive state, and that newborns are extremely sensitive to their new surroundings and parents (Nugent, 2013). The NBAS uniquely identifies and assesses a newborn's 18 reflex behavioral and social competencies and helps to provide a window into the infant's temperament to aid the parents in their parenting techniques.

Based on current research, which comment by Leana would make the nurse worry that she may have a difficult time getting enough sleep after she returns home and understanding her newborn's behavior?

- a. "I didn't think I'd like breastfeeding, but in reality, it's very enjoyable."
- b. "I walk my dog daily; I'm looking forward to walking the baby as well."
- c. "My husband knows nothing about newborns, but he is usually a fast learner."
- d. "I know that the baby will sleep just fine because I've read everything I can about the subject."

---

Look in [Appendix A](#) for the best answer and rationale.

### *What If... 17.3*

**Leana Cooper does not have an episiotomy incision; therefore, the nurse expects her to have little perineal discomfort. Instead, she states her perineal pain is excruciating. Would the nurse bring her something for pain or assume she's exaggerating her pain level?**

## **Nursing Care of a Woman and Family in Preparation for Health Agency Discharge**

The greatest need of a postpartal woman before discharge from a healthcare agency is education to prepare her to care for herself and her newborn at home. [Box 17.10](#) shows an interprofessional care map illustrating both nursing and team planning for a postpartal woman.

**AN INTERPROFESSIONAL CARE MAP FOR A POSTPARTAL WOMAN**

Leana Cooper is 6 hours postpartum after birth of an 8-lb 2-oz baby girl. She states, “I haven’t urinated since before the birth. What kind of mother am I going to be if I can’t even manage my own care?” Her husband Mike pulls you aside and says, “Sometimes, I see my wife crying for no reason. Why is she so upset over little things? Isn’t she as happy as I am?”

**Family Assessment:** Couple has been married for 3 years. Husband works as a pharmacist. Will be taking a week off to help care for new baby. Leana is on maternity leave from her job as a court reporter.

**Patient Assessment:** Labor and birth were without incident. Abdomen soft. Uterus 1/2 fingerbreadth above umbilicus, soft, and displaced to the right. Moderate lochia rubra. Bladder firm on palpation above symphysis pubis. Resonant on percussion. Vital signs within acceptable parameters.

**Nursing Diagnosis:** Altered urinary elimination related to perineal edema and decreased bladder tone from fetal head pressure during labor and birth.

**Outcome Criteria:** Patient attempts common measures to initiate voiding; voids more than 100 ml within 2 hours’ time. Voices she understands crying is a common reaction after birth.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess amount of urine voided during labor and reassess fundal height and position.	Discuss importance of drinking fluid to help initiate bladder reflex.	Retention of urine can predispose to infection and uterine atony.	Patient voids 100 ml by 2 hours’ time; fundal height is 1 cm below umbilicus after voiding.
<i>Teamwork and Collaboration</i>				
Nurse/primary healthcare provider	Determine which member of patient’s primary care team is on call.	If patient has not voided by 8 hours after birth, notify team member.	Bladder distention can interfere with uterine involution; possible loss of bladder tone.	Primary healthcare provider is notified of patient’s inability to void.

*Procedures/Medications for Quality Improvement*

Nurse	Assess what measures patient thinks would help her to void.	Instigate measures patient suggests, such as ambulating to bathroom and increased privacy.	Respecting patient's preferences helps her to maintain sense of control.	Patient ambulates to bathroom to void with assistance from nurse.
-------	---	--	--	---

*Nutrition*

Nurse	Assess whether intake, both intravenous and oral, has been adequate since birth.	Stress importance of drinking extra water during the postpartum period.	Ample fluid is needed to counteract diuresis and ensure good urine output.	Patient confirms she has been drinking 1 glass of fluid an hour. Knows to drink 6 to 8 glasses of fluid daily.
-------	--	---	--	--

*Patient-Centered Care*

Nurse	Assess patient's knowledge of postpartal care measures.	Teach normal physiologic changes that occur after birth and importance of preventing complications.	The more informed patients are, the more they can participate in self-care.	Patient states she understands the importance of a good fluid output to help prevent urinary tract infection.
-------	---	---	---	---

*Psychosocial/Spiritual/Emotional Needs*

Nurse	Assess how often episodes of crying occur.	Emphasize "baby blues" are common during the postpartal period.	The change to being a parent is a major role change.	Patient states she views inability to void as a temporary setback, nothing to interfere with her success as a parent.
-------	--	---	--	---

*Informatics for Seamless Healthcare Planning*

Nurse/primary healthcare provider	Assess patient to see whether she understands the importance of monitoring	Once voiding pattern is reestablished, instruct patient in Kegel	Kegel exercises help strengthen perineal muscles.	Patient describes Kegel exercises she will continue to use to
-----------------------------------	--	--	---	---

voiding at home. exercises.

strengthen  
perineal  
muscles.

How to bathe and breastfeed the baby, how to care for the infant's cord and circumcision if the infant has one, a review of how much infants sleep during 24 hours, and how to fit a newborn into the family's pattern of living are topics parents like to discuss before discharge. A great deal of teaching can be done by a comment such as "Notice how large all newborns' heads seem" while you are showing the parents how to bathe the baby, or "Babies like to be bundled firmly" while you are helping dress the child, or "Notice how uneven newborn respirations are." This kind of informal instruction saves parents many anxious moments when they are at home. Common instructions for a woman for her first week at home are summarized in [Table 17.3](#).

**TABLE 17.3 POSTPARTAL DISCHARGE INSTRUCTIONS**

<b>Area</b>	<b>Instructions</b>
Work	All women should avoid heavy work (lifting or straining) for at least the first 3 weeks after birth. Women differ in their concept of heavy work, so it is a good idea to explore what a woman considers heavy work. If she plans to do too much, you can perhaps help her to modify her plans. It is usually advised that a woman not return to an outside job for at least 3 weeks (or better, 6 weeks), not only for her own health but also for enjoyment of the early weeks with her newborn.
Rest	A woman should plan at least one rest period each day while her baby sleeps and try to get a good night's sleep. If she has other family members dependent on her, explore the possibility of having a neighbor, another family member, or a person from a community health agency relieve her so she can rest.
Exercise	A woman should limit the number of stairs she climbs to one flight/day for the first week at home. This limitation may involve some planning on her part, especially if her washing machine is in the basement or if she must go up and down stairs to check on her baby. Help her plan for a place for the baby to sleep downstairs to alleviate the second concern. She should continue with muscle-strengthening exercises, such as abdominal crunches.
Hygiene	A woman may take either tub baths or showers. She should continue to apply any perineal cream or ointment. Remind her to cleanse her perineum from front to back after voiding to prevent fecal contamination. Any perineal stitches will be absorbed within 10 days.

Coitus	Coitus is safe as soon as a woman's lochia has turned to alba and, if present, an episiotomy is healed (usually the first week after birth). Vaginal cells may not be as thick as formerly because pre-pregnancy hormone balance has not yet completely returned to supply lubrication. Use of a contraceptive foam or lubricating jelly will aid comfort. Be certain she knows safer sex precautions.
Contraception	If desired, a woman should begin a contraception measure with the initiation of coitus. If she wants an intrauterine device, this may be fitted immediately after birth or at her first postpartal checkup. Combination oral contraceptives are begun about 2–3 weeks after birth due to clotting factor risks and interference with milk production for women who are breastfeeding (progestin-only oral contraceptives can be started earlier). A diaphragm must be refitted at a 6-week checkup. Until she returns for this checkup, an over-the-counter spermicidal jelly and condoms can provide protection.
Follow-up	A woman should notify her primary care provider if she notices an increase, not a decrease, in lochial discharge, or if lochia serosa or lochia alba becomes lochia rubra; if lochia has a foul odor; if she has a temperature greater than 101°F; or if symptoms of sadness last longer than 2 weeks. A woman should schedule a 4- to 6-week checkup so she can be assured involution is complete and immunization if not previously immunized against the virus associated with cervical cancer (human papillomavirus) can be administered and so reproductive life planning (if desired) can be discussed.

Make certain a woman is aware that she must return to her primary care provider for an examination 4 to 6 weeks after birth for a postpartum exam for herself and that she should make an appointment to take her baby to a primary care provider for an examination within the first 3 to 5 days postpartum. A follow-up consultation with a community lactation consultant and lactation support group is highly recommended, especially with mothers who experience initial difficulties or who are breastfeeding for the first time (Busch et al., 2014; Holmes, McLeod, & Bunik, 2013).

## MATERNAL IMMUNIZATIONS

Recent maternal natal immunization guidelines, supported by the Centers for Disease Control and Prevention (CDC, 2017a, 2017b) and the American Congress of Obstetricians and Gynecologists (ACOG, 2015), recommend that each pregnant woman receive a Tdap and seasonal influenza vaccine with each pregnancy. Determine if this was provided prenatally to the women, and if not, inform her primary provider of the need to administer the Tdap and seasonal influenza (if applicable) vaccines prior to

discharge. Other close caregivers of the newborn (partners and grandparents) are also recommended to be up-to-date on their Tdap and influenza vaccines (ACOG, 2015). If a woman does not have an adequate rubella antibody titer and anticipates further pregnancies, she should also be asked if she wants a rubella immunization before discharge and her provider made aware of this need. Women who are Rh negative and who have had an Rh-positive infant will receive Rh<sub>0</sub>(D) immunoglobulin (RhIG) or Rh antibodies to prevent isoimmunization concerns in a future pregnancy (Kline, 2012).

Be certain that home care instructions for the family are given both verbally and in writing. Getting ready to go home, dressing the baby, seeing him or her in new clothes for the first time, and experiencing the thrill of realizing the baby is really theirs to take home is so exciting that it is easy for oral instructions to go unheard.

Many healthcare agencies have a community liaison person, ideally a nurse, who calls or makes a home visit to women after discharge. This person helps the new mother assess her own health and that of her baby and answers questions from families who lose their instructions or are unable to interpret them after they have returned home.

Making a telephone call to or visiting a family 24 hours after discharge is another way to evaluate whether the family is able to continue self-evaluation and infant care and is able to integrate the new infant into the family. Such calls or visits also have the potential to reduce the number of acute care visits and rehospitalizations for newborns.

## POSTPARTAL EXAMINATION

Every woman should have a checkup by her primary care provider at 4 to 6 weeks after birth (the end of the postpartal period) to assure herself and her healthcare provider that she is in good health and has no residual problems from her pregnancy or signs of postpartum depression.

During this examination, the woman's abdominal wall is inspected for tone and to determine that her uterus involution is so complete that the uterus is no longer palpable abdominally. Her breasts are inspected to see whether they have returned to their nonpregnant state if she is not breastfeeding. If she is breastfeeding, assess that she is free of nipple pain or damage and has an established milk supply; discuss any concerns regarding returning to work or school to ensure her goals of breastfeeding are successful. Most important, a thorough internal examination is performed to be certain involution is complete, the ligaments and the pelvic muscle supports have returned to functional alignment, and any lacerations sustained during birth have healed (Table 17.4).

**TABLE 17.4 SIX-WEEK PHYSICAL ASSESSMENT**

Area of Assessment	Data Collection
History	Assess chief concern, family profile (support system, bonding, self-esteem, family integrity), interval history, and review of systems (urinary system for pain, frequency, or stress)

incontinence along with gastrointestinal tract and reproductive tract in particular). Assess maternal intake because some new mothers are too fatigued to eat well.

**Physical Examination**

Expected Findings

General appearance	Alert; positive mood. If not, woman is probably still extremely fatigued.
Weight	Achievement of prepregnant weight; if not, this will be her baseline postpregnant weight.
Hair	Healthy, firm hair; excess loss of hair from early postpartal period has halted.
Eyes	Pink and moist conjunctiva; if pallor persists, diet may be inadequate in iron.
<b>Breasts</b>	
Breastfeeding woman	Full and firm to palpation; blue veins prominent under skin. Areola darkens and nipple elongates. No palpable nodules or lumps. If erythematous or extremely tender, mastitis or nipple fissure may be present. An occasional filled milk gland may present as a lump; reexamine after breastfeeding.
Nonbreastfeeding woman	Return to prepregnant size; no palpable nodules or lumps.
Abdomen	Striae less prominent; linea nigra fading, muscle tone improving. No distended bowel from constipation. No distended bladder from retention. No history of pain, frequency, or blood on urination. Urinary symptoms probably reflect urinary infection that needs specific treatment.
Perineum and uterus	Lochia no longer present; cervix closed; uterus has returned to prepregnant size. Pap test is normal. Ask woman to bear down during pelvic examination to observe for uterine prolapse, rectocele, or cystocele. If involution is not complete, reason for subinvolution must be investigated.
Lower extremities	Varicosities barely noticeable
Rectum	Hemorrhoids receded to prepregnant size or are no longer observable.
Mental	Positive interaction with infant, appropriate personal hygiene (clean hair, etc.). No indication of postpartal depression or psychosis is present.

**Laboratory Reports**

Laboratory values	Hct: 37%; Hgb: 11–12 g/100 ml. If these are low, reassess diet; possibly iron supplement may be needed. Rubella antibody titer: 1:8; if low, additional immunization is recommended before a second pregnancy.
Immunization status	Assess need for human papillomavirus (HPV) [Gardasil] or rubella vaccine.

Hct, hematocrit; Hgb, hemoglobin.

If a woman has hemorrhoids or varicosities as a result of the pregnancy, her primary care provider will discuss with her whether further management of these conditions are necessary. Always ask about the possibility of intimate partner violence because this can increase during the postpartal period because of the added stress of adding a new family member (Malta, McDonald, Hegadoren, et al., 2012). Review the necessity of having a breast examination, Papanicolaou (Pap) smear, and pelvic examination every year as a means of screening for breast, cervical, and uterine cancer. If a woman is older than 40 years, include a discussion about the need for mammogram examinations. Encourage women who have stopped smoking during pregnancy to continue to be smoke free as yet another good health measure for both themselves and their new child, especially if she is breastfeeding.

If reproductive life planning was not discussed immediately after birth, this visit is the opportune time for such a discussion. If a woman desires to use a diaphragm or a cervical cap, these can be fitted during this examination. Injectable progesterone (depot medroxyprogesterone acetate) also can be begun at this time or an intrauterine device (IUD) can be placed. Women who are breastfeeding can begin on progesterone-only birth control pills, implant, or an IUD (Academy of Breastfeeding Medicine [ABM], 2015; Costa, Cecatti, Krupa, et al., 2012).

### *QSEN Checkpoint Question 17.6*

#### **INFORMATICS**

The nurse cares for Leana Cooper at a 6-week postpartum visit. The nurse reads in Leana's electronic health record that her fundal height has been progressing in a healthy and predicted manner. What should her fundal height be during this current visit?

- At least six fingerbreadths below the umbilicus
- No longer palpable over the symphysis pubis
- Four centimeters below the top of the iliac crest
- Still palpable above her pubic hair line

*Look in Appendix A for the best answer and rationale.*

## **Nursing Care of a Postpartal Woman and Family With**

## Unique Needs

### A WOMAN WHO CHOOSES NOT TO KEEP HER CHILD

Although the availability of birth control information and the availability of postcoital pregnancy protection have reduced the number of unwanted or unintended pregnancies, some women still may complete a pregnancy and then give up their child for adoption immediately after birth. There are numerous reasons for a decision such as this: The pregnancy may have been unplanned, a woman may be unmarried, she may not be ready or want to assume the responsibilities of parenthood, or her marriage may be failing and she does not want to raise a child alone. She may feel that her family is already complete. She may want to finish school before having a child, or she may want to pursue a career.

During pregnancy, most women decide whether they will keep their child. During labor, they express confidence in their decision, but with the actual birth of their child, they may find their resolve wavers. A woman who was certain she was going to surrender her child for adoption may realize she wants to keep the child. A woman who was certain she was going to keep her child could become aware for the first time of the responsibility involved and decide that the best course for the child is adoption. In either event, a woman's feelings can become confused.

For a woman who chooses not to keep her child, the wait in the birthing room for preparations to transfer the baby to a nursery may seem unusually long. She may also be alone, with no partner or support person with her during this time. Every woman has a right to see, hold, and feed her child if she wishes. A woman who is not going to keep her child may feel proud that she has produced a healthy baby. The realization that the baby is well can provide a foundation on which to build a sounder future so she does not have to make this choice again.

Do not attempt to change a woman's mind about keeping her child or placing the child for adoption during the postpartal period because she is extremely vulnerable to suggestion at this time, and such decisions are too long range and too important to be made at such an emotional time. Her earlier conclusion may be the sound one. Instead, offer nonjudgmental support. Be especially aware of your own feelings about this issue to avoid influencing a woman's decision making unnecessarily.

During the taking-in phase of the puerperium, be especially careful that you do not "lead" the woman's thinking. Women enjoy having decisions made for them during this time and may ask what you think is best. An answer such as "You're the one who has to make this decision. What are your thoughts about it?" can help her begin to think through the problem.

It is not uncommon for women who surrender their infants for adoption to experience grief reactions, the same as those of women whose children have died. If a woman decides to surrender her child for adoption, refer her to an official adoption agency, if she has not contacted one already, because an official agency gives a woman the best assurance the parents chosen for her child will be appropriate. This assurance

can help relieve any misgivings or guilt she may feel in future years about surrendering the child, such as wondering whether the child is well cared for and is getting everything the mother could have given her.

Some women do not openly voice a wish to give up their child, but their actions demonstrate they feel little attachment to their newborn. A woman who wants to keep her baby has a tentative but eager approach to her newborn, whereas a woman who has doubts is slow to make contact, barely touching the baby even by the time of discharge, and asking few questions about newborn care. When this happens, the hospital social service department can be of assistance in helping the woman plan the child's future.

It is a fallacy to assume that everything will work out once the woman and infant arrive home. The number of children who experience intrafamily maltreatment seen in hospital emergency departments is proof of the harm that can follow when assessment to detect poor parent-child bonding is inadequate in the first few days of life (Louwers, Korfage, Affourtit, et al., 2012).

## **A WOMAN WHO IS DISCHARGED BUT WHOSE CHILD REMAINS HOSPITALIZED**

Newborns who are ill at birth often are transported to a regional center or to a neonatal intensive care nursery for care, a move that automatically separates them from their parents. Encourage parents to take photographs of the baby on their phone or using a camera before transport and to be certain they have the nursery telephone number and the name of a nurse to contact for questions or information. Most transport teams call the parents after they arrive at the transfer hospital to assure them their infant managed the stress of transport well.

Maintaining communication with the nursery is important so parents can begin to bond with their child despite the imposed separation. Urge them to call the nursery at least once daily to ask about their infant. If the infant is hospitalized in the same hospital, help transport the mother to the nursery, so that she can see and, ideally, hold her child daily. Without this assistance, some women will be so overwhelmed by the technology in the nursery, they are reluctant to call or visit. Assure a mother her telephone calls and visits are expected and valued. A new movement is forming to allow the mother to room-in with the baby in "family style" hospital rooms. This allows the mother (and partner/father) to be close and with their baby, especially for breastfeeding and bonding promotion. Visiting in an intensive care nursery is further discussed in [Chapter 26](#).

It is easy for a woman who is separated from her newborn to feel despondent. Be certain to evaluate whether a woman seems depressed or needs additional support to overcome this unexpected outcome to her pregnancy.

## **A FAMILY WHO IS ADOPTING A CHILD**

A family who is adopting an infant may come into the hospital or birthing center to

meet their new infant for the first time. Such a couple needs the same introduction to newborn care as biologic parents. Additional needs of adopting parents are discussed in [Chapter 3](#).

#### *What If... 17.4*

**The nurse is interested in exploring one of the 2020 National Health Goals related to postpartal care (see [Box 17.1](#)). Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Cooper family and also advance evidence-based practice?**

### KEY POINTS FOR REVIEW

- The postpartal period (puerperium) is the 6-week period after childbirth. Women move through an initial “taking-in” phase, in which they are dependent; a “taking-hold” phase, in which they manifest independence; and a “letting-go” phase, in which the mother role is finally defined.
- Rooming-in is the preferred healthcare agency arrangement for postpartal families because it allows a new family the best chance for quality interaction and promote breastfeeding ([Baby-Friendly USA, n.d.](#); [Holmes et al., 2013](#)). The more time new parents spend with a newborn, the more likely it is that effective bonding will occur. Help parents to feel comfortable with their newborn by offering anticipatory guidance and role modeling infant care as this not only helps in planning nursing care that meets QSEN competencies but also best meets the family’s total needs.
- “Postpartal blues” are a normal accompaniment to childbirth. You can assure a woman that such feelings are normal and offer supportive care until the emotion passes.
- Uterine involution is the process whereby the uterus returns to its prepregnant state. A uterus decreases in size one fingerbreadth (1 cm) a day until it disappears under the pubic bone at about day 10. Lochia is the name of the vaginal flow after childbirth: The flow is lochia rubra (red) for the first 1 to 3 days, lochia serosa (pink to brown) on days 4 through 10, and lochia alba (white) until 2 to 6 weeks after the birth.
- A woman is at great risk for hemorrhage in the postpartal period, so assessments done to reveal this are some of the most critical assessments made in nursing. Do not discount the importance of these assessments because the overall content of the postpartal period is so focused on wellness.
- Lactation is the production of breast milk. Colostrum is present immediately after birth; milk forms on the third to fourth postpartal day. A feeling of fullness and firmness on this day is termed *filling*; if warmth and discomfort occur, it is termed *engorgement*. Assessing the mother’s milk production, infant’s latch, painful nipples,

and ability to transfer milk is crucial in the early postpartum period.

- Women may need various comfort measures to alleviate pain from uterine pain (afterpains) and breast tenderness. Application of cold or heat and administration of analgesics are important nursing interventions.
- Women need to learn about self-care before healthcare agency discharge, so they can maintain self-care at home. A follow-up telephone call or home visit can be helpful to answer questions. All women should conscientiously return for a health assessment visit at 6 weeks after childbirth to be certain their reproductive organs have returned to their nonpregnant state. Menstrual flow should return within 6 to 10 weeks in the nonbreastfeeding mother or after 3 to 4 months in the breastfeeding mother.

### CRITICAL THINKING CARE STUDY

Katie is a 30-year-old primigravida. She is being discharged with her healthy daughter Sarah this evening. Katie delivered vaginally 50 hours ago without complications and is breastfeeding without difficulty. You chart evidence of positive bonding behaviors. Her postdelivery hemoglobin is 9.5 mg/dl. She has a history of depression during high school. Her mother is planning to help for the next few weeks until Katie and Sarah get settled at home.

1. While preparing for Katie's discharge, you would anticipate teaching about which factors that are most concerning to you?
2. Katie's mother is a support person for her, so how can you include her family in the education?
3. What parenting behaviors would indicate positive bonding between Katie and Sarah?

## Nursing Care of a Family With a Newborn

*Carlotta Ruiz, a 29-year-old woman, has just given birth to her second child, a 39 weeks and 2 days, 6-lb, 5-oz baby girl named Beth. Apgar scores at 1 and 5 minutes were 6 and 8, respectively. Vital signs are temperature (axillary), 98.2°F (36.8°C); heart rate, 136 beats/min; and respirations, 74 breaths/min. Beth is 18.5 in. long, with a head circumference of 34 cm and a chest circumference of 32 cm. She has a small port-wine birthmark on her right thigh.*

*While Jose, Carlotta's husband, is in the room, Carlotta tells you she is a "veteran" at baby care. Jose adds, "Little Joe [their 3-year-old] will be so excited to see his new sister. That's all he's been talking about."*

*When Carlotta is alone, you notice she seems apprehensive about caring for her new daughter. She tells you, "She's so much smaller than Joe was. And why does it sound like she has a cold? Or have this rash all over her? Isn't it bad enough she has a birthmark?"*

*Previous chapters described the care of a pregnant woman and family during the antepartal, intrapartal, and postpartal periods. This chapter adds information about caring for the family with a newborn. The newborn period is a critical one for a family because it lays the foundation for the rest of the family's childrearing years.*

**Does Carlotta know as much about newborns as she thought? What additional teaching does this family need?**

### KEY TERMS

acrocyanosis  
 acute bilirubin encephalopathy  
 caput succedaneum  
 cavernous hemangioma  
 central cyanosis  
 cephalohematoma  
 conduction  
 convection  
 erythema toxicum

**evaporation**  
**hemangioma**  
**jaundice**  
**lanugo**  
**meconium**  
**milia**  
**mongolian spot**  
**natal teeth**  
**neonatal period**  
**nevus flammeus**  
**newborns**  
**physiologic jaundice**  
**pseudomenstruation**  
**radiation**  
**strawberry hemangioma**  
**subconjunctival hemorrhage**  
**thrush**  
**transitional stool**  
**vernix caseosa**

## **OBJECTIVES**

**After mastering the contents of this chapter, you should be able to:**

1. Describe the normal characteristics of a term newborn.
2. Identify 2020 National Health Goals related to newborn care that nurses could help the nation achieve.
3. Assess a newborn for normal growth and development.
4. Formulate nursing diagnoses related to a newborn or the family of a newborn.
5. Identify expected outcomes for a newborn and family during the first 4 weeks of life to help them manage seamless transitions across different healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care for a normal newborn, such as instructing parents on the care of their newborn.
8. Evaluate outcome criteria for the achievement and effectiveness of care.
9. Integrate knowledge of newborn growth and development with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

Newborns undergo profound physiologic changes at the moment of birth (and, probably, psychological changes as well) as they are released from a warm, snug, dark, liquid-filled environment that has met all of their basic needs into a chilly, unbounded, brightly lit, gravity-based, outside world. Within minutes after being plunged into this strange environment, a newborn has to initiate respirations and adapt a circulatory system to extrauterine oxygenation. Within 24 hours, neurologic, renal, endocrine, gastrointestinal, and metabolic functions must be operating competently for life to be sustained.

How well a newborn makes these major adjustments depends on his or her genetic composition, the competency of the recent intrauterine environment, gestational duration, presence of fetal anomalies, the care received during labor and birth, and the care received during the newborn or **neonatal period** (the time from birth through the first 28 days of life) (Swanson & Sinkin, 2015). One half of all deaths that occur during the first year of life occur in the neonatal period and more than one million babies die every year in the first 24 hours after birth—an indication of how hazardous a time this is for an infant (Save the Children, 2014).

Newborn health is so important to families that the 2020 National Health Goals related to newborn health have been revised (Box 18.1). Nurses play a major role in achieving these goals because nurses are uniquely suited to give care to newborns and newborn instructions to parents.

### BOX 18.1

#### Nursing Care Planning Based on 2020 National Health Goals

A number of 2020 National Health Goals speak directly to the newborn period:

- Increase the proportion of mothers who breastfeed their babies in the early postpartal period from a baseline of 74% to 81.9%.
- Increase the proportion of mothers who continue exclusive breastfeeding until their babies are 3 months old from a baseline of 33.6% to 46.2%.
- Increase the percentage of healthy full-term infants who are put to sleep on their backs from a baseline of 69% to 75.9%.
- Reduce the proportion of young children aged 3 to 5 years with dental caries in their primary teeth (which could originate from nighttime bottle feeding) from a baseline of 33.3% to 30%.
- Reduce the perinatal mortality rate to no more than 5.9 per 1,000 live births from a baseline of 6.6 per 1,000 live births (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by encouraging women to not only begin breastfeeding but to also continue breastfeeding through the first 6 months of life, by advising parents of the importance of placing infants in their own beds and on their backs to sleep, and advising parents of the danger of tooth decay from allowing a baby to drink from a bottle of milk or juice while falling asleep. By discussing early

signs and symptoms of illness in a newborn, parents can learn to better evaluate their newborn's health and ask for their primary care provider's opinion before their infant becomes seriously ill.

### *Nursing Process Overview*

## FOR HEALTH PROMOTION OF THE TERM NEWBORN

### **ASSESSMENT**

The assessment of a newborn includes a review of the mother's pregnancy history; a physical examination of the infant; an analysis of laboratory reports such as hematocrit, bilirubin, and blood type; and an assessment of parent–child interactions to be certain bonding is beginning. This assessment begins immediately after birth and is continued at every contact during a newborn's birthing center stay, at early home visits, and at well-baby and sick baby visits. Teaching new mothers and their partners to make assessments concerning their infant's temperature, respiratory rate, and overall health is crucial so they can continue to monitor their infant's health at home.

### **NURSING DIAGNOSIS**

Nursing diagnoses associated with newborns center on the difficulty of establishing respirations, beginning nutrition, and assisting with parent–newborn bonding.

Examples include:

- Ineffective airway clearance related to mucus in the airway
- Ineffective thermoregulation related to heat loss from exposure in the birthing room
- Imbalanced nutrition, less than body requirements, related to poor sucking reflex
- Readiness for enhanced family coping related to birth of infant
- Health-seeking behaviors related to newborn needs

If a minor deviation from the normal is present, such as a birthmark, a diagnosis such as “Parental fear related to hemangioma on left thigh of newborn” might be relevant.

### **OUTCOME IDENTIFICATION AND PLANNING**

Nursing care planning should take into account the newborn's needs during this transition period, a mother's need for adequate rest during the postpartum period, and the parents' need to become acquainted with their new child. Try to adapt teaching time to the schedules of the mother, her partner, and the newborn. Although the woman must learn as much as possible about newborn care, she also must go home from the healthcare setting with enough energy to practice what she has learned. Important planning measures for newborns include helping them regulate their temperature and helping them grow accustomed to feeding. Refer parents to helpful websites and other resources when appropriate.

## IMPLEMENTATION

Role modeling by the nurse during the newborn period is an effective way to help new parents grow confident with their newborn. Parents will be observing you closely. Conserving newborn warmth and energy, to help prevent hypoglycemia and respiratory distress, should be an important consideration during all interventions.

## OUTCOME EVALUATION

An evaluation of expected outcomes should reveal that a baby's primary caregiver is able to give beginning newborn care with confidence. Be certain a woman and her partner make arrangements for continued health supervision for their newborn, so the infant's long-term health needs are met.

Examples indicating achievement of outcomes concerning newborns include:

- Infant establishes respirations of 30 to 60 breaths/min.
- Infant maintains temperature at 97.8° to 98.6°F (36.5° to 37°C).
- Mother demonstrates competence in caring for newborn.
- Infant breastfeeds well with a strong sucking reflex.

## The Profile of a Newborn

It is not unusual to hear the comment “all newborns look alike” from people viewing a nursery full of babies. In actuality, every child is born with individual physical and personality characteristics that make him or her unique right from the start (Fig. 18.1).

**Figure 18.1** Personality is apparent in a newborn from the start. Note the alert, searching interest.

Some newborns are born stocky and short, some are large and bony, and some are

thin and rangy. Some have a temperament that causes them to feed greedily, protest procedures loudly, and respond to their parent's inexperienced handling with restlessness and spitting up. Other newborns are sleepy, make no protest over procedures or diaper changes, and seem passive in their new life circumstances. With experience in working with newborns, it becomes easier to differentiate newborns who are merely demonstrating these extremes of normal behavior from those whose behavior or appearance indicates a need for more skilled care because their adjustment to independent life is not progressing smoothly (Box 18.2).

## BOX 18.2

### Nursing Care Planning Using Assessment

#### ASSESSING THE AVERAGE NEWBORN

## VITAL STATISTICS

Vital statistics measured for a newborn usually consist of the baby's weight, length, and head and chest circumferences. The technique for obtaining these is shown in Chapter 34, along with other aspects of health assessment. Be certain all healthcare providers who care for newborns are aware of safety issues specific to newborn care when taking these measurements, such as not leaving a newborn unattended on a bed or scale and protecting against hypothermia.

## WEIGHT

As long as newborns are breathing well, they are weighed nude and without a blanket

soon after birth in the birthing room (Fig. 18.2). Measurements such as body length and head, chest, and abdominal circumferences are also done but can be obtained later because performing these measurements while an infant is still damp exposes the newborn unnecessarily to chilling.

**Figure 18.2** Weighing a newborn. Notice the protective hand held over the infant.

A newborn's weight is important because it helps to determine maturity as well as establish a baseline against which all other weights can be compared. Following this initial weight, an infant is weighed nude once a day, at approximately the same time every day, during a hospital or birthing center stay.

The birth weight of newborns varies depending on the racial, nutritional, intrauterine, and genetic factors that were present during conception and pregnancy. The weight in relation to the gestational age should be plotted on a standard neonatal graph, such as those available at the Centers for Disease Control and Prevention (CDC) website based on World Health Organization (WHO) growth standards at [http://www.cdc.gov/growthcharts/who\\_charts.htm#TheWHOGrowthCharts](http://www.cdc.gov/growthcharts/who_charts.htm#TheWHOGrowthCharts). Plotting weight this way helps identify newborns who are at risk because they are less than usual weight. This information also separates those who are small for their gestational age (newborns who have suffered intrauterine growth restriction) from preterm infants (infants who are healthy but small in weight only because they were born early).

Plotting weight in conjunction with height and head circumference is also helpful because it highlights disproportionate measurements. All three of these measurements should fall near the same percentile in an individual child. For example, a newborn who falls within the 50th percentile for height and weight but whose head circumference is in

the 90th percentile may have abnormal head growth. A newborn who is in the 50th percentile for weight and head circumference but in the 3rd percentile for height may have a growth problem. Such discrepancies must be monitored over time to determine trends and any needed interventions.

According to [CDC \(2010\)](#) Growth Chart data, the average birth weight (50th percentile) for a mature female newborn is 3.4 kg (7.5 lb) and for a mature male newborn is 3.5 kg (7.7 lb). Newborn weights vary according to ethnicity and background. The arbitrary lower limit of expected birth weight for all newborns is 2.5 kg (5.5 lb). Birth weight exceeding 4.7 kg (10 lb) is unusual, but weights as high as 7.7 kg (17 lb) have been documented ([CDC, 2010](#)).

If a term newborn weighs more than 4.7 kg, the baby is said to be macrosomic, a condition that usually occurs in conjunction with a maternal illness, such as gestational diabetes ([Feldman, Tieu, & Yasumura, 2016](#)). Second-born children usually weigh more than first-born ones. Birth weight continues to increase with each succeeding child in a family.

During the first few days after birth, a newborn loses 5% to 10% of birth weight (6 to 10 oz) ([Thulier, 2016](#)). This weight loss occurs because a newborn is no longer under the influence of salt- and fluid-retaining maternal hormones. This causes diuresis to begin to remove a part of the infant's high fluid load. In addition, the newborn voids and passes stool. Breastfed newborns have a limited intake until about the third day of life because of the relatively low caloric content and small amount of colostrum they ingest; formula-fed newborns need time to establish effective sucking. This lack of intake also plays a part in weight loss.

After this initial loss of weight, a newborn has about 1 day of stable weight and then begins to gain weight. The breastfed newborn recaptures birth weight within 10 days; a formula-fed infant accomplishes this gain within 7 days. After this, all infants begin to gain about 2 lb per month (6 to 8 oz per week) for the first 6 months of life.

While the newborn is still in the birthing center, compare the weight obtained each day with that of the preceding day to be certain an infant is not losing more than 10% of birth weight because abnormal loss of weight may be the first indication that a newborn has an inborn error of metabolism, such as adrenocortical insufficiency (salt-dumping type) or is becoming dehydrated.

### *What If . . . 18.1*

**Mrs. Ruiz tells the nurse she wants to weigh Beth on an infant scale after each feeding to be certain Beth's getting enough breast milk. Would the nurse agree that is a good idea? What would the nurse want Mrs. Ruiz to know before she does this?**

## **Length**

A newborn's length at birth in relation to weight is a second important determinant used to confirm that a newborn is healthy.

- The average birth length (50th percentile) of a mature female newborn is 49 cm (19.2 in.).
- For mature males, the average birth length is 50 cm (19.6 in.).
- The lower limit of expected birth length is arbitrarily set at 46 cm (18 in.).
- Although rare, babies with lengths as great as 57.5 cm (24 in.) have been reported.

### Head Circumference

Head circumference is measured with a tape measure drawn across the center of the forehead and then around the most prominent portion of the posterior head (the occiput) (see [Chapter 34](#), [Fig. 34.5](#)).

- In a mature newborn, the head circumference is usually 34 to 35 cm (13.5 to 14 in.).
- A mature newborn with a head circumference greater than 37 cm (14.8 in.) or less than 33 cm (13.2 in.) should be carefully assessed for neurologic involvement, although some well newborns have these measurements.

### Chest Circumference

Chest circumference is measured at the level of the nipples. If a large amount of breast tissue or edema of the breasts is present, this measurement will not be accurate until the edema has subsided. The chest circumference in a term newborn is about 2 cm (0.75 to 1 in.) less than head circumference.

## VITAL SIGNS

Vital sign measurements begin to change from those present in intrauterine life at the moment of birth.

### Temperature

The temperature of newborns is about 99°F (37.2°C) at birth because they have been confined in their mother's warm and supportive uterus. Temperature will fall almost immediately to below normal because of heat loss, the temperature of birthing rooms (approximately 68° to 72°F [21° to 22°C]), and the infant's immature temperature-regulating mechanisms if the baby is not protected from heat loss at birth and in the moments afterward.

The majority of heat loss occurs because of four separate mechanisms: convection, radiation, conduction, and evaporation ([Fig. 18.3](#)).

**Figure 18.3** Heat loss in the newborn. **(A)** Convection. **(B)** Radiation. **(C)** Conduction. **(D)** Evaporation.

- **Convection** is the flow of heat from the newborn's body surface to cooler surrounding air. Eliminating drafts, such as from air conditioners, is an important way to reduce convection heat loss.
- **Radiation** is the transfer of body heat to a cooler solid object not in contact with the baby, such as a cold window or air conditioner. Moving an infant as far from the cold surface as possible helps reduce this type of heat loss.
- **Conduction** is the transfer of body heat to a cooler solid object in contact with a baby. For example, a baby placed on the cold base of a warming unit quickly loses heat to the colder metal surface. Covering surfaces with a warmed blanket or towel is necessary to help minimize conduction heat loss.
- **Evaporation** is loss of heat through conversion of a liquid to a vapor. Newborns are wet when born, so they can lose a great deal of heat as the amniotic fluid on their skin evaporates. To prevent this type of heat loss, lay a newborn on the mother's abdomen immediately after birth and cover with a warm blanket for skin-to-skin contact (Moore, Anderson, Bergman, et al., 2012). In addition, drying the infant—especially the face and hair—also effectively reduces

evaporation because the head, which is a large surface area in a newborn, can be responsible for a great amount of heat loss. Covering the hair with a cap after drying further reduces the possibility of evaporation cooling.

A newborn not only loses heat easily by the means just described but also has difficulty conserving heat under any circumstance. Insulation, an efficient means of conserving heat in adults, is not as effective in newborns because they have little subcutaneous fat to provide insulation. Shivering, a means of increasing metabolism and thereby providing heat in adults, is also rarely seen in newborns.

Newborns can conserve heat by constricting blood vessels and moving blood away from the skin. *Brown fat*, a special tissue found in mature newborns, apparently helps to conserve or produce body heat by increasing metabolism as well as regulating body temperature similar to that of a hibernating animal. The greatest amounts of brown fat are found in the intrascapular region, the thorax, and behind the kidneys.

Other ways newborns are able to increase their metabolic rate and produce more heat include kicking and crying. This reaction, however, also forces them to increase their respiratory rate to allow them to take in more oxygen. All newborns can easily become fatigued from this extra exertion, thus placing additional strain on an already stressed cardiovascular system. An immature newborn with poor lung development may have extreme difficulty making such an adjustment and may fail to deliver sufficient oxygen to body systems.

In addition, as muscles become overstressed, they release lactic acid. Every newborn is born slightly acidotic. Any new buildup of acid created by cold exposure may lead to further acidosis that could be life-threatening.

Drying and placing newborns on their mother's abdomen (covered by a warm blanket), drying and wrapping them and placing them in warmed cribs, or drying and placing them under a radiant heat source is an excellent mechanical measure to help conserve heat or prevent heat loss. Perform all early newborn care speedily and expose the newborn to cool air as little as possible. Be certain that any procedure during which a newborn must be uncovered such as resuscitation or circumcision is done under a radiant heat source.

If chilling is prevented by these methods, a newborn's temperature stabilizes at 98.6°F (37°C) within 4 hours after birth. In contrast to an adult who typically runs an increased temperature with an infection, a newborn may run a subnormal temperature. Therefore, if a newborn's temperature does not stabilize shortly after birth, the cause needs to be investigated to rule out an infection ([Ramachandrappa & Jain, 2015](#)).

## Pulse

The heart rate of a fetus in utero averages 110 to 160 beats/min. Immediately after birth, as the newborn struggles to initiate respirations, the heart rate may be as rapid as 180 beats/min. Within 1 hour after birth, as the newborn settles down to sleep, the heart rate stabilizes to an average of 120 to 140 beats/min.

The heart rate of a newborn often remains slightly irregular because of immaturity

of the cardiac regulatory center in the medulla, and transient murmurs may result from the incomplete closure of fetal circulation shunts. During crying, the rate may rise again to 180 beats/min. In addition, heart rate can decrease during sleep, ranging from 90 to 110 beats/min.

You should be able to palpate femoral pulses in a newborn. Radial and temporal pulses are more difficult to palpate accurately. Therefore, a newborn's heart rate is best determined by listening for an apical heartbeat for a full minute rather than assessing a pulse in an extremity or over the carotid artery. Always palpate for femoral pulses and document that they are present because their absence suggests possible coarctation (narrowing) of the aorta, which is a cardiovascular abnormality (Lissauer, 2015).

## Respiration

The respiratory rate of a newborn in the first few minutes of life may be as high as 90 breaths/min. As respiratory activity is established and maintained over the next hour, this rate will settle to an average of 30 to 60 breaths/min. Respiratory depth, rate, and rhythm are likely to be irregular, and short periods of apnea (without cyanosis), sometimes called *periodic respirations*, are also common and normal during this time. Respiratory rate can be observed most easily by watching the movement of a newborn's abdomen because breathing primarily involves the use of the diaphragm and abdominal muscles.

Coughing and sneezing reflexes are present at birth and help clear the airway. Newborns are obligate nose breathers and show signs of distress if their nostrils become obstructed. Short periods of crying, which increase the depth of respirations and aid in aerating deep portions of the lungs, may be beneficial to a newborn. Long periods of crying, however, exhaust the cardiovascular system, become fatiguing, and serve no purpose.

## Blood Pressure

The blood pressure of a newborn is approximately 80/46 mmHg at birth. By the 10th day, it rises to about 100/50 mmHg and remains at that level for the infant year. Because measurement of blood pressure in newborns is somewhat inaccurate due to the small size of their arms, it is not routinely measured unless a cardiac anomaly is suspected. For an accurate reading, the cuff width used must be no more than two thirds the length of the upper arm or thigh.

Blood pressure tends to increase with crying (and a newborn cries when disturbed and manipulated by such procedures such as taking blood pressure), so a Doppler method may achieve better results (see [Chapters 34](#) and [36](#)). Hemodynamic monitoring is used when continuous assessment is required.

### *QSEN Checkpoint Question 18.1*

#### **PATIENT-CENTERED CARE**

Beth Ruiz, like all newborns, is in danger of losing body heat by conduction. The nurse is taking action to ensure that Beth's body temperature is maintained to protect her health and comfort. Under which condition is heat loss by conduction most likely to occur?

- a. A fan is operating in the room.
- b. Beth is wet from amniotic fluid at birth.
- c. She pulls off the cap the nurse put on her head.
- d. The nurse place her on a scale that has not been prewarmed.

---

*Look in [Appendix A](#) for the best answer and rationale.*

---

## PHYSIOLOGIC FUNCTIONS

Just as changes occur in vital signs after birth, so do changes in all major body systems.

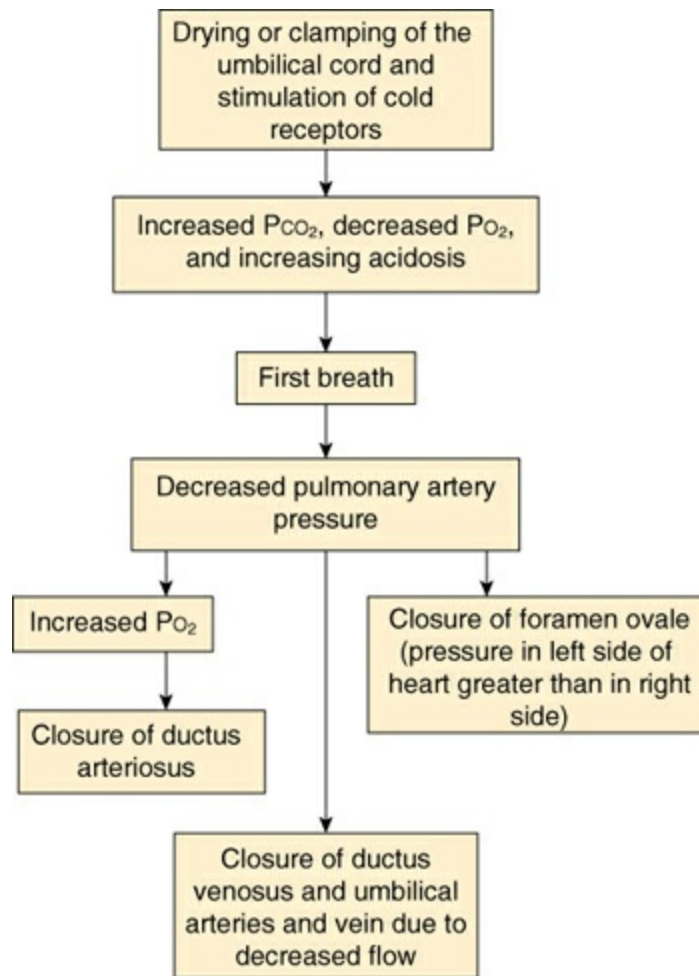

### Cardiovascular System

Changes in the cardiovascular system are necessary after birth because now, the lungs are responsible for oxygenating blood that was formerly oxygenated by the placenta. As soon as the umbilical cord is clamped, which stimulates a neonate to take in oxygen through the lungs, fetal cardiovascular shunts begin to close.

With the first breath, blood pressure decreases in the pulmonary artery (the artery leading from the heart to the lungs). As this pressure decreases, the ductus arteriosus, the fetal shunt between the pulmonary artery and aorta, begins to close. At the same time, increased blood flow to the left side of the heart causes the foramen ovale (the opening between the right and left atria) to close because of the pressure against the lip of the structure (permanent closure does not occur for weeks). With the remaining fetal circulatory structures (umbilical vein, two umbilical arteries, and ductus venosus) no longer receiving blood from the placenta, the blood within them clots and closes them, and the vessels atrophy over the next few weeks.

[Figure 18.4](#) summarizes these respiratory and cardiovascular changes that occur at birth. The peripheral circulation of a newborn remains sluggish for at least the first 24 hours, which can cause cyanosis in the infant's feet and hands (**acrocyanosis**) and for a newborn's feet to feel cold to the touch.

**Figure 18.4** Circulatory events at birth.

## Blood Values

A newborn's blood volume is 80 to 110 ml/kg of body weight or about 300 ml total. Because a newborn has more red blood cells than the average adult, the hemoglobin level averages 17 to 18 g/100 ml of blood (the average for an adult is 11 to 12 g/ml). A newborn's hematocrit is between 45% and 50% (for an adult, 36% to 45%). A newborn's red blood cell count is about 6 million cells/mm<sup>3</sup> (for an adult, 3.5 to 5.5 million cells/mm<sup>3</sup>).

Capillary heel sticks may reveal a falsely high hematocrit or hemoglobin value because of sluggish peripheral circulation. Before obtaining a blood specimen from a heel, warm the foot by wrapping it in a warm cloth to increase circulation and improve the accuracy of this value.

Once proper lung oxygenation has been established, the need for the high red cell count diminishes so, within a matter of days, red cells begin to be destroyed. As these cells are broken down, bilirubin is released and the serum indirect bilirubin level rises. At birth, the indirect bilirubin level is between 1 and 4 mg/100 ml. Any increase over this amount reflects that excessive red blood cells have begun their breakdown (Maheshwari & Carlo, 2016).

A newborn has a corresponding high white blood cell count, about 15,000 to 30,000 cells/mm<sup>3</sup> at birth (40,000 cells/mm<sup>3</sup> if the birth was stressful). Seeing the count increased, therefore, is not evidence of infection but reflects how stressful an event birth is for a fetus. However, although the high white blood cell count makes infection difficult to prove in a newborn, infection must not be dismissed as a possibility if other signs of infection such as pallor, respiratory difficulty, or cyanosis are present. Usual blood values in a newborn are available at <http://thePoint.lww.com/Flagg8e>.

## Blood Coagulation

Vitamin K, synthesized through the action of intestinal flora, is responsible for the formation of factor II (prothrombin), factor VII (proconvertin), factor IX (plasma thromboplastin component), and factor X (Stuart-Prower factor) in the clotting sequence. Because a newborn's intestine is sterile at birth unless membranes were ruptured more than 24 hours, it will take about 24 hours for flora to accumulate and for ongoing vitamin K to be synthesized. This causes most newborns to be born with a lower than usual level of vitamin K, leading to a prolonged coagulation or prothrombin time.

Because almost all newborns can be predicted to have this diminished blood coagulation ability, vitamin K (AquaMEPHYTON) is usually administered intramuscularly into the lateral anterior thigh, the preferred site for all injections in newborns, immediately after birth (Box 18.3). If parents object to an injection, vitamin K can be administered orally, although it is not as effective (Karch, 2013). Whether giving this orally or by injection, be certain the administration doesn't interfere with parent bonding or beginning breastfeeding as these are also vitally important in the first hours after birth.

### BOX 18.3

#### Nursing Care Planning Based on Responsibility for Pharmacology

##### **VITAMIN K (PHYTONADIONE, AQUAMEPHYTON)**

**Action:** Vitamin K is used to prevent and treat hemorrhagic disease in newborns. It is a necessary component for the production of certain coagulation factors (II, VII, IX, and X) and is produced by microorganisms in the intestinal tract (Karch, 2013).

**Pregnancy Risk Category:** C

**Dosage:** Prophylaxis: 0.5 to 1.0 mg intramuscularly (IM) one time in the first hour after birth; treatment of hemorrhagic disease: 1 to 2 mg IM or subcutaneously (SC) daily

**Possible Adverse Reactions:** Local irritation, such as pain and swelling at the site of injection.

**Nursing Implications**

- Anticipate the need for injection within an hour after birth.
- Administer IM injection into a large muscle, such as the anterolateral muscle of a newborn's thigh.
- Be certain to administer the injection at a time it doesn't interrupt parent-child bonding or beginning breastfeeding.
- If giving vitamin K for treatment, obtain prothrombin time before administration (the single best indicator of vitamin K-dependent clotting factors).
- Assess for signs of bleeding in the infant, such as black, tarry stools (different from meconium stools, which have a greenish shade), hematuria (blood in urine), decreased hemoglobin and hematocrit levels, and bleeding from any open wound or at the base of the cord. (These signs would indicate more vitamin K is necessary because bleeding control has not been achieved.)

## The Respiratory System

A first breath is a major undertaking because it requires a tremendous amount of pressure (about 40 to 70 cm H<sub>2</sub>O) for a newborn to be able to inflate alveoli for the first time. The reflex to breathe is initiated by a combination of cold receptors; a lowered partial pressure of oxygen (P<sub>O</sub><sub>2</sub>), which falls from 80 mmHg to as low as 15 mmHg before a first breath; and an increased partial carbon dioxide pressure (P<sub>CO</sub><sub>2</sub>), which rises as high as 70 mmHg before a first breath.

Some fluid present in the lungs from intrauterine life makes a newborn's first breath possible because fluid eases surface tension on alveolar walls and allows alveoli to inflate more easily than if the lung walls were dry. About one third of this fluid is forced out of the lungs by the pressure of vaginal birth. The rest of the fluid is quickly absorbed by lung blood vessels and lymphatics after the first breath.

Once the alveoli have been inflated this first time, breathing becomes much easier for a baby, requiring only about 6 to 8 cm H<sub>2</sub>O pressure. Within 10 minutes after birth, most newborns have established easy respirations as well as a good residual volume. By 10 to 12 hours of age, vital capacity is established at newborn proportions (the heart in a newborn takes up proportionately more space than in an adult, so the amount of lung expansion space available for a large vital capacity is limited).

A baby born by cesarean birth does not have as much lung fluid expelled at birth as one born vaginally and so typically has more difficulty establishing respiration because excessive fluid blocks air exchange space. Preterm newborn alveoli may collapse each time they exhale (because of the lack of pulmonary surfactant). As a result, they also have difficulty establishing effective residual capacity and respirations. In these infants, because alveoli do not open well, the foramen ovale and ductus arteriosus also may not close as usual. This happens because their closure depends on free blood flow through the pulmonary artery and good oxygenation of blood.

Because of the association between ineffective respirations and heart disease, any newborn who had difficulty establishing respirations at birth needs to be examined

closely in the postpartal period for a cardiac murmur or any other indication that he or she still has the patent cardiac structures from fetal life, especially a patent ductus arteriosus (Benitz, 2015).

## The Gastrointestinal System

Although the gastrointestinal tract is usually sterile at birth, bacteria may be cultured from the tract in most babies within 5 hours after birth and from all babies at 24 hours of life. Most of these bacteria enter the tract through the newborn's mouth from airborne sources. Others may come from vaginal secretions at birth, from hospital bedding, and from contact at the breast. The accumulation of bacteria is helpful because bacteria in the gastrointestinal tract are necessary for digestion through probiotics and for the synthesis of vitamin K.

Although a newborn stomach holds about 60 to 90 ml, a newborn has limited ability to digest everything taken in, especially fat and starch because the pancreatic enzymes, lipase and amylase, remain deficient for the first few months of life. Also, because the cardiac sphincter between the stomach and esophagus is immature, a newborn tends to regurgitate easily. Immature liver function can lead to a tendency toward lowered glucose and protein serum levels.

### Stools

The first stool of a newborn is usually passed within 24 hours after birth. It consists of **meconium**, a sticky, tar-like, blackish-green, odorless material formed from mucus, vernix, lanugo, hormones, and carbohydrates that accumulated in the bowel during intrauterine life. If a newborn does not pass a meconium stool by 24 to 48 hours after birth, the possibility of some problem such as meconium ileus, imperforate anus, or volvulus should be suspected.

About the second or third day of life, newborn stool changes in color and consistency. Termed a **transitional stool**, bowel contents appear both loose and green; they may resemble diarrhea to the untrained eye.

- By the fourth day of life, breastfed babies pass three or four light yellow stools per day that have a soft consistency. They are not foul smelling because breast milk is high in lactic acid, which reduces the amount of putrefactive organisms in the stool.
- A newborn who receives formula usually passes two or three bright yellow stools a day of soft consistency. These have a more noticeable odor, compared with those of breastfed babies.
- A newborn placed under phototherapy lights as therapy for jaundice will have bright green stools because of increased bilirubin excretion.
- Newborns with bile duct obstruction have clay-colored (gray) stools because bile pigments cannot enter the intestinal tract.
- Blood-flecked stools usually indicate an anal fissure.

- Occasionally, a newborn has swallowed some maternal blood during birth and either vomits fresh blood immediately after birth or passes a black tarry stool after two or more days. Whether bleeding is caused by ingestion of maternal blood at birth or newborn bleeding may be differentiated by a dipstick Apt-Downey test. If stools remain black or tarry, this suggests newborn intestinal bleeding rather than swallowed blood.
- If mucus is mixed with stool or the stool is watery and loose, a milk allergy, lactose intolerance, or some other condition interfering with digestion or absorption is suspected.

## The Urinary System

The average newborn voids within 24 hours after birth. A newborn who does not take in much fluid for the first 24 hours may void later than this, but the 24-hour point is a general rule. Newborns who do not void within this time need to be assessed for the possibility of urethral stenosis or absent kidneys or ureters.

The kidneys of newborns do not concentrate urine well, making newborn urine usually light colored and odorless. The infant is about 6 weeks of age before much control over reabsorption of fluid in tubules and concentration of urine becomes evident.

A single voiding in a newborn is only about 15 ml and may be easily missed in an absorbent diaper. Specific gravity ranges from 1.008 to 1.010. The daily urinary output for the first 1 or 2 days is about 30 to 60 ml total. By week 1, total daily volume rises to about 300 ml. The first voiding may be pink or dusky because of uric acid crystals that were formed in the bladder in utero; this looks a lot like blood in urine but is an innocent finding. If tested for protein, a small amount may be normally present in voidings for the first few days of life until the kidney glomeruli are more mature. Diapers can be weighed to determine the amount and timing of voiding, which is done when there is a concern.

The possibility of obstruction in the urinary tract can also be assessed by observing the force of the urinary stream in both male and female infants. Males should void with enough force to produce a small projected arc; females should produce a steady stream, not just continuous dribbling. Projecting urine farther than normal may signal urethral obstruction because it indicates urine is being forced through a narrow channel.

## The Immune System

Newborns have limited immunologic protection at birth because they are not able to produce antibodies until about 2 months (the reason most immunizations are not administered until 2 months of age). Newborns are, however, born with passive antibodies (immunoglobulin G) passed to them from their mother that crossed the placenta. In most instances, these include antibodies against poliomyelitis, measles, diphtheria, pertussis, chickenpox, rubella, and tetanus. Newborns are routinely

administered a hepatitis B vaccine before they leave their birth setting to promote antibody formation against this disease (CDC, 2016). Because the newborn has little natural immunity against herpes simplex, healthcare personnel with herpes simplex eruptions (cold sores) should not care for newborns until the lesions have crusted. Without antibody protection, herpes simplex type 2 infections can become systemic or create a rapidly fatal form of the disease in a newborn (James & Kimberlin, 2015).

## The Neuromuscular System

Term newborns demonstrate neuromuscular function by moving their extremities, attempting to control head movement, exhibiting a strong cry, and demonstrating newborn reflexes. Limpness or total absence of a muscular response to manipulation is not normal and suggests narcosis, shock, or cerebral injury. A newborn occasionally makes twitching or flailing movements of the extremities in the absence of a stimulus because of the immaturity of the nervous system; these are common and normal. Newborn reflexes can be tested with consistency by using a number of simple maneuvers.

### The Blink Reflex

A blink reflex in a newborn serves the same purpose as it does in an adult—to protect the eye from any object coming near it by rapid eyelid closure. It may be elicited by shining a strong light such as a flashlight into an eye. A sudden movement toward the eye sometimes can elicit the blink reflex, but this is not as reliable.

### The Rooting Reflex

If a newborn's cheek is brushed or stroked near the corner of the mouth, the infant will turn the head in that direction. This reflex serves to help a newborn find food; when a mother holds the child and allows her breast to brush the newborn's cheek, the reflex causes the baby to turn toward the breast. The reflex disappears at about the sixth week of life, not coincidentally at the same time a newborn's eyes focus steadily so a food source can be seen.

### The Sucking Reflex

When a newborn's lips are touched, the baby makes a sucking motion. Like the rooting reflex, this reflex also helps a newborn find food. The sucking reflex begins to diminish at about 6 months of age. It disappears immediately if it is never stimulated such as in a newborn with a tracheoesophageal fistula who cannot take in oral fluids. It can be maintained in such an infant by offering the child a nonnutritive sucking object such as a pacifier.

### The Swallowing Reflex

The swallowing reflex in a newborn is the same as in the adult. Food that reaches the posterior portion of the tongue is automatically swallowed. Gag, cough, and sneeze reflexes also are present in newborns to maintain a clear airway.

### The Extrusion Reflex

In order to prevent the swallowing of inedible substances, a newborn extrudes any substance that is placed on the anterior portion of the tongue. If newborns are offered solid food before this reflex fades at 4 months, it will look as if they are rejecting the food. Be certain parents are aware of this reflex so they don't offer solid food this early.

### The Palmar Grasp Reflex

Newborns grasp an object placed in their palm by quickly closing their fingers on it (Fig. 18.5). Mature newborns grasp so strongly they can be raised from a supine position and suspended momentarily from an examiner's fingers. This reflex disappears at about 6 weeks to 3 months of age; after it fades, a baby begins to grasp meaningfully.

**Figure 18.5** The palmar grasp reflex.

### The Step (Walk)-in-Place Reflex

Newborns who are held in a vertical position with their feet touching a hard surface will take a few quick, alternating steps (Fig. 18.6). This reflex disappears by 3 months of age.

**Figure 18.6** The step-in-place reflex.

### The Placing Reflex

The placing reflex is elicited by touching the anterior lower leg against a surface such as the edge of a table. The newborn makes a few quick lifting leg motions, as if to step onto the table.

### The Plantar Grasp Reflex

When an object touches the sole of a newborn's foot at the base of the toes, the toes grasp in the same manner as the fingers. This reflex disappears at about 8 to 9 months of age in preparation for walking.

### The Tonic Neck Reflex

When the arm and leg on the side toward which the head is turned extend, and the opposite arm and leg contract (Fig. 18.7). This posture is most evident in the arms but should not be totally absent in the legs. If you turn a newborn's head to the opposite side, he or she may change the extension and contraction of legs and arms accordingly. It is also called a "boxer" or "fencing reflex." Unlike other reflexes, the purpose or function of this reflex is not known. The reflex typically disappears between the second and third months of life.

**Figure 18.7** The tonic neck reflex.

### The Moro Reflex

A Moro (startle) reflex ([Fig. 18.8](#)) can be elicited with a loud noise or by jarring the bassinet. The most accurate method of eliciting the reflex is to hold a newborn in a supine position and then allow the head to drop backward about 1 in. In response to this sudden backward head movement, the newborn first extends arms and legs, then swings the arms into an embrace position and pulls up the legs against the abdomen ([Lehman & Schor, 2016](#)). The reflex simulates the action of someone trying to ward off an attacker and then covering up to protect the body. It is strong for the first 8 weeks of life and then fades by the end of the fourth or fifth month.

**Figure 18.8** The Moro reflex.

### The Babinski Reflex

When the sole of a newborn's foot is stroked in an inverted "J" curve from the heel upward, a newborn fans the toes (positive Babinski sign) (Fig. 18.9). This is in contrast to the adult, who flexes the toes if the foot is stroked this way. The reflex remains positive (toes fan) until at least 3 months of age, when it is supplanted by the down-turning response.

**Figure 18.9** The Babinski reflex. When the examiner moves her finger upward, the newborn's toes will fan outward.

### The Magnet Reflex

If pressure is applied to the soles of the feet of a newborn lying in a supine position, he or she pushes back against the pressure. This and the two following reflexes are tests of spinal cord integrity.

### The Crossed Extension Reflex

When a newborn is lying supine, if one leg is extended and the sole of that foot is irritated by being rubbed with a sharp object, such as a thumbnail, the infant raises the other leg and extends it as if trying to push away the hand irritating the first leg.

### The Trunk Incurvation Reflex

When a newborn lies in a prone position and is touched along the paravertebral area on the back by a probing finger, the newborn flexes the trunk and swings the pelvis toward the touch ([Fig. 18.10](#)).

**Figure 18.10** The trunk incurvation reflex. When the paravertebral area is stroked, the newborn flexes his or her trunk toward the direction of the stimulation.

### The Landau Reflex

When a newborn is supported in a prone position by a hand, the newborn should demonstrate some muscle tone. A newborn may not be able to lift the head or arch the back in this position but neither should the infant sag into an inverted “U” position. The latter response indicates extremely poor muscle tone, which needs to be investigated.

### The Deep Tendon Reflexes

Both a patellar and a biceps reflex are intact in a newborn (see [Chapter 34](#) for the technique to elicit these).

### *QSEN Checkpoint Question 18.2*

#### **QUALITY IMPROVEMENT**

A Moro reflex is the single best assessment of neurologic ability in a newborn. Unit protocols should specify what action for eliciting a Moro reflex in Beth?

- a. Turn her onto her abdomen and see if she can turn her head.
- b. Make a sharp noise, such as clapping your hands.
- c. Lift her head while she is supine and allow it to fall back 1 in.
- d. Gently shake Beth's bassinette until she responds by flailing out her arms.

*Look in [Appendix A](#) for the best answer and rationale.*

## **The Senses**

The senses in newborns, probably because they are so important for survival, are already fully developed at birth.

### Hearing

Newborns appear to recognize their mother's voice almost immediately and calm to the sound since they have heard it in utero. In fact, by 25 to 27 weeks gestation, hearing is functional and the fetus can hear the mother's heartbeat and voice. Hearing continues to develop so that the fetus hears a broader range of frequencies throughout gestation and shortly after birth ([Clark-Gambelunghe & Clark, 2015](#)). As soon as amniotic fluid drains or is absorbed from the middle ear by way of the eustachian tube within hours after birth, hearing becomes acute. Newborns respond with generalized activity to a sound such as a bell. They appear to have difficulty locating where a sound is coming from.

### Vision

A pupillary reflex or ability to contract the pupil is present from birth. The fetus has a blink or squint reflex in response to a bright light in utero by 26 weeks gestation; newborns demonstrate they can see by blinking at a strong light (blink reflex) or by following a bright light or toy a short distance with their eyes as soon as they are born ([Clark-Gambelunghe & Clark, 2015](#)). Be certain parents know their newborn cannot follow an object past the midline or appears to lose track of objects easily. Teach also that newborns focus best on black and white objects at a distance of 9 to 12 in.

### Touch

The sense of touch is also well developed at birth. Newborns quiet down at a soothing touch, cry at painful stimuli, and show sucking and rooting reflexes that are elicited by

touch.

## Taste

A newborn has the ability to discriminate taste because taste buds are developed and functioning even before birth. A fetus in utero, for example, will swallow amniotic fluid more rapidly than usual if glucose is added to sweeten its taste. The swallowing decreases if a bitter flavor is added. After birth, a baby continues to show a preference for sweet over bitter tastes.

## Smell

The sense of smell is present in newborns as soon as the nose is clear of lung and amniotic fluid. Newborns probably turn toward their mothers' breasts partly out of recognition of the smell of breast milk and partly as a manifestation of the rooting reflex.

## The Physiologic Adjustment to Extrauterine Life

All newborns appear to move through periods of irregular adjustment in the first 6 hours of life, until their body systems stabilize. These periods were first described by Desmond in 1963 and are termed three periods of reactivity (Desmond, Franklin, Vallvona, et al., 1963) (Table 18.1). Newborns who are ill or who had difficulty in utero or at birth may not pass through these typical stages. For example, they may never have periods of alertness or periods of quiet, their vital signs may not fall and rise again but remain rapid, or their temperature may remain subnormal. Demonstration of these typical reactivity patterns indicates a newborn's neurologic system is intact and healthy and the newborn is adjusting well to extrauterine life. Explain these periods to new mothers because the alert periods are ideal periods for mother–infant bonding to begin.

**TABLE 18.1 PERIODS OF REACTIVITY: NORMAL ADJUSTMENT TO EXTRAUTERINE LIFE**

Assessment	First Period (First 15–30 min)	Resting Period (30–120 min)	Second Period (2–6 hr)
Color	Acrocyanosis is present.	Color begins to stabilize.	Quick color changes occur with movement or crying.
Temperature	Temperature begins to fall from intrauterine temperature of about 100.6°F (38.1°C).	Temperature stabilizes at about 99°F (37.2°C).	Temperature increases to 99.8°F (37.6°C).
Heart rate	Heart rate is rapid, as much as	Heart rate slows	Wide swings in rate

	180 beats/min while crying.	to 120–140 beats/min.	occur with activity but stabilize at 120–140 beats/min.
Respirations	Breathing is irregular; 30–90 breaths/min while crying; some nasal flaring and occasional retraction may be present.	Breathing slows to 30–50 breaths/min; barreling of chest may occur.	Breathing rate becomes irregular with activity but stabilizes at 30–60 breaths/min.
Activity	Alert; watching	Sleeping	Awakening
Ability to respond to stimulation	Vigorous reaction	Difficult to arouse	Becoming responsive again
Mucus	Visible in mouth	Small amount present while sleeping	Mouth full of mucus, possibly causing gagging
Bowel sounds	Can be heard after first 15 minutes	Present	Often passage of first meconium stool

From Desmond, M. M., Franklin, R. R., Vallvona, C., et al. (1963). The clinical behavior of the newly born: The term infant. *Journal of Pediatrics*, 62(3), 307–325.

## Assessments for Well-Being

A number of traditional standardized assessments as well as a history and physical examination are done at birth to evaluate a newborn for maturity and general well-being.

### APGAR SCORING

At 1 minute and 5 minutes after birth, newborns are observed and rated according to an Apgar score, an assessment scale used as a standard for newborn evaluation since 1958 (Apgar, Holaday, James, et al., 1958). As shown in Table 18.2, heart rate, respiratory effort, muscle tone, reflex irritability, and color of the infant are each rated 0, 1, or 2. There is a high correlation between low 5-minute Apgar scores and neurologic illness (American Academy of Pediatrics [AAP], 2015b). The following points are considered in obtaining the rating:

#### TABLE 18.2 APGAR SCORING

Apgar scoring is done at one and five minutes after birth. The newborn is considered to be “vigorous” if the initial scores are 7 and above. If the five-minute score is less than 7,

scoring is done every five minutes thereafter until the score reaches 7. The numbers in the left-hand column represent the number of points that are assigned to each parameter when the criteria in the corresponding column are met.

	Heart Rate	Respiratory Effort	Muscle Tone	Reflex Irritability	Color
2	Heart rate >100 beats per minute (bpm)	Strong, vigorous cry	Maintains a position of flexion with brisk movements	Cries or sneezes when stimulated <sup>a</sup>	Body and extremities pink
1	Heart rate present, but <100 bpm	Weak cry, slow or difficult respirations	Minimal flexion of extremities	Grimaces when stimulated	Body pink, extremities blue
0	No heart rate	No respiratory effort	Limp and flaccid	No response to stimulation	Body and extremities blue (cyanosis) or completely pale (pallor)

<sup>a</sup>Stimulation is provided by suctioning the infant or by gently flicking the sole of the foot.

Reprinted with permission from Hatfield, N. T., & Kincheloe, C. (2017). *Introductory maternity and pediatric nursing* (4th ed.). Philadelphia, PA: Wolters Kluwer.

## Heart Rate

Auscultating a newborn heart with a stethoscope is the best way to determine heart rate; however, heart rate also may be obtained by observing and counting the pulsations of the umbilical cord at the abdomen if the cord is still uncut.

## Respiratory Effort

Respirations are counted by observing chest movements. A mature newborn usually cries and aerates the lungs spontaneously at about 30 seconds after birth. By 1 minute, he or she is maintaining regular, although rapid, respirations. Difficulty with breathing might be anticipated in a newborn whose mother received large amounts of analgesia or general anesthetic during labor or birth.

## Muscle Tone

Term newborns hold their extremities tightly flexed, simulating their intrauterine position. Muscle tone is tested by observing their resistance to any effort to extend their extremities.

## **Reflex Irritability**

One of two possible cues is used to evaluate reflex irritability: response to a suction catheter in the nostrils or response to having the soles of the feet slapped. A baby whose mother was heavily sedated for birth will probably demonstrate a low score in this category.

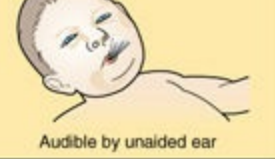

## **Color**

All infants appear cyanotic at the moment of birth. They grow pink with or shortly after the first breath, which makes the color of newborns correspond to how well they are breathing. Acrocyanosis (cyanosis of the hands and feet) is so common in newborns that a score of 1 in this category can be thought of as normal.

## **The Respiratory Evaluation**

Good respiratory function has the highest priority in newborn care, so the assessment for it is ongoing at every newborn contact. The Silverman-Andersen index, originally devised in 1956 ([Silverman & Andersen, 1956](#)), is a standard method, which can be used to estimate degrees of respiratory distress in newborns. For this assessment, a newborn is observed and then scored on each of five criteria ([Fig. 18.11](#)).

SCORE			
Feature observed	0	1	2
Chest movement	 Synchronized respirations	 Lag on inspiration	 Seesaw respirations
Intercostal retraction	 None	 Just visible	 Marked
Xiphoid retraction	 None	 Just visible	 Marked
Nares dilatation	 None	 Minimal	 Marked
Expiratory grunt	 None	 Audible by stethoscope	 Audible by unaided ear
Total score: 0 indicates no respiratory distress; 1-3 indicate mild distress; 4-6 indicate moderate distress; 7-10 indicate severe distress			

**Figure 18.11** Grading of neonatal respiratory distress based on the Silverman-Andersen index. (Silverman, W. A., & Andersen, D. H. [1956]. A controlled clinical trial of effects of water mist on obstructive respiratory signs, death rate and necropsy findings among premature infants. *Pediatrics*, 17[4], 1-9.)

### Concept Mastery Alert

As with any patient, the nurse assesses for pain with vital signs and any procedure.

### QSEN Checkpoint Question 18.3

#### INFORMATICS

Beth Ruiz had Apgar scores of 6 at 1 minute and 8 at 5 minutes after birth. Which of the following are the five areas assessed with Apgar scoring?

- Heart rate, respiratory effort, muscle tone, reflex irritability, and color

- b. Respiratory rate, abdominal tone, reflexes, color, and head circumference
- c. Color, breathing rate, cry, amount of brown fat, and response to loud noise
- d. Abdominal tone, persistence, reflexes, blood pressure, and response to pain

Look in *Appendix A* for the best answer and rationale.

## THE ASSESSMENT OF GESTATIONAL AGE

Newborns are said to be term if they are born between 37 and 42 weeks of gestation or within 2 weeks of their due date. Gestational age for an infant born 5 days after the due date would be recorded as 40 + 5; an infant born 3 days before the due date would be recorded as 40 – 3. Specific findings from physical assessment also provide clues to a newborn’s gestational age. As early as 1966, Usher and colleagues (Usher, McLean, & Scott, 1966) proposed five criteria to evaluate gestational maturity (Table 18.3). These quick criteria can be used for an assessment of all newborns in a birthing room.

**TABLE 18.3 CLINICAL CRITERIA FOR GESTATIONAL ASSESSMENT**

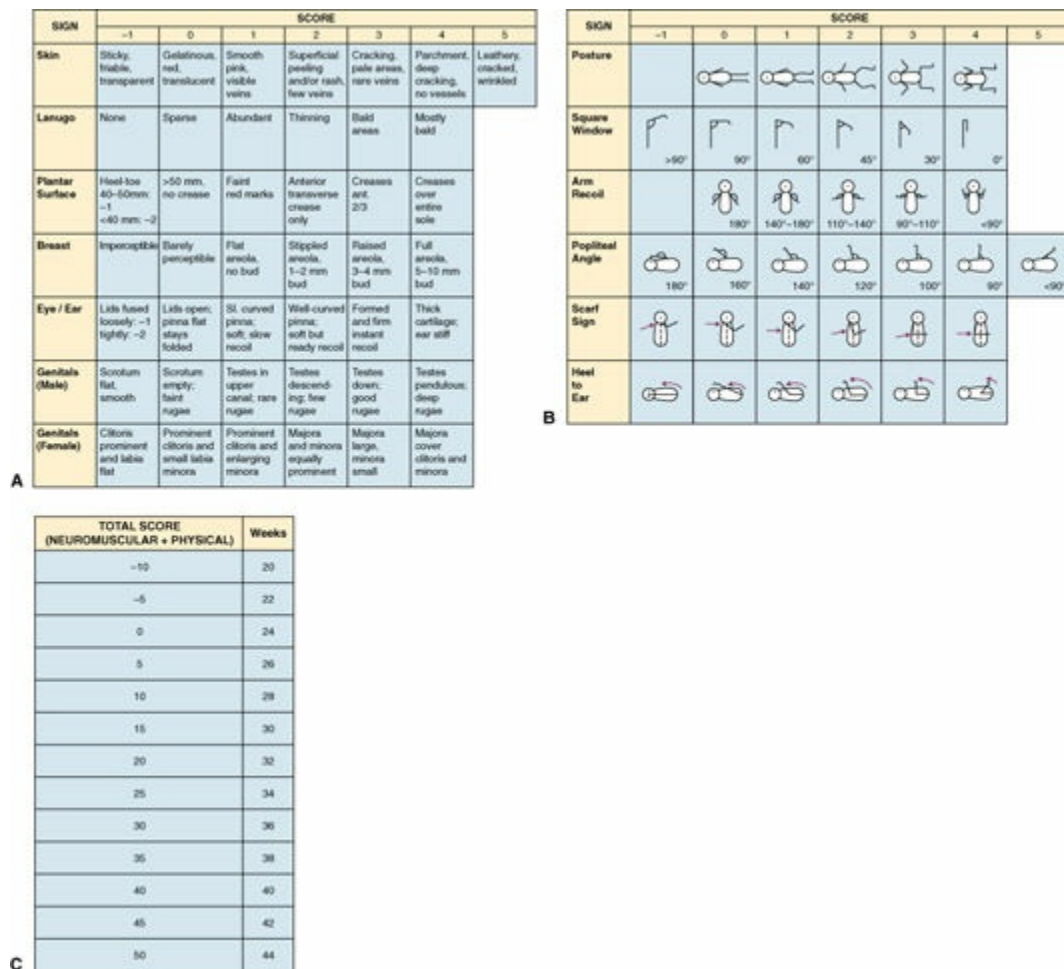

Finding	Gestation Age (In Weeks)		
	0–36	37–38	39 and Over
Sole creases	Anterior transverse crease only	Occasional creases in anterior two thirds	Sole covered with creases
Breast nodule diameter (mm)	2	4	7
Scalp hair	Fine and fuzzy	Fine and fuzzy	Coarse and silky
Ear lobe	Pliable; no cartilage	Some cartilage	Stiffened by thick cartilage
Testes and scrotum	Testes in lower canal; scrotum small; few rugae	Intermediate	Testes pendulous, scrotum full; extensive rugae

Usher, R., McLean, F., & Scott, K. E. (1966). Judgment of fetal age. *Pediatric Clinics of North America*, 13(4), 835–840.

### Maturity Rating

Many healthcare facilities do not routinely do maturity testing. They rely on the ultrasound, done at 20 weeks gestation, to assess maturity in most cases. The Ballard or Dubowitz test may be performed if the mother did not have prenatal care or if there is another question regarding maturity of the newborn. Gestational rating scales such as the Ballard or Dubowitz use extensive criteria to assess gestational age. The process of rating the infant, completed shortly after birth, includes physical maturity and

neuromuscular maturity (Fig. 18.12). The newborn's skin, lanugo, foot creases, breast maturity, eyes and ears, and genitalia are observed and given a score of -1 to +5, as described in Figure 18.12A. See Chapter 26 for illustrations of mature and immature body features for the scale. For the second half of the examination, observe or position a newborn as shown in Figure 18.12B. Again, score the child's response numerically from -1 to +5. Then, the total score obtained (on both sections) is compared with the rating scale in Figure 18.12C. Using this standard method to rate maturity helps detect infants who were thought to be term but instead are actually preterm because of a miscalculated due date and who need additional observation and perhaps high-risk care.

**Figure 18.12** Ballard assessment of gestational age criteria. **(A)** Physical maturity assessment criteria. **(B)** Neuromuscular maturity assessment criteria. *Posture*: With infant supine and quiet, score as follows: arms and legs extended = 0; slight or moderate flexion of hips and knees = 2; legs flexed and abducted, arms slightly flexed = 3; full flexion of arms and legs = 4. *Square window*: Flex hand at the wrist. Exert pressure sufficient to get as much flexion as possible. The angle between hypothenar eminence and anterior aspect of forearm is measured and scored. Do not rotate wrist. *Arm recoil*: With infant supine, fully flex forearm for 5 seconds and then fully extend by

pulling the hands and release. Score as follows: remain extended or random movements = 0; incomplete or partial flexion = 2; brisk return to full flexion = 4. *Popliteal angle*: With infant supine and pelvis flat on examining surface, flex leg on thigh and fully flex thigh with one hand. With the other hand, extend leg and score the angle attained according to the chart. *Scarf sign*: With infant supine, draw infant's hand across the neck and as far across the opposite shoulder as possible. Assistance to elbow is permissible by lifting it across the body. Score according to location of the elbow: elbow reaches opposite anterior axillary line = 0; elbow between opposite anterior axillary line and midline of the thorax = 1; elbow at midline of thorax = 2; elbow does not reach midline of thorax = 3; elbow at proximal axillary line = 4. *Heel to ear*: With infant supine, hold infant's foot with one hand and move it as near to the head as possible without forcing it. Keep pelvis flat on examining surface. (C) Scoring for the Ballard assessment scale. The point total from assessment is compared to the left column. The matching number in the right column reveals the infant's age in gestation weeks. (From Ballard, J. L., Khoury, J. C., Wedig, K., et al. [1991]. New Ballard score, expanded to include extremely premature infants. *Journal of Pediatrics*, 119[3], 417–424.)

### **The Brazelton Neonatal Behavioral Assessment Scale**

Term newborns are physically active and emotionally prepared to interact with the people around them. They are people oriented from the beginning, and how much so can be demonstrated by the way they immediately attune to human voices or concentrate on their mother's face (Fig. 18.13).

**Figure 18.13** A newborn alerts at the sight of her parent's face and sound of her voice.

The *Brazelton Neonatal Behavioral Assessment Scale* is a rating scale of six different categories of behavior: habituation, orientation, motor maturity, variation, self-quieting ability, and social behavior and was devised by Brazelton in the early 1970s (Brazelton, 1973) to evaluate a newborn's behavioral capacity or ability to respond to set stimuli.

A total evaluation takes 20 to 30 minutes to complete. To perform an assessment using the scale requires training to ensure it is used consistently. Unlike many assessment scales, the infant is scored on best performance rather than on average performance. Although not used routinely, many of the items tested on the scale, such as how infants alert to a voice (e.g., eyes widen, head held as if listening) or how they naturally cuddle when held next to their parent, are excellent examples of newborn behavior to point out to parents to help them interact with their newborn.

### **The Health History**

The history of a newborn is obtained from examination of the mother's pregnancy record if this is available, her labor and birth record, and an interview with the mother. Important information to gather includes:

- Any complications of pregnancy such as gestational diabetes, hypertension, premature rupture of membranes, serious falls, or other injuries
- Length of pregnancy and length of labor
- Type of birth (vaginal or cesarean) and whether the infant breathed spontaneously or needed assistance at birth

## The Physical Examination

A newborn is given a preliminary physical examination as soon as parents have had an initial time to spend with their new child in addition to height and weight determinations, to establish gestational age and to detect any observable condition such as difficulty breathing, a congenital heart anomaly, or any birthmarks (Table 18.4). This assessment may be the responsibility of the primary care provider or a nurse depending on the facility and circumstances of birth. Always complete such assessments quickly to prevent exposing a newborn to chilling, yet not so swiftly that important findings are overlooked (Gooding & McClead, 2015).

**TABLE 18.4 CONGENITAL ANOMALY APPRAISAL**

Procedure	Abnormalities Considered
Inquire for hydramnios or oligohydramnios	Presence of hydramnios (excessive amount of amniotic fluid) suggests congenital gastrointestinal obstruction. Oligohydramnios (lessened amount of amniotic fluid) suggests genitourinary obstruction or extreme prematurity.
Appearance of abdomen	Distended abdomen suggests ascites or tumor. Empty abdomen suggests diaphragmatic hernia.
Passage of nasogastric tube (#8 feeding catheter) through nares into stomach	Failure to pass nasogastric tube through nares on either side establishes choanal atresia. Failure to pass it into the stomach confirms presence of esophageal atresia.
Aspiration of stomach contents from feeding tube with recording of color and amount of fluid obtained	With excess of 20 ml of fluid or yellow fluid, duodenal or ileal atresia is suspected.
Insertion of feeding tube into rectum	Failure to pass or obtain meconium on tip suggests imperforate anus or higher obstruction.
Counting of umbilical arteries	The presence of one artery suggests possible congenital urinary or cardiac anomalies or chromosomal trisomy (if other portions of examination are consistent).

## THE APPEARANCE OF A NEWBORN

Although all newborns have similar physical findings, each is unique and has individual differences from all others.

## The Skin

General inspection of a newborn's skin includes color, any birthmarks, and general appearance.

## The Color

Most term newborns have a ruddier complexion for their first month than they will have later in life because of the increased concentration of red blood cells in their blood vessels and a decrease in the amount of subcutaneous fat, which makes blood vessels more visible. Infants with poor central nervous system control or respiratory difficulty may appear pale and cyanotic. In darker skinned newborns, cyanosis may appear as dusky grey or whitish around the child's mouth.

## Cyanosis

Generalized mottling of the skin is a common finding in newborns. The lips, hands, and feet are likely to appear blue from immature peripheral circulation (termed *acrocyanosis*). This can be so prominent in some newborns that the infant's hands appear as if a stricture at the wrist must be cutting off circulation because there is usual skin color on one side and blue on the other. Acrocyanosis is a normal finding at birth through the first 24 to 48 hours after birth.

In contrast, **central cyanosis**, or cyanosis of the trunk, is always a cause for concern. Central cyanosis indicates decreased oxygenation that could be occurring as the result of a temporary respiratory obstruction and also could reflect a serious underlying respiratory or cardiac disease. Mucus obstructing a newborn's respiratory tract causes sudden cyanosis and apnea, but this can be relieved by suctioning the mucus from the mouth and nose. In newborns, always suction the mouth before the nose because suctioning the nose first may trigger a reflex gasp, possibly leading to aspiration if there is mucus in the posterior throat. Follow mouth suctioning with suction to the nose because the nose is the chief conduit for air in newborns.

## Hyperbilirubinemia

Hyperbilirubinemia is caused by the accumulation of excess bilirubin in blood serum. In the average newborn, the skin and sclera of the eyes begin to appear noticeably yellow on the second or third day of life as a result of a breakdown of fetal red blood cells (called **physiologic jaundice**). This occurs because, as the high red blood cell count built up in utero is being reduced, heme and globin are released.

- Heme is further broken down into iron (which is reused and not involved in the jaundice) and protoporphyrin.
- Protoporphyrin is then broken down into indirect bilirubin, a compound which is fat-soluble and therefore cannot be excreted by the kidneys. In order to be removed from the body, it must be converted by the liver enzyme glucuronyl transferase into direct bilirubin, which is water-soluble, and is then incorporated

into the stool and excreted as feces.

Newborns can have difficulty with this process because their immature liver function prevents indirect bilirubin from being converted to direct bilirubin. As long as the buildup of indirect bilirubin that occurs remains in the circulatory system, the red coloring of the blood cells covers the yellow tint of the bilirubin. After the level of this indirect bilirubin rises to more than 7 mg/100 ml, however, bilirubin permeates through the blood vessels to tissue outside the circulatory system and the infant begins to appear jaundiced (Squires & Balistreri, 2016).

Carefully observe infants who are prone to extensive bruising (large, breech, or preterm babies) for **jaundice** because bruising leads to hemorrhage of blood into the subcutaneous tissue or skin; this blood then has to be broken down so can add to the amount of indirect bilirubin accumulating. A **cephalohematoma** is a collection of blood under the periosteum of the skull bone caused by pressure at birth. As the red blood cells in this type of lesion are hemolyzed, additional indirect bilirubin is also released and so can be yet another cause of jaundice (Rozance & Rosenberg, 2017)

Another reason indirect bilirubin levels can increase is if a newborn has an intestinal obstruction because, in this case, stool cannot be evacuated. Intestinal flora in the bowel then breaks down bile into its basic components, one of which is indirect bilirubin. Early feeding of newborns promotes intestinal movement and excretion of meconium and helps prevent indirect bilirubin buildup from this source.

Above normal indirect bilirubin levels are potentially dangerous because, if enough indirect bilirubin (about 20 mg/100 ml) leaves the bloodstream, it can interfere with the chemical synthesis of brain cells, resulting in permanent cell damage, a condition termed **acute bilirubin encephalopathy** or *kernicterus*. If this occurs, permanent neurologic damage, including cognitive, vision, and hearing problems, may result.

The level of jaundice developing in newborns can be grossly judged by estimating the extent to which it has progressed on the surface of the infant's body because it is noticed first in the head and then spreads downward onto the body and legs.

Various commercial devices (transcutaneous bilirubinometry devices) are available to measure skin tone and help in estimating the level of bilirubin present. Although use of these devices rarely replaces serum measurements, they can be used to identify infants who need serum bilirubin determinations.

Treatment for physiologic jaundice or the routine rise in indirect bilirubin in newborns is rarely necessary, except for preventive measures such as early feeding to speed the passage of meconium.

There is no set level at which indirect serum bilirubin requires treatment because other factors, such as age, maturity, and breastfeeding status, affect this determination. If the level rises to more than 10 to 12 mg/100 ml, treatment is usually considered. Phototherapy (exposure of the infant to light to initiate maturation of liver enzymes) is common therapy (see Chapter 26). If this is necessary, the incubator and light source can be moved to the mother's room so the mother is not separated from her baby. Some infants need continued therapy after discharge and receive phototherapy at home either

by a light-emitting diode (LED) or fluorescent lights over their crib or a phototherapy blanket (Muchowski, 2014).

Compared with formula-fed babies, a small proportion of breastfed babies may have more difficulty converting indirect bilirubin to direct bilirubin because breast milk contains pregnanediol (a metabolite of progesterone), which depresses the action of glucuronyl transferase. However, breastfeeding alone rarely causes enough jaundice to warrant therapy and in most cases, healthcare providers should promote breastfeeding in infants with jaundice (Muchowski, 2014). A decision to stop breastfeeding in the first 2 weeks of life due to jaundice must be taken very seriously because of the high risk that the interruption will interfere with establishing breastfeeding for the mother–infant dyad.

## Pallor

Pallor in newborns is potentially serious because it usually occurs as the result of anemia, which may be caused by a number of circumstances such as:

- Low iron stores caused by poor maternal nutrition during pregnancy.
- Blood incompatibility in which a large number of red blood cells were hemolyzed in utero.
- Fetal–maternal transfusion.
- Inadequate flow of blood from the cord into the infant before the cord was cut.
- Excessive blood loss when the cord was cut.
- Internal bleeding. To detect this, a baby who appears pale should be watched closely for signs of blood in the stool or vomitus.

Newborns identified as having anemia need therapy such as supplemental iron or a packed red cell transfusion to restore their blood volume.

## The Harlequin Sign

Occasionally, because of immature blood circulation, a newborn who has been lying on his or her side appears red on the dependent side of the body and pale on the upper side, as if a line had been drawn down the center of the body. This is a transient phenomenon and, although startling, is of no clinical significance. The odd coloring fades immediately if the infant's position is changed or the baby kicks or cries.

## Birthmarks

Several common types of birthmarks occur in newborns. It is important to be able to differentiate the various types of hemangiomas that occur because some are more serious than others, and you do not want to give family members false reassurance nor worry them unnecessarily about these lesions.

## Hemangiomas

**Hemangiomas** are vascular tumors of the skin and occur in three distinct types (Table

18.5).

**TABLE 18.5 VASCULAR DISORDERS OF THE NEWBORN**

Type	Description	Location	Treatment
Nevus flammeus	<ul style="list-style-type: none"> <li>• Two types:               <ul style="list-style-type: none"> <li>○ Benign macular purple or dark-red lesion (also called a <i>port-wine stain</i>) (see Fig. 18.14A)</li> <li>○ Light-pink patches: <i>stork bites</i> or <i>telangiectasia</i> (see Fig. 18.14B).</li> </ul> </li> <li>• Present at birth</li> </ul>	<ul style="list-style-type: none"> <li>• Port wine: face, thighs</li> <li>• Stork bites: nape of neck</li> </ul>	<ul style="list-style-type: none"> <li>• Port wine:               <ul style="list-style-type: none"> <li>○ May spontaneously fade</li> <li>○ Cosmetically cover</li> <li>○ Laser later in life</li> </ul> </li> <li>• Stork bites: do not fade; no treatment because usually covered by hair</li> </ul>
Infantile hemangiomas (also called <i>strawberry hemangiomas</i> )	<ul style="list-style-type: none"> <li>• Elevated areas formed by immature capillaries and endothelial cells (see Fig. 18.14C)</li> <li>• Appear at birth or within 2 weeks after birth</li> <li>• Size may enlarge up to 1 year of age.</li> <li>• After 1 year of age, hemangiomas tend to be absorbed and shrink in size. By the time the child is 7 years old, 70% have involuted to a reasonable level; most involution completed by 10 years</li> </ul>	Can occur anywhere on the infant; most common on scalp, face, neck	<ul style="list-style-type: none"> <li>• Educate parent about expected increase in size for up to one year and that they are likely to resolve with time.</li> <li>• Propranolol (Inderal) and corticosteroids can be used to reduce size.</li> <li>• Surgical excision is rarely done due to risk for complications.</li> </ul>
Cavernous hemangioma	<ul style="list-style-type: none"> <li>• Caused by dilated vascular spaces</li> <li>• Raised and irregular shape; resemble a strawberry hemangioma (see Fig. 18.14D)</li> <li>• Do not disappear with time</li> <li>• Some may have additional lesions on internal organs</li> </ul>	Most commonly appear on the face, behind the ears, and the neck	<ul style="list-style-type: none"> <li>• Surgical removal if they interfere with sight or breathing</li> <li>• Steroids, interferon alfa-2a, vincristine, or radiation may reduce size of lesions; risk vs. benefit must be</li> </ul>

such as the spleen or liver.

considered

- Hematocrit levels to assess for blood loss if child has internal cavernous lesions

Paller, A. S., & Mancini, A. J. (2016). Vascular disorders of infancy and childhood. In A. S. Paller & A. J. Mancini (Eds.), *Hurwitz clinical pediatric dermatology* (5th ed., pp. 279–316). New York, NY: Elsevier; Chinnadurai, S., Fannesbeck, C., Snyder, K. M., et al. (2016). Pharmacologic interventions for infantile hemangioma: A meta-analysis. *Pediatrics*, *137*(2), e20153896.

**Figure 18.14** Types of hemangiomas found on a newborn. **(A) Nevus flammeus** (port-wine stain) formed of a plexus of newly formed capillaries in the papillary layer of the corium. It is deep red to purple, does not blanch on pressure, and does not fade with age. **(B)** A telangiectasia or stork beak mark, commonly occurring on nape of neck. It blanches on pressure; although it does not fade, it is not noticeable as it becomes covered by hair. **(C) Strawberry hemangiomas** consist of dilated capillaries in entire dermal and subdermal layers. They continue to enlarge after birth but usually disappear by age 10 years. **(D) Cavernous hemangiomas** consist of a communicating network of venules in subcutaneous tissue and do not fade with age.

## Mongolian Spots

**Mongolian spots** are collections of pigment cells (melanocytes) that appear as slate-

gray patches across the sacrum or buttocks and possibly on the arms and legs of newborns. They tend to occur most often in children of Asian, Southern European, or African ethnicity and disappear by school age without treatment (Smith & Grover, 2016). Be sure to educate parents that these are not bruises.

### *What If . . . 18.2*

**Beth's father tells the nurse he's not worried about the port-wine stain on his baby's thigh because he knows all birthmarks fade by school age. How would the nurse respond to him?**

## **Vernix Caseosa**

**Vernix caseosa** is the white, cream cheese–like substance that serves as a skin lubricant in utero. It is typically noticeable on a term newborn's skin, at least in the skin folds, at birth. Document the color of any vernix present because it takes on the color of the amniotic fluid (yellow vernix implies the amniotic fluid was stained from excessive bilirubin or a blood dyscrasia may be present; green vernix suggests meconium was present in the amniotic fluid).

Handle newborns with gloves to protect yourself from exposure to vernix. Remove only the vernix that is contaminated by meconium or blood (Lovejoy-Bleum, 2014). Never rub it away harshly because newborn skin is tender and breaks in the skin caused by too vigorous attempts at removal could open portals of entry for bacteria.

## **Lanugo**

**Lanugo** is the fine, downy hair that covers a term newborn's shoulders, back, upper arms, and possibly also the forehead and ears. Postterm infants (born after more than 42 weeks of gestation) rarely have lanugo. Babies born at 37 to 39 weeks, in contrast, have a generous supply of lanugo. Following birth, lanugo is rubbed away by the friction of bedding and clothes against the newborn's skin. By 2 weeks of age, it has usually totally disappeared.

## **Desquamation**

Within 24 hours after birth, the skin of most newborns begins to dry. The dryness is particularly evident on the palms of the hands and soles of the feet and results in areas of peeling similar to those caused by sunburn. This is a reaction to suddenly living in an air-filled rather than a liquid-filled environment. No treatment is needed. Parents may apply mild lotion to prevent excessive dryness if they wish.

Newborns who are postterm and have suffered intrauterine malnutrition may have such extremely dry skin that it has a leathery appearance and there are actual cracks in the skin folds. This should be differentiated from normal desquamation because it helps to diagnose the newborn as postterm.

## Milia

Sebaceous glands in a newborn are immature, so at least one pinpoint white papule (a plugged or unopened sebaceous gland) is usually found on a cheek or across the bridge of the nose of every newborn. Such lesions, termed **milia** (Fig. 18.15), disappear by 3 to 4 weeks of age as the sebaceous glands mature and the plugged ones drain. Advise parents to wait for the milia to resolve spontaneously; recommend that they avoid scratching or squeezing the papule, which could lead to secondary infection.

**Figure 18.15** Milia are unopened sebaceous glands frequently found on the nose, chin, or cheeks of a newborn.

## Erythema Toxicum

**Erythema toxicum** commonly presents on the skin of most term newborns (Fig. 18.16). The rash usually appears in the first to fourth day of life but may appear as late as 2 weeks of age. It begins with small papules, increases in severity to become erythematous by the second day and then disappears by the third day. It is sometimes called a *flea-bite rash* because the lesions are so minuscule. One of the chief

characteristics of the rash is its lack of pattern. It occurs sporadically and unpredictably and may last hours or days. It is probably caused by the newborn's eosinophils reacting to the rough environment of sheets and clothing rather than a smooth liquid against the skin. It requires no treatment. It is important it be differentiated from lesions of herpes simplex (clustered vesicles) because herpes simplex is a serious finding in a newborn (Paller & Mancini, 2016).

**Figure 18.16** Erythema toxicum is found on almost all newborns. The reddish rash consists of sporadic pinpoint papules on an erythematous base. It fades spontaneously in a few days.

### Forceps Marks

Forceps are rarely used for birth today, but if they are used (see [Chapter 23](#)), they may leave a circular or linear contusion matching the rim of the forceps blade on the infant's cheek ([Fig. 18.17](#)). The mark occurs with normal forceps use and does not denote unskilled or overly vigorous application of forceps. The mark disappears in 1 to 2 days, along with the edema that accompanies it. Closely assess the face of a newborn with a forceps mark especially during a crying episode to be certain the infant's mouth is symmetrical, to detect any potential facial nerve injury requiring further evaluation.

**Figure 18.17** Forceps marks are commonly found in newborns born by forceps. Such marks are transient and disappear in a day or two.

### Skin Turgor

Like adult skin, newborn skin should feel resilient if the underlying tissue is well hydrated. Grasp a fold of the skin between your thumb and fingers and evaluate if it feels elastic. When released, the skin should fall back to form a smooth surface. If severe dehydration is present, the skin will not smooth out again but will remain as an elevated ridge. Poor turgor is seen in newborns who suffered malnutrition in utero, who have difficulty sucking at birth, or who have certain metabolic disorders such as adrenocortical insufficiency. Poor turgor always needs to be reported as it suggests poor hydration.

### *QSEN Checkpoint Question 18.4*

#### **SAFETY**

Beth Ruiz has milia on her nose. What teaching point would constitute a quality and safety risk?

- “These will disappear on their own, so you don’t need to take any action.”
- “Wash Beth the same way that the nurse first taught you.”
- “Try to gently scratch off these spots in a few days.”
- “Make sure that you keep Beth bundled warmly.”

*Look in [Appendix A](#) for the best answer and rationale.*

### **THE HEAD**

A newborn’s head usually appears disproportionately large because it is about one fourth of the total body length compared with an adult, whose head is one eighth of total height. Other features include:

- The forehead appears large and prominent.
- The chin appears to be receding, and it quivers easily if the infant is startled or

cries.

- If a newborn has hair, the hair should look full bodied; both poorly nourished and preterm infants have thin, lifeless hair.
- If internal fetal monitoring was used during labor (see [Chapter 24](#)), a newborn may have a pinpoint ulcer at the point where the monitor was attached.

## Fontanelles

The fontanelles are the spaces or openings where the skull bones join. The anterior fontanelle is located at the junction of the two parietal bones and the two fused frontal bones. It is diamond-shaped and measures 2 to 3 cm (0.8 to 1.2 in.) in width and 3 to 4 cm (1.2 to 1.6 in.) in length. The posterior fontanelle is located at the junction of the parietal bones and the occipital bone. It is triangular and measures about 1 to 2 cm (0.4 to 0.7 in.) in length.

The anterior fontanelle can be felt as a soft spot. It should not appear indented (a sign of dehydration) or bulging (a sign of increased intracranial pressure) when the infant is held upright. The fontanelle may bulge if the newborn strains to pass a stool, cries vigorously, or is lying supine. The anterior fontanelle normally closes at 12 to 18 months of age. In some newborns, the posterior fontanelle is so small that it cannot be palpated readily. It closes by the end of the second month.

## Sutures

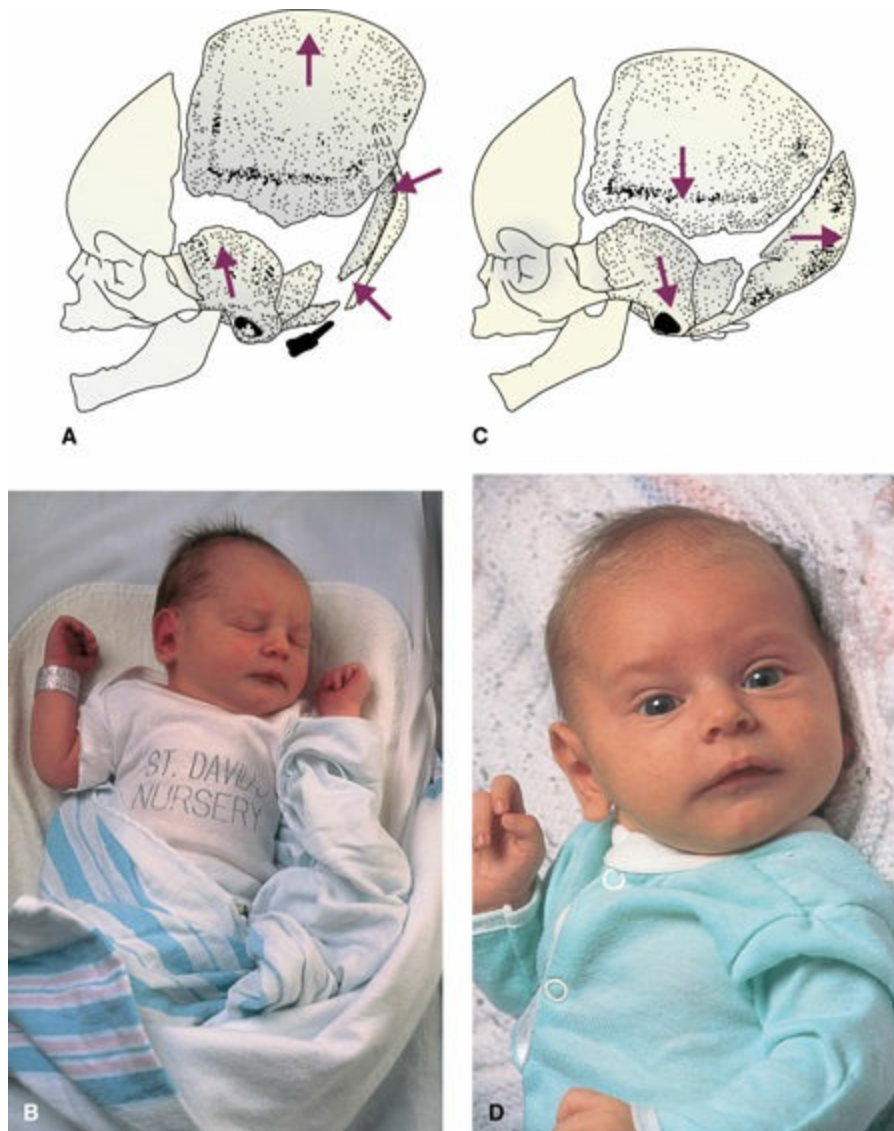

The skull *sutures*, the separating lines of the skull, may override at birth because of the extreme pressure exerted on the head during passage through the birth canal. If the sagittal suture between the parietal bones overrides, the fontanelles are less perceptible than usual. The overriding subsides in 24 to 48 hours.

Suture lines should never appear widely separated in newborns. Wide separation suggests increased intracranial pressure because of abnormal brain formation, abnormal accumulation of cerebrospinal fluid in the cranium (hydrocephalus), or an accumulation of blood from a birth injury such as subdural hemorrhage. Fused suture lines also are abnormal; they require X-ray confirmation and further evaluation because this will prevent the head from expanding with brain growth.

## Molding

The part of the infant's head that engaged the cervix (usually the vertex) molds to fit the cervix contours during labor. After birth, this area appears prominent and asymmetric ([Fig. 18.18](#)). You can assure parents the head will evolve to a more rounded shape within a few days after birth.

**Figure 18.18** Molding. (A,B) The infant head molds to fit the birth canal more easily. On palpation, the skull sutures will be felt to be overriding. (C,D) The head shape returns to normal within 1 week.

### Caput Succedaneum

**Caput succedaneum** (Fig. 18.19A) is edema of the scalp that forms on the presenting part of the head. It occurs in cephalic births and can either involve wide areas of the head or be so confined that it's the size of a large egg. The edema, which crosses the suture lines, is gradually absorbed and disappears within several days. No treatment is needed (Gooding & McCLead, 2015).

**Figure 18.19** (A) Caput succedaneum. From pressure of the birth canal, an edematous area is present beneath the scalp. Note how it crosses the midline of the skull. (B) Cephalohematoma. A small capillary beneath the periosteum of the skull bone has ruptured, and blood has collected under the periosteum of the bone. Note how the swelling now stops at the midline. Because the blood is contained under the periosteum, it is necessarily stopped by a suture line.

### Cephalohematoma

A *cephalohematoma*, a collection of blood between the periosteum of a skull bone and the bone itself, is caused by rupture of a periosteal capillary because of the pressure of birth (see Fig. 18.19B). Although the blood loss is negligible, edema, which appears by 24 hours after birth, appears severe and is well outlined as an egg shape. It may be discolored (black and blue) because of the presence of coagulated blood underneath the periosteum. Unlike a caput, a cephalohematoma is confined to an individual bone, so the associated swelling stops at the bone's suture line.

Cephalohematomas will subside without treatment. It may take weeks for the blood under the periosteum to be absorbed. As the blood breaks down, the infant needs to be observed for jaundice that can occur from the large amount of indirect bilirubin that may be released (Muchowski, 2014).

### Craniotabes

*Craniotabes* is a localized softening of the cranial bones probably caused by pressure of the fetal skull against the mother's pelvic bone in utero. It is more common in first-born infants than in infants born later because of the lower position of the fetal head in the pelvis during the last 2 weeks of pregnancy in primiparous women. With craniotabes, the skull is so soft that the pressure of an examining finger can indent it. The bone then returns to its normal contour after the pressure is removed. The condition corrects itself without treatment after a few months as the infant ingests calcium from milk (Gomella,

Cunningham, Eyal, et al., 2013).

Craniotabes is an example of a condition that is normal if seen in a newborn but would be pathologic in an older child or adult (because then it probably would be the result of faulty calcium metabolism or kidney dysfunction).

## THE EYES

To inspect the eyes of a newborn, lay the infant in a supine position and lift the head; this maneuver usually causes the baby to open his or her eyes. It's rare to see tears in a newborn because their lacrimal ducts do not fully mature until about 3 months of age. Almost without exception, the irises of the eyes look gray or blue; the surrounding sclera may appear light blue due to its thinness. The iris will assume its permanent color between 3 and 12 months of age.

The eyes should appear clear, without redness or purulent discharge. Occasionally, the administration of an antibiotic ointment such as erythromycin at birth, to protect against chlamydia, has caused the eyes to appear reddened with a slight discharge; if this has occurred, it lasts for about 24 hours of life then clears.

Pressure during birth sometimes ruptures a conjunctival capillary of the eye, resulting in a small **subconjunctival hemorrhage** on the sclera. This appears as a red spot, usually on the inner aspect of the eye, or as a red ring around the cornea. The bleeding is slight, requires no treatment, and is completely absorbed within 2 or 3 weeks. While it may appear as if the baby is bleeding from within the eye and that his or her vision might be impaired, you can assure a mother and her partner that these hemorrhages occur often and will soon resolve.

Slight edema is often present around the orbit or on the eyelids and remains for the first 2 or 3 days until the newborn's kidneys are capable of evacuating fluid more efficiently.

Be certain the cornea of each eye appears round and proportionate in size to an adult eye because a cornea that appears larger than usual may be the result of congenital glaucoma. An irregularly shaped pupil or discolored iris may denote a congenital formation such as a coloboma (see [Chapter 50](#)). The pupil, as in adults, should appear dark. A white pupil suggests the presence of a congenital cataract, glaucoma, retinoblastoma, or other eye disorder and should be reported ([Gomella et al., 2013](#)).

## THE EARS

A newborn's external ear is not as completely formed as it will be eventually, so the pinna tends to bend forward easily. In a term newborn, however, the pinna should be strong enough to recoil after bending.

The level of the top part of the external ear should be even to a line drawn from the inner canthus to the outer canthus of the eye and back across the side of the head (see [Chapter 34](#)). Ears that are set lower than this are found in infants with certain chromosomal abnormalities, particularly trisomy 18 and 13, syndromes in which there

are other physical variations coupled with varying degrees of cognitive impairment (Saenz, Meeks, Tsai, et al., 2016).

A small tag of skin is sometimes found just in front of an ear. Although these tags may be associated with chromosomal abnormalities or kidney disease, they usually are isolated findings of no consequence. They can be removed by ligation immediately or within the first week of life. Always inspect closely in front of newborns' ears for pinpoint-size openings that may lead down to a hollow sinus because an open track under the skin lined with squamous epithelium may also be present at these sites. The sinus itself is usually small and inconsequential, but advise parents that the closed space can become infected. If this occurs, the site will appear red and swollen and the infant will need an antibiotic ointment. The parents can have the tract removed surgically to prevent further infection.

Amniotic fluid and flecks of vernix usually still fill the ear canal, obliterating the tympanic membrane and its accompanying landmarks; therefore, visualization of the membrane is usually not attempted.

The AAP recommends all newborns be screened for hearing before discharge from their birth setting (AAP, 2013). Hearing screening is done with a reliable standardized method such as the otoacoustic emissions test or automated auditory brainstem response test. While waiting for a hearing examiner, infants can be tested by ringing a small bell held about 6 in. from each ear. A hearing infant will blink, attend to the bell's sound, and possibly startle.

## THE NOSE

A newborn's nose usually has milia present and tends to appear large for the face. Always test for choanal atresia (blockage at the rear of the nose) when examining a newborn by closing the infant's mouth while compressing one naris at a time with your fingers. Note any distress with breathing while one side of the nose is blocked this way.

## THE MOUTH

A newborn's mouth should open evenly when he or she cries. If one side of the mouth curves more than the other, facial nerve injury may have occurred. The tongue may appear short or "tongue tied" because the frenulum membrane is attached close to the tip. At one time, it was almost routine to snip a newborn's frenulum membrane to lengthen it. Now, this procedure is regarded as unnecessary unless the infant has difficulty sucking or latching because snipping leaves a portal of entry for infection, risks hemorrhage because of the low level of vitamin K in most newborns, and could cause feeding difficulties by making the tongue sore and irritated. As the tongue grows, the frenulum recedes to its adult placement.

Inspect the palate of a newborn to be certain it is intact. Occasionally, one or two small round, glistening, well-circumscribed cysts (Epstein pearls) can be seen on the palate from extra calcium that was deposited in utero. Be sure to inform parents that

these pearl-like cysts are insignificant, require no treatment, and will disappear spontaneously within a week. Epstein pearls must be distinguished from **thrush**, a *Candida* infection, which appears on the tongue and sides of the cheeks as white or gray patches and requires treatment with an antifungal drug such as nystatin (Martin, Baumhart, D'Alesio, et al., 2012).

Small, white epithelial pearls (benign inclusion cysts) may be noticed on the gum margins. Like Epstein pearls, no therapy is necessary for these. It is highly unusual for a newborn to have teeth, but sometimes one or two (called **natal teeth**) will have erupted. Any teeth that are present must be evaluated for stability. If loose, they are usually extracted (they remove easily) to prevent possible aspiration during feeding (Martin et al., 2012).

Most newborns have some mucus in the mouth. Newborns born by cesarean birth usually have more mucus than those born by vaginal birth. If a newborn is placed on the side, the mucus drains from the mouth and results in no distress. If the mouth is filled with so much mucus that the neonate seems to be blowing bubbles, suspect a tracheoesophageal fistula. It is important that this be confirmed or ruled out before the newborn is fed; otherwise, formula could be aspirated into the lungs from the inadequately formed esophagus (see Chapter 45 for a discussion of such fistulas).

## THE NECK

The neck of a newborn appears short with creased skin folds. The head should rotate or turn freely on it. If the neck is rigid, congenital torticollis, caused by injury to the sternocleidomastoid muscle during birth, might be present (see Chapter 27). In newborns whose membranes were ruptured more than 24 hours before birth, nuchal rigidity may be an early sign of meningitis.

The neck of a newborn is not strong enough to support the total weight of the head but in a sitting position, a newborn should make a momentary effort at head control. When lying prone, newborns can raise the head slightly, usually enough to lift the nose out of mucus or spit-up milk. If they are pulled into a sitting position from a supine position, the head will lag.

The trachea usually appears prominent on the front of the neck. The thymus gland also appears enlarged because of the rapid growth of glandular tissue early in life. Even though the thymus appears to be enlarged and bulging, it is rarely a cause of respiratory difficulty; it plays a critical a role in providing immunity so is not removed (Benjamin, Mezu-Ndubuisi, & Maheshwari, 2015).

## THE CHEST

The chest in most newborns looks small because the head is so large in proportion to it (an important finding at birth so the largest diameter of the baby is born first). The chest averages 2 cm (0.75 to 1 in.) smaller in circumference than the head and is as wide in the anteroposterior diameter as it is across. Both right and left sides should appear

symmetric. At around 2 years of age, the chest measurement typically exceeds that of the head.

The clavicles should appear straight and feel smooth. A *crepitus* (crackling) or an actual separation of one or both clavicles suggests a fracture occurred during birth (can happen with large infants).

A supernumerary nipple (usually found below and in line with the normal nipples) may be present. In both female and male infants, the breasts may be engorged because of the influence of maternal hormones during pregnancy. Occasionally, the breasts may secrete a thin, watery fluid popularly termed *witch's milk*. As soon as the hormones are cleared from the infant's system (about 1 week), the engorgement and fluid will subside. Fluid should never be expressed from infants' breasts because the manipulation could introduce bacteria and lead to *mastitis* (infection of the breast).

Respirations are normally rapid (30 to 60 breaths/min) but not distressed. *Retraction* (drawing in of the chest wall with inspiration) should not be present. An infant who is breathing with retractions (Fig. 18.20) is using such a strong force to pull air into the respiratory tract that he or she is pulling in the anterior chest muscle as well. This breathing is not sustainable for a long period of time, and immediate help such as oxygen, is needed.

**Figure 18.20** Sternal retractions are a sign of respiratory distress requiring immediate intervention, such as mechanical ventilation or increased oxygen.

Because a newborn's lung alveoli open slowly over the first 24 to 48 hours and the baby invariably has mucus in the back of the throat, listening to lung sounds often reveals rhonchi—the sound of air passing over mucus. An abnormal sound, such as grunting, suggests *respiratory distress syndrome*, and a high, crowing sound on inspiration suggests stridor or immature tracheal development, both conditions that need immediate consultation (see [Chapter 40](#)).

## THE ABDOMEN

The contour of a newborn abdomen looks slightly protuberant. A scaphoid or sunken appearance suggests missing abdominal contents or a diaphragmatic hernia (bowel or other abdominal organs positioned in the chest instead of the abdomen). Bowel sounds show the bowel is beginning peristalsis and should be present within 1 hour after birth. On the right side, the edge of the liver is usually palpable 1 to 2 cm below the costal margin. On the left side, the edge of the spleen may be palpable 1 to 2 cm below the left costal margin.

For the first hour after birth, the stump of the umbilical cord appears as a white, gelatinous structure marked with the blue and red streaks of the one umbilical vein and the two arteries. Any child with a single umbilical artery needs close needs and assessment for anomalies that are frequently associated with the lack of an umbilical artery (Gutvitz, Walfisch, Beharier, et al., 2016).

Always inspect the cord clamp to be certain it is secure. After the first hour of life, the cord will begin to dry, shrink, and turn brown as if it were the dead end of a vine. By the second or third day, it will have turned black. On day 6 to 10, it breaks free, leaving a granulating area a few centimeters wide that will heal during the following week.

There should be no bleeding at the base of the cord and it should not appear wet. A moist or odorous cord suggests infection, requiring immediate antibiotic therapy to prevent the infectious organisms from entering the newborn's bloodstream and causing septicemia. Moistness at the base of the cord also may indicate a patent urachus (a narrow opening that connects the bladder and the umbilicus), which requires surgical repair (Gleason, Bowlin, Bagli, et al., 2015).

Inspect the base of the cord to be certain no abdominal wall defect such as an umbilical hernia is present. If there is an abdominal wall defect smaller than 2 cm in diameter, it will usually close on its own by school age; a larger defect may require surgical correction. Taping or putting buttons or coins on the cord are home remedies that may be seen. There is no evidence for these actions. To the contrary, heavy taping may worsen the condition by preventing the development of abdominal wall muscle and may also may keep the cord moist, increasing the risk for infection.

When a newborn voids, it demonstrates that there is at least one kidney functioning (but not necessarily two). Attempt to verify the presence of kidneys by deep palpation of the right and left abdomen within the first few hours after birth before the intestines fill with air, making palpation more difficult (see [Chapter 34](#)). A small kidney suggests decreased function; an enlarged kidney suggests a polycystic kidney or pooling of urine from a urethral obstruction.

To finish an abdominal assessment, elicit an abdominal reflex. Stroking each quadrant of the abdomen with a finger should cause the umbilicus to move or “wink” in that direction. This superficial abdominal reflex, a test of spinal nerves T8 through T10, is usually present at birth, but may not be observable until it is stronger at about the 10th day of life.

### **QSEN Checkpoint Question 18.5**

#### **TEAMWORK & COLLABORATION**

Mrs. Ruiz is preparing to take her new daughter home and has asked an unlicensed care provider when Beth's dried umbilical cord will fall off. The nurse should confirm that the care provider has stated what time?

- a. Day 1
- b. Days 2 to 3
- c. Days 6 to 10
- d. Day 30

*Look in [Appendix A](#) for the best answer and rationale.*

#### **THE ANOGENITAL AREA**

Examine the anus to ascertain its presence and patency. Test for anal patency and that the anus is not covered by a membrane (imperforate anus) by gently inserting the tip of your gloved and lubricated little finger. Note the time after birth when the infant first passes meconium. If a newborn does not do so in the first 24 hours, there may be an anatomical or physiologic problem that needs to be assessed.

#### **The Male Genitalia**

The scrotum in most male newborns is edematous and has rough rugae on the surface. It may be deeply pigmented in dark-skinned newborns. Both testes should be palpable in the scrotum. If one or both testicles are not present (cryptorchidism), referral is needed to further investigate the problem. This condition could be caused by agenesis (absence of the testes), ectopic testes (the testes are present in the abdomen but cannot enter the scrotum because the opening to the scrotal sac is closed), or undescended testes (the vas deferens or artery is too short to allow the testes to descend). Make a practice of pressing your nondominant hand against the inguinal ring before palpating for testes, so they do not slip upward and out of the scrotal sac as you palpate ([Fig. 18.21](#)). Newborns with agenesis of the testes are usually referred for investigation of kidney anomalies because the testes arise from the same germ tissue as the kidneys ([Hutson & Thorup, 2015](#))

**Figure 18.21** Press the nondominant hand against the inguinal ring when palpating the testes.

Always elicit a cremasteric reflex by stroking the internal side of the thigh while inspecting testes (as the skin on the thigh is stroked, the testis on that side moves perceptibly upward). The response is indication that spinal nerves T8 through T10 are intact, although it may be absent before 10 days of age when nerve stabilization is complete.

The penis of newborns appears small, approximately 2 cm long. Shorter length requires referral to an endocrinologist to investigate any other anomalies. Inspect the tip of the penis to be certain the urethral opening is at the tip of the glans, not on the dorsal surface (epispadias) or on the ventral surface (hypospadias). In most newborns, the prepuce (foreskin) slides back very little from the meatal opening, so don't try to retract it.

### **The Female Genitalia**

The vulva in female newborns may appear swollen because of the effect of maternal hormones during intrauterine life. Some female newborns also have a mucus vaginal secretion, sometimes blood tinged (**pseudomenstruation**), which is also caused by maternal hormones. The discharge does not indicate an infection or trauma and disappears in 1 or 2 days.

### **THE BACK**

A newborn normally assumes the position maintained in utero for days after birth, with the back rounded and arms and legs flexed across the abdomen and chest. A child who was born in a frank breech position tends to straighten the legs at the knee and bring them up next to the face. The position of a baby with a face presentation sometimes simulates opisthotonos (backward arching of the spine) for the first week because the curve of the back is concave.

The spine of a newborn typically appears flat in the lumbar and sacral areas; these

curves appear after a child is able to sit and walk. Inspect the base of a newborn's spine carefully to be certain there is no pinpoint opening, dimpling, or sinus tract in the skin, which suggest a dermal sinus or spina bifida occulta (see [Chapter 27](#)) ([Lewis, 2014](#)).

## THE EXTREMITIES

The arms and legs of a newborn appear short in proportion to the trunk. The hands seem plump and are typically clenched. Newborn fingernails feel soft and smooth and extend over the fingertips. Test the upper extremities for muscle tone by unflexing the arms for approximately 5 seconds then letting them return to their flexed position (which typically occurs immediately if muscle tone is good). Next, hold the arms down by the sides and note their length. The fingertips on both sides should reach as far as the mid-thigh. Unusually short arms may signify achondroplasia (dwarfism) and would require further evaluation.

Observe for curvature of the little finger, and inspect the palm for a simian crease (a single palmar crease). Although curved fingers and simian creases can occur normally, they are commonly seen in children with Down syndrome ([Nussbaum, McInnes, & Willard, 2016](#)).

When a newborn moves, the arms and legs should move symmetrically (unless the infant is demonstrating a tonic neck reflex). Asymmetry suggests birth injury, such as injury to a clavicle or to the brachial or cervical plexus or fracture of a long bone. Assess for webbing (syndactyly) between fingers as well as missing or extra fingers (polydactyly). Test to see whether the fingernails fill immediately after blanching from pressure to test for adequate blood circulation.

Newborn legs appear bowed and short. The sole of the foot is flat because of an extra pad of fat in the longitudinal arch. The foot of a term newborn has many crisscrossed lines on the sole, covering approximately two thirds of the foot. If these creases cover less than two thirds of the foot or are absent, it suggests the infant is preterm.

Move the ankle through a range of motion to evaluate that the heel cord is not unusually tight. Check for ankle clonus by supporting the lower leg in one hand and dorsiflexing the foot sharply two or three times by pressure on the sole of the foot with the other hand. After the dorsiflexion, one or two continued movements are normal. Rapid alternating contraction and relaxation (clonus) is not normal and suggests neurologic or calcium insufficiency. The feet may turn in (varus deviation) because of their former intrauterine position. This is benign if the feet can be brought to the midline position by easy manipulation. When the infant begins to bear weight, the feet will align themselves without treatment.

If a foot does not align readily or will not turn to a definite midline position, a talipes deformity (clubfoot) may be present and warrants specialty referral.

To test if the femur is situated comfortably in the hip socket, with a newborn in a supine position, flex both hips and abduct the legs as far as they will go (typically 180 degrees or the knees touch or nearly touch the surface of the bed) ([Fig. 18.22](#)). If the hip

joint seems to lock short of this distance (160 to 170 degrees), it suggests hip subluxation (Sankar, Horn, Wells, et al., 2016). Confirm subluxation by holding the infant's legs with the fingers on the greater and lesser trochanters and then abduct the hips; if subluxation is present, a "clunk" of the femur head striking the shallow acetabulum can be heard (Ortolani sign). If the femur can be felt to actually slip in and out of the socket, this is a Barlow sign. A subluxated hip may be bilateral or unilateral. Like talipes disorders, it is important that a hip subluxation be identified early because correction is most successful if initiated early.

**Figure 18.22** Hip abduction in a newborn. Both hips should abduct so completely that they lie almost flat against the mattress (180 degrees).

Lastly, inspect the feet for missing or extra toes or unusual spacing of toes, particularly between the big toe and the others; although this finding can be a normal finding in some families, it is also present in certain chromosomal disorders. When placed on their abdomen, newborns should be capable of bringing their arms and legs underneath them and raising their stomach slightly off the bed. The preterm newborn is not able to do this.

## LABORATORY STUDIES

After the first hour of undisturbed rest, depending on health agency policy, newborns may have a heel-stick test for hematocrit, hemoglobin, and hypoglycemia determinations. Hemoglobin is assessed to detect newborn anemia that could have been caused by hypovolemia because of bleeding from placenta previa or abruptio placentae or by a cesarean birth that involved incision into the placenta. Another condition as dangerous as anemia is the presence of excess red blood cells (polycythemia), probably

caused by excessive flow of blood into an infant from the umbilical cord. A heel-stick hematocrit reveals both hypovolemia and hypervolemia if they are present. A normal hematocrit at 1 hour of life is about 50% to 55%.

Hypoglycemia, like anemia, produces few symptoms in newborns, so glucose is also tested with the heel capillary blood sample. A serum glucose reading that is less than 40 mg/100 ml of blood (30 mg/100 ml in the first 3 days of life) indicates hypoglycemia. To correct this condition, the infant is prescribed oral glucose or is breastfed immediately because either will elevate the infant's blood sugar to a safe level. It is important to treat hypoglycemia quickly because if brain cells become completely depleted of glucose, brain damage can result. Newborn symptoms of hypoglycemia include jitteriness, lethargy, seizures, and intravenous glucose may be prescribed. A continuous intravenous infusion of glucose may be necessary if the newborn is unable to maintain glucose levels higher than 40 mg/100 ml.

Heel sticks require a minimum of blood and are minimally traumatic.

## The Care of a Newborn at Birth

Birthing rooms provide an island for newborn care separate from the supplies needed for the mother's care. Necessary equipment includes a radiant heat table or warmed bassinet; a warm, soft blanket; and equipment for oxygen administration, resuscitation, suction, eye care, identification, and weighing of a newborn.

Newborns should be handled gently at birth. The image of an obstetrician holding a newborn up by the heels and spanking to stimulate breathing exists only in movies because such treatment is probably painful after the months spent in a flexed position in utero. In addition, gentle stimulation, such as rubbing the back, will stimulate breathing.

### NEWBORN IDENTIFICATION AND REGISTRATION

Newborn identification is an important nursing responsibility. Nurses must be certain the infant has an identification band in place, so medicine administration or performing procedures can be done safely.

#### Identification Banding

One traditional form of identification used with newborns is a plastic bracelet with a permanent lock that requires cutting to be removed. A number that corresponds to the mother's hospital number; the mother's name; and the sex, date, and time of the infant's birth are printed on the band. If an identification band is attached to a newborn's arm or leg, two bands should be used because bands can slide off easily. A newer form of identification band has a built-in sensor unit that sounds an alarm—similar to those attached to clothing in department stores to stop shoplifting—if a baby is transported beyond set hospital boundaries (Fig. 18.23).

**Figure 18.23** This newborn is wearing a security band, which sets off an alarm and locks exits if an infant is taken off the unit.

After identification bands are attached, an infant's footprints may be taken (Fig. 18.24A) and thereafter kept with the baby's electronic record for permanent identification (see Fig. 18.24B). Babies who are born elsewhere and then admitted to the hospital should have bands applied and their footprints taken on admission.

**Figure 18.24 (A)** Footprinting a newborn for identification. **(B)** Newborn footprints.

## Infant Abduction

Infant identification is important because a newborn may be handed to the wrong mother or be switched or abducted from a healthcare facility. The profile of someone who might abduct a newborn is a woman who has recently lost a pregnancy or had an infant stillborn. She often is someone familiar with hospitals and may pretend to be a volunteer or a healthcare worker and say she needs to take a baby out the mother's room for a procedure. Although rare, all healthcare personnel need to be vigilant, take measures to prevent infant abduction, and alert parents to the danger so they can also be vigilant (Box 18.4) (National Center for Missing & Exploited Children, 2016).

### BOX 18.4

#### Nursing Care Planning Based on Family Teaching

#### MEASURES TO HELP PREVENT ABDUCTION FROM A BIRTH SETTING UNIT

**Q.** Beth's mother tells you, "I've read babies are being kidnapped from hospitals. How can we make sure that doesn't happen to us?"

**A.** Although abduction is rare, it can happen. To minimize the risk, use the following guidelines:

- Review the hospital's newborn identification procedure with a nurse so you are familiar with it and can feel comfortable with the safeguards being taken.
- Check that identification bands are in place on your infant as you care for her because these can slide off easily over small hands or feet. If a band or necklace is missing, ask a nurse to replace it immediately.
- Do not allow any person without proper hospital identification to remove your baby from your room. Be certain they describe why they are taking your baby.
- Do not leave your baby unattended in your room. Either return the baby to the nursery or take your baby with you if you are leaving your room, for example, to walk in the hallway.
- Report the presence of any suspicious person you observe in the unit.
- Some hospitals use a microchip system embedded in identification bands, similar to the tag used to thwart shoplifting in department stores, which sounds an alarm if a baby is removed from the unit. If this type of band is used, be certain it is removed before hospital discharge, or it will set off an alarm as you leave.

## Birth Registration

The primary care provider who supervised a newborn's birth has the responsibility to be certain a birth registration is filed with the Bureau of Vital Statistics for the state in

which the infant was born. The infant's name, the mother's name, the father's name (if the mother chooses to reveal this), and the birth date and place are recorded. This official birth information is important for eligibility for school, voting, passports, and Social Security benefits.

### Birth Record Documentation

The infant's chart is also a vital piece of documentation because it serves as a baseline for the infant's health. It should contain the following:

- Time of birth
- Time the infant breastfed
- Whether respirations were spontaneous or aided
- Apgar score at 1 minute and at 5 minutes of life
- Whether eye prophylaxis was given
- Whether vitamin K was administered
- General condition of the infant
- Number of vessels in the umbilical cord (Fig. 18.25)
- Whether cultures were taken
- Whether the infant voided and whether he or she passed a stool

**Figure 18.25** A chart abbreviation for a three-vessel cord.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for ineffective thermoregulation related to newborn's transition to extrauterine environment

**Outcome Evaluation:** Newborn establishes axillary temperature of 98.6°F (37°C) by 1 hour after birth.

Following birth, a newborn is placed on the mother's abdomen for a period of skin-to-skin contact to help retain heat. Allow the mother to begin breastfeeding if she wishes and to allow time for parents to enjoy and get acquainted with their newborn. It's important not to interrupt this time because newborns are alert (first period of activity) and respond well to the parents' first tentative touches or interactions with them during this time (Box 18.5). After about 30 minutes, begin routine care such as

footprinting and administering eye drops if the parents want eye drops administered. Be certain to adhere to standard infection precautions, such as wearing gloves, when caring for newborns. Grasp a newborn securely when lifting off the mother's abdomen. Newborn skin is slippery, and infants can slip through your hands easily.

## BOX 18.5

### Nursing Care Planning to Respect Cultural Diversity

What new parents believe is usual newborn care is not consistent across cultures and actually varies a great deal. Although it is enjoyable to point out the positive aspects of their new child to parents in order to aid parent–child bonding, in some areas of the world, such as Cambodia and Laos, newborns are not given compliments this way because it is believed compliments could leave them vulnerable to invading spirits. In other cultures, it is vitally important for a newborn to have an amulet (good-luck charm) tied around the neck or wrist to ward off danger. Respect these as important items and leave them in place when caring for the infant.

In the traditional Haitian culture and some Native American cultures, infants are not named immediately but only after a set period of time (to be certain the name will truly reflect the child's personality). Oiling the infant's body and placing a belly band over the umbilical cord (thought to reduce the incidence of umbilical hernias) also are common care practices. Being aware of cultural variations in newborn care such as these helps you plan care specific and meaningful to individual parents and can aid parent–child bonding as well as parent–nurse relationships.

All of the measures mentioned previously such as skin-to-skin contact, gently rubbing a newborn dry, swaddling the infant with a blanket, and placing a cap on the infant's head (Fig. 18.26) help to prevent heat loss and also mimic the tight confines of the uterus, which can offer a sense of security and comfort (Pillai Riddell, Racine, Gennis, et al., 2015).

**Figure 18.26** A newborn wrapped and capped to conserve body heat.

Although the temperature of newborns who are dried, wrapped, and then held by their parents immediately after birth apparently falls slightly lower than that of infants placed in heated cribs, their core temperature does not fall below safe limits.

At the end of the first hour of life, a newborn can be bathed quickly to remove excess vernix caseosa and blood, then dressed in a shirt and diaper, swaddled in a blanket, and placed in a bassinet or returned to the parents.

During the first day of life, a newborn's temperature is usually taken and recorded every 4 to 8 hours. After that, it is done daily in the healthcare facility unless indicated. If an infant has difficulty maintaining temperature, place him or her in a warmed incubator or on a radiant heat warmer and notify the primary care provider because the infant may be more immature than was estimated or is ill in some way.

**Nursing Diagnosis:** Risk for ineffective airway clearance related to presence of mucus in mouth and nose at birth

**Outcome Evaluation:** Neonate maintains a respiratory rate of 30 to 60 breaths/min without evidence of retraction or grunting by 5 minutes after birth.

A number of measures help ensure a newborn is breathing effectively.

**Record the First Cry.** A crying infant is a breathing infant because the sound of crying is made by a current of air passing over the larynx. The more lusty the cry, the greater the assurance the newborn is breathing deeply and forcefully. Vigorous crying may also help blow off the extra carbon dioxide that makes all newborns slightly acidotic. Although gentleness is necessary to make an infant's transition from intrauterine life to extrauterine life as nontraumatic as possible, there is no need to completely halt the initial crying of a newborn.

A newborn who does not breathe spontaneously at birth or who takes a few quick, gasping breaths but then is unable to maintain respirations needs resuscitation as an emergency measure. An infant with grunting respirations needs careful observation for respiratory distress syndrome (see [Chapter 26](#)).

**Promote Adequate Breathing Pattern and Prevent Aspiration** Although not done routinely, if a newborn appears to have a great deal of mucus in the mouth following birth, the primary care provider can suction mucus from the infant's mouth with a bulb syringe. If needed, this is done before the infant is laid on the mother's abdomen in order to prevent aspiration of the secretions. If the infant continues to have an accumulation of mucus in the mouth or nose after these first steps, you may need to suction further after the baby is placed under a warmer. Use a bulb syringe or a soft, small (#10 or 12) catheter. Always suction gently to prevent mucous membrane irritation that could leave a portal of entry for infection. Brisk suctioning also has been associated with bradycardia in newborns because of vagal nerve stimulation. With a bulb syringe, decompress the bulb before inserting it into the infant's mouth

or nose; otherwise, the force of decompression of the bulb could push secretions back into the pharynx or bronchi. Although the use of the procedure is not standardized, when an infant is born with meconium-stained amniotic fluid, intubation may be performed so deep tracheal suction can be accomplished before the first breath to help prevent meconium aspiration into the lungs. The use of surfactant and inhaled nitric oxide may also be helpful to assist breathing if meconium aspiration has occurred (discussed in [Chapter 26](#)) ([Carlo & Ambalavanan, 2016](#)).

**Nursing Diagnosis:** Risk for infection related to newly clamped umbilical cord and exposure of eyes to vaginal secretions

**Outcome Evaluation:** Area around cord is dry and free of erythema. Eyes are free of inflammation and drainage. Axillary temperature is maintained between 97.6°F and 98.6°F (36.5°C and 37°C).

**Inspect and Care for the Umbilical Cord.** The umbilical cord pulsates for a moment after an infant is born as a last flow of blood passes from the placenta into the infant. Two clamps are then applied to the cord about 8 in. from the infant's abdomen, and the cord is cut between the clamps. The woman's partner may choose to cut the cord. The infant cord is then reclamped by a permanent cord clamp, such as a Hazeltine or a Kane clamp (see [Chapter 15, Fig. 15.28](#)).

Every time you handle a newborn, inspect the cord to be certain it is clamped securely because if it loosens before thrombosis obliterates the umbilical vessels, hemorrhage could result. As previously mentioned, the number of cord vessels should be counted immediately after the cord is cut because they are most visible before drying begins. Until the cord falls off, at about 7 to 10 days of life, be certain diapers are folded below the level of the umbilical cord to help keep the cord dry. Advise parents to keep the cord dry until it falls off. Discourage the use of creams, lotions, and oils near the cord because these tend to slow drying and may invite infection. Remind them to use sponge baths until the cord falls off. Some healthcare agencies recommend that parents apply rubbing alcohol to the cord site once or twice a day to hasten drying. Most agencies recommend using no products because any manipulation of the cord could invite infection ([Gooding & McClead, 2015](#)). After the cord falls off, a small, pink, granulating area about a quarter of an inch in diameter may remain. This should also be left clean and dry until it has healed (about 24 to 48 more hours). If the ulcerous area is still present after a week, it may require cautery with silver nitrate (a quick office procedure) to speed healing.

**Administer Eye Care.** Although the practice may eventually become obsolete, as it is in some countries, most birth settings in the United States and Canada still administer prophylactic eye treatment (erythromycin ointment) to help prevent gonorrheal and chlamydia conjunctivitis. Such infections are usually acquired from the mother as the infant passes through the birth canal; therefore, if a mother is certain she does not have either of these diseases, she can request eye drops not be given. Eye prophylaxis

is typically applied immediately after birth and should be given within the first 24 hours for maximal effectiveness (U.S. Preventive Services Task Force, 2011). If it is given, allow parents to interact with their infant before the procedure so their newborn can focus on them without blurry vision caused by the ointment.

If applying eye ointment, always use a single-use tube or package of ointment to avoid transmitting an infection from one newborn to another. First dry the newborn's face with a soft gauze square. Open the newborn's eyes by shading them from the light and then press on both the lower and upper lids one eye at a time with a finger and your thumb. Squeeze a line of ointment along the lower eyelid from the inner canthus outward. Let the eye close to allow the ointment to spread across the conjunctiva.

If it is the healthcare policy to instill eye ointment, babies born at home or other settings such as a car or taxi should have the prophylactic treatment administered on admission to the hospital unless the parents are certain they are both free of gonorrheal and chlamydial infections and they refuse the treatment.

**General Infection Precautions.** Each newborn's private bassinet should have compartments that hold a supply of diapers, shirts, gowns, and individual equipment for bathing and temperature taking. Avoid sharing of these items to prevent the spread of infection.

Healthcare workers caring for newborns should thoroughly wash their hands and arms to the elbows with an antiseptic soap before handling infants. Although not proven to reduce infections, agency personnel are usually required to wear cover gowns or nursery uniforms when directly caring for infants (Webster & Pritchard, 2011).

Staff members with infections (particularly sore throats, upper respiratory tract infections, or herpes lesions) should be excluded from caring for mothers or infants until the condition has completely cleared. If a mother might have a contagious illness, her newborn should be excluded from her room until there is no longer a possibility of contagion. Daily photographs and videos can help the mother follow the baby's progress. The mother should manually express breast milk during this time to help maintain her milk supply. The mother can resume breastfeeding as soon as it is safe for her infant.

Any baby born outside a hospital or under circumstances conducive to infection, such as rupture of membranes more than 24 hours before birth, should be kept in the mother's room until negative cultures show the newborn is free of infection. Likewise, any newborn in whom symptoms of infection develop should be housed in the mother's room or an isolation nursery to prevent the spread of infection to other babies in a common nursery. Encourage parents to visit the baby to help decrease any worries due to the isolation. When visiting isolation nurseries, parents are required to use the same infection control techniques staff members use such as masks or gowns.

## Nursing Care of a Newborn and Family in the Postpartal Period

Newborns are cared for in either a birthing room or a transitional nursery for optimal safety in the first few hours of life. [Box 18.6](#) shows an interprofessional care map illustrating both nursing and team planning for newborn care during a healthcare agency stay.

### BOX 18.6

#### Nursing Care Planning

##### AN INTERPROFESSIONAL CARE MAP FOR A TERM NEWBORN

Carlotta Ruiz has just given birth to her second child, a 39 weeks and 2 days, 6-lb, 5-oz baby girl. While Jose, Carlotta’s husband, is in the room, Carlotta tells you she is a “veteran” at baby care. When Carlotta is alone, however, you notice she seems apprehensive about caring for her new daughter.

**Family Assessment:** Family is composed of two parents, a 3-year-old sibling, and newborn. They live in a three-bedroom flat over a dry cleaning store. Father clerks in a grocery store; mother works as a school bus driver. Finances rated as “hanging in there.”

**Patient Assessment:** Birth from left occipitoanterior (LOA) position. Apgar score: 6 at 1 minute; 8 at 5 minutes after administration of blow-by oxygen. Respirations are 74 breaths/min. She has a 2 × 3 cm red pigmented area on outer right thigh. Mother attempted breastfeeding in birthing room, but newborn had difficulty sucking because of rapid respirations. Remainder of physical examination within acceptable parameters.

**Nursing Diagnosis:** Risk for ineffective parenting related to infant’s smaller than expected size and birthmark

**Outcome Criteria:** Respiratory rate is decreased to 30 to 50 breaths/min, infant sucks well at breast every 2 to 3 hours, and mother voices she is pleased with infant’s appearance and progress.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome

## THE INITIAL FEEDING

The Baby-Friendly Hospital Initiative (BFHI) is a global program sponsored by the WHO and the [United Nations Children's Fund \(UNICEF\)](#) to encourage and recognize hospitals and birthing centers that offer an optimal level of care for infants that promotes breastfeeding.

To qualify as a Baby-Friendly–designated facility, a setting must:

1. Maintain a written breastfeeding policy that is routinely communicated to all healthcare staff.
2. Educate all healthcare staff in skills necessary to implement the written policy.
3. Inform all pregnant women about the benefits and management of breastfeeding.
4. Help mothers initiate breastfeeding within 1 hour of birth.

5. Show mothers how to breastfeed and how to maintain their milk supply, even if they are separated from their infants.
6. Offer breastfed newborns no food or drink other than breast milk unless medically indicated.
7. Practice “rooming in” or allow mothers and infants to remain together 24 hours a day.
8. Encourage unrestricted or “on-demand” breastfeeding.
9. Give breastfeeding infants no pacifiers or artificial nipples.
10. Foster the establishment of breastfeeding support groups and refer mothers to them on discharge from the birth setting ([UNICEF, 2016](#)).

After a first feeding in the birthing room, both formula-fed and breastfed infants do best with an “on-demand” schedule (i.e., are fed when they are hungry). Many need to be fed as often as every 1.5 to 2 hours in the first few days and weeks of life. [Chapter 19](#) discusses techniques of both breastfeeding and formula feeding. Nurses can play an important role in helping new mothers establish breastfeeding during the infant’s first weeks of life.

## BATHING

The Association of Women’s Health, Obstetric and Neonatal Nurses recommends that most newborns receive a complete sponge bath in 2 to 4 hours after birth when their temperature and vital signs are stable. There is no need to use antibiotic cleansers and no need to remove all vernix ([Association of Women’s Health, Obstetric and Neonatal Nurses, 2013](#)). Babies of mothers with HIV infection should have a thorough bath immediately to decrease the possibility of HIV transmission. Thereafter, all babies are sponge bathed once a day, although the procedure may be limited to washing only the baby’s face, diaper area, and skin folds. Wear gloves when handling newborns until the first bath to avoid exposing your hands to body secretions such as the vernix caseosa.

Plan to help a mother give a first bath before (not after) a feeding to prevent spitting up or vomiting and possible aspiration. Check to be certain the mother’s room is warm (about 75°F [24°C]) to prevent chilling. Supply bath water at 98° to 100°F (37° to 38°C), a temperature that feels pleasantly warm to the elbow or wrist, plus a washcloth, towel, comb, and clean diaper and shirt.

As a rule, bathing should proceed from the cleanest parts of the body to the most soiled areas—that is, from the eyes and face to the trunk and extremities and, last, to the diaper area. Wipe a newborn’s eyes with clear water from the inner canthus outward, using a clean portion of the washcloth for each eye to prevent spread of infection to the other eye. Remind the mother to wash around the cord with care so she doesn’t soak the cord and to give particular care to the creases of skin where milk tends to collect if the child spits up after feedings. If the mother wants to use a mild neutral soap for sponging, be sure she rinses well so no soap is left on the skin (soap is drying and newborns are susceptible to desquamation) and also to dry well. It’s good for parents to wash the infant’s hair daily during the bath. The easiest way to do this is to first soap the

hair with the baby lying in the bassinet. Then, hold the infant in one arm over a basin of water as you would a football (Fig. 18.27). Pour water from the basin over the hair to rinse. Dry the hair well to prevent chilling. Inform the parents that lathering and gently massaging all parts of the head including the soft spots will help prevent buildup of scales.

**Figure 18.27** A football hold. Such a position supports the infant's head and back and leaves the nurse's or mother's other hand free for assembling or using equipment.

In male infants, the foreskin of the uncircumcised penis should not be forced back while washing the penis, or constriction of the penis may result. Wash the vulva of a female infant, wiping from front to back to prevent contamination of the vagina or urethra by rectal bacteria.

Most healthcare agencies do not apply powder or lotion to newborns because some infants are allergic to these products and breathing in powder can cause respiratory distress (adult talcum powders contain zinc stearate, which is irritating to the respiratory tract). If a newborn's skin seems extremely dry and portals for infection are becoming apparent because of cracking in the skin, a lubricant such as Nivea oil, added to the bath water or applied directly to the baby's skin, should relieve the condition.

## **SLEEPING POSITION**

Sudden infant death syndrome (SIDS) is the sudden, unexplained death of an infant younger than 1 year of age. Although the specific cause of SIDS cannot be explained, these interventions have been shown to decrease the incidence of the syndrome: place infant on the back to sleep; use a firm sleep surface; breastfeeding; room sharing without bed sharing; routine immunizations; consideration of using a pacifier; avoidance of soft bedding, overheating; and exposure to tobacco smoke, alcohol, and illicit drugs ([National Institutes of Health \[NIH\], 2015](#)).

## **DIAPER AREA CARE**

Preventing diaper dermatitis, or diaper rash, is a practice parents need to start from the very beginning with their newborns ([Visseher, Adam, Brink, et al., 2014](#)). Advise parents to change diapers frequently and, with each diaper change, wash the area with clear water and dry well. For yourself, wear gloves for diaper care as part of standard precautions.

## **METABOLIC SCREENING TESTS**

Newborns born in a hospital or birthing center are routinely screened for more than 30 metabolic or inherited disorders by a screening technique that requires a small blood sample obtained by a heel stick and then dropped onto special filter paper ([Tluczek & De Luca, 2013](#)). Ideally, a baby should have received formula or breast milk for 24 hours before the blood is obtained for best results.

If, for some reason, blood testing is not done before discharge, alert parents that they need to schedule screening tests at an ambulatory visit in 2 to 3 days' time. Always assess at a newborn's first health supervision visit that screening was done.

## **HEPATITIS B VACCINATION**

All newborns born in a hospital or a birthing center receive a first vaccination against hepatitis B within 12 hours after birth; a second dose will then be administered at 1 month and a third one at 6 months. Infants whose mothers are positive for the hepatitis B surface antigen (HBsAg) also receive hepatitis B immune globulin (HBIG) at birth ([AAP, 2015a](#)).

## **VITAMIN K ADMINISTRATION**

Newborns are at risk for bleeding disorders during the first week of life because their gastrointestinal tract is sterile at birth and therefore unable to produce vitamin K, a vitamin necessary for blood coagulation. A single dose of 0.5 to 1.0 mg of vitamin K administered intramuscularly within the first hour of life helps prevent such problems ([Phillippi, Holley, Morad, et al., 2016](#)).

## **CIRCUMCISION**

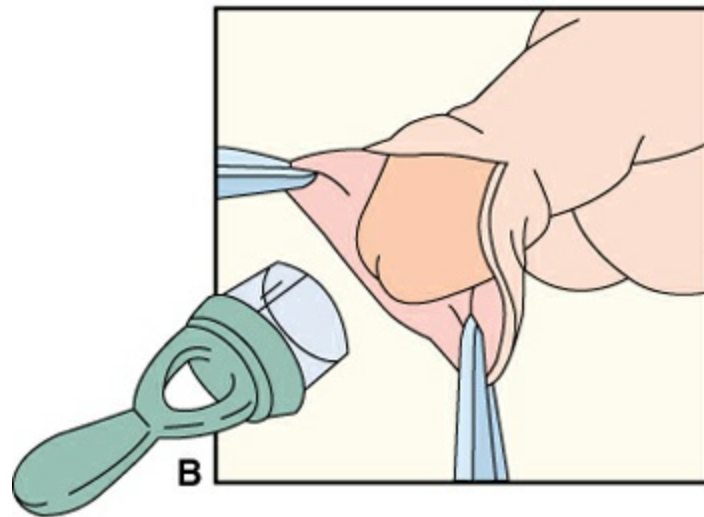

Circumcision is the surgical removal of the foreskin of the penis. Except for a baby who has constriction (phimosis) of the foreskin that obstructs the urinary meatal opening (rare), there are few medical indications to circumcise a male newborn. Some parents elect not to have their male infant circumcised because the operation is painful and increases the risk of cold exposure and infection. Scientific evidence shows that circumcision reduces the risk of HIV, human papillomavirus (HPV), and cancer in the male as well as cervical cancer in a female sexual partner, suggesting that the preventive health benefits of male infant circumcision may outweigh the risks. At this point, the AAP has declined to recommend routine circumcision for boys. Therefore, parents are free to evaluate risks and benefits and then make this health decision for their child

(AAP, 2012). Circumcision is performed as a religious rite among some groups such as Jewish and Muslim communities. Contraindications for circumcision include a history of a bleeding tendency in the family or hypospadias or epispadias because the prepuce skin may be needed when a plastic surgeon repairs these defects.

The procedure is best performed during the first or second day of life, after the baby has synthesized enough vitamin K to reduce the chance of faulty blood coagulation rather than immediately after birth when the level of vitamin K is at a low point.

For the procedure, an infant is placed in a supine position and restrained either manually or with a commercial swaddling board. Application of EMLA cream (a *eutectic mixture of local anesthetics*) or a similar compound is a popular choice for local anesthesia. Regional block anesthesia may also be used if an anesthetist is involved.

For the actual procedure, a specially designed plastic bell (Plastibell) is fitted over the end of the penis. A suture is then tied around the rim of the bell and a circle of the prepuce is cut away, allowing the remaining foreskin to be easily retracted and the glans to be fully exposed (Fig. 18.28). The rim of the bell will remain in place for about 1 week and then fall off by itself. While in place, the bell helps protect against infection and bleeding because it prevents the healing penis from sticking to a diaper. Petrolatum ointment may be applied to further decrease the possibility of penile secretions adhering to the diaper and causing pain at a diaper change.

**Figure 18.28** The technique for performing circumcision using a Plastibell. **(A)** An incision is made at the top of the foreskin. **(B)** The Plastibell is placed over the head of the penis, and the foreskin is pulled over the Plastibell. **(C)** A suture is tied around the foreskin over

the tying groove in the Plastibell. Excess skin beyond the suture is trimmed away. The Plastibell falls off in 3 to 7 days. (Courtesy of Hollister Inc., Libertyville, IL.)

Complications that can occur from circumcision include hemorrhage, infection, and urethral fistula formation. To keep the risk of these complications to a minimum, check the infant for bleeding every 15 minutes for the first hour and observe closely for about 2 more hours. Document that the infant is voiding after the procedure to be certain the urethra is not occluded.

The circumcision site appears red but should not have a strong odor or discharge. A film of light yellow mucus often covers the glans (similar to a scab) by the second day after surgery and should not be washed away because it serves a protective function.

Teach parents to keep the area clean from feces and covered with petrolatum (if used) for about 3 days or until healing is complete. If they notice any redness or tenderness, or if the baby cries as if in constant pain, they should report it to their primary care provider because this suggests an infection.

## **The Assessment of a Family's Readiness to Care for a Newborn at Home**

It is important to assess how prepared each family is to care for their newborn at home to be certain the newborn will remain safe and develop a sense of security. Parents may need to plan changes in their routine, such as shifting their usual dinner time. Their sleep schedules are certain to be disrupted because infants wake during the night for one or more feedings for about the first 4 months of life.

The physical environment of the home to which a newborn will be discharged is important to explore with parents. Pertinent questions and areas to consider include:

- How many other people live in the home? (Infections spread more rapidly in crowded homes.)
- Are there any pets in the home? Will a large dog, for example, be a safe pet around the baby?
- Is there a bed for the baby? (A separate baby bed helps prevent SIDS.)
- Who will be the primary caregiver? (This is the person who needs to be given discharge instructions.)
- Does the mother have anyone to turn to if she has questions about the baby? (This is especially important at night when a primary health provider's office will be closed.)
- Is there a refrigerator in the home? (Formula or breast milk will need to be stored.)
- Is there adequate heat? (An infant needs a temperature of 70° to 75°F during the day and 60° to 65°F at night.)
- Are the windows draft free and screened to keep out insects such as mosquitoes?

- If housing is in poor condition, is there a danger that rodents might attack the baby?
- Is there a danger of lead poisoning? (An older home may have lead-based paint on the walls, which chips and can be eaten by infants.)
- Does the family have a source of income? (If not, what sort of referral is needed to care for the child?)
- Does the mother have a concrete plan for continuing health care for the infant?

These are not prying questions but a means of determining whether the home will be adequate and safe for a newborn. A home assessment will also help the nurse determine when additional resources are needed by the family. In some cases, the home environment may be unsafe and a referral to social services may be necessary before the newborn is discharged.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Health-seeking behaviors related to the needs of a newborn after discharge from the healthcare facility

**Outcome Evaluation:** Parents state ways in which they have already altered their home and lifestyle to accommodate their newborn and indicate they are prepared for other changes; mother voices relative confidence in her ability to care for a newborn and states names of individuals within her family or community who can serve as resources when needed.

Remind a woman and her partner before discharge to consider how they will care for their child at home. Many couples mull over these concerns during pregnancy, whereas others wait until the child is born to address these important issues.

Mothers who are young, without family support, or those who did not receive regular prenatal care may be particularly unprepared for the hours and effort involved in newborn care. To assist them, try to anticipate problems most relevant to them. If there are other children or pets at home, for example, discuss that sibling or pet jealousy may naturally occur. Check the child's identification band against the mother's band a final time before discharge.

**Daily Home Care.** Newborns thrive on a gentle rhythm of care and a sense of being able to anticipate what is to come next. At the same time, however, there is no set time at which an infant must be bathed or put to sleep. If the house is cold, a newborn does not need a bath every day. If a parent works evenings, it may be important to have the baby awake later in the evening so that parent has time to spend with the child.

Your aim in helping parents plan their schedule of care is to arrive at one that:

- Offers some consistency (a mother cannot expect an infant to stay awake until midnight five nights a week, then go to sleep at 7 pm on the sixth night)
- Appears to both satisfy the infant and offer the mother and her partner a sense of well-being and contentment with the child

**Sleep Patterns.** A newborn sleeps an average of 16 hours out of every 24 during the first week home, sleeping about 4 hours at a time. It is exhausting for a parent who is already tired from labor and birth to have to awaken during the night to feed a newborn.

Advise couples that their newborn needs fluid and nutrition, so it is not recommended to eliminate night feedings in the early weeks of life. Teach them not to put formula-fed infants to sleep with a bottle of formula, glucose water, or fruit juice because, after their teeth erupt, having a carbohydrate-rich beverage near their teeth all night can lead to early childhood caries (cavities), a syndrome popularly known as “baby-bottle caries” (Moyer, 2014). Knowing their baby is not sick when she or he wakes up at night, that you are concerned and willing to listen to questions, and that every other parent of a newborn is also up at night does not solve the problem of sleep-deprived parents and caretakers, but it is a help.

**Crying. Newborns** typically cry an average of 2 hours of every 24 during the first 7 weeks of life. The frequency seems to peak at age 6 or 7 weeks and then tapers off.

Almost all infants have a period during the day when they are wide awake and invariably fussy. Help new parents to recognize this as common for most newborns so they don’t worry it means their child is ill. Parents might use this fussy time for bathing or playing with the infant. Unfortunately, the most typical time for wakefulness is between 6 and 11 pm, when parents may be tired and least able to tolerate crying. Helping them recognize when they need a break from care during this time can be very helpful. Other family members or close friends who can assist with the baby can be crucial. Taking a break from care can be the difference between a parent shaking a baby (can lead to shaken baby syndrome, which can be lethal) and being rested and able to effectively meet the infant’s and family’s needs (Allen, 2014).

Whether to use pacifiers to reduce crying is a question parents must decide for themselves, depending on how they feel about them and their infant’s needs. It is rare for an infant to have such a need for sucking that the baby must have a pacifier in the mouth constantly. An infant who completes a feeding and still seems restless and discontented, who actively searches for something to put into the mouth, and who sucks on hands and clothes may need the increased sucking activity a pacifier provides. One drawback of pacifiers is the problem of cleanliness: They tend to fall and are then put back into the infant’s mouth. Clipping the pacifier onto the infant’s shirt helps prevent this problem. If parents use pacifiers, be certain they are of one-piece construction, so loose parts cannot be aspirated. Mothers who are breastfeeding should use pacifiers sparingly until breastfeeding is well established because sucking

on a pacifier takes less effort than sucking at a breast (Nyquist, Haggkvist, Hansen, et al., 2013).

### ***QSEN Checkpoint Question 18.6***

#### **EVIDENCE-BASED PRACTICE**

Shaken baby syndrome, or abusive head trauma caused by a parent or caregiver shaking an infant in anger or frustration, creates a potentially lethal situation because forceful shaking can lead to subdural bleeding. To investigate whether a nurse-initiated program could reduce the incidence of abusive head trauma by shaking, nurse researchers offered an educational program including a leaflet explaining abusive head trauma, helpful ways to cope safely with an infant's crying, and an 8-minute video on the subject given to all new mothers at their hospital. Results of the study showed a decrease from 2.8 injuries per year (14 cases in 5 years prior to the intervention) to 0.7 injuries per year (2 cases in 3 years) or a 75% reduction in injuries following the intervention (Altman, Canter, Patrick, et al., 2011).

The nurse notices Mrs. Ruiz grows irritated with Beth when Beth doesn't suck readily when she begins to breastfeed. Based on the previous study, what is the best action for the nurse to take?

- a. Evaluate whether Beth can hear because this may be the underlying problem.
- b. List the dangers of shaken baby syndrome for Mrs. Ruiz.
- c. Discuss the fact that breastfeeding is a new skill, so infants take time to learn this.
- d. Suggest that Mrs. Ruiz ask the physician for a sedative so she can better tolerate newborn crying.

*Look in Appendix A for the best answer and rationale.*

***Car Safety.*** Automobile accidents are a safety problem all during childhood, beginning with the newborn period. For protection while in automobiles, newborns should always be transported in rear facing car seats placed in the back seat (AAP, 2016) (Fig. 18.29). Without this protection, if a car should stop suddenly, an infant could be seriously injured or die. At a speed of only 30 mph, an infant may hit the dashboard with a force equal to a fall from a three-story building. If an adult holding the infant is not wearing a seat belt, the adult can be thrown against the infant, causing even more damage.

When purchasing a car seat, advise parents to ascertain that the seat meets current federal guidelines. Guidance for parents regarding car seats can be found at an AAP-sponsored website at <https://www.healthychildren.org/English/safety-prevention/on-the-go/pages/Car-Safety-Seats-Information-for-Families.aspx>. Some hospitals and Red Cross chapters loan infant car seats for temporary use, such as when visiting out of state with grandparents or when first coming home from the hospital. New cars are

mandated to be equipped with lower anchors and tethers for safe use of car seats. A mirror can be positioned in the back seat so a parent can observe the infant from the front seat while driving.

**Figure 18.29** To be safe, newborns need to ride in an appropriately sized backward facing car set while in an automobile. Be sure every family leaving the healthcare facility is properly equipped.

The ideal model has a five-point harness with broad straps, which helps spread the force of a collision over the chest and hips, and a shield, which cushions the head. Advise parents not to use a sack sleeper or papoose bunting nor should they wrap the baby in a bulky blanket which could prevent a secure fit of the infant in the seat. To provide extra warmth, a blanket can be draped over the child and straps as needed. To support the baby's head, parents can use a rolled-up receiving blanket or towel on each side of the head or purchase commercial head supports.

Caution parents that plastic car seats grow extremely hot in the summer, so they should test the temperature of the surface before placing their infant into the seat. Stress also that it is as dangerous to not use a car seat as it is to use one improperly, such as not fastening the harness securely or not attaching the seat to the car correctly.

### *What If... 18.3*

**The nurse notices the Ruiz family does not have a car seat to transport Beth home. Would the discharge nurse insist they will have to stay in the hospital until they purchase a car seat?**

***Continued Health Maintenance for a Newborn.*** Parents do not need to continue to weigh a newborn or take an infant's temperature at home because these practices can

cause worry, as weight fluctuates day by day, and infant activity and clothing can influence temperature. Instead, teach parents to judge their infant's state of health by the child's overall appearance, eagerness to eat, general activity, and disposition as well as weight gain assessed at healthcare visits.

Make certain parents make and keep their healthcare appointment for a first newborn assessment according to their primary care provider's schedule (2 to 6 weeks). Just as conscientious healthcare throughout pregnancy promotes the birth of a healthy child, obtaining routine health care promotes optimum health for the newborn from birth through adolescence. Parents must now begin a healthcare program to keep the child well.

#### *What If . . . 18.4*

**The nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to newborn care (see [Box 18.1](#)). What would be a possible research topic to explore pertinent to this goal that would be applicable to both Beth and her family and that would also advance evidence-based practice?**

### **KEY POINTS FOR REVIEW**

- A newborn history and physical examination yields important information on the infant's appearance, gestational age, and any factors that suggest additional care is needed.
- Using a standardized method of assessment, such as an Apgar score, is important to assess and document that an infant is adjusting well to extrauterine life.
- Converting from fetal to newborn respiratory function is a major step in extrauterine adaptation. Newborns need particularly close observation during the first few hours of life to determine if this adaptation occurs.
- Maintaining body heat is a second major challenge for newborns. When a procedure requires undressing an infant for an extended period of time, the procedure should be done under a radiant heat source to guard against chilling and hypothermia.
- Newborns may suffer hypoglycemia in the first few hours of life because they use so much energy to establish respirations and maintain heat. Signs of jitteriness and a blood glucose level of less than 40 mg/100 ml by heel stick help to identify hypoglycemia.
- A great deal of nurses' responsibility for newborns is being certain a mother and her partner spend some time with their newborn in the birth setting and give some of the care, so they feel confident in giving care at home. Be certain they are well informed about controversial topics such as circumcision and prophylactic antibiotic eye drops because this helps in planning nursing care that not only meets QSEN competencies and also meets a family's comprehensive needs.

- Assess that identification bands are securely attached while a newborn is hospitalized; match mother's to baby's one last time before discharge. To help prevent the possibility of infant abduction, be certain of the identification of anyone to whom you give a newborn.
- Be certain that caregivers have a car seat to use at discharge for their infant, that they know how to use it properly, and that they know to schedule a well-child visit at 2 to 6 weeks of age.

### CRITICAL THINKING CARE STUDY

U2 is a 7-lb, 5-oz neonate born in the “dirty backseat” of a taxi because her 16-year-old mother, Debbie Tillerman, didn't realize she was in labor. The baby's grandparents are angry with Debbie because, although grounded for breaking a house rule, she took the bus to visit her boyfriend out of town and was there when her labor started. Apgar scores were not recorded. The grandparents want the baby moved to the neonatal intensive care unit because, although the baby's weight is that of a term newborn, they are concerned the baby is preterm. “Don't trust anything Debbie tells you about her due date,” they tell you. “She lies all of the time.”

1. What standardized assessment would you want to do on U2 to assess if she is a preterm or not? Who would you ask to obtain a pregnancy history: Debbie or the grandparents?
2. Debbie is going to call her baby U2 rather than a typical name. Would you be concerned about this? Would you talk to her about changing it before the birth certificate is filed?
3. What special care will U2 need because she was born in the “dirty backseat” of a taxi cab? Are there any special instructions Debbie will need to know to care for her?

## Nutritional Needs of a Newborn

*Linda Satir is a mother of a 7-lb full-term female newborn. During the pregnancy, she and her husband, Paul, both agreed Linda would breastfeed. Linda will be returning to work as an executive assistant after her 6-week maternity leave. She attempted to breastfeed her newborn in the birthing room with minimal success. While you are assisting her with breastfeeding, she says, “Did I make the right choice? Maybe I should formula feed her. Paul could help that way and I won’t have to worry about what to do when I’m back at work.”*

*Previous chapters described the care of a woman and family during the antepartal, intrapartal, postpartal, and newborn periods. This chapter addresses the challenges parents face when feeding their newborn.*

**How would you answer Linda?**

### KEY TERMS

**colostrum**  
**engorgement**  
**interferon**  
**lactoferrin**  
**let-down reflex**  
**lysozyme**  
**prolactin**

### OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe nutritional requirements for a term newborn.
2. Identify 2020 National Health Goals related to newborn nutrition.
3. Assess the nutritional intake and feeding method of a newborn to determine if the infant has an adequate nutritional status.
4. Formulate nursing diagnoses related to newborn nutrition.
5. Assist parents with newborn nutrition while they are adapting to their new role.

6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care, such as supporting a mother to initiate breastfeeding.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of newborn nutrition with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

Proper nutrition is essential for optimal growth and development, especially in the first few months of life because brain growth proceeds at such a rapid rate during this time. Feeding for a newborn extends beyond the physiologic need of adequate nutrition, however; it also fulfills important psychological needs. During feeding, a parent is close to the infant, and a baby is apt to be particularly sensitive to the parent's demonstration of affection or lack of warmth. The feeding experience, therefore, enables an emotional bond between infant and caregiver and helps provide an environment that enhances the psychosocial development of the infant as well as aids physical growth (Lutter & Morrow, 2013). Box 19.1 shows 2020 National Health Goals related to newborn nutrition.

#### BOX 19.1

#### Nursing Care Planning Based on 2020 National Health Goals

The 2020 National Health Goals address increasing the proportion of infants who are breastfed. Goals include increasing:

- Ever breastfed to more than 81.9%.
- Exclusive breastfeeding at 3 months to more than 46.2%.
- Exclusive breastfeeding at 6 months to more than 25.5%.
- Breastfeeding at 6 months to more than 60.6%.
- Breastfeeding at a year to more than 34.1%.
- Increasing proportion of employers that have worksite lactation support programs from 25% to 38%.
- Increasing proportion of live births that occur in facilities that provide recommended care for lactating mothers and their babies from 2.9% to 8.1%.

The goals also address reducing:

- Proportion of breastfed newborns who receive supplemental formula within first 2 days from 24.2% to 14.2% (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by educating women while they are pregnant about the importance of breastfeeding as well as by supporting a family

during the subsequent year while a woman is breastfeeding. Home visits with families and well-child health assessments provide opportunities to advocate for continued and exclusive breastfeeding.

### *Nursing Process Overview*

## FOR PROMOTING NUTRITIONAL HEALTH IN A NEWBORN

### **ASSESSMENT**

An assessment of newborn nutrition begins during pregnancy with an assessment of the mother's and her partner's attitudes and choices about infant feeding.

Breastfeeding is widely accepted as the preferred method of human newborn nutrition and should be recommended. However, if a mother chooses not to breastfeed as a personal preference, it is important she not be made to feel guilty for her choice. Most importantly, parents need to feel comfortable with and confident about the feeding method they choose.

Part of a feeding assessment includes recognizing signs of hunger in the newborn. Ask parents if they can identify restlessness, tense body posture, and mouth movements as signs of hunger in their infant. Otherwise, they may wait for their infant to cry, and this is actually a late sign of newborn hunger. Assess adequate intake by monitoring voiding and stooling patterns for the expected quantity and ensuring the newborn wakes for feedings at least every 3 hours after the first 24 hours of life (Box 19.2). Newborns are often sleepy the first 24 hours after birth, and they may not wake for feedings every 3 hours during that time period. If they have no risk factors for hypoglycemia, they may wait longer than 3 hours during the first 24 hours of life. Breastfed newborns may lose up to 3% of birthweight on day 1, 5% of birth weight on day 2, and 7% of birthweight on day 3. A formula-fed newborn's weight loss is not as much as a breastfed newborn. A formula-fed newborn regains birth weight at about 10 days; a breastfed infant does so at about 14 days.

### BOX 12.2

## **Nursing Care Planning Using Assessment**

### **ASSESSING THE NEWBORN FOR ADEQUATE NUTRITION**

### **NURSING DIAGNOSIS**

Nursing diagnoses in relation to nutrition usually center on a woman's choice regarding the method of feeding or a newborn's nutritional intake and feeding patterns. Examples of nursing diagnoses include:

- Effective breastfeeding related to a well-prepared mother and a healthy newborn who is able to latch properly and transfer milk effectively
- Risk for ineffective breastfeeding related to a poor latch, or ineffective transfer of milk
- Imbalanced nutrition, less than body requirements, related to poor newborn response, poor latch, or ineffective transfer of milk
- Risk for impaired parenting related to inability to exclusively breastfeed the newborn if the mother's desire was to exclusively breastfeed

### **OUTCOME IDENTIFICATION AND PLANNING**

Human milk is the ideal food for newborns. Patient education regarding infant feeding begins during the prenatal period. The discussion should provide the expectant couple with information to make an informed choice about feeding their infant and address their questions and concerns regarding breastfeeding. Maternal and infant risk factors that may interfere with successful breastfeeding should be identified as they arise. Possible risk factors are listed in [Table 19.1](#). There may be medical contraindications to breastfeeding. After birth, a teaching plan addressing the

nutritional needs of both the mother and her newborn should be developed. Refer patients and their families to helpful websites and other resources on infant feeding when appropriate (see [Chapter 9](#)).

**TABLE 19.1 RISK FACTORS THAT MAY INTERFERE WITH SUCCESSFUL BREASTFEEDING**

<b>History/Related Maternal Risk Factors</b>	<b>Physical Exam/Related Maternal Risk Factors</b>	<b>History/Related Infant Risk Factors (Including Birth History)</b>	<b>Physical Infant Risk Factors</b>
<ul style="list-style-type: none"> <li>• Lack of experience breastfeeding</li> <li>• Parity</li> <li>• Advanced maternal age</li> <li>• History of breast surgery (reduction/augmentation)</li> <li>• No breast enlargement during pregnancy</li> <li>• Social (no one breastfed in family), cultural beliefs</li> <li>• Interpersonal violence or other home stressors</li> <li>• Infertility, using oral contraceptive pills/hormonal birth control</li> <li>• Late or inconsistent prenatal care</li> <li>• Depression, hypertension, obesity</li> <li>• Malnutrition, anemia</li> <li>• Endocrine (thyroid, diabetes, hypertension, obesity)</li> <li>• Delivery related (vaginal delivery vs. caesarean section), blood loss during delivery, retained placenta fragments</li> </ul>	<ul style="list-style-type: none"> <li>• Abnormal breast tissue distribution, tubular breast</li> <li>• Breast surgeries (reduction/augmentation, mastectomy)</li> <li>• Cracked nipples (nipple infection)</li> <li>• Type of nipple (inverted nipples, flat, small, large, nipple piercing)</li> <li>• Breast engorgement</li> <li>• Edema</li> <li>• Vasospasm of nipple</li> <li>• Mastitis, milk duct obstruction, bleb</li> <li>• Maternal pain level</li> <li>• Maternal obesity</li> <li>• Poor positioning</li> <li>• Poor latch</li> </ul>	<ul style="list-style-type: none"> <li>• Anesthesia during labor</li> <li>• Length of labor, pushing 2 hours or longer</li> <li>• Delivery related (vaginal delivery vs. cesarean section)</li> <li>• Use of vacuum, forceps</li> <li>• Type of suctioning at birth, meconium aspiration</li> <li>• Apgar (fetal distress)</li> <li>• Skin-to-skin postbirth</li> <li>• Prematurity (preterm, late preterm)</li> <li>• NICU admission (separation from mother)</li> <li>• Multiples</li> <li>• Risk for hypoglycemia</li> </ul>	<ul style="list-style-type: none"> <li>• Oral feeding</li> <li>• Palate</li> <li>• Tongue</li> <li>• Uncoordinated sucking</li> <li>• Sleepiness</li> <li>• Drug effects</li> <li>• Sepsis</li> <li>• Hypoglycemia</li> <li>• Gestational age (preterm, full term)</li> <li>• LGA or macrosomia</li> <li>• Jaundice</li> <li>• Caput succedaneum</li> <li>• Congenital anomalies</li> </ul>

<ul style="list-style-type: none"> <li>• Pain management, epidural medications</li> <li>• Tobacco use, intravenous drug use/substance use, toxicology screen</li> <li>• Early return to work</li> </ul>	<p>(SGA, LGA, &lt;37 wk, diabetic mother)</p> <ul style="list-style-type: none"> <li>• Pacifier use first 3 wk</li> <li>• Supplemental formula feeding</li> <li>• History of jaundice or at risk for jaundice</li> <li>• Voiding and stools quantity less than expected</li> <li>• Circumcision</li> <li>• Weight loss 10% or greater from birth weight</li> </ul>
---	--

NICU, neonatal intensive care unit; SGA, small for gestational age; LGA, large for gestational age. Flagg, J. (2015). Breastfeeding problems associated with maternal and/or infant risk factors. *Journal of Pregnancy and Child Health, 2*(2), e119.

Expectant parents cannot make an informed choice if they are not aware of the nutritional and health benefits of breast milk (Table 19.2). Parents who choose formula feeding can practice behaviors, such as skin-to-skin contact, to promote bonding. They require instructions on formula preparation, safe feeding techniques, and appropriate volumes for newborn and infant feeding. Mothers should consult their pediatric care provider regarding the type and preparation of formula to provide to their newborn.

**TABLE 19.2 NUTRITIONAL AND HEALTH BENEFITS OF BREASTFEEDING**

Condition	% of Lowered Risk
Lower respiratory tract infections	72
Gastrointestinal infections	64
Otitis media (exclusive vs. formula fed)	50
Atopic dermatitis	42
Diabetes types 1 and 2	19–27/39
Obesity	7–27
Sudden infant death syndrome	36

Childhood leukemias	15–19
Maternal breast cancer	28
Ovarian cancer	21

## IMPLEMENTATION

An intervention related to newborn nutrition is supporting a mother's choice of a feeding method and helping her feel confident in her ability to feed her infant. In addition to providing classes on breastfeeding prior to delivery, it is important to provide mothers with information on breastfeeding support groups at the time of discharge. Mothers may need to see a lactation consultant in the following situations:

- LATCH score less than 7 for two consecutive feeds
- Nipple trauma, absence of prenatal breast changes
- Pain throughout feed
- Infant weight loss is 8% of birth weight (less than 2% to 3% per day)
- Inadequate output
- No or limited swallowing after 24 hours of age
- History of unsuccessful breastfeeding
- History of breast surgery
- Abnormal infant oral anatomy
- Mother of neonatal intensive care unit (NICU) infant/separation from infant
- Late preterm (34 to 36 6/7), small for gestational age (SGA), large for gestational age (LGA)
- Infant jaundice
- Multiple births
- Birth interventions
- Unrelieved fullness or engorgement ([Wambach & Riordan, 2016](#))

Hospitals seeking to improve lactation support or seeking the Baby-Friendly Hospital certification may provide mother's breastfeeding support groups.

Components of the United States Baby-Friendly Hospital Initiative\* include:

- Have a written breastfeeding policy that is routinely communicated to all healthcare staff.
- Train all healthcare staff in skills necessary to implement policy.
- Inform all pregnant women about the benefits and management of breastfeeding.
- Help mothers initiate breastfeeding within 1 hour of birth.
- Show mothers how to breastfeed and how to maintain lactation, even if they are separated from their infants.
- Give newborn infants no food or drink other than breast milk, unless medically

indicated.

- Practice “rooming-in” by allowing mothers and infants to remain together 24 hours a day.
- Encourage breastfeeding on demand.
- Give no pacifiers or artificial nipples to breastfeeding infants.
- Ensure continuity of care, foster the establishment of breastfeeding support groups, and refer mothers to them on discharge from the hospital or clinic.

\*Reprinted from Baby-Friendly USA. (2012). *The ten steps to successful breastfeeding*. Retrieved from <https://www.babyfriendlyusa.org/about-us/baby-friendly-hospital-initiative/the-ten-steps>.

## OUTCOME EVALUATION

The evaluation is an important final step to ensure a newborn receives adequate nutrition because unforeseen circumstances, such as jaundice, infant tongue-tie, or late preterm delivery may require the mother to provide expressed breast milk until the problem is resolved. Mothers may need to pump to provide breast milk to their newborns in the following circumstances:

- Infants in NICU
- Infants with weight loss greater or equal to 8%, LATCH scores less or equal to  $7 \times 2$  and in need of supplementation
- Infants close to 24 hours old and who have not nursed
- Mothers using breast shield
- Mothers with a history of breast surgery
- Mothers with medical conditions (i.e., hemorrhage or shock)([Wambach & Riordan, 2016](#))

There are alternative methods to provide expressed breast milk until successful breastfeeding is established. These include cup feeding, finger feeding, spoon feeding, and bottle feeding. It is possible the introduction of a bottle prior to 3 weeks of age could cause nipple confusion. If a nipple is used, a slow-flow nipple is recommended to encourage the newborn to initiate and control the flow. Full-term healthy newborns may be sleepy the first 24 hours after birth. Unless they are at risk for hypoglycemia, they may be fed at all feeding cues. Risk factors for hypoglycemia in newborns include:

- Preterm (less than 37 weeks gestation)
- Intrauterine growth restriction
- Low birth weight (less than 2.5 kg)
- SGA (less than 10%)
- Maternal diabetes
- LGA (greater than 90%)
- Hypothermia
- Infection/other illness in the newborn
- Severe intrapartum asphyxia
- Maternal use of  $\beta$ -blockers, such as labetalol (Trandate) ([Wambach & Riordan,](#)

2016)

Examples suggesting successful expected outcomes related to newborn feeding include:

- Newborn wakes for feedings every 2 to 3 hours after the first 24 hours of life.
- Newborn feeds 10 to 30 ml of formula with iron every 3 to 4 hours after the first 24 hours of life.
- Mother expresses satisfaction with her chosen method of newborn feeding.
- Newborn voids and defecates once within the first 24 hours, twice within the second 24 hours, three times within the third 24 hours, and four times within the fourth 24 hours. From day 5 on, the newborn voids five to six times daily as a measure of adequate hydration. Stools are meconium at birth, brown by day 2, green by day 3 or 4, and then seedy yellow. The newborn usually has one or more stools daily by day 5.

## Nutritional Allowances for a Newborn

Nutritional allowances for a newborn need to take into account total calories, protein, vitamins, minerals, and fluid.

### CALORIES

Growth in the neonatal period and early infancy is more rapid than in any other period of life (U.S. Department of Agriculture, 2016); therefore, the caloric requirements exceed those at any other age. For example, an infant up to 2 months of age requires 100 to 120 calories per kilogram of body weight (50 to 55 kcal/lb) every 24 hours to provide an adequate amount for maintenance and growth. After 2 months of age, this amount gradually declines until the requirement at 1 year is 100 kcal/kg (45 kcal/lb) per day. In contrast, the adult caloric requirement is 42 kcal/kg (20 kcal/lb) per day (U.S. Department of Agriculture, 2016). During growth spurts, more calories are needed to supply additional energy.

Commercial infant formulas are designed to provide approximately the same number of calories as breast milk, 20 calories per ounce. They contain about 9% to 12% of their calories as protein and 45% to 55% of calories as lactose carbohydrate. The balance (34% to 46%) is fat, of which linoleic acid accounts for about 4%.

### PROTEIN

The newborn has a high requirement of protein, which is necessary for the formation of new cells, during this period to provide for a rapid growth of new cells as well as maintenance of existing cells. The nutritional allowance of protein for the first 2 months of life is 2.2 g per kilogram of body weight. Both human milk and commercial formulas provide all the essential amino acids necessary to form protein. Histidine, an amino acid that appears to be essential for infant growth but is not necessary for adult growth, is

found in both milk forms.

Unaltered cow's milk is not recommended for newborns because it contains about 16% of its calories as protein, whereas human milk contains about 8%. This means cow's milk can create such a rich solute load (i.e., the amount of urea and electrolytes that must be excreted in the urine) that a newborn's kidneys could be overwhelmed. In addition, cow's milk can cause microscopic bleeding of the gastrointestinal tract, leading to blood loss and anemia. These problems occur because the protein in cow's milk, *casein*, differs from that in human milk, *lactalbumin*, both in composition and in amount. This is important because the amount of casein present in milk determines its curd tension. Because of the increased amount of casein in cow's milk, the curd is large, tough, and difficult to digest, whereas in human milk, the curd is softer and digests easily. This is the rationale behind recommending formula-fed infants be given a commercial formula containing albumin rather than cow's milk. Cow's milk products, such as yogurt and cottage cheese, should not be introduced until 9 to 12 months of age because of this same reason.

## FAT

Linoleic acid, an essential fatty acid, is necessary for brain growth and skin integrity in infants. When the amount of linoleic acid is sufficient, the infant can then manufacture docosahexaenoic acid (DHA), an omega-3 fatty acid, and arachidonic acid (ARA), an omega-6 fatty acid, both of which are important for brain growth. Breast milk contains a generous supply of all three of these fatty acids. Commercial formulas contain varying amounts depending on the brand and type of fats included in the formula.

Because fat is so important for brain and nerve growth, use of fat-free milk for long periods in newborns and infants (when other sources of food are not being offered) can result in linoleic acid deficiency. Therefore, parents should not feed fat-free milk as a means of preventing obesity in newborns or young infants. In addition, fat-free milk does not contain sufficient calories for a newborn; it only has about half as many calories as commercial formulas or breast milk.

## CARBOHYDRATE

Lactose, the disaccharide found in human milk and added to commercial formulas, appears to be the most easily digested of the carbohydrates. Lactose also improves calcium absorption and aids in nitrogen retention. It produces stools consisting predominantly of gram-positive rather than gram-negative bacteria and therefore decreases the possibility of gastrointestinal illness (which usually results from gram-negative organisms). Adequate lactose also allows protein to be used for building new cells rather than for calories, encouraging normal water balance and preventing abnormal metabolism of fat. Lactose intolerance, which can occur in older children, is rarely present in newborns; they typically use the calories provided by lactose well.

## FLUID

It is important to maintain a sufficient fluid intake in newborns because their metabolic rate is so high (and metabolism requires water). In addition, a newborn's body surface area is large in relation to body mass. This means a baby loses water by evaporation much more readily than does an adult, and, because the kidneys of a newborn are not yet capable of fully concentrating urine, a newborn cannot conserve body water by this mechanism to prevent dehydration.

Another difference between newborns and adults is that body water is distributed differently. In a newborn, 30% to 35% of body weight is extracellular fluid; in an adult, this proportion is only 20%. Consequently, if a newborn's extracellular fluid store is depleted through loss of fluid or inadequate fluid intake, as much as 35% of a newborn's fluid component may be lost.

Because of all these factors, a newborn needs 150 to 200 ml/kg (2.5 to 3.0 oz/lb) of water intake every 24 hours (adults require 2,400 ml per day or less than 1 oz/lb). This requirement can be supplied completely by breastfeeding or formula feeding. Fruit juice is not recommended for infants younger than 6 months because it supplies no protein and, if not pasteurized, can carry infectious organisms ([American Academy of Pediatrics \[AAP\], 2012c](#)).

### *QSEN Checkpoint Question 19.1*

#### **PATIENT-CENTERED CARE**

A nursing assessment of Linda Satir's plan for her infant's nutrition should begin with which of the following?

- An assessment of Linda's beliefs and attitudes about breastfeeding
- An assessment of the infant's body mass index and glucose levels
- An assessment of Linda's education level and reading ability
- An assessment of the infant's ability to suck and swallow

*Look in [Appendix A](#) for the best answer and rationale.*

## MINERALS

A number of minerals are particularly important to early growth.

### **Calcium**

Calcium is important to the newborn because a newborn's skeleton grows so rapidly. Because milk is high in calcium, tetany resulting from a low calcium level seldom occurs in infants who suck well, regardless of whether they are fed human milk or commercial formula ([U.S. Department of Agriculture, 2016](#)).

### **Iron**

A newborn (37 or more weeks gestation age) whose mother had adequate iron intake

during pregnancy will be born with iron stores that, theoretically, will last for the first 3 months of life, until the newborn begins to produce adult hemoglobin. Because not all mothers eat an iron-rich diet during pregnancy (and socioeconomic level is not a good criterion for judging the quality of a diet), the AAP recommends infants who are formula fed ingest an iron-enriched formula for the entire first year of life) ([U.S. Department of Agriculture, 2016](#)). Some women who breastfeed are also advised to supplement iron to ensure their infant does not develop iron-deficiency anemia ([U.S. Department of Agriculture, 2016](#)).

## Fluoride

Fluoride is essential for building sound teeth and for preventing tooth decay. Because teeth are already set in their primary form during pregnancy, it is important for women to drink fluoridated water during pregnancy. A lactating mother should continue drinking fluoridated water (although only a small amount of fluoride passes into breast milk), and formulas should be prepared with fluoridated water. This is an essential point to remember because a mother may think she is helping her child by using bottled, “natural” water in formula rather than chlorinated (and fluoridated) water from a tap.

If a mother is breastfeeding and a source of fluoridated water is not available (the family drinks well, spring, or bottled water or the tap water is not fluoridated), a fluoride supplement, 0.25 mg daily, may be given to the infant beginning at 6 months of age.

## VITAMINS

Although both breast milk and commercial formulas contain sufficient vitamins for growth, the AAP now recommends that breastfed newborns be given a supplement of 400 international units per day of vitamin D, beginning in the first few days of life. Newborns who are fully or partially formula fed also benefit from a daily 400 international units vitamin D supplement ([U.S. Department of Agriculture, 2016](#)).

## Breastfeeding

It is universally agreed that human milk is the preferred food for newborns because it provides numerous health benefits to both a mother and an infant; it remains the ideal nutritional source for infants through the first year of life ([U.S. Department of Agriculture, 2016](#)). Nurses are prime healthcare professionals to teach women about the benefits of breastfeeding and provide anticipatory guidance for problems that may occur. You can also help create an atmosphere conducive to breastfeeding success in healthcare facilities by implementing steps, such as:

- Educating all pregnant women about the benefits and management of breastfeeding
- Helping women initiate breastfeeding within half an hour after birth
- Assisting mothers to breastfeed and maintain lactation even if they should be

separated from their infant

- Not giving newborns food or drink other than breast milk unless medically indicated, so they are hungry to breastfeed. Advise women they need not introduce solid food until at least 4 months.
- Not giving newborns pacifiers to quiet them as this can reduce the sucking initiative
- Supporting rooming-in (such as allowing mothers and infants to remain together) 24 hours a day
- Encouraging breastfeeding on demand
- Fostering the establishment of breastfeeding support groups and referring mothers to them on discharge from the birthing center or hospital ([Baby-Friendly USA, 2012](#))

## PHYSIOLOGY OF BREAST MILK PRODUCTION

Breast milk is formed in the acinar or alveolar cells of the mammary glands ([Fig. 19.1](#)). With the delivery of the placenta following birth, the level of progesterone in a woman's body falls dramatically, stimulating the production of **prolactin**, an anterior pituitary hormone. Prolactin acts on the acinar cells of the mammary glands to stimulate the production of milk. In addition, when an infant sucks at a breast, nerve impulses travel from the nipple to the hypothalamus to stimulate the production of prolactin-releasing factor. This factor stimulates further active production of prolactin. Other anterior pituitary hormones, such as adrenocorticotrophic hormone, thyroid-stimulating hormone, and growth hormone, probably also play a role in growth of the mammary glands and their ability to secrete milk. Regardless of the gestational age of the infant, the mother should be able to produce a sufficient quantity of breast milk for the infant, providing she empties the breasts through breastfeeding or expressing milk (manually or by using a breast pump). A hospital-grade breast pump is recommended to establish and maintain lactation if the infant is unable to latch and transfer breast milk through breastfeeding ([U.S. Department of Agriculture, 2016](#)).

**Figure 19.1** Anatomy of the breast.

**Colostrum**, a thin, watery, yellow fluid composed of protein, sugar, fat, water, minerals, vitamins, and maternal antibodies, is secreted by the acinar breast cells starting in the fourth month of pregnancy. For the first 3 or 4 days after birth, colostrum production continues. Because it is high in protein and fairly low in sugar and fat, colostrum is easy to digest and capable of providing adequate nutrition for a newborn until it is replaced by transitional breast milk on the second to fourth day. True or mature breast milk is produced by the 10th day.

Milk flows from the alveolar cells, where it is produced, through small tubules to reservoirs for milk, the lactiferous sinuses, located behind the nipple. This constantly forming milk is called fore milk. Its availability depends very little on the infant's sucking at the breast. As the infant sucks at the breast, oxytocin, released from the posterior pituitary, causes the collecting sinuses of the mammary glands to contract, forcing milk forward through the nipples, making it available for the baby. This action is called a **let-down reflex**. A let-down reflex may also be triggered by the sound of a baby crying or by thinking about the baby. New milk, called hind milk, is formed after the let-down reflex. Hind milk, which is higher in fat than fore milk, is the milk that makes a breastfed infant grow most rapidly. The release of oxytocin has a second advantage in that, by causing smooth muscle contraction, it helps contract the uterus. As a result, a woman may feel a small tugging or cramping in her lower pelvis during the first few days of breastfeeding (i.e., afterpains) (U.S. Department of Agriculture, 2016).

## **ADVANTAGES OF BREASTFEEDING**

Little controversy exists that breastfeeding is the ideal nutrition for human infants. It is contraindicated in only a few circumstances, such as:

- An infant with galactosemia (such infants cannot digest the lactose in milk)
- Herpes lesions on a mother's nipples
- Maternal exposure to radioactive compounds (such as occurs with thyroid testing)
- Mothers receiving antimetabolites or chemotherapeutic agents
- Mothers receiving prescribed medications that would be harmful to an infant, such as lithium or methotrexate
- Women with maternal active, untreated tuberculosis, who need to be evaluated individually depending on the stage of their disease
- Women who are positive for HIV, who are advised not to breastfeed in the United States until further studies confirm the risk of not breastfeeding outweighs the risk of breast milk transmission of the virus ([Academy of Breastfeeding Medicine Protocol Committee, 2010a](#)). In developing countries, women who are HIV positive may be advised to breastfeed because commercial formula is not available.
- Women whose toxicology screens for substance abuse are positive, who need to be evaluated on an individual basis regarding recommendations to breastfeed

Cigarette smoking is not a contraindication to breastfeeding, but women should be aware some nicotine is carried in breast milk. Nicotine has the potential to decrease a mother's milk supply (Reece-Stremtan & Marinelli, 2015). If the infant is exposed to secondhand smoke, it could lead to an increase in respiratory illnesses. The nurse needs to be aware of a number of other situations that call for individual planning in consultation with a lactation consultant.

### **Advantages of Breastfeeding for Women**

A woman gains several physiologic benefits from breastfeeding:

- The release of oxytocin from the posterior pituitary gland aids in uterine involution.
- Breastfeeding may serve a protective function in preventing breast cancer and possibly ovarian cancer.
- A woman may return to her prepregnant weight sooner, and if menstruation is delayed, this may serve as a temporary family planning method.
- Successful breastfeeding can have an empowering effect because it is a skill only a woman can master.
- Breastfeeding reduces the cost of feeding and preparation time for infant feeding.
- A long-term effect may include a decreased risk of hip fractures and osteoporosis in the postmenopausal period for the woman ([U.S. Department of Agriculture, 2016](#)).
- Breastfeeding provides an excellent opportunity to enhance a true symbiotic bond between mother and child. Although this does readily occur with breastfeeding, a woman who holds her baby to formula feed can form this bond as well.

Common reasons women give for not exclusively breastfeeding or discontinuing

breastfeeding include (a) insufficient milk supply, (b) feeling very tired, (c) having trouble with the infant latching to breast, and (d) wanting to allow their partner to feed the infant (U.S. Department of Agriculture, 2016). According to the Agency for Healthcare Research & Quality, reasons for discontinuing breastfeeding during the first week of life include latching difficulty (47%), soreness/cracked nipples (35%), perceived low milk supply (27%), prefers others to feed baby (8%), and work/school-related issues (6%). Reasons during the first 1 to 3 months of life include perceived low milk supply (37%), work/school related issues (35%), latching difficulty (15%), soreness/cracked nipples (12%), prefer others to feed baby (12%), and partner preference (2%) (Ip, Chung, Raman, 2007). Some women are reluctant to breastfeed because they fear having to be available to feed their baby every 3 or 4 hours will tie them down. Like mothers who formula feed, however, they can leave a bottle with expressed breast milk with a caregiver if they need to be away from their baby at the time of a feeding.

### *QSEN Checkpoint Question 19.2*

#### **EVIDENCE-BASED PRACTICE**

The AAP (Hagan, Shaw, & Duncan, 2017) recommends infants be exclusively breastfed for 6 months. To discover the characteristics of women who were exclusively breastfeeding at the time of hospital discharge, researchers studied all term hospital births in the province of Ontario, Canada, for a year. From this pool of over 90,000 infants, 56,865 were identified as still being exclusively breastfed at discharge. Characteristics of women who were exclusively breastfeeding were older age, nonsmoking, higher income, and no pregnancy complications or reproductive assistance. They also had a single rather than twin infants and had attended prenatal classes. Patients of obstetricians were less likely to exclusively breastfeed than those cared for by midwives or family physicians. Women who had a planned cesarean birth were more apt to breastfeed than those who had an unplanned cesarean birth.

Based on the previous findings, which statement by Linda would be the best indicator that she will be successful at exclusive breastfeeding?

- a. "I enjoyed going for prenatal visits."
- b. "I wish my husband earned more money."
- c. "I can't wait until discharge when I can have a cigarette."
- d. "I like having my first baby at 23; I'm young enough to adjust."

*Look in Appendix A for the best answer and rationale.*

### **Advantages for Infants**

Breastfeeding has major physiologic advantages for infants as well as it does for women. Breast milk contains secretory immunoglobulin A (IgA), which binds large molecules of foreign proteins, including viruses and bacteria, thus keeping them from

being absorbed from the gastrointestinal tract.

**Lactoferrin** is an iron-binding protein in breast milk that interferes with the growth of pathogenic bacteria. The enzyme **lysozyme** in breast milk apparently actively destroys bacteria by lysing (dissolving) their cell membranes, possibly increasing the effectiveness of antibodies. Leukocytes in breast milk provide protection against common respiratory infectious invaders. Macrophages, responsible for producing **interferon** (a protein that protects against viruses), help interfere with virus growth. The bifidus factor is a specific growth-promoting factor for the beneficial bacteria *Lactobacillus bifidus*. The presence of *L. bifidus* in breast milk interferes with the colonization of pathogenic bacteria in the gastrointestinal tract, thus reducing the incidence of diarrhea (U.S. Department of Agriculture, 2016).

In addition to these anti-infective properties, breast milk contains the ideal electrolyte and mineral composition for human infant growth. It is high in lactose, an easily digested sugar that provides ready glucose for rapid brain growth. The protein in breast milk is easily digested, and the ratio of cysteine to methionine (two amino acids) in breast milk favors rapid brain growth in the early months. It contains nitrogen in compounds other than protein, so an infant can receive cell-building materials from sources other than just protein.

Breast milk contains more linoleic acid, an essential fatty acid for skin integrity, and less sodium, potassium, calcium, and phosphorus than do many formulas. Breast milk also has a better balance of trace elements, such as zinc. These levels of nutrients are enough to supply the infant's needs, yet they spare the infant's kidneys from having to process a high renal solute load of unused nutrients. Exclusively breastfeeding for at least 3 to 4 months or longer was found to reduce the incidence of certain allergies in 42% of infants where there was a family history of allergies (U.S. Department of Agriculture, 2016).

Yet, another advantage of breastfeeding is that breastfed newborns appear to be able to regulate their calcium/phosphorus levels better than infants who are formula fed. Decreased calcium levels in a newborn can lead to tetany (muscle spasm). The increased concentration of fatty acid in commercial formulas may bind calcium in the gastrointestinal tract, also increasing the danger of tetany. Breastfeeding may also help prevent excessive weight gain in infants. It has been shown that exclusive breastfeeding into the infant's fourth month of life can decrease obesity as late as adolescence (Wallby, Lagerberg, & Magnusson, 2017).

In addition, a great deal of discussion about the benefits of breastfeeding has centered on the effects of breastfeeding on the formation of the dental arch because babies suck differently from a breast than from a bottle (Fig. 19.2). Babies pull their tongue backward as they suck from a breast. They thrust their tongue forward to suck from a rubber nipple. That may make breastfeeding the best preparation for forming common speech sounds (U.S. Department of Agriculture, 2016).

**Figure 19.2** Differences in the sucking mechanism. **(A)** Breastfeeding. (1) Lips of the infant clamp in a C shape. The cheek muscles contract. (2) The tongue thrusts forward to grasp the nipple and areola. (3) The nipple is brought against the hard palate as the tongue pulls backward, bringing the areola into the mouth. (4) The gums compress the areola, squeezing milk into the back of the throat. **(B)** Formula feeding. The large rubber nipple of a bottle strikes the soft palate and interferes with the action of the tongue. The tongue moves forward against the gums to control the overflow of milk into the esophagus.

### QSEN Checkpoint Question 19.3

#### INFORMATICS

Linda asks the nurse why breastfeeding is so beneficial for her newborn. The nurse would want her to know breast milk has which of the following characteristics?

- It is more nutritious than formula because it never needs to be warmed.
- It will provide immunity as well as nutrients for her newborn.
- It will protect her child from gastrointestinal cancer.
- It will ensure her baby will never be obese as an adult.

Look in [Appendix A](#) for the best answer and rationale.

## TECHNIQUES OF BREASTFEEDING

Ask all women during pregnancy whether they plan to breastfeed their newborns because thinking about feeding in advance allows a woman and her partner to make an informed choice. If a partner expresses jealousy at the thought of breastfeeding, early discussion can help address this common sensation, with the eventual realization that parenting will involve many other opportunities for interaction with their child.

No preparation of the nipples is needed during pregnancy. In addition, oxytocin, which is released with nipple stimulation, could lead to preterm labor. Less than 1% of women have inverted nipples. A nipple shield (a plastic shell) may be suggested to help her nipples become more everted ([U.S. Department of Agriculture, 2016](#)).

### Beginning Breastfeeding

Skin-to-skin contact should be initiated within the first hour of delivery, while the infant is in the first reactivity period ([U.S. Department of Agriculture, 2016](#)).

Skin-to-skin contact is defined as placing the undressed infant on the mother's chest against her skin. When placed in this position, the infant will root toward the nipple and initiate a latch. This may be more successful in an unmedicated birth of a full-term infant. A mother breastfeeding for the first time may require additional support ([Box 19.3](#)). Pumping with a hospital grade pump or manual expression is an alternative method to provide breast milk to a newborn who is unable to latch or if mother and baby are separated.

#### BOX 19.3

#### Nursing Care Planning

### AN INTERPROFESSIONAL CARE MAP FOR A WOMAN WHO IS BREASTFEEDING FOR THE FIRST TIME

Linda Satir is a new mother of a term baby girl. During the pregnancy, she and her husband, Paul, both agreed Linda would breastfeed. She attempted to breastfeed her newborn in the birthing room, with minimal success. As you offer to help her feed

her baby for the second time, she says, “Do you think I made the right choice? Maybe I should formula feed her. Paul could help that way and I won’t have to worry about what to do when I go back to work.”

**Family Assessment:** Patient lives with husband in two-bedroom trailer in suburban trailer park. Husband works as an interpreter for local chamber of commerce. Linda will be returning to work as an executive assistant at an advertising agency after her 6-week maternity leave.

**Patient Assessment:** Mother is 2 hours postpartum. Newborn had difficulty latching onto breasts immediately after birth. Nipples without signs of redness or irritation. Breasts slightly firm. Colostrum present. Patient discouraged with first breastfeeding attempt.

**Nursing Diagnosis:** Risk for ineffective breastfeeding related to anxiety and inexperience

**Outcome Criteria:** Patient describes ways to properly position a newborn at the breast; states newborn is latching on and sucking; verbalizes increasing satisfaction and confidence with each feeding session.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
-------------------------	------------	--------------	-----------	------------------

*Activities of Daily Living, Including Safety*

Nurse	Assess patient’s usual daily activity pattern.	Review with patient activities she may need to adjust to accommodate time for breastfeeding.	Preplanning can help to avoid time management problems.	Patient describes her daily routines and identifies adjustments she can make to aid successful breastfeeding.
-------	--	--	---	---

*Teamwork and Collaboration*

Nurse/lactation consultant	Investigate whether patient would like to speak to a lactation consultant; determine which lactation	If patient agrees, initiate a referral to a lactation consultant.	Lactation consultants can provide an additional source of support, encouragement, and information.	Patient meets with consultant if desired.
----------------------------	--	---	--	---

consultant is available.

*Procedures/Medications for Quality Improvement*

Nurse	Observe patient breastfeeding to determine technique she uses.	Make suggestions as necessary regarding technique such as how to break suction, remove newborn from breast, or begin next feeding on breast newborn used most recently.	Additional suggestions can help make breastfeeding successful by encouraging patient to relax during feedings.	Patient states she is willing to try additional suggestions to help improve breastfeeding success.
-------	--	---	--	--

*Nutrition*

Nurse	Assess patient's present daily fluid intake.	Urge patient to drink at least four to six 8-oz glasses of fluid per day.	Adequate fluid intake is essential to maintain an adequate milk supply.	Patient confirms she drinks suggested fluid every day and will continue to do this at home.
-------	--	---	---	---

*Patient-Centered Care*

Nurse/lactation consultant	Assess patient's knowledge about breastfeeding. Allow time for questions.	Educate patient regarding any gaps in knowledge.	The better informed women are about breastfeeding, the more apt they are to feel comfortable with the process.	Patient asks questions regarding areas of breastfeeding of which she is unsure.
----------------------------	---	--	--	---

*Psychosocial/Spiritual/Emotional Needs*

Nurse/lactation consultant	Assess what patient thought	Acknowledge breastfeeding involves newly	Assurance can increase self-esteem when a	Patient states she is willing to try for a
----------------------------	-----------------------------	--	---	--

	breastfeeding would be like.	learned skills and may not be as easy as it looks.	person is learning a new skill.	longer time than a few feedings to see if she can be successful at breastfeeding.
--	------------------------------	--	---------------------------------	---

*Informatics for Seamless Healthcare Planning*

Nurse	Assess steps patient intends to take to ensure breastfeeding success after returning home or to work.	Provide feedback and suggestions, reinforcing accomplishments and assisting with any difficulties.	Feedback and positive reinforcement promote self-confidence and learning, enhancing the success and effectiveness of teaching and breastfeeding.	Patient describes well-thought-out plans for continuing breastfeeding and integrating it into her lifestyle.
Nurse	Assess if local support organization is available for referral.	Suggest patient keep telephone numbers of support group and lactation consultant available if she needs additional help while at home or work.	Support can go a long way toward preventing a patient from becoming discouraged once she returns home.	Patient states she will contact support people as necessary if she has questions after discharge.

Manual expression of breast milk consists of supporting the breast firmly, then placing the thumb and forefinger on the opposite sides of the breast just behind the areolar margin, and first pushing backward toward the chest wall and then downward until secretions begins to flow (Box 19.4). Women should avoid soap on the nipples as it may lead to dryness and skin breakdown. The release of oxytocin by breastfeeding, pumping, or manual expression initiates let-down of milk and also stimulates uterine contraction. The average quantity a mother may produce and guidelines for breast milk storage include 37 ml (7 to 123 ml) within the first 24 hours, 500 ml by day 5, 750 ml/day by month 3, and 800 ml/day by month 6. For mothers of twins, it can vary at approximately 2,100 ml/day.

**MANUAL BREAST MILK EXPRESSION**

**Purpose:** To assist a woman to manually express milk so she can strengthen her milk supply or supply milk for her newborn should she be separated from the newborn

Procedure	Principle
1. Explain the procedure to the patient.	1. Explanations help decrease anxiety and enhance learning; they also provide information for the patient to carry out the procedure on her own.
2. Assemble equipment, including a clean towel and collection container.	2. Assembling equipment aids in organization and efficiency.
3. Wash your hands and put on clean gloves; have patient wash her hands.	3. Hand washing prevents the transmission of infection; use of gloves protects self and patient from possible infection.
4. Provide privacy and help the woman assume a comfortable sitting position.	4. The let-down reflex may not occur readily if the woman is tense or nervous.
5. Help the woman place her right hand on her right breast, with her right thumb on the top of the breast at the outer limit of the areola and her right fingers underneath the breast. Tell the woman to press inward toward the chest wall (Fig. A).	5. Milk is expressed by pressure on the collecting ducts, not the nipple.

6. Help the woman hold the collecting jar just under her nipple.

7. Have the woman slide her hand forward in a milking motion, causing the milk to be expressed from the nipple into the container (Fig. B).

6. Collecting bottles should be made of plastic marked “safe for infants” as this best preserves antibodies found in milk; having the container close by prevents waste of any breast milk that is expressed.

7. Pressure on the lactiferous sinuses pushes milk forward.

8. Encourage the woman to move her thumb and fingers around her breast, repeating the technique.
  9. Caution the woman not to use excess force at any point when using the technique.
  10. After collection, refrigerate milk if it will be used within 24 hours; freeze if this time is longer.
  11. Reinforce the woman's success with this maneuver, regardless of the amount of breast milk expressed.
8. Repeating the technique ensures all milk sinuses are emptied.
  9. Excess force could damage sensitive breast tissue.
  10. Breast milk spoils in the same manner as cow's milk if not protected.
  11. Manual breast milk expression is an easy technique to carry out once it is learned, but it can be difficult to grasp at first. Positive reinforcement enhances progress and self-esteem.

### What If . . . 19.1

**Linda told the nurse she doesn't really want to breastfeed but her husband is insisting she do so? What would the nurse do?**

## Prolonged Jaundice in Breastfed Infants

Jaundice occurs in as many as 15% of breastfed infants because pregnanediol (a breakdown product of progesterone) in breast milk depresses the action of glucuronyl transferase, the enzyme that converts indirect bilirubin (which cannot be excreted) to the direct form, which is then readily excreted in bile ([Academy of Breastfeeding Medicine Protocol Committee, 2010b](#)). To prevent this excess buildup of bilirubin (i.e., hyperbilirubinemia) in their newborn, women should feed frequently in the immediate postpartum period because colostrum is a natural laxative and helps promote passage of both meconium and bile. Newborns who are discharged early from their birth setting or born at home need to be observed carefully for jaundice. Breastfeeding rarely results in a serum bilirubin level high enough to warrant therapy or to require discontinuation of breastfeeding, however, because pregnanediol remains in breast milk for only 24 to 48 hours ([Academy of Breastfeeding Medicine Protocol Committee, 2010b](#)).

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Health-seeking behaviors related to lack of knowledge about lactation and breastfeeding techniques

**Outcome Evaluation:** Woman states correct information as to how lactation begins and is maintaining an adequate supply; demonstrates effective positioning for baby and herself by 24 hours.

In cultures where breastfeeding is practiced by almost all mothers, the technique is learned early in life by observation. In the United States, a woman may have had few, if any, opportunities to observe breastfeeding and so may need some advice ([Box 19.5](#)). Many hospitals employ International Board Certified Lactation Consultants (IBCLC) who provide lactation support for breastfeeding mothers. IBCLC also provide education and training to hospital staff who provide maternal child care.

BOX 19.5

Nursing Care Planning to Respect Cultural Diversity

Women are recognized as the “keepers of the culture,” or the main people who transmit customs to the next generation. Chief among these customs is the preferred method for feeding newborns. The rate of breastfeeding varies in communities from almost 84.6% to a low of 30% as this is both sociodemographically and culturally influenced (AAP, 2012a). If a woman comes from a family where no one has ever breastfed, she may be very interested in being a “pioneer” in her family. Or, she may be more interested in following her family’s tradition of formula feeding.

How soon women want to begin breastfeeding after birth is also culturally determined. Although it is recommended women begin this immediately after birth, some cultures believe colostrum is not appropriate for newborns and so have a cultural preference not to begin breastfeeding until milk is present, at about 3 days of age. Be certain to assess each family individually to recognize cultural preferences.

Support, adequate instruction, and reassurance from healthcare personnel are important for helping a woman feel secure enough to successfully breastfeed (Barnes, Cox, Doyle, et al., 2010). Rooming-in is ideal for breastfeeding because the infant can be fed with feeding cues. Nurses should discuss safe sleep with new mothers and counsel mothers to place newborns on a firm mattress and on their back with no blankets or covers. The room should be a comfortable temperature, and the newborn should not be exposed to environmental tobacco smoke. Caretakers should avoid excessive alcohol causing intoxication and medications or drugs that alter mental status. Pacifiers may be introduced at 3 weeks of age if breastfeeding is well established and there are no latch concerns (Centers for Disease Control and Prevention, 2016).

#### ***Provide Information Regarding Lactation and Proper Positioning Techniques.***

Mature breast milk may appear thin and blue-tinged in appearance. Some women may need assurance that this color and consistency are normal; otherwise, they may think their milk is not nutritious enough.

Before breastfeeding, recommend a woman wash her hands to be certain they are free of pathogens picked up from handling perineal pads or other sources. Washing her breasts is not necessary unless she notices caked colostrum on the nipples. There are several positions a mother may use when breastfeeding. The side-lying position (Fig. 19.3) may permit the mother to rest while feeding. This may be difficult as the initial feeding position as it requires the newborn to latch more independently. Figure 19.4A shows a sitting position with a pillow under the newborn. Using a football hold with the newborn supported on a pillow also may be helpful, especially if a mother had a cesarean birth (Fig. 19.4B). This position is also helpful if the baby is having difficulty latching due to large breasts that obstruct the mother’s view or less prominent nipples that provide little palate stimulation.

**Figure 19.3** A side-lying position for breastfeeding.

A

B

**Figure 19.4** (A) A sitting position for breastfeeding with a nursing

pillow. (B) A football hold for breastfeeding. (Courtesy of Lourdes Forster, MD, FAAP. From Chung, E. K. [2010]. *Visual diagnosis and treatment in pediatrics*. Philadelphia, PA: Lippincott Williams & Wilkins.)

Brushing the infant’s cheek with a breast nipple stimulates a newborn’s rooting reflex. The newborn will then turn toward the breast. Do not try to initiate a rooting reflex by pressing a baby’s face against the mother’s breast as this will cause the child to turn away from the mother and toward your hand. An assessment tool such as the LATCH assessment (Table 19.3) can be helpful. This charting system, similar to an Apgar score, provides a systematic method for gathering information about breastfeeding progress. The system assigns a numerical score of 0, 1, or 2 to five key components of breastfeeding; 10 is a perfect score, meaning the woman is ready to independently breastfeed. The LATCH score is a useful tool to identify mother–infant pairs who might benefit from additional skilled support to encourage them to continue exclusive breastfeeding.

**TABLE 19.3 LATCH BREASTFEEDING CHARTING SYSTEM**

	0	1	2
<b>L:</b> Latch	Too sleepy or reluctant; no latch achieved	Repeated attempts; necessary to hold nipple in mouth; stimulate to suck	Grasps breast; tongue down; lips flanged; rhythmic sucking
<b>A:</b> Audible swallowing	None	A few swallows with stimulation	Spontaneous and intermittent under 24 hr old; spontaneous and frequent over 24 hr old
<b>T:</b> Type of nipple	Inverted	Flat	Everted (after stimulation)
<b>C:</b> Comfort (breast/nipple)	Engorged; cracked, bleeding, large blisters, or bruises; severe discomfort	Filling; reddened/small blisters or bruises; mild/moderate discomfort	Soft, nontender
<b>H:</b> Hold (positioning)	Full assist (staff holds infant)	Minimal assist (staff places pillows for support,	No assist from staff; mother able

at breast)	elevates head of bed); teach one side, mother does other; mother takes over feeding	to position/hold baby by herself
------------	---	----------------------------------

Add up total score. A perfect score is 10, meaning a woman is ready to independently breastfeed. From Jensen, D., Wallace, S., & Kelsay, P. (1994). LATCH: A breastfeeding charting system and documentation tool. *Journal of Obstetric, Gynecologic, and Neonatal Nursing*, 23(1), 27–32.

During the first few days of life, because they are receiving only colostrum and need the nutrients and fluid obtained by frequent sucking, newborns should be fed with all feeding cues (mouth opening, eyes open, bringing hands to mouth). Frequent feeding also is advantageous to establish a milk supply.

A mother should be taught how to properly take her newborn off the breast while he or she is sucking. This may be necessary if the latch is painful. Teach a woman to insert a clean finger with a short fingernail in the corner of the infant’s mouth or pull down the infant’s chin to release suction. Otherwise, the baby may pull too hard on the nipple, causing nipple cracking or soreness.

**Promote Adequate Sucking.** Often, a newborn being breastfed becomes sleepy at the breast, especially in the first 24 hours of life. Jaundice and hypoglycemia are also causes of sleepiness at the breast. To both stimulate milk production effectively and ensure adequate breast milk intake, a woman may need to keep the infant awake and urge him or her to suck. Placing the newborn skin to skin will often provide the proper environment to arouse the newborn to feed.

If an infant is not latching properly, a hospital-grade pump or hand expression may be used to provide express breast milk to the newborn.

**Provide Immediate Support if Problems Arise.** Successfully breastfeeding their newborn in the hospital increases the likelihood mothers will be successful breastfeeding after discharge (Perry, Ip, Chau, et al., 2013).

The nurse should provide an individual feeding plan to the mother upon discharge, ideally in consultation with an IBCLC. Early follow-up and referral to breastfeeding support groups will promote successful breastfeeding during the newborn period. The first 4 weeks postpartum are usually the most challenging for a new breastfeeding mother. After 4 weeks, breastfeeding, if successfully accomplished, is easier than formula feeding.

**Provide Information Regarding Techniques for Burping the Breastfed Baby.** Some infants seem to swallow little air when they breastfeed, whereas others swallow a great deal. As a rule, it is helpful to burp newborns after they have emptied the first breast and again after the total feeding to help evacuate air from their stomachs.

Placing the baby over one shoulder and gently patting or stroking the back is a time-honored position. However, this position is not always satisfactory for a newborn who has poor head control because a parent may have difficulty supporting

the baby and patting the back at the same time.

Holding the baby in a sitting position on the lap and then leaning the child forward against one hand, with the index finger and thumb supporting the head, is often the best position to use. This position provides head support and leaves the other hand free to pat the baby's back (Fig. 19.5). Parents usually need to be shown this method because it does not seem as natural as placing a baby against the shoulder. Laying the baby prone across the lap is yet another alternative position.

**Figure 19.5** A nurse burps a newborn using a sitting position. Notice how the infant's head is supported by the nurse's hand.

***Support for a Mother Who Is Breastfeeding Multiple Infants.*** Because of in vitro fertilization, an increasing number of women are giving birth to multiple newborns. Reassure women they can provide breast milk to more than one newborn. Nurses can recommend pillow supports designed to allow twins to feed simultaneously. These pillows are similar to the pillows used to support one baby but are wider on the sides to support two babies for simultaneous feedings (Fig. 19.6).

**Figure 19.6** Breastfeeding multiples. **(A)** Breastfeeding positions for mothers of multiples. (Copyright 2006 by Marvelous Multiples, Inc. Used with permission.) **(B)** The mother of twins may find a wider, firmer pillow easier to use when breastfeeding. (Photo of My Brest Friend Twin Nursing Pillow used with permission from My Brest Friend, <https://www.mybrestfriend.com>.)

**Nursing Diagnosis:** Pain related to breast engorgement or sore nipples

**Outcome Evaluation:** Patient states she is experiencing little or no discomfort; breastfeeds without undue discomfort; infant grasps nipple firmly. Nipples are intact with bruising or blisters. Nipple trauma may be evaluated using the following scale:

- Stage 1: superficial intact
- Stage 2: superficial with tissue breakdown
- Stage 3: partial erosion
- Stage 4: full thickness erosion (Mohrbacher, 2017)

On the third or fourth day after birth, when breast milk volume increases, women often notice breast distention, accompanied by hardness, and tenderness, and the skin may appear red, tense, and shiny. This is physiologic **engorgement**, caused by vascular and lymphatic congestion arising from an increase in the blood and lymph supply to the breasts. Newborns have difficulty latching when breasts are engorged because the areola can be too hard to grasp (Fig. 19.7). A woman also may have difficulty breastfeeding her newborn because her breasts are uncomfortable (Strong, 2011).

**Figure 19.7** Breast engorgement may cause problems when

breastfeeding. **(A)** When sucking at a nonengorged breast, the infant's lips compress the areola and fit neatly against the sides of the nipple. The infant also has adequate room to breathe. **(B)** When a breast is engorged, the infant has difficulty grasping the nipple. Breathing ability may also be compromised.

***Prevent or Relieve Engorgement.*** There are few evidence-based methods for relieving engorgement; a common suggestion is to empty the breasts of milk by having the infant feed more often. Unfortunately, a woman's breasts are sometimes so painful it is difficult for her to continue to breastfeed unless she is given something such as a mild analgesic for pain relief. Good breast support from a firm-fitting bra also helps prevent a pulling, heavy feeling.

If an infant cannot grasp a nipple to latch properly because of engorgement, moist heat applied to both breasts or standing under a warm shower for a few minutes before feeding, combined with massage to begin milk flow, often promotes breast softness so a newborn can suck. Manual expression or the use of a breast pump to completely empty the breasts after the baby has breastfed can help maintain or promote a good milk supply during a period of engorgement ([Fig. 19.8](#)).

**Figure 19.8** A nurse and mother discuss the advantages and disadvantages of an electric breast pump (shown on the table) and a manual pump (shown in the mother's hands).

Fortunately, engorgement is a transient problem. Unfortunately, it occurs just as women are beginning to feel skilled at breastfeeding. Because their breasts are swollen, hot, and tender, they may worry an infection has developed or their baby is not getting enough milk. Assure a mother that symptoms of engorgement are actually a normal finding. Assure her that engorgement is only temporary and should begin to subside 24 hours after it first became apparent. If engorgement persists after 24 hours or beyond the first week postpartum, the mother may be experiencing pathologic

engorgement and should consult with an IBCLC. Excessive engorgement is a risk factor for mastitis, a breast infection.

***Promote Healing of Sore Nipples.*** Painful nipples may result from:

- Improper positioning of the newborn. The newborn's body should face the mother with the head and body in alignment. The newborn's head should be at a level position or in the sniffing position. When the newborn's chin is on the chest, it cannot open its mouth wide enough to achieve a good latch.
- Improperly removing a newborn from the breast
- Prolonged breastfeeding for comfort after the newborn's nutritional needs are met
- Abnormalities of the palate and/or tongue. A palate that is high arched or flat may affect proper latching. An abnormal frenulum of the lip or tongue may prevent a proper latch. The infant can be provided expressed breast milk through pumping until evaluation by a lactation consultant.
- Improper use of the breast pump may cause sore nipples. Setting the vacuum at too high a pressure or pumping for an excessive period of time can damage the nipple. Fifteen minutes is usually sufficient to empty the breast. The breast flange comes in several sizes to accommodate different size nipples. A flange that is an improper size can damage the nipple. Websites such as [www.medela.com](http://www.medela.com) and [www.ameda.com](http://www.ameda.com) offer guidance on the proper sizing of the breast flange. Hospital pumps have a frequency setting in addition to a vacuum or pressure setting. The frequency should be set high (frequent cycles per minute) to mimic the sucking that a newborn provides at the breast until the milk begins to flow and the frequency can be decreased.

Appropriate nipple care is important to prevent skin breakdown of the nipples. The nurse can also recommend applying a few drops of breast milk to the nipples after feeding and gently massaging it into the areola. The components of breast milk have healing properties.

Sore nipples are not a contraindication to breastfeeding as long as a proper latch is obtained. If the latch is too painful, the mother can pump to provide expressed breast milk to her newborn and ensure her milk supply is protected. A nipple shield, worn while breastfeeding, can protect the nipple while the reasons for poor latch are determined (**Figure 19.9A**). A nipple shell is worn over the nipple in between feedings to promote healing and protect the nipple from irritation (**Figure 19.9B**).

**Figure 19.9** (A) Nipple shields. (B) Nipple shells.

**Nursing Diagnosis:** Anxiety related to inability to measure amount of milk taken by the baby

**Outcome Evaluation:** Mother states her newborn seems satisfied after feeding and voices confidence her baby is obtaining enough milk; baby voids six to eight times per day after the first week, stools are yellow and frequent, and the newborn is waking for 8 to 12 feedings in a 24-hour period.

Breastfeeding mothers may fear their newborns are not getting adequate amounts of breast milk at each feeding. This may be especially true when the newborn cries for reasons other than hunger. Mothers cannot measure the amount of breast milk the newborn ingests each feeding. Nurses can reassure mothers by instructing them to look for signs the newborn is voiding and defecating within the acceptable range and waking for feedings 8 to 12 times in 24 hours. The newborn can be weighed prior to and after a feeding to determine intake in instances where there are concerns. The scale must be calibrated and have the ability to detect weight gain as little as 2 g. If there are any concerns regarding the newborn's ability to transfer milk or the mother's milk supply, an early discharge appointment with their pediatric care provider is indicated.

### *What If... 19.2*

**Linda tells the nurse she is unsure her baby is getting enough milk when she breastfeeds. How would the nurse assure Linda that her baby is receiving adequate nutrition?**

**Nursing Diagnosis:** Deficient knowledge related to potential harm to baby from drugs taken by breastfeeding mother

**Outcome Evaluation:** Mother states she is aware almost all drugs taken may be excreted in breast milk; voices importance of consulting her newborn's primary

healthcare provider before taking any medication.

Medication and drugs ingested by the mother are present in human milk in varying degrees. Many factors affect the quantity of the substance in human milk. Substances may transfer to human milk if they obtain high concentrations in maternal plasma, are low in molecular weight (below 500), are low in protein binding, and are high in lipid solubility. The most important determinant is plasma level. As the mother's plasma level rises, the level in human milk rises. As soon as the mother's plasma level falls, an equilibrium forces the substance out of the human milk into the maternal plasma for elimination. This factor is important when considering the timing of substance ingestion by the mother and the timing of the newborn's feeding. Substances that are in human milk may not enter the newborn's circulation due to several factors. The substance may be destroyed or fail to be absorbed by the newborn's gut. Premature infants (less than 34 weeks) may be more affected by substances than late preterm infants (34 to 36 6/7 weeks or full-term infants (37 or more weeks). During early lactation (days 1 to 3), the volume of milk the newborn ingests is small, so medication the mother is taking postdelivery is not a concern. If the relative infant dose is less than 10%, it is considered safe. Most medications are less than 1%. In most cases, the benefits of breastfeeding outweigh the risks of medication use by the mother. Encourage the mother to consult her pediatric care provider for guidance. A list of drugs breastfeeding mothers should avoid because of their documented harmful effects on infants is available at <http://www.thePoint.com/Flagg8e> (Hale & Rowe, 2017).

**Nursing Diagnosis:** Effective breastfeeding related to mother's desire to provide the best nutrition for her child

**Outcome Evaluation:** Mother states she intends to continue exclusive breastfeeding the first 6 months and add complementary foods at 6 months and continue breastfeeding through the first year and beyond if she desires.

**Anticipate Potential Problems and Suggest Methods for Resolving Them.** Common problems and solutions that can arise with breastfeeding once a mother returns home are summarized in Table 19.4.

**TABLE 19.4 COMMON CONCERNS OF BREASTFEEDING PARENTS**

Concern	Cause	Nursing Interventions
Mother worries about amount of milk being taken.	Mother cannot see the amount taken.	Assure mother the best way to judge amount taken is to note whether infant appears content between feedings and is wetting diapers.
Infant does not suck well.	Possible effect of analgesia from	Adjust feeding pattern to infant's needs; assure mother effect of analgesia is temporary.

	labor. Mother is trying to feed when infant is not hungry. Infant exhausted by crying from hunger.	Encourage rooming-in. Encourage feeding on hunger cues, not on a set schedule.
Mother reports infant's stools are loose and thin.	Stools should be looser and lighter in color than in formula-fed babies.	Examine stools; explain normal stool pattern and transitions.
Father feels shut out of parent-child relationship.	Father does not participate in infant feeding.	Show father other ways of interacting with infant than through feeding.
Mother reports sore nipples.	Infant is not gripping entire areola. The nipple is kept wet.	Help infant to grasp nipple correctly; expose nipple to air between feedings; aloe vera or lanolin applied to nipples helps heal tissue.
Mother reports engorgement.	Lymphatic filling as milk production begins.	Encourage infant to suck (engorgement subsides best if infant can be encouraged to suck); apply warm packs to breasts or have mother take a warm shower before feeding to help soften breast tissue.
Mother is concerned about breastfeeding in public.	A woman may feel uncomfortable breastfeeding at work or other public places.	Encourage a woman to use discretion to avoid confrontation (unless she wants to make a point that breastfeeding is a natural action) and to speak to a work site administrator about comfortable arrangements.

Fatigue can be another problem on returning home if a woman does not take adequate measures to conserve her energy. Sitting relaxed in a comfortable chair with her feet elevated, feeding her baby, and enjoying this time are excellent ways to rest as well as to promote effective feeding.

Remind women a good fluid intake is necessary to maintain an adequate milk supply. Recommend they drink at least four 8-oz glasses of fluid a day; many may need to drink six glasses. They also need to increase their calorie intake by about 500 calories per day.

There are no dietary restrictions when breastfeeding other than eating uncooked or undercooked food, which could present a risk for bacterial infection. Alcohol and caffeine can affect the newborn and should be avoided by the breastfeeding mother.

Positive support by healthcare providers, family, friends and the work environment is important as a protective factor for continuation of breastfeeding.

### ***QSEN Checkpoint Question 19.4***

#### **TEAMWORK & COLLABORATION**

The discharge coordinator is discussing some of the statements made by Linda. Which of the following would indicate she needs further teaching about breastfeeding from the nurse?

- a. “I know breastfeeding is recommended for the first year of my baby’s life.”
- b. “To prevent nipple pain, I may need to vary the position I use to feed.”
- c. “While breastfeeding, I need to drink at least 12 glasses of fluid a day.”
- d. “I recognize that breastfeeding may help me lose some pregnancy weight.”

*Look in Appendix A for the best answer and rationale.*

***Provide Information on Supplemental Feedings.*** Mothers may ask about breast milk collection and storage in preparation for their return to work. Once the infant is sleeping a 4- or 5-hour stretch, the mother could pump after feeding the infant and collect that breast milk for future feedings (U.S. Department of Agriculture, 2016).

Bottles and nipples should be washed using normal dishwashing practice. An easy way to recall breast milk storage is 4 hours at room temperature, 4 days in the refrigerator, and 4 months in the freezer. The bottle used should be plastic and marked “safe for infant feeding”; otherwise, it may contain substances that can leech into stored milk and which may be associated with chromosomal aberrations (Rasmussen & Geraghty, 2011). Commercially prepared formula may be used if expressed breast milk is not available.

***Provide Information for a Mother Who Works Outside the Home.*** Some women return to work while continuing to breastfeed by bringing their infants with them to their workplace. Others express breast milk for a caregiver to give by bottle while they work. As there are many considerations to think about, women should review with their employer the best way for them to continue successful breastfeeding at their work site (Payne & Nicholls, 2010). Federal law has provisions that entitle a mother to the time and a suitable place to pump while at work up through the first

year of her child's life (Centers for Disease Control and Prevention, 2016) (Box 19.6).

## BOX 19.6

### Nursing Care Planning to Empower a Family

#### SUGGESTIONS FOR RETURNING TO WORK WHILE BREASTFEEDING

**Q.** Linda Satir asks you, “How can I continue to breastfeed after I return to work in 6 weeks?”

**A.** Common suggestions include:

- Some women are able to arrange for child care near or at their work site so they can breastfeed at lunch or during a morning or afternoon break. Discuss with your employer or your immediate work supervisor whether this would be a possibility for you.
- Breastfeeding can be done in a public place, such as a lounge area, without undue exposure if you wear a smock-type or buttoned blouse that you lift or unfasten only as far as is necessary; covering any bared breast with a shawl or towel ensures modesty.
- If you are not able to breastfeed during work hours, you will need to express milk manually at least once during the day to maintain a milk supply. You might want to rent an electric pump to keep at work. Expressed breast milk can be safely stored in a refrigerator or in an iced container for 24 to 48 hours and used by your caregiver to feed the infant the next day.
- Plastic that does not contain bisphenol A is the best type of storage container for breast milk because antibodies apparently cling to glass and may therefore be lost to the milk.
- Any reminder of a baby may cause leaking of milk from breasts. Wear gauze pads inside your bra to prevent stains on your clothing and keep an extra change of clothing at work. Pressing against your breasts with the heel of your hands may be helpful in halting leakage.
- Drink four to six 8-oz glasses of fluid during the day to ensure a high fluid intake.
- Try to arrive early at your day care center or sitter so you can breastfeed just before leaving the baby.
- Fatigue can interfere with breastfeeding. Relax and enjoy your baby during the time you are home.

#### *What If . . . 19.3*

**Linda tells the nurse she doesn't know how she will manage breastfeeding when she returns to work. How would the nurse advise her?**

***Provide Information on Weaning.*** The AAP (2016) recommends infants be exclusively breastfed for the first 6 months and breastfed with complementary foods for the first year of life; the World Health Organization recommends exclusive breastfeeding for 6 months and continuation for 2 years (U.S. Department of Agriculture, 2016) (Fig. 19.10).

**Figure 19.10** Some women choose to breastfeed their child beyond 1 year of age. Accepting various preferences of this kind is important to care planning.

***QSEN Checkpoint Question 19.5***

**SAFETY**

When teaching Linda about newborn feeding, the nurse would include which statement(s) to reflect safety and evidence-based practice? Select all that apply.

- a. Breastfeeding exclusively for 6 months can reduce the risk of obesity later in life.
- b. Maternal benefits of breastfeeding include a decreased risk of breast and ovarian cancer.
- c. Benefits to the infant from formula feeding include increased calcium density in the spine.
- d. Once breastfeeding is established, pacifier use may help to decrease the risk of sudden infant death syndrome.

Look in *Appendix A* for the best answer and rationale.

## Formula Feeding

Human milk is recognized as the ideal food for the newborn. There are many reasons why mothers do not breastfeed for the first year of life (Box 19.7). These may include partner unsupportive, prefer someone else feed the infant possibly due to maternal fatigue, nipple soreness, newborn fussy or difficult and question whether they are receiving adequate nutrition, returning to work or school, and real or perceived inadequate milk supply.

### BOX 19.7

#### Nursing Care Planning Tips for Effective Communication

Mrs. Morgan, Linda's roommate in the hospital, is a new mother who has chosen to formula feed her newborn. You notice on the second day after birth she is studying her baby closely.

*Tip:* Avoid imposing your opinion on someone because it is not therapeutic. Allowing a woman to explain her individual situation helps you to understand the woman's decision and to offer her support.

**Nurse:** Is everything all right? You look worried.

**Mrs. Morgan:** I feel guilty I'm not breastfeeding.

**Nurse:** What made you decide not to breastfeed?

**Mrs. Morgan:** I work as an electrician at a construction site. I can't breastfeed or pump milk on a scaffold a hundred feet in the air in freezing weather.

**Nurse:** Let's talk about how formula feeding seems to be the best option for you.

## PREPARING FOR FORMULA FEEDING

Women should use commercial formulas for formula feeding if they choose not to breastfeed because they contain the recommended nutritional requirements.

### Commercial Formulas

The contents of commercial formulas are supervised by the U.S. Food and Drug Administration (FDA). Formulas are available in three types: modified milk based, soy based, and elemental (fat, protein, and carbohydrate content is modified, such as in lactose-free formula). Modified milk-based formulas are used for the majority of newborns; lactose-free formulas are used for newborns with lactose intolerance or galactosemia (inability to use sugar). Soy formulas were devised for infants who are allergic to cow's milk protein, although such infants may be given casein hydrolysate formulas, which have protein particles too small to be recognized by the immune

system. Elemental formulas are used for infants with protein allergies or fat malnutrition.

If the mother is not breastfeeding, then the newborn should be formula fed and continue on formula for the first year of life. Modified milk-based, soy-based, and lactose-free formulas all contain supplemental vitamins as well as 20 calories per ounce (the same number of calories as breast milk) when prepared according to directions. Advise parents to purchase formula with added iron to ensure that their newborn receives enough of this element to prevent iron-deficiency anemia (Szymlek-Gay, Lönnerdal, Abrams, et al., 2012). Participation in a supplemental food program, such as the Special Supplemental Nutrition Program for Women, Infants and Children (WIC), are available to help low-income parents afford formula ([www.fns.usda.gov/wic](http://www.fns.usda.gov/wic)).

Commercial formulas are supplied in four separate forms:

- Powder that is prepared by adding water as directed
- Condensed liquid that is diluted with an equal amount of water
- Ready-to-feed, which requires no dilution
- Individually prepackaged and prepared bottles of formula

The powder is the least expensive. A single bottle is easy to prepare by vigorous shaking. The prepackaged type does not need refrigeration or preparation (simply remove the bottle cap and it is ready), but it is the most expensive type. Cost should not be the only basis for a parent's choice, however. Tolerance of the formula by the infant and convenience for the parents are also factors.

### Calculating a Formula's Adequacy

To calculate the adequacy of a formula, the following may be used:

1. The total fluid ingested for 24 hours must be sufficient to meet the infant's fluid needs: 75 to 90 ml (2.5 to 3 oz) of fluid per pound of body weight (150 to 200 ml/kg) per day.
2. The number of calories required per day is 50 to 55 per pound of body weight (100 to 120 kcal/kg).

For example, a 7-lb infant needs 17.5 to 21 oz (7 lb × 2.5 to 3 oz) of fluid per day. As commercial formula contains 20 calories per ounce, this amount will also supply the infant's calorie needs (350 to 420 calories per day). The total volume can be divided into six feedings of 3 to 3.5 oz each. A 9-lb infant would need 22.5 to 27 oz of fluid per day, supplying 450 to 540 calories per day.

A quick rule of thumb to estimate how much an infant will drink at a feeding is to add two or three to the infant's age in months. After initially taking 0.5 to 1 oz for the first 2 days, a newborn (0 age) will take 2 to 3 oz each feeding; a 3-month-old child, 5 to 6 oz; and a 6-month-old child, 8 oz. As infants change from six to five feedings a day (at about 4 months of age, when they begin to sleep through the night), they begin to take more at each feeding, keeping their total intake the same. Knowing the minimum requirements for fluid and calories per day, being able to calculate whether formula is adequate, and assessing if an infant appears content and is gaining weight allows for

evaluating the adequacy of a formula-fed infant's intake.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Health-seeking behaviors related to techniques of formula feeding

**Outcome Identification:** Patient verbalizes knowledge of techniques of formula feeding by hospital discharge.

**Provide Information Regarding Supplies Needed.** Most parents today do not prepare a full day's supply of formula at once but rather prepare it bottle by bottle, as needed. Caution parents to keep opened cans of liquid formula covered and refrigerated, discarding any unused formula within 24 hours. They should use glass or plastic bottles that are noted to not contain polycarbonate (bisphenol A), as these are the only types safe for infant feeding ([Centers of Disease Control and Prevention, 2016](#)).

Nipples for bottles should be firm enough so an infant sucks vigorously. A soft, flabby nipple allows a baby to suck in milk so rapidly the need for sucking may not be satisfied. A way to judge a nipple's adequacy is to hold a bottle of milk with nipple attached upside down. The milk should drip from it at a rate of about one drop per second. Bottle caps to cover nipples are helpful to keep nipples clean when outdoors or during transport.

**Provide Information Regarding Formula Preparation.** Infant formula of any type must be prepared with careful attention to cleanliness to prevent pathogenic microorganisms from growing in it.

When using presterilized formula, the parent need only do the following to prepare a bottle of formula:

- Wash off the top of the can with warm, soapy water and rinse.
- Open the can and pour the desired amount of formula and water into a previously cleaned bottle.
- Put on the nipple, taking care not to handle the nipple projection.
- Place the bottle cap over the nipple and refrigerate or use to feed immediately.

If using powdered formula, the parent simply combines tap water and the measured amount of powder into a previously cleaned bottle, caps the bottle, and shakes it to mix the ingredients.

**Provide Information Regarding Feeding Techniques.** Whether to warm formula or not is a parental decision because infants who are fed cooled formula directly from the refrigerator seem to thrive as well as those who are fed warmed formula. The best method to warm formula is to stand the bottle in a bowl of warm water or hold it under a faucet of running hot water for a few minutes. Caution parents not to use a

pan on the stove to warm formula because if the pan boils dry, the bottle of milk will burst.

It also is not recommended to warm bottles in a microwave oven because the milk in the center of the bottle can become hotter than that near the sides. Finally, with all warming methods, parents should test the temperature of the formula by allowing a drop or two to fall onto the inside of a wrist to make certain it is not overheated enough to burn the baby's mouth.

With any type of bottle, any contents remaining after a feeding should be discarded, not stored and reused. When sucking, an infant exchanges a small amount of saliva for milk. Because milk is a good growth medium for bacteria and everyone's mouth harbors many bacteria, the bacterial content in reused formula is likely to be high.

Like breastfeeding, formula feeding an infant is a skill that needs some practice. A parent needs a comfortable chair and adequate time (at least half an hour) to enjoy the process and not rush the baby (Fig. 19.11). Holding the baby with the head slightly elevated reduces the danger of aspiration and retention of air bubbles. Caution parents to be certain the nipple is kept filled so the baby sucks milk, not air. Babies in the early weeks should be burped to raise air from their stomach after every ounce of milk taken. The technique is the same as that used for breastfed infants.

**Figure 19.11** A newborn receives a bottle feeding from her father. Notice the *en face* position: The father and baby are both looking directly at each other.

Remind parents not to prop up bottles because babies are in danger of aspiration

if a bottle is propped. In addition, an increased incidence of otitis media (middle ear infection) has been associated with bottle propping because the infant’s head is not upright and formula may enter the eustachian tubes. Propping also can limit the amount of parent–child interaction. Another precaution is not to put a baby to bed with a bottle of formula. This practice can lead to “baby-bottle caries,” or tooth decay of the lower teeth (Bishop, 2011) (see Chapter 29), because the formula remains in contact with the teeth for an extended time. Some common problems and solutions that can arise with formula feeding are summarized in Table 19.5.

**TABLE 19.5 COMMON CONCERNS OF FORMULA-FEEDING PARENTS**

Concern	Possible Causes	Nursing Interventions
Infant sucks for a few minutes and then stops and cries.	Either nipple is blocked and infant is unable to get milk, or flow is too fast and baby has choking sensation.	Show parent how to test flow of milk from the nipple (hold bottle upside down); milk should flow from nipple at rate of about 1 drop per second.
Infant does not burp well after feeding.	Some infants swallow little air with feeding and so don’t need extensive burping. Parent may be handling infant too tentatively or not burping effectively.	Observe baby feeding and parent’s technique of handling; rubbing newborn’s back may be more effective than patting it.
Parent reports constipation in infant.	Bowel movements from formula-fed infants are not as loose as those from breastfed infants, so parents may be concerned.	Examine stools; assure parent and explain normal stool pattern and that straining to pass stool is normal.

**QSEN Checkpoint Question 19.6**

**QUALITY IMPROVEMENT**

Linda’s husband, Paul, plans to offer their baby bottled breast milk once daily when Linda returns to work. Educational literature available on the unit should include which guideline?

- a. He should stop feeding bottled milk if he notices the baby has loose yellow stools.
- b. He should microwave the milk for a full minute to be certain it is absolutely sterile.
- c. He should prop the bottle so the baby continues to enjoy breastfeeding best.
- d. After the baby drinks from a bottle, he should discard any milk still in the bottle.

*Look in Appendix A for the best answer and rationale.*

## Discharge Planning for Newborn Nutrition

Mothers only remain in a hospital or birthing center for a short time, so teaching parents about either breastfeeding or formula feeding is crucial. Be certain to review a mother's plans for feeding her baby before discharge so there is time to answer any remaining questions. Connect the mother to local breastfeeding support groups in the area.

Review with the mother the criteria to use to assess if her infant is receiving adequate intake based on the recommended voiding and stooling pattern previously described.

Ensure the newborn has a follow-up appointment with a pediatric primary care provider. Nurses can increase a mother's self-confidence by empowering women to learn to make decisions regarding feeding and to not be reluctant to ask for help when they need it.

### *What If . . . 19.4*

**The nurse is interested in exploring one of the 2020 National Health Goals related to newborn nutrition (see Box 19.1). Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Satir family and that would also advance evidence-based practice?**

### KEY POINTS FOR REVIEW

- Human milk is the ideal food and the preferred feeding method for newborns because it provides antibodies as well as nutrients. Encourage all mothers to breastfeed by providing them with the knowledge, skill, and support to be successful. This helps in planning nursing care that not only meets QSEN competencies but best meets the family's total needs.
- Linoleic acid is an essential fatty acid that is necessary for growth and skin integrity and cannot be manufactured by the body. It is supplied by both infant formula and human milk but not by fat-free milk.
- Both breast milk and commercial formulas contain 20 kcal/oz. A term newborn requires 120 kcal/kg per day and 150 to 200 ml/kg of fluid per day.
- Encourage mothers who are breastfeeding to drink fluoridated water; formula-feeding mothers should prepare formula using fluoridated water to help build strong teeth in the infant.
- Both breastfed and partially breastfed newborns need supplemental vitamin D (400 IU). Newborns who are formula fed should be fed iron-fortified formula to avoid iron-deficiency anemia; breastfed babies may require an iron supplement for the same reason.
- Drugs pass into breast milk and their effects vary depending on their availability to

accumulate in breast milk and the infant's ability to absorb the drug. A breastfeeding mother should consult with her child's pediatric care provider before discontinuing breastfeeding due to concerns with her medication usage. In most cases, the benefits of breastfeeding outweigh the risk of discontinuing breastfeeding due to the mother's medication use.

- If a baby will be formula fed, be certain the parents understand how to prepare the formula.
- Caution parents not to prop bottles because it increases the risk for aspiration and otitis media. It also deprives infants of the pleasure of being held for feedings.
- To avoid baby-bottle caries (decay of the lower teeth), advise parents not to put the newborn to bed with a bottle.

### CRITICAL THINKING CARE STUDY

Shannon, 30 years old, and her husband, Jason, have three boys, with the youngest being 17 months old. Shannon has just given birth to her fourth child. Shannon is a smoker and wants to breastfeed her baby girl just like she did with all of her boys. Throughout the pregnancy, multiple ultrasounds were performed to check the baby's growth, which measured the infant 1 week under estimated gestational age. When the baby was born, she weighed 5 lb and 13 oz. In the birthing room, the infant did not latch.

1. Because of the infant's inability to latch on to the breast, what nursing interventions would you include in your plan of care for this infant?
2. On day 2, the newborn weighs 4 lb and 14 oz. Should you be concerned with the amount of weight loss? What should you do?
3. According to the AAP, what should you advise Shannon concerning her smoking habit and breastfeeding? Is her infant at an increased risk for sudden infant death syndrome?

UNIT 4

The Nursing Role in Caring for a  
Family During Complications of  
Pregnancy, Birth, or the Postpartal  
Period

## Nursing Care of a Family Experiencing a Pregnancy Complication From a Preexisting or Newly Acquired Illness

*Angelina Gomez, 22 years old, is a gravida 1, para 0 woman, 34 weeks pregnant, whom you meet in the emergency room. Her electronic record shows you she had rheumatic fever with mitral valve stenosis as a child. During this pregnancy, she developed gestational diabetes. At 34 weeks, she has already been hospitalized twice for hyperglycemia. This afternoon, she fainted while participating in her weekly hour-long aerobics class. Her serum glucose at the moment is 207 mg/dl. Blood pressure is 90/40 mmHg; pulse rate is 130 beats/min; the fetal heart rate is 180 beats/min. A uterine monitor shows she is having moderate-strength contractions 7 minutes apart. Angelina asks you, "If exercise is supposed to be good for you, why did this happen?"*

*Previous chapters discussed normal pregnancy and the minor discomforts that may occur. This chapter adds information about illnesses and other events that can complicate pregnancy when they occur prior to or during pregnancy. As more women wait until they are older than age 30 years to have their first child, more and more women enter pregnancy with a preexisting disorder, such as cardiac or respiratory illness, that can complicate pregnancy.*

**How would you answer Angelina? Do you think she realizes pregnancy often becomes high risk not because of any one factor but an accumulation of them?**

### KEY TERMS

deep vein thrombosis (DVT)  
glucose challenge test  
glycosuria  
glycosylated hemoglobin (HbA1c)  
high-risk pregnancy  
hyperglycemia  
hypoglycemia

**megaloblastic anemia**  
**orthopnea**  
**paroxysmal nocturnal dyspnea**  
**peripartal cardiomyopathy**

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Define *high-risk pregnancy*, including preexisting factors that contribute to its development such as diabetes mellitus or cardiovascular disease.
2. Identify 2020 National Health Goals related to complications of pregnancy that nurses can help the nation achieve.
3. Assess a woman with an illness during pregnancy for changes occurring in the illness because of the pregnancy or in the pregnancy because of the illness.
4. Formulate nursing diagnoses related to the effect of a preexisting or newly acquired illness on pregnancy.
5. Identify expected outcomes that will contribute to a safe pregnancy outcome when illness occurs with pregnancy as well as help families manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care for a woman when illness complicates pregnancy, such as teaching her how to measure blood glucose.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of high-risk pregnancy and the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

Although pregnancy can be a stressful time, generally, women experience overall good health during pregnancy, perhaps in part because of their extra care and concern in keeping healthy for two. This extra motivation also encourages a woman with a high-risk pregnancy to carefully follow a therapeutic regimen established for her to keep herself and her fetus safe.

Unit 4 addresses the nursing role and care you might provide to families with pregnancy complications, which are common. This chapter focuses on women who enter pregnancy with a chronic condition, such as cardiovascular or kidney disease, and those who experience unintentional injury or develop a chronic illness during pregnancy. Both the woman and the fetus can be at risk for complications. Either the

pregnancy can complicate the disease or the disease can complicate the pregnancy, affecting the fetus or leaving the woman less equipped to function in the future or undergo a future pregnancy. Nursing care needs to include close observation of both maternal health and fetal well-being, education for the woman and her family about special danger signs to watch for during pregnancy, and actions to minimize complications whenever possible, including:

- Preventing disorders from affecting the health of the fetus
- Helping a woman regain her health as quickly as possible so she can continue a healthy pregnancy and prepare herself psychologically and physically for labor, birth, and the arrival of her newborn
- Helping a woman learn more about her illness so she can continue to safeguard her health during her childrearing years

Conditions that cause severe symptoms such as a marked change in fluid and electrolyte balance, altered cardiovascular or respiratory function, or severe blood loss are especially dangerous to a fetus (Gregory, Korst, Lu, et al., 2013). Because of this danger, 2020 National Health Goals related to complications of pregnancy have been established (Box 20.1).

#### BOX 20.1

#### Nursing Care Planning Based on 2020 National Health Goals

Several National Health Goals are aimed at reducing complications of pregnancy that arise from existing or newly acquired disorders.

- Reduce the rate of fetal deaths to 5.6 per 1,000 live births from a baseline of 6.2 per 1,000 live births.
- Reduce the rate of maternal deaths to 11.4 per 100,000 live births from a baseline of 12.7 per 100,000 live births.
- Reduce the rate of maternal illness and complications during pregnancy to 28 per 100 births from a baseline of 31.1 per 100 births (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation reach these goals by educating women about the importance of entering pregnancy in the best state of health possible. Helping women who have diabetes mellitus understand the importance of pre-pregnancy care so they enter pregnancy without hyperglycemia is an important step toward reducing congenital anomalies in newborns. Supporting women with kidney, heart, or respiratory disease during pregnancy to continue to follow their medical regimen is yet another way.

#### *Nursing Process Overview*

#### FOR CARE OF A WOMAN WITH A PREEEXISTING OR NEWLY ACQUIRED ILLNESS

## ASSESSMENT

An accurate prenatal assessment of a woman with a preexisting or newly acquired illness requires a thorough understanding of the signs and symptoms of the illness in addition to an understanding of the course of a normal pregnancy (Fig. 20.1).

Assessment techniques include objective measures such as establishing baseline vital signs as well as subjective factors such as the extent of edema or level of exhaustion a woman is experiencing. Such assessment is best made by healthcare personnel who care for a woman consistently throughout the pregnancy so that subtle changes can be recognized. It's also important to teach a woman how to assess her own health in relation to objective parameters. She could report exhaustion, for example, in relation to daily activity such as "Two weeks ago I could walk a block without being short of breath. Today I could walk only half a block" or "The last time I was in for a checkup, edema didn't occur until bedtime. Now I notice it every afternoon by the time my son comes home from school."

**Figure 20.1** It is important to establish baseline vital signs to later identify a complication related to a preexisting condition. (Monkey Business Images/Shutterstock.com)

## NURSING DIAGNOSIS

Nursing diagnoses developed for a woman with a high-risk pregnancy address her specific, disease-related condition as well as any therapeutic restrictions her condition might require. Examples of possible nursing diagnoses include:

- Ineffective tissue perfusion (cardiopulmonary) related to poor heart function secondary to mitral valve prolapse during pregnancy
- Pain related to pyelonephritis secondary to uterine pressure on ureters
- Social isolation related to prescribed bed rest during pregnancy secondary to

concurrent illness

- Ineffective role performance related to increasing level of daily restrictions secondary to chronic illness and pregnancy
- Knowledge deficit related to normal changes of pregnancy versus illness complications
- Fear regarding pregnancy outcome related to chronic illness
- Health-seeking behaviors related to the effects of illness on pregnancy
- Situational low self-esteem related to illness during pregnancy

## **OUTCOME IDENTIFICATION AND PLANNING**

Be certain that expected outcomes are realistic in light of a woman's pregnancy and the restrictions placed on her by her health. Remember that one family member with illness affects all family members; therefore, outcomes should relate to the entire family's health.

When making plans with a woman who has a preexisting medical condition, base them on the pattern of her life before the pregnancy. For example, to ensure a pregnant woman receives enough rest during pregnancy, planning for an afternoon rest period each day is usually adequate. However, for a woman with cardiac disease who took two rest periods a day before pregnancy, this would be ineffective because now she probably needs four rest periods. A primary goal for a woman with a severe chronic condition might be to maintain her health during pregnancy so she can remain at home as long as possible, thereby minimizing hospitalization and family disruptions.

Planning for a new illness may be difficult for a woman because of the shock of the diagnosis. Be careful, however, not to make plans for her such as "Your best plan would be to begin strict bed rest." Instead, give a woman the available alternatives such as "There are two possible therapies. Let me review with you the advantages and disadvantages of each one." Allowing a woman to choose among alternatives in this way helps her to participate in her own care and also maintain self-esteem as well as helps her move a step toward parenthood and assuming care for her family.

Refer women and their families to online resources for further information when appropriate. Helpful resources addressing complications of pregnancy and childbirth and support programs are available.

## **IMPLEMENTATION**

Nursing interventions for a pregnant woman with a chronic illness may focus on teaching her new or additional measures to maintain health during the pregnancy. Imaginative solutions to problems may need to be created because, otherwise, a woman may be unable to adjust to the extent of changes she must make.

## **OUTCOME EVALUATION**

If an evaluation of outcomes at healthcare visits reveals that an expected outcome is not being met, a new assessment, analysis, and planning need to be done. In some instances, an outcome is not met because a woman did not understand the need for an additional pregnancy measure. At other times, a woman may need better psychological support to continue to follow a healthcare routine consistently because 9 months is a long time to adhere to restrictions. Make evaluation ongoing to ensure that you know throughout the pregnancy whether interventions are successful. Some examples of outcomes that might be established include:

- Patient states she rests for 2 hours morning and afternoon; dependent edema remains at 1+ or less at next prenatal visit.
- Family members state they are all participating in an exercise program since mother developed gestational diabetes.
- Patient reports no burning on urination or flank pain at next prenatal visit.
- Patient states she understands the importance of taking daily thyroid medicine for total length of pregnancy.

## The Nursing Role and Nursing Care During Pregnancy Complications

All types of women desire pregnancy, including those with an underlying disease process, such as diabetes or heart disease, which can worsen with pregnancy. Some complications lead to early pregnancy loss or preterm delivery (see [Chapter 21](#)). Other complications arise due to specific characteristics of the mother, such as her age or her use of substances (see [Chapter 22](#)). Still, other complications happen during labor itself, related to contractions, to the mother’s pelvis, or to the baby (see [Chapter 23](#)). At times, complications in pregnancy or during labor lead to cesarean delivery, and nurses need to be prepared to care for the family experiencing this type of delivery (see [Chapter 24](#)). Infections or bleeding can also occur in the postpartum period, which can complicate a mother’s recovery (see [Chapter 25](#)).

### IDENTIFYING A HIGH-RISK PREGNANCY

A **high-risk pregnancy** is one in which a concurrent disorder, pregnancy-related complication, or external factor jeopardizes the health of the woman, the fetus, or both.

It’s important that women with such pregnancies be identified because illness during pregnancy can complicate not only the pregnancy but also a woman’s entire lifestyle and that of her family. In most instances, more than one factor contributes to the classification of a pregnancy as high risk. The pregnancy of a woman with diabetes, for example, is automatically considered as having a greater-than-normal risk because it forces a fetus to grow in an environment in which **hyperglycemia** (increased serum glucose levels) becomes the rule. During such a pregnancy, a woman, worrying that something will happen to her baby, may fail to begin the “pregnancy work” that she must do so bonding can take place. At birth, her child is in double jeopardy: Not only is the baby born with altered glucose metabolism but he or she also is at high risk for poor maternal–child or parent–child attachment.

Remembering that the term “high risk” rarely refers to just one causative factor but includes psychological and social as well as physical aspects helps in the planning of holistic, and ultimately effective, nursing care. Preexisting or newly acquired maternal illnesses that can make a pregnancy high risk are discussed in this chapter. [Chapter 21](#) discusses conditions directly related to pregnancy that can make a pregnancy high risk.

Chapter 22 covers populations that are at high risk because of age (younger than 18 years or older than 40 years), the presence of a disability or trauma, or drug abuse.

## Cardiovascular Disorders and Pregnancy

The number of women of childbearing age who have heart disease is diminishing as more and more congenital heart anomalies (discussed in Chapter 41) are corrected in early infancy. Also, rheumatic fever is being more actively prevented and treated so that cardiac damage from this disorder is also reduced. For these reasons, cardiovascular disease (even with hypertension included), which was once a major threat to pregnancy, now complicates only approximately 1% of all pregnancies. Cardiovascular disease is still a concern in pregnancy, however, because it can lead to such serious complications. It is responsible for 5% of maternal deaths during pregnancy (Cunningham, Leveno, Bloom, et al., 2014).

The cardiovascular disorders that most commonly cause difficulty during pregnancy are valve damage concerns caused by rheumatic fever or Kawasaki disease and congenital anomalies such as atrial septal defect or uncorrected coarctation of the aorta (Gordon, Jimenez-Fernandez, Daniels, et al., 2014). Aortic dilatation may occur from Marfan syndrome and is also a concern (Easterling & Stout, 2012). As the number of women delaying their first pregnancy until later in life increases, there is a corresponding increase in the incidence of coronary artery disease and varicosities during pregnancy. In contrast, heart disease that occurs specifically with pregnancy (peripartum heart disease) still only rarely occurs as it is apparently unrelated to age. With improved management of women with cardiac disorders, women who might never have risked pregnancy in the past are able to complete pregnancies successfully today.

A woman with cardiovascular disease needs an interprofessional team approach to care during pregnancy. Ideally, she should visit her pregnancy care provider for preconception care so her state of health and baseline data when she is not pregnant can be established. She should begin prenatal care as soon as she suspects she is pregnant (1 week after the first missed menstrual period or as soon as she has a positive home pregnancy test), so her general condition and circulatory system can be monitored from the beginning of pregnancy.

Pregnancy taxes the circulatory system of every woman, even those without cardiac disease, because both the blood volume and cardiac output increases approximately 30% (and up to as much as 50%) during pregnancy. Half of this increase occurs by 8 weeks; it is maximized by midpregnancy (Ayad, Hassanein, Mohamed, et al., 2016).

Because of the increased blood flow past valves, functional (innocent) or transient murmurs can be heard in many women without heart disease during pregnancy. Heart palpitations on sudden exertion are also usual.

The danger of pregnancy in a woman with cardiac disease occurs primarily because of this increase in circulatory volume. The most dangerous time for her is in weeks 28 to 32, just after the blood volume peaks. However, if heart disease is severe, symptoms

can occur at the very beginning of pregnancy. Toward the end of pregnancy, her heart may become so overwhelmed by the increase in blood volume that her cardiac output falls to the point vital organs (including the placenta) can no longer be perfused adequately. When this happens, the oxygen and nutritional requirements of her cells and those of the fetus are not met.

The estimation of whether a woman with cardiovascular disease can complete a pregnancy successfully depends on the type and extent of her disease. As a rule, a woman with an artificial but well-functioning heart valve, a woman with a pacemaker implant, and even a woman who has had a heart transplant can expect to have successful pregnancies as long as they have effective prenatal and postnatal care (Abdalla & Mancini, 2014).

To predict a pregnancy outcome, heart disease is divided into four categories based on criteria established by the New York Heart Association (Table 20.1). A woman with class I or II heart disease can expect to experience a normal pregnancy and birth. Women with class III can complete a pregnancy by maintaining special interventions such as bed rest. Women with class IV heart disease are usually advised to avoid pregnancy because they are in cardiac failure even at rest and when they are not pregnant.

**TABLE 20.1 CLASSIFICATION OF HEART DISEASE**

Class	Description
I	Uncompromised. Ordinary physical activity causes no discomfort. No symptoms of cardiac insufficiency and no anginal pain.
II	Slightly compromised. Ordinary physical activity causes excessive fatigue, palpitation, and dyspnea or anginal pain.
III	Markedly compromised. During less than ordinary activity, woman experiences excessive fatigue, palpitations, dyspnea, or anginal pain.
IV	Severely compromised. Woman is unable to carry out any physical activity without experiencing discomfort. Even at rest, symptoms of cardiac insufficiency or anginal pain are present.

From Criteria Committee of the New York Heart Association. (1994). *Nomenclature and criteria for diagnosis of diseases of the heart and great vessels* (9th ed.). Boston, MA: Little, Brown & Co.

## A WOMAN WITH CARDIAC DISEASE

Cardiac disease can affect pregnancy in different ways depending on whether it involves the left or the right side of the heart.

### A Woman With Left-Sided Heart Failure

Left-sided heart failure occurs in conditions such as mitral stenosis, mitral insufficiency, and aortic coarctation. In these instances, the left ventricle cannot move the large volume of blood forward that it has received by the left atrium from the pulmonary

circulation. This causes back pressure—the left side of the heart becomes distended, systemic blood pressure decreases in the face of lowered cardiac output, and pulmonary hypertension occurs. When pressure in the pulmonary vein reaches a point of about 25 mmHg, fluid begins to pass from the pulmonary capillary membranes into the interstitial spaces surrounding the lung alveoli and then into the alveoli themselves (pulmonary edema). Pulmonary edema produces profound shortness of breath as it interferes with oxygen–carbon dioxide exchange (Brashers & Huether, 2017). If pulmonary capillaries rupture under the pressure, small amounts of blood leak into the alveoli and the woman develops a productive cough with blood-speckled sputum. Because of the limited oxygen exchange, a woman with left-sided heart failure is at an extremely high risk for spontaneous miscarriage, preterm labor, or even maternal death. As pulmonary edema becomes severe, a woman cannot sleep in any position except with her chest and head elevated (**orthopnea**), as elevating her chest this way allows fluid to settle to the bottom of her lungs and frees space for gas exchange. She may also notice **paroxysmal nocturnal dyspnea**—suddenly waking at night with shortness of breath. This occurs because heart action is more effective when she is at rest. With the more effective heart action, interstitial fluid returns to the circulation. This overburdens her circulation, causing increased left-side failure and increased pulmonary edema.

If mitral stenosis is present, it is so difficult for blood to leave the left atrium that a secondary problem of thrombus formation can occur from noncirculating blood. If coarctation of the aorta is causing the difficulty, dissection of the aorta from high blood pressure from trying to push blood past the constriction can occur. To prevent thrombus formation, a woman may be prescribed an anticoagulant. If an anticoagulant is required, low–molecular-weight heparin is the drug of choice for early pregnancy because it does not cross the placenta and so does not have teratogenic effects. To decrease the strain on the aorta, antihypertensives may be prescribed to control blood pressure, diuretics to reduce blood volume, and  $\beta$ -blockers to improve ventricular filling. A woman will be scheduled for serial ultrasound and nonstress tests after weeks 30 to 32 of pregnancy to monitor fetal health and to rule out poor placental perfusion (Dennis, 2016).

### **A Woman With Right-Sided Heart Failure**

Right-sided heart failure occurs when the right ventricle is overwhelmed by the amount of blood received by the right atrium from the vena cava. It can be caused by an unrepaired congenital heart defect such as pulmonary valve stenosis, but the anomaly most apt to cause right-sided heart failure in women of reproductive age is Eisenmenger syndrome, a right-to-left atrial or ventricular septal defect with an accompanying pulmonary valve stenosis (Bhatt & DeFaria Yeh, 2015).

With this, congestion of the systemic venous circulation and decreased cardiac output to the lungs occurs. Blood pressure decreases in the aorta because less blood is able to reach it; in contrast, pressure is high in the vena cava from back pressure of blood. Both jugular venous distention and increased portal circulation are evident. The liver and spleen both become distended. Extreme liver enlargement can cause dyspnea

and pain in a pregnant woman because the enlarged liver, as it is pressed upward by the enlarged uterus, puts extreme pressure on the diaphragm. Distention of abdominal and lower extremity vessels can lead to exudate of fluid from the vessels into the peritoneal cavity (i.e., ascites) or peripheral edema.

Women who have an uncorrected anomaly of this type may be advised not to become pregnant. If they do plan a pregnancy, because they need oxygen administration and frequent arterial blood gas assessments to ensure fetal growth, they can expect to be hospitalized for at least some days during the last part of pregnancy. During labor, they may need a pulmonary artery catheter inserted to monitor pulmonary pressure. Women with this condition also need extremely close monitoring after epidural anesthesia to minimize the risk of hypotension.

## **A WOMAN WITH PERIPARTUM HEART DISEASE**

An extremely rare condition, **peripartal cardiomyopathy**, can originate in pregnancy in women with no previous history of heart disease (Desplantie, Tremblay-Gravel, Avram, et al., 2015). Although the cause is unknown, this apparently occurs because of the stress of the pregnancy on the circulatory system. The mortality rate can be as high as 50%. It occurs most often in Black multiparas in conjunction with gestational hypertension. A woman develops signs of myocardial failure such as shortness of breath, chest pain, and nondependent edema. Her heart increases in size (i.e., cardiomegaly). For therapy, she must sharply reduce her physical activity; many women also need a diuretic, an arrhythmia agent, and digitalis therapy to maintain heart function. Low-molecular-weight heparin may be administered to decrease the risk of thromboembolism. Immunosuppressive therapy is yet another possibility to improve symptoms.

If the cardiomegaly persists past the postpartum period, it is generally suggested a woman not to attempt any further pregnancies because the condition tends to recur or worsen in additional pregnancies. At the same time, oral contraceptives are contraindicated because of the danger of thromboembolism that these can create. Some women's disease progresses so much that following pregnancy, a woman may need a heart transplant (Dalzell, Cannon, Simpson, et al., 2015).

## **ASSESSMENT OF A WOMAN WITH CARDIAC DISEASE**

Nurses play a major role in the care of pregnant women with cardiovascular disease because continuous assessment of women's health status, health education, and health-promotion activities are so essential. Assessment begins with a thorough health history to document prepregnancy cardiac status (Box 20.2). Document a woman's level of exercise performance (i.e., what level she can do before growing short of breath and what physical symptoms she experiences, such as cyanosis of the lips or nail beds). Ask if she normally has a cough or edema (it's important that women with cardiac disease always report coughing during pregnancy because pulmonary edema from heart failure

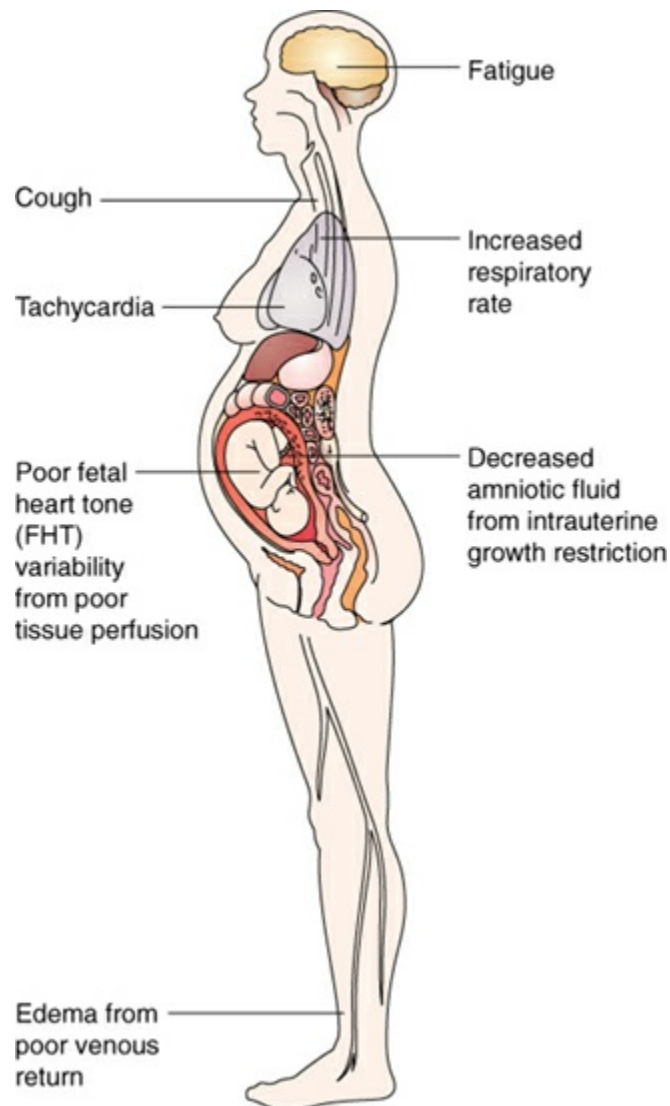

may first manifest itself as a simple cough).

## BOX 20.2

### Nursing Care Planning Using Assessment

#### ASSESSING A PREGNANT WOMAN WITH CARDIAC DISEASE

Documenting edema is also important because the usual innocent edema of pregnancy must be distinguished from the beginning of edema from heart failure (serious). An important difference is the usual edema of pregnancy involves only the feet and ankles but becomes systemic with heart failure. It can begin as early as the first trimester, and other symptoms such as irregular pulse, rapid or difficult respirations, and perhaps chest pain on exertion will probably also be present. Be certain to record a baseline blood pressure, pulse rate, and respiratory rate in either a sitting or lying position at the first prenatal visit; at future health visits, always obtain these in the same

position for the most accurate comparison. Making comparison assessments for nail bed filling (should be <5 seconds) and jugular venous distention can also be helpful throughout pregnancy.

If a woman's heart disease involves right-sided heart failure, assess liver size at prenatal visits. Keep in mind that liver assessments can become difficult and probably inaccurate late in pregnancy because the enlarged uterus presses the liver upward under the ribs and makes it difficult to palpate.

For an additional cardiac status assessment, an electrocardiogram (ECG) or an echocardiogram may be done at periodic points in pregnancy. Assure the woman that an ECG merely measures cardiac electrical discharge and so cannot harm her fetus in any way. Echocardiography uses ultrasound and, likewise, will not harm her fetus.

## FETAL ASSESSMENT

At the point that maternal blood pressure becomes insufficient to provide an adequate supply of blood and nutrients to the placenta, fetal health can be compromised. For this reason, the infants of women with severe heart disease tend to have low birth weights or be small for gestational age because of acidosis, which develops due to poor oxygen/carbon dioxide exchange or not being furnished with enough nutrients. This can result in preterm labor, which exposes the newborn to the hazards of immaturity as well as low birth weight. If the placenta is not filling well, a fetus may not respond well to labor (evidenced by late deceleration patterns on a fetal heart monitor), and a cesarean birth may be necessary (an increased risk for both the mother and fetus).

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Deficient knowledge regarding steps to take to reduce the effects of maternal cardiovascular disease on the pregnancy and fetus

**Outcome Evaluation:** Patient identifies danger signs such as angina pain and steps to take when they occur; maternal blood pressure is maintained above 100/60 mmHg and fetal heart rate at 110 to 160 beats/min.

Be certain that goals and outcomes established with a woman with heart disease are realistic. Not all women with heart disease, for example, will be able to complete a pregnancy successfully; some infants of women with severe involvement will be born with the effects of placental insufficiency, such as neurologic involvement or cognitive challenge. However, there are positive actions a woman with heart disease can take to reduce or eliminate complications during pregnancy, such as increasing periods of rest to strengthen heart action.

*Promote Rest.* As a rule, women with cardiac disease need two rest periods a day (fully resting, not getting up frequently) and a full night's sleep (not tossing and turning) to obtain adequate rest. Rest should be in the left lateral recumbent position to prevent supine hypotension syndrome and increased heart effort.

Women should plan activities so they stop exercising before the point when cardiac output becomes insufficient to meet systemic body demands causing peripheral and uterine/placental constriction. Be certain they know exactly how much they should limit their exercise. Some women, for example, may need to discontinue employment early in pregnancy rather than work until the end. A prescription to allow "normally heavy" housework may mean nothing more strenuous than dusting to some women. To others, it may mean washing windows, turning mattresses, and shoveling snow. Ask enough questions, therefore, to make certain a woman's definition of "heavy work" is the same as yours and her primary care provider's.

*Promote Healthy Nutrition.* A woman with cardiac disease may need closer supervision of nutrition during pregnancy than the average woman because she must gain enough weight to ensure a healthy pregnancy and a healthy baby, but she must not gain so much weight that her heart and circulatory system become overburdened.

Be certain she is remembering to take her prenatal vitamins. These contain an iron supplement to help prevent anemia. Anemia is important to prevent because it places an extra burden on the heart because her circulatory system must circulate blood more vigorously than usual to distribute oxygen to all body cells. If a woman was following a sodium-restricted diet before pregnancy, this may be continued during pregnancy; although typically, a woman's sodium intake is only limited, not severely restricted, during pregnancy because it's important to obtain enough sodium to maintain fluid volume and balance as well as furnish an adequate supply of blood to the fetus.

*Educate Regarding Medication.* Women taking cardiac medication, such as digoxin, before pregnancy may need to increase their maintenance dose because of their expanded blood volume during pregnancy. A woman who was not digoxin dependent before pregnancy may need such therapy prescribed as pregnancy advances and her cardiac output has to be increased or strengthened. To aid a woman in continuing to think of herself as basically a well person, help her to understand this does not mean her heart function is weakening, but rather, it is only temporarily being stressed by the increased circulatory load of pregnancy. Digoxin also has a unique use during pregnancy as it can be administered to the woman to slow the fetal heart if fetal tachycardia is present. Antihypertensive and arrhythmia agents such as adenosine,  $\beta$ -blockers, and calcium channel blockers to reduce hypertension are safe to use during pregnancy and are also frequently prescribed. Nitroglycerin, a compound often prescribed for angina, although not well studied during pregnancy (a category C drug), is also considered safe (Karch, 2015).

A woman who was taking penicillin prophylactically because she had rheumatic

fever as a child (which is often taken for 10 years after the occurrence of rheumatic fever, or at least until age 18 years) should continue to take this drug during pregnancy because penicillin is not known to be a teratogen (a category B drug). Close to the anticipated day of birth, some primary care providers prescribe an additional course of ampicillin, amoxicillin (Amoxil), or clindamycin (Cleocin) to prevent streptococci bacteria from invading the denuded placental site on the uterus and creating a subacute bacterial endocarditis.

It is often difficult to keep healthy women from taking over-the-counter medicines during pregnancy; conversely, it can be just as difficult to encourage women to take medicine prescribed during pregnancy. Help women with heart disease to understand there are valid exceptions to the rule of “no medicine during pregnancy” so they make out reminders to adhere to their prescribed regimen.

### *What If . . . 20.1*

**Angelina is diagnosed as having class II heart disease. Because of her work as a fundraiser, she is on her feet all day. What suggestions could the nurse make to help her incorporate more rest into each day?**

*Educate Regarding Avoidance of Infection.* A systemic infection almost automatically increases body temperature, forcing a woman to expend more energy and increase her cardiac output as her metabolism increases, an effect that could be too extreme for a woman with heart disease to withstand. Caution women with heart disease, therefore, to avoid visiting or being visited by people with infections and to alert healthcare personnel at the first indication of an upper respiratory tract infection or urinary tract infection (UTI) so that, if warranted, antibiotic therapy can begin early in the course of the infection. Monthly screening for bacteriuria with a clean-catch urine test at prenatal visits should help detect UTIs.

*Be Prepared for Emergency Actions.* If women with heart disease overexert during a prenatal visit, they may need supplemental oxygen or cardiac resuscitation. The rules for cardiac resuscitation for women who are pregnant do not differ from the usual technique (**Box 20.3**).

### BOX 20.3

#### Nursing Care Planning Using Procedures

### CARDIOPULMONARY RESUSCITATION DURING PREGNANCY

**Purpose:** To restore cardiac and respiratory function

Plan

Principle

- |  |  |
|--|--|
| <ol style="list-style-type: none"> <li>1. Determine the woman is unconscious and not breathing by shaking and shouting her name.</li> <li>2. Call for emergency help and have them bring a cardiac defibrillator.</li> <li>3. Begin chest compressions. Place both hands on the lower sternum just above the xiphoid process and compress the chest a distance of 2 in. at a rate of 100 times a minute.</li> <li>4. A second rescuer can deliver respiratory ventilations at a rate of 1 breath every 6 to 8 seconds (8 to 10 breaths/min).</li> <li>5. If an automated external defibrillator (AED) is necessary, remove any fetal or uterine monitors if these are in place. Follow standard application and procedure according to agency protocol.</li> <li>6. When the emergency rescue team has arrived and relieved you as a first responder, place a rolled or folded towel under the woman's right hip.</li> </ol> | <ol style="list-style-type: none"> <li>1. Shaking the shoulders and shouting are effective actions to determine unconsciousness and rouse a woman who may have fainted or is asleep.</li> <li>2. The woman may need more than simple resuscitation.</li> <li>3. External chest compressions stimulate the action of the heart to maintain tissue perfusion. Allow chest recoil after each compression.</li> <li>4. Ventilation improves oxygenation.</li> <li>5. AED is effective at stimulating heart action and is not detrimental to pregnancy or a fetus.</li> <li>6. A towel placed under one hip helps to prevent uterine compression on the vena cava and helps prevent supine hypotension syndrome.</li> </ol> |
|--|--|

### *What If . . . 20.2*

**Angelina tells the nurse she has abruptly discontinued taking the daily penicillin she has been prescribed for her heart disease since childhood. As it has been a long time since she had rheumatic fever, would the nurse recommend she could omit taking this during pregnancy?**

## **Nursing Interventions During Labor and Birth**

Frequently assess a woman's blood pressure, pulse, and respirations and monitor fetal heart rate and uterine contractions during labor for women with heart disease to be certain their circulatory system is not failing and the placenta is filling adequately. A rapidly increasing pulse rate (.100 beats/min) is an indication a heart is pumping ineffectively and so has increased its rate in an effort to compensate. Normally, it's good to advise a woman to assume a side-lying position during labor to reduce the

possibility of supine hypotension syndrome. If a woman has some pulmonary edema, however, it may be necessary for her to elevate her head and chest (a semi-Fowler's position) to ease the work of breathing. If this is necessary, be certain to place a towel under her right hip to shift the uterus off the vena cava, the same as would happen with a side-lying position. Remember, fatigue is a symptom of heart decompensation. Evaluate women carefully, therefore, to determine whether the fatigue a woman reports is heart or labor related.

Women with extreme heart disease may need oxygen administered during labor because of the need for extra oxygen due to the exertion of labor; continuous hemodynamic monitoring such as by a Swan-Ganz catheter to monitor heart function may be prescribed. Many women with heart disease should not push with contractions, as pushing requires more effort than they should expend. That makes epidural anesthesia the anesthetic of choice for women with heart disease because this decreases the sensation of pushing and can make both labor and birth less taxing. Because of the lack of pushing, low forceps or a vacuum extractor may be used for birth. A woman may be disappointed during labor to learn her labor is not going to be "natural." Stress that these measures may not be what she anticipated, but they can help her achieve her ultimate goal, a healthy newborn and a mother able to care for her new baby.

### **Postpartum Nursing Interventions**

The period immediately after birth is a critical time for a woman with heart disease because, with delivery of the placenta, the blood that supplied the placenta is released into her general circulation, increasing her blood volume by 20% to 40%. During pregnancy, the increase in blood volume that occurred did so over a 6-month period, so her heart had time to gradually adjust to this change. After birth, the increase in pressure takes place within 5 minutes, so the heart must make a rapid and major adjustment (Easterling & Stout, 2012).

To compensate for these circulatory changes, a woman may need a program of decreased activity and possibly anticoagulant and digoxin therapy until her circulation stabilizes. Antiembolic stockings or intermittent pneumatic compression (IPC) boots may be prescribed to increase venous return from the legs. If prophylactic antibiotics had not been started prior to birth, they should be started immediately after birth to discourage subacute bacterial endocarditis caused by the introduction of microorganisms through the placental site.

A woman with heart disease is often interested in close inspection of her baby immediately after birth because she wants to know if her infant has a heart defect or was harmed by any medication she took during pregnancy. Be certain to point out that acrocyanosis is normal in newborns, so she does not interpret her baby's peripheral cyanosis as cardiac inadequacy.

In the postpartum period, a stool softener can be prescribed to prevent straining with bowel movements. Agents to encourage uterine involution, such as oxytocin (Pitocin), should be used with caution because they tend to increase blood pressure, which

necessitates increased heart action. As a rule, women with heart disease can breastfeed without difficulty. Kegel exercises are acceptable for perineal strengthening immediately, but the woman should not begin postpartum exercises to improve abdominal tone until her primary care provider approves them. Before discharge, be certain a woman has thought through if she will need help at home, so she can continue getting periods of rest. Also ensure that she schedules a return appointment for a postpartum checkup for both her gynecologic health and her cardiac status.

## **A WOMAN WITH AN ARTIFICIAL VALVE PROSTHESIS**

In the past, women with heart valve prostheses were advised not to become pregnant for fear the increased blood volume gained during pregnancy would overwhelm the artificial valve. Today, evidence shows women with a valve prosthesis can complete a pregnancy safely (Yarrington, Valente, & Economy, 2015). One potential problem involves the use of oral anticoagulants women take to prevent the formation of blood clots at the valve site. Because the usual maintenance drug for this, sodium warfarin (Coumadin), increases the risk of congenital anomalies in infants (pregnancy risk category D), women are usually placed on low–molecular-weight heparin therapy (category C) before becoming pregnant and during pregnancy. Subclinical bleeding from continuous anticoagulant therapy has the potential to cause placental dislodgement. Therefore, observe a woman who is taking an anticoagulant for signs of petechiae and premature separation of the placenta during both pregnancy and labor.

## **A WOMAN WITH CHRONIC HYPERTENSIVE VASCULAR DISEASE**

Women with chronic hypertensive disease enter pregnancy with an elevated blood pressure (140/90 mmHg or above). Hypertension of this kind is usually associated with arteriosclerosis or renal disease, making it a problem for the older pregnant woman. Chronic hypertension can be serious because it places both the woman and fetus at high risk because of poor heart, kidney, and/or placental perfusion during the pregnancy (Almasi, Pariente, Kessous, et al., 2016). Management includes a prescription of  $\beta$ -blockers and calcium channel blockers to reduce blood pressure by peripheral dilation to a safe level but not to reduce it below the threshold that allows for good placenta circulation. Labetalol (Trandate) and nifedipine (Procardia) are typical drugs that may be prescribed.

## **A WOMAN WITH VENOUS THROMBOEMBOLIC DISEASE**

The incidence of venous thromboembolic disease increases during pregnancy because of a combination of stasis of blood in the lower extremities from uterine pressure and hypercoagulability (the effect of elevated estrogen; Box 20.4). When the pressure of the fetal head at birth puts additional pressure on lower extremity veins, damage can occur to the walls of the veins. With this triad of effects in place (stasis, vessel damage, and

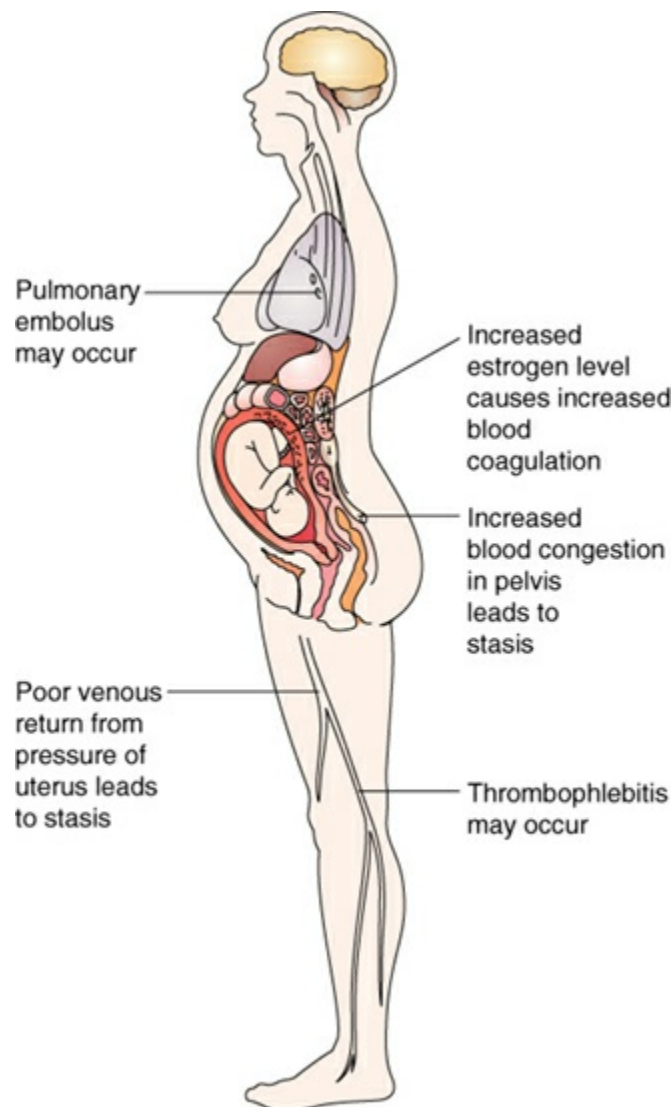

hypercoagulation), the stage is set for thrombus formation in the lower extremities. The likelihood of **deep vein thrombosis (DVT)**, formation of a blood clot in the veins of the lower extremities, leading to pulmonary emboli is highest in women 30 years of age or older because increased age is yet another risk factor for thrombosis formation (Goodacre & Hunt, 2016).

#### BOX 20.4

### Nursing Care Planning Using Assessment

#### ASSESSING A PREGNANT WOMAN WITH VENOUS THROMBOEMBOLIC DISEASE

The risk of thrombus formation can be reduced through common-sense measures such as avoiding the use of constrictive knee-high stockings, not sitting with legs crossed at the knee, and avoiding standing in one position for a long period. If a

thrombus does occur during pregnancy, a woman may notice pain and redness usually in the calf of a leg. It is diagnosed by a woman's history and Doppler ultrasonography. In order to keep the thrombus from moving and becoming a pulmonary embolus, a woman will be treated with bed rest and intravenous heparin for 24 to 48 hours. After this, she may be prescribed subcutaneous heparin she can self-inject every 12 or 24 hours for the duration of the pregnancy. It is generally recommended the lower abdomen be used for rotating sites for subcutaneous heparin administration. With pregnancy, however, this site is usually avoided and the injection sites are limited to the arms and thighs. Heparin dosage is regulated by the anti-Xa test, the most accurate assay for monitoring unfractionated heparin and low-molecular-weight heparin (Bates, Middeldorp, Rodger, et al., 2016).

The signs of a pulmonary embolism, such as chest pain, a sudden onset of dyspnea, a cough with hemoptysis, tachycardia or missed beats, or dizziness and fainting need to be recognized because it is an immediate emergency and measures should be immediately begun (discussed in Chapter 25).

Caution women taking heparin during pregnancy not to take any additional injections once labor begins to help reduce the possibility of hemorrhage at birth. Women taking heparin are not candidates for routine episiotomy or epidural anesthesia for this same reason unless at least 4 hours has passed since the last heparin dose was given. Either heparin or sodium warfarin (Coumadin) can be prescribed after birth if a woman is not breastfeeding; however, Coumadin should be used cautiously while breastfeeding. The majority of thromboses that occur with pregnancy occur in the postpartum period; additional measures of care for a woman with DVT, such as heat, elevation, and bed rest are discussed in Chapter 25.

A particular group of women has been identified as being more susceptible to thrombi formation, spontaneous miscarriage, fetal death, and hypertension of pregnancy than others. They include women with antiphospholipid antibodies (aPLAs) (Leaf & Connors, 2017). It is not known why aPLAs occur in some women, but these antibodies probably represent an autoimmune process. Women who are identified as aPLA positive may be started on a prophylactic program of aspirin or subcutaneous heparin during pregnancy that is continued postpartum to reduce the possibility of DVT. Administration of a corticosteroid may help to reduce the formation of additional antibodies and so may also be prescribed. After pregnancy, such women should not begin an oral contraceptive because it can increase blood coagulation and the possibility of thrombi formation.

### *QSEN Checkpoint Question 20.1*

#### **PATIENT-CENTERED CARE**

Angelina develops a DVT while in the hospital on bed rest and is prescribed low-molecular-weight heparin. The nurse identifies which action as important when planning care for her?

- a. Showing her how to self-administer the drug as a rectal suppository
- b. Cautioning her that her hemoglobin level will be closely monitored during therapy
- c. Allowing her to choose a subcutaneous site for the injection
- d. Monitoring her white blood cell count daily for decreased coagulation

*Look in [Appendix A](#) for the best answer and rationale.*

## Hematologic Disorders and Pregnancy

Hematologic disorders during pregnancy involve either blood formation or coagulation disorders.

### ANEMIA AND PREGNANCY

Because the blood volume expands during pregnancy slightly ahead of the red cell count, most women have a pseudoanemia in early pregnancy. This condition is normal and should not be confused with true types of anemia that occur as complications of pregnancy. True anemia is typically considered to be present when a woman's hemoglobin concentration is less than 11 g/dl (hematocrit <33%) in the first or third trimester of pregnancy or when the hemoglobin concentration is less than 10.5 g/dl (hematocrit <32%) in the second trimester ([Samuels, 2012](#)).

#### A Woman With Iron-Deficiency Anemia

Iron-deficiency anemia is the most common anemia of pregnancy, complicating as many as 15% to 25% of all pregnancies ([Chmielewska, Dziechciarz, Gieruszczak-Białek, et al., 2016](#)). Many women enter pregnancy with a deficiency of iron stores resulting from a combination of a diet low in iron, heavy menstrual periods, or unwise weight-reducing programs. Iron stores are also apt to be low in women who were pregnant less than 2 years before the current pregnancy or those from low socioeconomic levels who have not had iron-rich diets. Iron-deficiency anemia is confirmed by a corresponding low serum iron level (under 30  $\mu\text{g/dl}$ ) and an increased iron-binding capacity (over 400  $\mu\text{g/dl}$ ).

Iron is made available to the body by absorption from the duodenum into the bloodstream after it has been ingested. In the bloodstream, it is bound to transferrin for transport to the liver, spleen, and bone marrow. At these sites, it is incorporated into hemoglobin or stored as ferritin.

The type of anemia is characteristically a microcytic (i.e., small red blood cell) and hypochromic (i.e., less hemoglobin than the average red cell) anemia, which occurs when such an inadequate supply of iron is ingested that iron is not available for incorporation into red blood cells. A woman experiences extreme fatigue and poor exercise tolerance because she cannot transport oxygen effectively. The condition is mildly associated with low birth weight and preterm birth. Because the body recognizes

that it needs increased nutrients, some women with this condition develop pica, or the craving and eating of substances such as ice or starch (Rabel, Leitman, & Miller, 2016). It is also associated with restless leg syndrome (Singh, Chaudhary, Sonker, et al., 2016).

To prevent this common anemia, women should take prenatal vitamins containing 27 mg of iron as prophylactic therapy during pregnancy. In addition, they need to eat a diet high in iron and vitamins (e.g., green leafy vegetables, meat, and legumes) so the supplement is truly a supplement. Women who develop iron-deficiency anemia will be prescribed therapeutic levels of medication (120 to 200 mg elemental iron per day), usually in the form of ferrous sulfate or ferrous gluconate.

Iron is absorbed best in an acid medium. Advise women, therefore, to take iron supplements with orange juice or a vitamin C supplement, which supplies ascorbic acid. If they are not already enrolled in the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) but are eligible ([www.fns.usda.gov/wic](http://www.fns.usda.gov/wic)), making a referral could help ensure a better diet. When women begin to take a prescribed iron supplement, new red blood cells should begin to increase almost immediately, or their reticulocyte count should rise from a range of between 0.5% and 1.5% to 3% and 4% by 2 weeks. Some women report constipation or gastric irritation when taking oral iron supplements. Increasing roughage in the diet and always taking the pills with food can help reduce these symptoms. Ferrous sulfate turns stools black, so caution women about this to prevent them from worrying that they are bleeding internally. If iron-deficiency anemia is severe and a woman has difficulty with oral iron therapy, intravenous iron can be prescribed.

### **A Woman With Folic Acid–Deficiency Anemia**

Folic acid, or folate or folacin, one of the B vitamins, is necessary for the normal formation of red blood cells in the woman as well as being associated with preventing neural tube and abdominal wall defects in the fetus. Folic acid–deficiency anemia occurs most often in multiple pregnancies because of the increased fetal demand; in women with a secondary hemolytic illness in which there is rapid destruction and production of new red blood cells; in women who are taking hydantoin, an anticonvulsant agent that interferes with folate absorption; and in women who have poor gastric absorption, such as in those who have had a gastric bypass for morbid obesity (Pentieva, Selhub, Paul, et al., 2016).

The anemia that develops is a **megaloblastic anemia** (enlarged red blood cells). Because of the size of the cells, the mean corpuscular volume will be elevated in contrast to the lowered level seen with iron-deficiency anemia. Slow to progress, the deficiency may take several weeks to develop or may not be apparent until the second trimester of pregnancy. Full blown, it may be a contributory factor in early miscarriage or premature separation of the placenta.

All women expecting to become pregnant are advised to begin a supplement of 400 µg folic acid daily in addition to eating folate-rich foods (e.g., green leafy vegetables, oranges, dried beans). Over-the-counter women's multivitamin preparations generally

do contain adequate folic acid for pregnancy so be certain women are specifically taking a prenatal or women's multivitamin. Women who develop folic acid–deficiency anemia are prescribed even higher or therapeutic levels of folic acid (Clark, Thomson, & Greer, 2012).

## A WOMAN WITH SICKLE-CELL ANEMIA

Sickle-cell anemia is a recessively inherited hemolytic anemia caused by an abnormal amino acid in the beta chain of hemoglobin. If the abnormal amino acid replaces the amino acid valine, sickling hemoglobin (HbS) results; if it is substituted for the amino acid lysine, nonsickling hemoglobin (HbC) results. An individual who is heterozygous (i.e., has only one gene in which the abnormal substitution has occurred) has the sickle-cell trait (HbAS). If the person is homozygous (i.e., has two genes in which the substitution has occurred), sickle-cell disease (HbSS) results (Rote & McCance, 2017).

With the disease, the majority of red blood cells are irregular or sickle shaped, so they cannot carry as much hemoglobin as normally shaped red blood cells can. When oxygen tension becomes reduced, as occurs at high altitudes, or blood becomes more viscous than usual, such as occurs with dehydration, the cells clump together because of their irregular shape, resulting in vessel blockage with reduced blood flow to organs. The cells then will hemolyze (i.e., be destroyed), thus reducing the number available and causing a severe anemia.

Approximately 1 in every 10 Blacks has the sickle-cell trait or carries a recessive gene for S hemoglobin but is asymptomatic; theoretically, 1 in every 400 Blacks has the disease, although with interracial marriages increasing, the disease is no longer confined to one ethnic group (Boga & Ozdogu, 2016).

Although the sickle-cell trait does not appear to directly influence the course of pregnancy, preterm birth, growth restriction, miscarriage, or perinatal mortality, rates tend to be higher for women with the homozygous disease. At any time in life, sickle-cell anemia is a threat to life if vital blood vessels such as those to the liver, kidneys, heart, lungs, or brain become blocked. In pregnancy, blockage to the placental circulation can directly compromise the fetus, causing low birth weight and possibly fetal death.

### Assessment

All Black women who have not been previously tested should be screened for sickle-cell anemia at a first prenatal visit. Hemoglobin levels for all women with sickle-cell disease should then be obtained throughout pregnancy. A woman with sickle-cell disease may normally have a hemoglobin level of 6 to 8 mg/100 ml. Unless she receives active interventions to raise this level, she will maintain it during pregnancy, potentially reducing oxygen to the fetus. If a hemolytic sickle-cell crisis occurs, a woman's hemoglobin level can fall to 5 or 6 mg/100 ml in a few hours, causing an accompanying rise in indirect bilirubin because the woman cannot conjugate the bilirubin released

from so many destroyed red blood cells.

Because a pregnant woman with sickle-cell anemia has vascular stasis, they are more susceptible to bacteriuria than other women; periodically collect a clean-catch urine sample during pregnancy to detect developing bacteriuria while a woman is still asymptomatic.

Throughout pregnancy, monitor a woman's nutritional intake to be certain she is consuming sufficient amounts of folic acid and possibly an additional folic acid supplement, which is necessary for replacing red blood cells that have been destroyed. Women should *not* take a routine iron supplement as sickled cells cannot incorporate iron in the same manner as non-sickled cells. Ensure the woman is drinking at least eight glasses of fluid daily to be certain she is guarding against dehydration. Early in pregnancy, when she may be nauseated, it is easy for her fluid intake to decrease, causing dehydration and a subsequent sickle-cell crisis.

Assess a woman's lower extremities at prenatal visits for varicosities or pooling of blood in leg veins, which can lead to red cell destruction. Standing for long periods during the day increases this pressure, whereas sitting on a chair with the legs elevated or lying on the side in a modified Sims position encourages venous return from the lower extremities. Help a woman plan her day so she has limited long periods of standing and adequate rest periods.

Fetal health is usually monitored during pregnancy by an ultrasound examination at 16 to 24 weeks to assess for intrauterine growth restriction and by weekly nonstress or ultrasound examinations beginning at about 30 weeks. Blood flow through the uterus and placenta may be measured by blood flow velocity. If blood flow velocity is reduced, the chance of intrauterine growth restriction increases.

## Therapeutic Management

Interventions to prevent a sickle-cell crisis can include periodic exchange or blood transfusions throughout pregnancy to replace sickled cells with non-sickled cells. An exchange transfusion serves a secondary purpose of removing a quantity of the increased bilirubin resulting from the breakdown of red blood cells as well as restoring the hemoglobin level (Benites, Benevides, Valente, et al., 2016). If a crisis occurs, controlling pain, administering oxygen as needed, and increasing the fluid volume of the circulatory system to lower viscosity are important interventions (see Chapter 44 for a further discussion of therapy for sickle-cell anemia).

If a woman develops an infection that raises her temperature and causes her to perspire more than usual (which creates dehydration) or contracts a respiratory infection that compromises air exchange so that her PO<sub>2</sub> is lowered, hospitalization for observation may be necessary to rule out the development of a sickle-cell crisis and subsequent hemolysis of crowded cells (Oteng-Ntim, Meeks, Seed, et al., 2015).

When the fetus is mature, the time and method of birth are individualized. Be certain to keep a woman in labor well hydrated and help her resist strenuous exertion. If an operative birth is necessary, epidural anesthesia is the method of choice because general

anesthesia poses a possible risk of hypoxia. In the postpartal period, early ambulation and wearing pressure stockings or IPC boots can help reduce the risk of thromboembolism from stasis in lower extremities.

Women are generally interested in determining at birth whether their child has inherited the disease. Because the disorder is recessively inherited, if one of the parents has the disease and the other is free of the disease and trait, the chance the child will inherit the disease is zero. If a woman has the disease and her partner has the trait, the chance the child will be born with the disease is 50%. If both parents have the disease, all their children will also have the disease (see [Chapter 8](#)).

Electrophoresis of red blood cells obtained from maternal serum or by amniocentesis during pregnancy can reveal the presence of the disease on the few  $\beta$ -hemoglobin chains already present in fetal life. If not assessed during pregnancy, although the symptoms of sickle-cell disease do not become clinically apparent until 3 to 6 months of age, a routine newborn serum screening at birth will also reveal the disease.

### ***QSEN Checkpoint Question 20.2***

#### **SAFETY**

Angelina is friends with a woman in the clinic who has sickle-cell anemia, and they often talk together about their care. Which statement would alert the nurse that her friend may need further instruction on prenatal care?

- a. “I understand why folic acid is important for red cell formation.”
- b. “I’m careful to drink at least eight glasses of fluid every day.”
- c. “I take an iron pill every day to help grow new red blood cells.”
- d. “I’ve temporarily stopped jogging so I don’t risk becoming dehydrated.”

*Look in [Appendix A](#) for the best answer and rationale.*

### **The Woman With Thalassemia**

The thalassemias are a group of autosomal recessively inherited blood disorders that lead to poor hemoglobin formation and severe anemia. They occur most frequently in Mediterranean, African, and Asian populations ([Charoenboon, Jatavan, Traisrisilp, et al., 2016](#)). Symptoms first appear in childhood. Treatment focuses on combating anemia through such measures as folic acid supplementation and perhaps blood transfusion to infuse hemoglobin-rich red blood cells. Women with thalassemia do not usually take an iron supplement during pregnancy because they could receive an iron overload because iron is infused with blood transfusions. Care of a child with both forms of thalassemia, alpha and beta, is discussed in [Chapter 44](#).

### **The Woman With Malaria**

Malaria is a protozoan infection that is transmitted to people by *Anopheles* mosquitoes

(Andrews, Lynch, Eckert, et al., 2015). The infection causes red blood cells to stick to the surface of capillaries causing obstruction of these vessels and resulting in end-organ anoxia and blood not reaching organs effectively.

Although the disorder does not have a high incidence in the United States, newly immigrated women may be infected with it. It's important to consider during pregnancy as it can not only make women high risk for blood clotting during pregnancy but also, if untreated, can be transmitted to a fetus by mother-to-fetus transmission.

The incubation period for the most frequently occurring type is 12 to 14 days. The most noticeable symptoms are elevated liver function tests accompanying fever, malaise, and headache. Because of the altered blood cells, thrombocytopenia (i.e., low platelet count), anemia, and renal failure can develop.

Malaria can be prevented by wearing clothing that covers most of the body as well as using an insect repellent when in an area infested with mosquitoes, sleeping at night with a mosquito net, or keeping windows closed to prevent mosquitoes from entering. As further prevention, urge women to delay travel to endemic areas until after pregnancy if possible.

Treatment is with a combination of antimalarial drugs, which will both stop the course of the disease and help reduce the incidence of low birth weight and preterm birth. Sulfadoxine/pyrimethamine is safe to administer during the last trimester of pregnancy. Chloroquine is safe to administer all during pregnancy and so is the drug of choice (Adeola & Okwilagwe, 2015). Quinine, atovaquone and proguanil (Malarone), or tetracyclines, although effective against the disease, should not be used at any point in pregnancy or with women who are breastfeeding as they are teratogenic.

## COAGULATION DISORDERS AND PREGNANCY

Most coagulation disorders are sex linked or occur only in males and so have little effect on pregnancies. However, one of them, von Willebrand disease, is a coagulation disorder inherited as an autosomal dominant trait and so does occur in women (Neff & Sidonio, 2014). Women will have normal platelet counts, but bleeding time is prolonged. Levels of factor VIII-related antigen (VIII-R) and factor VIII coagulation activity (VIII-C) are both reduced. From the time she was a child, a woman with the disorder might have noticed menorrhagia or frequent episodes of epistaxis. If these symptoms were not severe, however, the condition can go undiagnosed until pregnancy when a woman experiences a spontaneous miscarriage or postpartum hemorrhage. Replacement of the missing coagulation factors by infusion of cryoprecipitate or fresh frozen plasma may be necessary before labor to prevent excessive bleeding with birth.

Hemophilia B (Christmas disease, factor IX deficiency) is a sex-linked disorder, so the actual disease occurs only in males. However, female carriers may have such a reduced level of factor IX (only 33% of normal) that hemorrhage with labor or a spontaneous miscarriage can be a serious complication. As with von Willebrand disease, carriers of the disorder need to be identified before pregnancy. Restoration of factor IX levels can be quickly restored by infusion of factor IX concentrate or fresh

frozen plasma.

Maternal serum analysis can be used to detect whether a fetus has a coagulation disorder during pregnancy. If there is a family history of a coagulation disorder, before an internal fetal heart rate monitor is attached or fetal scalp blood sampling is done, it should be determined if the fetus has a coagulation defect. If one is present, these procedures are contraindicated because they could result in extensive fetal blood loss.

Idiopathic thrombocytopenic purpura (ITP), which is a decreased number of platelets, is not inherited, can occur at any time in life, and so occasionally occurs during pregnancy. The cause of the condition is unknown, but because symptoms usually occur shortly after a viral invasion such as an upper respiratory tract infection, it is assumed to be an autoimmune reaction (an antiplatelet antibody that destroys platelets is apparently released) (Hisano, Tsukada, Sago, et al., 2015).

Laboratory studies reveal a marked thrombocytopenia (platelet count may be as low as 20,000/mm<sup>3</sup> from a usual count of 150,000/mm<sup>3</sup>). Without an adequate level of platelets, the woman is prone to frequent nosebleeds and minute petechiae or large ecchymoses appear on her body.

The illness typically runs a 1- to 3-month limited course, but because a low platelet count also appears with hypertension of pregnancy with HELLP (**h**emolysis, **e**levated **l**iver enzymes, **l**ow **p**latelet count) syndrome, a serious complication of pregnancy (see [Chapter 21](#)), the condition is frightening until it is differentiated as ITP. Oral prednisone or a platelet transfusion or plasmapheresis may be administered to temporarily increase the platelet count to prevent increased bleeding at birth. The antiplatelet factor can cross the placenta and cause accompanying platelet destruction in the newborn or allow a newborn to be born with the illness, so a careful assessment of the baby is necessary at birth (see [Chapter 44](#) for care of the child with ITP).

## Renal and Urinary Disorders and Pregnancy

Adequate kidney function is important for a successful pregnancy outcome because a woman is excreting waste products not only for herself but also for the fetus. This dual function makes any condition that interferes with kidney or urinary function always potentially serious.

### A WOMAN WITH A URINARY TRACT INFECTION

As many as 4% to 10% of nonpregnant women have asymptomatic bacteriuria (i.e., organisms are present in the urine without symptoms of infection). In a pregnant woman, because the ureters dilate from the effect of progesterone, stasis of urine can occur. The minimal presence of abnormal amounts of glucose (**glycosuria**) that also occurs with pregnancy provides an ideal medium for growth for any organisms present. Combined, these factors cause asymptomatic UTIs in as many as 10% to 15% of pregnant women (Widmer, Lopez, Gülmezoglu, et al., 2015). Asymptomatic infections are potentially dangerous because they can progress to pyelonephritis (i.e., infection of

the pelvis of the kidney) and are associated with preterm labor and premature rupture of membranes. Women with known vesicoureteral reflux (i.e., backflow of urine into the ureters) tend to develop UTIs or pyelonephritis more often than others. The organism most commonly responsible for UTI is *Escherichia coli* from an ascending infection. A UTI can also occur as a descending infection or can begin in the kidneys from the filtration of organisms present from other body infections. If the infectious organism is determined to be *Streptococcus B*, vaginal cultures should be obtained because streptococcal B infection of the genital tract is associated with pneumonia in newborns.

### Assessment

A UTI typically manifests as frequency and pain on urination. With pyelonephritis, a woman develops pain in the lumbar region (usually on the right side) that radiates downward. The area feels tender to palpation. She may have accompanying nausea and vomiting, malaise, pain, and frequency of urination. Her temperature may be elevated only slightly or may be as high as 103° to 104°F (39° to 40°C). The infection usually occurs on the right side because there is greater compression and urinary stasis on the right ureter from the uterus being pushed that way by the large bulk of the intestine on the left side. A urine culture will reveal over 100,000 organisms per milliliter of urine, a level diagnostic of infection.

### Therapeutic Management

Obtain a clean-catch urine sample for culture and sensitivity to assess for asymptomatic bacteriuria or symptoms of UTI (see [Chapter 11](#)). A sensitivity test will then determine which antibiotic will best combat the infection. Amoxicillin, ampicillin, and cephalosporins are effective against most organisms causing UTIs and are safe antibiotics during pregnancy. The sulfonamides can be used early in pregnancy but not near term because they can interfere with protein binding of bilirubin, which then leads to hyperbilirubinemia in the newborn. Tetracyclines are contraindicated during pregnancy as they cause retardation of bone growth and staining of the deciduous teeth ([Karch, 2015](#)).

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for infection related to stasis of urine with pregnancy

**Outcome Evaluation:** Oral temperature is below 100.4°F (38°C), and a clean-catch urine specimen has a bacteria count below 100,000 colonies per milliliter.

As part of prenatal education, remind all women during pregnancy of common measures to prevent UTIs, such as:

- Voiding frequently (at least every 2 hours)
- Developing a habit of urinating as soon as the need is felt and emptying the bladder completely when urinating
- Wiping front to back after voiding and bowel movements
- Wearing cotton, not synthetic fiber, underwear
- Voiding immediately after sexual intercourse
- Drinking a glass of cranberry juice daily

The pregnant woman with a UTI needs to take the additional measure of drinking an increased amount of fluid to flush out the infection from the urinary tract. To be most effective, do not simply tell her to “push fluids” or “drink lots of water.” Give her a specific amount to drink every day (up to 3 to 4 L per 24 hours) to make certain she increases her fluid intake sufficiently.

A woman can promote urine drainage by assuming a knee–chest position for 15 minutes morning and evening. In this position, the weight of the uterus is shifted forward, releasing the pressure on the ureters and allowing urine to drain more freely.

If a woman has one UTI during pregnancy, the chances are high she will develop another late in pregnancy, when urinary stasis tends to grow even greater. She may, therefore, be kept on prophylactic antibiotics throughout the remainder of the pregnancy. Ask at prenatal visits whether she is continuing to take this type of prophylactic medicine. When women have pain and symptoms of urinary frequency, they usually take medication consistently. When they no longer have any clinical evidence they are ill, their compliance rate may begin to fall dramatically. Urge a woman to post a chart on her refrigerator door or in her bathroom as a reminder to take the medication. Encourage her not to leave the medication on the counter as a reminder because she needs to begin to childproof her home.

Pyelonephritis occurs as an extension of a UTI or infection that originated in or spread to the kidney (Suskind, Saigal, Hanley, et al., 2016). If this develops, a woman may be hospitalized for 24 to 48 hours while she is treated with intravenous antibiotics. After this acute episode, she will be maintained on a drug such as oral nitrofurantoin (Macrochantin) for the remainder of the pregnancy. Acidifying urine by the use of ascorbic acid (vitamin C), which is often recommended in nonpregnant women, is not usually recommended during pregnancy because a newborn can develop scurvy in the immediate neonatal period from vitamin C withdrawal.

After birth, a woman who developed more than one UTI may have an ultrasound scheduled to detect any urinary tract abnormality that might be present, such as vesicoureteral reflux, to help prevent future infections.

### ***QSEN Checkpoint Question 20.3***

#### **QUALITY IMPROVEMENT**

While reviewing antenatal electronic records, the charge nurse of a prenatal clinic

notes that a high number of pregnant women seen in the clinic, including Angelina Gomez, have developed UTIs during their pregnancies. The nurse should emphasize the need for staff nurses to do which of the following?

- a. Ensure that the housekeeping department is adequately cleaning the toilets.
- b. Suggest all women be prescribed a prophylactic antibiotic during their first trimester.
- c. Educate women on the need for sound perineal care during pregnancy.
- d. Urge women to restrict fluid to keep their urine acidic and concentrated.

*Look in [Appendix A](#) for the best answer and rationale.*

## **A WOMAN WITH A HYPERACTIVE BLADDER**

A hyperactive bladder refers to a bladder that contracts more frequently than usual, causing symptoms of frequency, urgency, and incontinence. During pregnancy, these symptoms can increase greatly because of the additional pressure from the uterus on the bladder. Fesoterodine (Toviaz; pregnancy category C), an antispasmodic drug frequently prescribed for the disorder should be used during pregnancy and breastfeeding only if the risk outweighs the benefit until it is proven not to be teratogenic ([Kahyaoglu Sut & Balkanli Kaplan, 2016](#)).

## **A WOMAN WITH CHRONIC RENAL DISEASE**

In the past, females with chronic renal disease did not reach childbearing age or were advised not to have children because of their automatic high-risk status during pregnancy. Today, with conscientious prenatal care, women with chronic renal disease and even women who have had renal transplants, can expect to have healthy pregnancies and healthy children ([Zhang, Ma, Hao, et al., 2015](#)).

Women with chronic renal disease need to be monitored carefully during pregnancy because their diseased kidneys may not produce erythropoietin, a glycoprotein necessary for red cell formation and so they may develop a severe anemia ([Box 20.5](#)). Fortunately, synthetic erythropoietin is now available and is safe to take during pregnancy ([Sienas, Wong, Collins, et al., 2013](#)).

BOX 20.5

**Nursing Care Planning Using Assessment**

### **ASSESSING A PREGNANT WOMAN WITH RENAL DISEASE**

Because the glomerular filtration rate normally increases during pregnancy, a woman's serum creatinine level (a measure of kidney function that elevates when kidneys are under stress) may be actually slightly below normal during pregnancy or may fall from a usual level of 0.7 mg/100 ml to about 0.5 mg/100 ml. Women with kidney disease who normally have a serum creatinine level greater than 2.0 mg/dl may be advised not to undertake a pregnancy in case the increased strain on already damaged kidneys leads to kidney failure.

Many women with renal disease routinely take a corticosteroid such as oral prednisone at a maintenance level. This drug therapy typically is continued throughout pregnancy. Although animal studies have shown an increased incidence of cleft palate from corticosteroid use during pregnancy, this does not appear to be true in humans. The infant may be hyperglycemic at birth, however, because of the suppression of insulin activity by the corticosteroid.

Women with severe renal disease may require dialysis to aid kidney function during pregnancy (Piccoli, Minelli, Versino, et al., 2016). With dialysis, there is a risk of

preterm labor, perhaps because progesterone is removed with the dialysis. To prevent this complication, progesterone may be administered intramuscularly before the procedure. If hemodialysis is used, it should be scheduled frequently and for short durations to avoid acute fluid shifts. The heparin administered in connection with hemodialysis is safe during pregnancy because it does not cross the placenta. Even in light of the expanding uterine size, peritoneal dialysis is actually preferred over hemodialysis because it normally causes less drastic fluid shifts. This can be accomplished on an ambulatory basis (continuous ambulatory peritoneal dialysis) throughout pregnancy.

If women are on a low-potassium diet to avoid a buildup of potassium that accumulates because their diseased kidneys do not evacuate it well, they may need a nutrition consultation to be certain they can continue to avoid potassium yet also eat a healthy pregnancy diet. They also may need a great deal of emotional support during pregnancy because they are aware of the stress of pregnancy on damaged kidneys. By being pregnant, they are risking not only the life of the child growing inside them but also their own life. They may also need extra time with their infant at birth for bonding because they may have been too concerned during pregnancy to begin this process.

Although successful pregnancies in women with kidney transplants are to be expected, women should be considered individually to determine whether they will be able to carry a pregnancy to term before a pregnancy is initiated (Kovács, Szabó, Jenei, et al., 2015). Criteria to be evaluated include:

- A woman's general health and the time since the transplant (preferably >2 years)
- A woman's serum creatinine level
- The presence of proteinuria or hypertension or signs of graft rejection
- Medications the woman is taking to reduce graft rejection

It is helpful if the drugs a woman is taking are limited to prednisone to ensure fetal safety during pregnancy.

## Respiratory Disorders and Pregnancy

Respiratory diseases have a wide range from mild (e.g., the common cold), to severe (e.g., pneumonia), to chronic (e.g., tuberculosis or chronic obstructive pulmonary disease [COPD]). Any respiratory condition can worsen in pregnancy because the rising uterus compresses the diaphragm, thus reducing the size of the thoracic cavity and available lung space. Any respiratory disorder can also pose serious hazards to the fetus if allowed to progress to the point where the mother's oxygen-carbon dioxide exchange is altered or the mother or fetus cannot receive enough oxygen.

### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for ineffective breathing pattern related to respiratory changes during pregnancy

**Outcome Evaluation:** Respiratory rate is 16 to 20 breaths/min, PO<sub>2</sub> is above 80 mmHg, PCO<sub>2</sub> is below 40 mmHg, and fetal heart rate is 110 to 160 beats/min with good variability.

Respiratory illnesses in women who are pregnant can become extremely serious and may require therapy such as oxygen and medication to help increase oxygenation in both the woman and her fetus.

## A WOMAN WITH ACUTE NASOPHARYNGITIS

Acute nasopharyngitis (i.e., the common cold) tends to be more severe during pregnancy than at other times because, during pregnancy, estrogen stimulation normally causes some degree of nasal congestion. This means that even with a minor cold, a woman can find it difficult to breathe. Women should not take high-dose aspirin as a remedy for a headache, which commonly accompanies an upper respiratory infection. It can interfere with blood clotting in both the mother and fetus as well as cause fetal constricted ductus arteriosus (Karch, 2015). Because common colds are invariably caused by a virus, antibiotic therapy is unnecessary except to prevent a secondary infection. And although most simple cough syrups don't contain ingredients that would make them unsafe for use during pregnancy, women should check with their healthcare provider before taking any over-the-counter medication other than honey and lemon lozenges. Urge women to use simple measures to combat a cold, such as:

- Be sure to get extra rest and sleep and eat a diet high in vitamin C (e.g., orange juice and fruit) to help boost the immune system.
- Take acetaminophen (Tylenol) every 4 hours for aches and pains (up to 3,000 mg/day). Do not take acetylsalicylic acid (Aspirin) during pregnancy because it can interfere with blood clotting.
- Use a room humidifier or apply a medicated vapor rub to the chest, especially at night, to moisten nasal secretions and help mucus drain.
- Use cool or warm compresses to relieve sinus headaches.

## A WOMAN WITH INFLUENZA

Influenza is caused by a virus, identified as type A, B, or C. The disease spreads in epidemic form and is accompanied by high fever, extreme prostration, aching pains in the back and extremities, and generally, a sore, raw throat. Contrary to early reports, influenza infection has not been clearly correlated with congenital anomalies in newborns, although it can be a cause of preterm labor. For unknown reasons, some studies have shown a link between influenza during pregnancy and schizophrenia in children born of that pregnancy (Cai, Wan, He, et al., 2015). Treatment includes an antipyretic such as acetaminophen (Tylenol) to control fever. The risk for the woman of

not taking oseltamivir (Tamiflu), an oral antiviral drug that is pregnancy category C, is greater than if it is taken, so it should be prescribed and begun immediately during pregnancy (Ghulmiyyah, Alame, Mirza, et al., 2016). Because influenza vaccines are made from inert viruses, women may also be immunized safely against influenza during pregnancy (Polyzos, Konstantelias, Pitsa, et al., 2015).

## A WOMAN WITH PNEUMONIA

Pneumonia is the bacterial or viral invasion of lung tissue by pathogens such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Mycoplasma pneumoniae*. After the invasion, an acute inflammatory response occurs in the lung alveoli, causing an exudate of red blood cells, fibrin, and polymorphonuclear leukocytes to flood into the alveoli. This process has the helpful effect of confining the bacteria or virus within segments of the lobes of the lungs, but it also has a less helpful effect of filling alveoli with fluid, blocking off breathing space. If the collection of fluid becomes extreme, it can limit the oxygen available not only to the woman but also to the fetus. Therapy involves the use of an appropriate antibiotic and perhaps oxygen administration. With severe disease, ventilation support may be necessary. Pneumonia during pregnancy is associated with fetal growth restriction and preterm birth because of the oxygen deficit (Leidecker & Dorman, 2016). If pneumonia is present during labor, oxygen should be administered so the fetus has adequate oxygen resources during contractions.

## A WOMAN WITH ASTHMA

Asthma is a disorder marked by reversible airflow obstruction, airway hyperreactivity, and airway inflammation. Symptoms are often triggered by an inhaled allergen such as pollen or cigarette smoke. With inhalation of the allergen, there is an immediate release of bioactive mediators such as histamine and leukotrienes from an immunoglobulin interaction. This results in constriction of the bronchial smooth muscle, marked mucosal inflammation and swelling, and the production of thick bronchial secretions. These three processes cause a woman to have difficulty pulling in air; on exhalation, she has so much difficulty releasing air she makes a high-pitched whistling sound (i.e., bronchial wheezing) from air being pushed past the bronchial narrowing. Asthma has the potential of reducing the oxygen supply to a fetus leading to preterm birth or fetal growth restriction if a major attack should occur during pregnancy; however, this is less of a threat with well-managed asthma (Charlton, Pierini, Klungsøyr, et al., 2016). Some women find that their asthma actually improves during pregnancy because of the high circulating levels of corticosteroids present. A woman should check with her primary care provider before pregnancy about the safety of the medications she routinely takes for this disorder to be certain it will be safe to continue during pregnancy and breastfeeding.

Women who have been taking a corticosteroid during pregnancy may need intravenous administration of hydrocortisone during labor because of the added stress

during this time.  $\beta$ -Adrenergic agonists such as terbutaline and albuterol may be taken safely during pregnancy, but because they have the potential to reduce labor contractions, the dosage may be tapered close to term if possible (Namazy & Schatz, 2015).

## A WOMAN WITH TUBERCULOSIS

Tuberculosis is a disease that should have been eradicated because of the effective treatment available. However, in highly populated areas, the incidence has actually increased and in some areas is at epidemic proportions. Worldwide, it is still one of the leading causes of death.

With tuberculosis, lung tissue is invaded by *Mycobacterium tuberculosis*, an acid-fast bacillus. Macrophages and T lymphocytes surround the invading bacillus, but rather than actually killing it, they merely surround and confine it. Fibrosis, calcification, and a final ring of collagenous scar tissue develop, effectively sealing off the organisms from the body and any further invasion or spread. The antibodies produced will thereafter cause a woman to have a positive response to a Mantoux test (purified protein derivative [PPD]) test.

### Assessment

Symptoms of tuberculosis, in addition to a chronic cough, are substantial weight loss, hemoptysis (coughing blood), a low-grade fever, extreme fatigue, and waking at night with night sweats. In high-risk areas, women should undergo skin testing (a PPD test) at their first prenatal visit. Women need to be cautioned that a positive reaction does not necessarily mean they have the disease; it can only mean they have at some time been exposed to tuberculosis and so have antibodies in their system. If a woman has a positive reaction, a chest X-ray (which is safe during pregnancy as long as her abdomen is lead shielded) or a sputum culture for acid-fast bacillus to confirm the diagnosis will be scheduled.

### Therapeutic Management

Women with active tuberculosis need treatment during pregnancy (Leidecker & Dorman, 2016). Isoniazid (INH), rifampin (RIF), and ethambutol hydrochloride (Myambutol)—the drugs of choice for tuberculosis—may be given without apparent teratogenic effects. INH, however, may result in a peripheral neuritis if a woman does not also take supplemental pyridoxine (vitamin B<sub>6</sub>). Ethambutol has the side effect of causing optic atrophy and loss of green color recognition in the woman. To detect this, test the woman's ability to recognize green at prenatal visits using the color section of a Snellen (eye test) chart. If symptoms develop, inform her health provider about possibly discontinuing the drug.

A woman who had tuberculosis earlier in life must be especially careful to maintain an adequate level of calcium during pregnancy to ensure the calcium tuberculosis

pockets in her lungs are not broken down and the disease is not reactivated. A woman is usually advised to wait 1 to 2 years after the infection becomes inactive before attempting to conceive as pressure on the diaphragm from the enlarging uterus changes the shape of the lung and can break open recently calcified pockets more readily than well-calcified lesions. Pockets may also break open during labor from the increased intrapulmonary pressure of pushing. Recent inactive tuberculosis may also become active during the postpartum period as the lung returns to its more vertical prepregnant position following birth.

Although tuberculosis can be spread by the placenta to the fetus, if it is active, it usually is spread to the infant after birth by the mother's coughing. Obtaining a negative sputum culture after birth rules out active tuberculosis. Urge the woman to continue taking her tuberculosis medications as prescribed during breastfeeding as only small amounts of these are secreted in breast milk and so are safe for her infant.

## **A WOMAN WITH CHRONIC OBSTRUCTIVE PULMONARY DISEASE**

COPD is constriction of the airway associated most often with long-term cigarette smoking. When women had their children between 20 and 30 years of age, COPD was rarely associated with pregnancy. Now that more and more women are waiting until age 35 to 40 years to have children, it is now possible to see the condition with pregnancy. Constrictive air disease limits the amount of oxygen that can reach the lungs, so the condition is associated with fetal growth restriction and preterm birth. Women may need additional rest during pregnancy because of fatigue and may need continuous supplemental oxygen during the day. If they experience sleep apnea, they may be prescribed continuous positive airway pressure (CPAP) at night ([Karaduman, Sari, Aydoğan, et al., 2016](#)). During labor, a woman might grow so short of breath from the exertion needed for pushing that she may be advised to have a cesarean birth.

Pregnancy may be the time a woman with COPD realizes she needs to stop smoking not only to preserve her own health but also to be able to supply a smoke-free environment for her baby. Offer support at prenatal visits for her attempt to do this, but caution her it is difficult to stop smoking unless her entire family takes this same step toward wellness.

## **A WOMAN WITH CYSTIC FIBROSIS**

Cystic fibrosis is a recessively inherited disease in which there is generalized dysfunction of the exocrine glands ([Leidecker & Dorman, 2016](#)). This dysfunction leads to mucus secretions, particularly in the pancreas and lungs, which become so viscid that normal lung and pancreatic functions become compromised.

Many men with cystic fibrosis are subfertile because their semen is so thick that sperm cannot be motile. Fertility may be lessened in women with the disorder because sperm cannot migrate through viscid cervical mucus. This can make reproductive

technologies such as alternative insemination or in vitro fertilization necessary for conception.

Persons with the disease typically show symptoms of chronic respiratory infection and overinflation of their lungs from the thickened mucus present; they have difficulty digesting fat and protein because the pancreas cannot release amylase. During a pregnancy, poor pulmonary function can result in inadequate oxygen supply to the fetus, resulting in an increased risk of growth restriction, preterm labor, and perinatal death. Identifying whether the fetus also has the disease can be done by chorionic villi sampling, amniocentesis, or identification of the abnormal gene on chromosome 7 in fetal cells obtained from the woman's blood serum. Screening for the disorder is included in routine neonatal screening programs after birth (Brennan & Schrijver, 2016).

Therapy for the illness consists of administration of pancrelipase (Pancrease) to supplement pancreatic enzymes. Although pancrelipase is a pregnancy risk category C drug (i.e., teratogenic effects are unknown), it does not appear to affect the fetus, so caution women to continue to take this even with nausea of early pregnancy. Women are often also prescribed a bronchodilator or antibiotic to reduce pulmonary symptoms. They should schedule a preconception meeting with their healthcare provider to discuss whether all of these will be safe during pregnancy. In addition to pharmacologic measures, women with cystic fibrosis must perform chest physiotherapy daily to reduce the buildup of lung secretions; this should continue during pregnancy. As women with the disorder excrete a higher level of sodium in perspiration than others, monitor them carefully during labor to be certain they do not become dehydrated.

### **Modifications for Pregnancy**

Because pancrelipase may interfere with iron absorption, a woman is at greater risk for iron-deficiency anemia during pregnancy than others. Therefore, an iron supplement usually is prescribed. They also have a higher than usual incidence of developing diabetes mellitus because of pancreas involvement; therefore, women also need close monitoring of serum glucose levels at prenatal visits to detect the development of gestational diabetes.

Chest physiotherapy can become difficult late in pregnancy because the process is exhausting, moving to new positions is difficult, and lying prone, a position used frequently in postural drainage, is contraindicated in late pregnancy. To continue this effectively, therefore, a woman may need to plan more frequent and shorter sessions in modified positions (other than prone) during pregnancy (Fig. 20.2). Fetal health will be monitored by ultrasound and nonstress tests to identify intrauterine growth restriction.

**Figure 20.2** Modified positions for chest physiotherapy during pregnancy: **(A)** chest physiotherapy for the upper lobes and **(B)** chest physiotherapy for the lower lobes.

### Modifications for the Postpartum Period

Help a woman plan how to conserve her energy for infant care in the immediate postpartum period so she does not become exhausted and can enjoy her newborn. The milk of a nursing mother with cystic fibrosis is high in sodium, and potentially places the infant at risk for hypernatremia, so women with cystic fibrosis are usually advised not to breastfeed (Brennan & Schrijver, 2016). Although not their first choice for infant care, you can assure mothers that their infant will do well on formula.

#### QSEN Checkpoint Question 20.4

#### TEAMWORK & COLLABORATION

Angelina had tuberculosis as a teenager, and her primary care provider orders a chest X-ray during pregnancy. The nurse would want care team members to know that this is necessary because of which danger of tuberculosis during pregnancy?

- Calcium deposits that wall off old tuberculosis lesions can break down.
- Latent tuberculosis can turn to pneumonia if a woman has a folic acid deficit.
- PPD tests are always negative during pregnancy so tuberculosis often goes undetected.
- The disease can result in neural tube defects in the fetus.

Look in [Appendix A](#) for the best answer and rationale.

### Rheumatic Disorders and Pregnancy

Several rheumatic disorders that occur in young adult women can be seen during pregnancy. Because most of these illnesses result in discomfort, the most common

primary nursing diagnosis for these is pain. Women may not be able to achieve a pain-free outcome during pregnancy because of the nature of these illnesses, but outcomes should center on a woman stating her pain level is tolerable and that she's finding enjoyment in being pregnant.

## **A WOMAN WITH RHEUMATOID ARTHRITIS**

Juvenile rheumatoid arthritis (JRA; sometimes referred to as chronic rheumatoid arthritis) is a disease of connective tissue marked by joint inflammation and contractures. Most likely the result of an autoimmune response, the disease pathology involves synovial membrane destruction, inflammation with effusion, swelling, erythema, and painful motion of the joints (Ngian, Briggs, Ackerman, et al., 2016). Untreated, formation of granulation tissue fills the joint space, resulting in permanent disfigurement and loss of joint motion.

Women with JRA frequently take corticosteroids, hydroxychloroquine, and nonsteroidal anti-inflammatory drugs (NSAIDs) to prevent joint pain and loss of mobility. Some women may be taking oral aspirin therapy. Although they should continue to take these medications during pregnancy to prevent joint damage, large amounts of salicylates have the potential to lead to increased bleeding at birth or possibly prolonged pregnancy (salicylate interferes with prostaglandin synthesis, so labor contractions are not initiated) (Karch, 2015). The infant may be born with a bleeding defect and may also experience premature closure of the ductus arteriosus because of the drug's effects. For this reason, the woman is asked to decrease her intake of salicylates approximately 2 weeks before term. A number of women also take low-dose methotrexate, a carcinogen (pregnancy risk category X). As a rule, they should stop taking this prepregnancy because of the danger of head and neck defects in the fetus.

Joint symptoms of the disease may improve during pregnancy because of the naturally increased circulating level of corticosteroids in the maternal bloodstream during pregnancy. During the postpartum period, when a woman's corticosteroid levels fall to prepregnancy levels, arthritis symptoms will probably recur (Ngian et al., 2016).

In the postpartum period, the determination as to the safety of breastfeeding must be individualized based on the medication each woman is taking. Those taking NSAIDs, such as ibuprofen, can breastfeed. Those taking methotrexate or large doses of aspirin may be advised not to breastfeed because of the danger to the infant.

## **A WOMAN WITH SYSTEMIC LUPUS ERYTHEMATOSUS**

Systemic lupus erythematosus (SLE) is a multisystem chronic disease of connective tissue that occurs most frequently in woman 20 to 40 years of age (Schreiber, 2016). Widespread degeneration of connective tissue (especially of the heart, kidneys, blood vessels, spleen, skin, and retroperitoneal tissue) occurs with onset of the illness. A marked skin change is a characteristic erythematous butterfly-shaped rash on the face.

In the kidneys, fibrin deposits develop, plugging and blocking the glomeruli and leading to necrosis and scarring. The thickening of collagen tissue in the blood vessels can cause vessel obstruction. This obstruction can be life-threatening to a woman if blood flow to vital organs becomes compromised and life-threatening to a fetus if blood flow to the placenta is obstructed. Many women with SLE have aPLAs, which increase the tendency for thrombi to form (Schreiber, 2016). In contrast, marked thrombocytopenia (i.e., decreased platelet count) may be present, so clotting may be deficient. Prior to pregnancy, a woman may be taking a combination of NSAIDs, low-molecular-weight heparin, salicylates, hydroxychloroquine, low-dose prednisone, or azathioprine (an immunosuppressant) to reduce disease symptoms. She can continue these during pregnancy if used with caution but may be asked to reduce the dose of salicylates 2 weeks prior to labor to prevent bleeding in the newborn and premature closure of the ductus arteriosus.

The naturally increased circulation of corticosteroids during pregnancy may lessen symptoms in some women. In others, the chief complication of the disorder—acute nephritis with glomerular destruction—may occur for the first time during pregnancy. With associated nephritis, a woman's blood pressure will rise sharply and she will develop hematuria, proteinuria with decreased urine output, and edema. It is difficult to differentiate these symptoms from the symptoms of gestational hypertension, except that with gestational hypertension, there is no hematuria. Frequent monitoring of serum creatinine levels will be necessary to assess if kidney function is adequate. If this value is over 1.5 mg/dl and proteinuria and a decreased creatinine clearance value are also present, the fetus is seriously threatened with growth restriction and the pregnancy is also threatened to be preterm. Dialysis to remove excess creatinine or plasmapheresis to replace platelets may be necessary to guard against hemorrhage in the woman at birth.

During labor, intravenous hydrocortisone may be administered to help a woman adjust to stress at this time. During the postpartum period, there may be an acute exacerbation of symptoms as corticosteroid levels again fall to normal. Infants of women with SLE may be born with a lupus-like rash, anemia, thrombocytopenia (low platelet count), and neonatal heart block. Such newborn symptoms last about 6 months and then fade. If congenital heart block occurs, a newborn pacemaker may be necessary. Screening for the exact type of autoantibodies present may be helpful in predicting which newborns will be susceptible to this.

## **Gastrointestinal Disorders and Pregnancy**

Although minor gastrointestinal discomforts (such as nausea, heartburn, and constipation) are common during pregnancy, acute abdominal pain and protracted vomiting are causes for concern because complications such as premature separation of the placenta or ectopic pregnancy often manifest with acute abdominal pain and protracted vomiting can lead to dehydration. In some women, sudden abdominal pain is caused by a condition completely unrelated to the pregnancy, such as ulcerative colitis,

hepatitis, hiatal hernia, or cholecystitis, conditions that may be known to a woman before she becomes pregnant or that may develop or be discovered during her pregnancy. In either event, they need a clear assessment and therapy to maintain the woman's overall health. Women who have colostomies may ask if they can complete a pregnancy without difficulty; the answer is yes. Even a previous liver transplant is not a contraindication to pregnancy (Margioulas-Siarkou, Kalogiannidis, Petousis, et al., 2016).

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Imbalanced nutrition, less than body requirements, related to a gastrointestinal disorder during pregnancy

**Outcome Evaluation:** Patient's weight gain amounts to 25 to 30 lb during pregnancy, hemoglobin is above 11 mg/dl, and specific gravity of urine is below 1.030.

Because most gastrointestinal disorders interfere with nutrition or fluid/electrolyte balance, a major intervention with all of these disorders is to ensure women are taking in adequate food and fluid for their well-being and that of their fetus, and to assess that their disease process is resolving.

## A WOMAN WITH APPENDICITIS

The incidence of appendicitis, or inflammation of the appendix, is high in late adolescents and occurs as frequently as 1 in 1,500 to 2,000 pregnancies (Debnath, Sharma, & Maurya, 2016).

### Assessment

History taking is important. Appendicitis usually begins with a few hours of nausea and then an hour or two of generalized abdominal discomfort. Then, comes the typical sharp, peristaltic, lower right quadrant pain of acute appendicitis.

Pain from an overstretched round ligament or a ruptured ectopic pregnancy may both cause sharp lower quadrant pain, so the pain from these needs to be differentiated from that of appendicitis. The major difference is that the pain of an overstretched round ligament fades almost instantly; appendicitis pain not only continues but grows more intense. With an ectopic pregnancy, a woman may experience morning sickness, and the pain she feels is either diffuse or sharp. With appendicitis, the nausea and vomiting is much more intense and the pain is sharp and localized at McBurney point (a point halfway between the umbilicus and the iliac crest on the lower right abdomen). In the pregnant woman, this can shift higher in the abdomen because the appendix is often

displaced so far up in the abdomen by the uterus that the pain may resemble the pain of gallbladder disease (Fig. 20.3).

**Figure 20.3** The change in position of appendix during pregnancy.

The woman's temperature is usually elevated, a urine sample reveals ketones, and a complete blood count reveals leukocytosis. Because pregnant women typically have an elevated white blood cell (WBC) count, however, an elevated WBC is not as diagnostic in pregnancy as it might be otherwise. An ultrasound or magnetic resonance imaging (MRI) scan will confirm the inflamed appendix.

Advise a woman in an emergency room that while she is waiting to be evaluated for possible appendicitis not to eat any food, drink any liquid, or consume any laxatives because increasing peristalsis could cause an inflamed appendix to rupture.

### **Therapeutic Management**

If a woman is near term (past 37 weeks) and the fetus is believed to be mature, a cesarean birth may be performed along with removal of the inflamed appendix at the same time. If appendicitis occurs early in pregnancy, the inflamed appendix is usually removed by laparoscopy. As long as the anesthesiologist is aware the woman is pregnant and carefully controls oxygen levels during anesthesia administration, the outcome of both the surgery and the pregnancy will be good.

If the appendix ruptures before surgery, the risk to both mother and fetus increases dramatically. This occurs because, with rupture, infected fecal material escapes into the peritoneum and could spread by the fallopian tubes to the fetus. Also, generalized peritonitis is such an overwhelming infection that it would be difficult for a woman's

body to combat it effectively and also maintain the pregnancy. As a third concern, peritoneal adhesions may develop after an appendix ruptures, resulting in future subfertility because of changes in the placement of fallopian tubes (Wu & Hueppchen, 2015).

## **A WOMAN WITH GASTROESOPHAGEAL REFLUX DISEASE OR HIATAL HERNIA**

Gastroesophageal reflux disease (GERD) refers to the reflux of acid stomach secretions into the esophagus (Zielinski, Searing, & Deibel, 2015). Hiatal hernia is a condition in which a portion of the stomach extends and protrudes up through the diaphragm into the esophagus, trapping stomach acid and causing it to reflux into the esophagus. Although these conditions can be present constantly, symptoms most often occur only sporadically after increased peristaltic action. Both conditions may generate symptoms for the first time during pregnancy as the uterus pushes the stomach up against the esophageal valve and increases the reflux of acid or the extent of the hernia. Symptoms include:

- Heartburn, which is particularly extreme when lying supine after a full meal
- Gastric regurgitation
- Dysphagia (difficulty swallowing)
- Possible weight loss because of the stomach pain
- Hematemesis (i.e., vomiting of blood) if extreme esophageal irritation occurs

During pregnancy, these conditions are usually diagnosed by ultrasound, although direct endoscopy could be used. In most women, an over-the-counter antacid or a prescription for a proton pump inhibitor such as esomeprazole magnesium (Nexium; pregnancy category B) will effectively dilute or inhibit gastric acid production and so relieve symptoms. As additional measures, advise a woman to wear clothing that is loose around her waist and to sleep with her head elevated on two or more pillows to help confine stomach secretions. Esomeprazole magnesium has not been studied as to its safety during breastfeeding, but as the uterine pressure is eliminated following birth, the symptoms generally become less noticeable or disappear and the woman no longer needs the drug. Some women may continue to have pain after birth and so need to take an acid inhibitor for several months until their irritated esophagus is completely healed.

## **A WOMAN WITH CHOLECYSTITIS AND CHOLELITHIASIS**

Cholecystitis (i.e., gallbladder inflammation) and cholelithiasis (i.e., gallstone formation) are most frequently associated with women older than 40 years of age, who are obese, are multiparas, and ingest a high-fat diet. Because gallstones form from cholesterol, the hypercholesterolemia that naturally occurs during pregnancy may be the reason an increased incidence of gallstone formation occurs during pregnancy in women prone to these. Symptoms they cause are constant aching and pressure in the right epigastrium, perhaps accompanied by jaundice.

Medical therapy to prevent both conditions is to lower fat intake; however, during pregnancy, women should not eliminate it entirely because of the importance of linoleic acid for fetal brain growth. If symptoms of acute cholecystitis occur during pregnancy, the condition can be diagnosed by ultrasound. It can generally be managed by temporarily halting oral intake to rest the gastrointestinal tract and administering intravenous fluids to provide fluid and nutrients as well as analgesics for pain. Surgery for gallbladder removal by laparoscopic technique may be done during pregnancy if a woman's symptoms cannot be controlled by conservative management (Jorge, Keswani, Veerappan, et al., 2015).

## A WOMAN WITH PANCREATITIS

Pancreatitis (i.e., inflammation of the pancreas) is a rare disorder that tends to occur in late adolescents and so may occur during pregnancy (Hacker, Whalen, Lee, et al., 2015). The woman experiences severe epigastric pain, nausea, vomiting, anorexia, and fever. Diagnosis may be difficult as serum amylase, which rises with pancreatitis, is also normally elevated during pregnancy. If serum amylase levels are greater than two times above normal, however, pancreatitis should be suspected. The disorder is treated the same during pregnancy as in nonpregnant women: nasogastric suction, bowel rest, analgesia (because pancreatic pain is sharp), and intravenous hydration through parenteral nutritional supplementation (Xu, Wang, & Zhang, 2015). The inflammation usually subsides within a week. Pregnancy loss, however, can occur from acidosis, hypovolemia, and fetal hypoxia (Abdullah, Kathiresan Pillai, Cheen, et al., 2015).

## A WOMAN WITH HEPATITIS

Hepatitis is a liver disease that occurs from invasion of the hepatitis A, B, C, D, or E virus. Hepatitis A is spread mainly by fecal–oral contact (children in day-care settings have a high incidence) or by ingestion of fecally contaminated water or shellfish. It has an incubation period of 2 to 6 weeks. Pregnant women exposed to hepatitis A may be given prophylactic  $\gamma$ -globulin to try to prevent the disease after exposure. This form follows a rather benign course and is not thought to be transmitted to the fetus (Rac & Sheffield, 2014).

Hepatitis B and C are spread by exposure to contaminated blood or blood products or by contact with contaminated semen or vaginal secretions (and so are considered sexually transmitted infections [STIs]). These can be transmitted to the fetus across the placenta. Hepatitis D and E are apparently spread by the same methods as hepatitis B and C but are rarely seen in pregnant women.

Hepatitis C demonstrates few symptoms, and these may not be present for 12 months after exposure. It is, however, the most common cause of chronic liver disease and liver transplantation in the United States (Rac & Sheffield, 2014).

Hepatitis B occurs about 1 in every 2,000 pregnancies (Rac & Sheffield, 2014). It has an incubation period of 6 weeks to 6 months. It occurs in both an acute and chronic

form, leading to liver cell necrosis with scarring and an inability to convert indirect to direct bilirubin or to excrete direct bilirubin. Women exposed to the virus receive immune globulin for prophylaxis; a hepatitis B vaccine can be administered to those who are at high risk, such as women who handle blood products, to prevent the illness.

### Assessment

With all forms of hepatitis, a woman experiences nausea and vomiting. Her liver area may feel tender to palpation. Urine will turn dark yellow from excretion of bilirubin; stools will be light-colored from lack of bilirubin. Jaundice occurs as a late symptom. On physical examination, hepatomegaly (i.e., enlargement of the liver) is noted. The serum bilirubin level is elevated. Levels of liver enzymes, such as transaminase, are increased. Specific antibodies against the virus can be detected in the blood serum, so women at high risk may be routinely screened for this during pregnancy. If a liver biopsy is necessary for diagnosis, this can be performed safely during pregnancy as this is done under local anesthesia.

### Therapeutic Management

A woman is usually prescribed bed rest and encouraged to eat a high-calorie diet because her liver has difficulty converting stored glycogen into glucose in its diseased state and so hypoglycemia can result. A cesarean birth may be planned at term to reduce the possibility of blood exchange between mother and fetus. Follow standard infection precautions when you give care to avoid contact with body fluids.

Hepatitis during pregnancy may lead to spontaneous miscarriage or preterm labor. Unlike most other diseases that cause maximum fetal threat in the first trimester, the later in pregnancy a woman contracts hepatitis B infection, the greater the risk the infant will be affected or develop hepatitis B. If this should occur, it is a serious consequence because a proportion of hepatitis B Ag-positive infants will develop liver cirrhosis or carcinoma later in life (Rac & Sheffield, 2014). Use precautions during birth to avoid exposure to maternal body fluids. After birth, a woman may breastfeed as the infection is apparently not transmitted by breast milk. The infant should be washed well to remove any maternal blood; hepatitis B immune globulin (HBIG) and the first dose of hepatitis B should be administered (see Chapter 34 for the full immunization series). The infant then needs to be observed carefully for symptoms of infection during the first few months of life and for chronic liver disease as he or she grows older.

## A WOMAN WITH INFLAMMATORY BOWEL DISEASE

Crohn disease (i.e., inflammation of the terminal ileus) and ulcerative colitis (i.e., inflammation of the distal colon) occur most often in late adolescents between ages 12 and 30 years. The cause of these diseases is unknown, but an autoimmune process is thought to be responsible. They are also associated with passive and active smoking (Dutta & Chacko, 2016). In both diseases, the bowel develops shallow ulcers. A woman

experiences chronic diarrhea, weight loss, occult blood in stool, and nausea and vomiting. If extreme, obstruction and fistula formation with peritonitis can occur. With Crohn disease, malabsorption, particularly of vitamin B (the absorption of which occurs almost entirely in the ileum), can occur. Because of the potential difficulty with absorbing nutrients in both disorders, women with these disorders need careful monitoring for weight gain during pregnancy. There is a potential for fetal growth restriction if extreme malabsorption occurs. Therapy for the disorders is rest for the gastrointestinal tract by administration of total parenteral nutrition. Sulfasalazine (Azulfidine), an anti-inflammatory and a mainstay of therapy, may be continued during pregnancy without fetal injury. Close to birth, the dosage of sulfasalazine, because of its sulfa base, is reduced because it may interfere with bilirubin binding sites and cause neonatal jaundice (Karch, 2015). Infliximab (IFX) and adalimumab (ADA) are other attractive treatment options, but there is still limited data on the benefit/risk profile during pregnancy (Shihab, Yeomans, & De Cruz, 2016).

## Neurologic Disorders and Pregnancy

Neurologic illness, as a whole, does not occur at a high incidence in women of childbearing age. However, any neurologic disease with symptoms of seizures must be carefully managed during pregnancy because the anoxia that could be caused by severe seizures could deprive a fetus of oxygen.

### A WOMAN WITH A SEIZURE DISORDER

Recurrent seizures have several causes, such as head trauma or meningitis. However, the causes of most recurrent seizures, such as epilepsy, are unknown (i.e., are idiopathic). Recurrent seizures are seen in about 3 to 5 women per 1,000 births.

### Therapeutic Management

The goal of care is to establish the best seizure control with the fewest possible number of antiseizure drugs prior to pregnancy. During pregnancy, because almost all antiseizure drugs are at least mildly teratogenic, dosages may have to be decreased even further to protect the fetus, which unfortunately then increases the risk of seizures (Videman, Tokariev, Stjerna, et al., 2016). Be certain women understand the rule “Do not take medication during pregnancy” does not apply to antiseizure medications so that they continue to conscientiously take them despite the nausea or vomiting of early pregnancy. It is important the levels of antiseizure drugs be monitored and the doses adjusted routinely during pregnancy and again after birth. As blood volume increases with pregnancy, some women may need their dosage increased or their serum level will be diluted. Common drugs prescribed to control seizures are trimethadione (Tridione; pregnancy risk category D); valproic acid (sodium valproate and divalproex sodium; pregnancy risk category D); carbamazepine (Tegretol; pregnancy risk category C);

ethosuximide (Zarontin; pregnancy risk category C), a drug often used to control absence seizures; and phenytoin sodium (Dilantin; pregnancy risk category D).

Women who have been taking phenytoin (Dilantin) for some time may have developed chronic hypertension, so a baseline blood pressure should be established early in pregnancy so any changes that occur with pregnancy can be interpreted correctly. Phenytoin (Dilantin) is recognized as the cause of a fetal syndrome, including cognitive impairment, vitamin K deficiency, and a peculiar facial proportion not unlike that of fetal alcohol sequence. To counteract the vitamin K deficiency and prevent hemorrhage in the newborn, women may be prescribed vitamin K during labor or the last 4 weeks of gestation.

### *Concept Mastery Alert*

Adverse effects of phenytoin sodium (Dilantin) include vitamin K deficiency and possible bleeding. This can be counteracted by administration of vitamin K supplementation in the last 4 weeks of gestation.

## **Nursing Diagnoses and Related Interventions**

**Nursing Diagnosis:** Risk for ineffective tissue (placental) perfusion related to hypoxia resulting from maternal seizure

**Outcome Evaluation:** Patient informs healthcare personnel about history of seizures; states importance of immediate care and oxygen therapy should she begin a seizure. Apgar score of infant is 7 to 10, with no apparent birth anomalies.

Absence seizures (often just a rapid fluttering of the eyelids or a moment's staring into space) should have no effect on a woman or fetus. Tonic-clonic seizures (sustained, full-body involvement) could affect a fetus because spasm of the woman's chest muscles could lead to hypoxia. If a seizure should occur during pregnancy, a woman must be evaluated to be certain the cause of the seizure was the underlying seizure disorder, not a sign of eclampsia (see [Chapter 21](#)). Nonpregnant women experiencing tonic-clonic seizures do not need oxygen administered during a seizure, but in pregnancy, administering oxygen by mask is a good prophylaxis to ensure adequate fetal oxygenation.

Woman who have recurrent seizures may worry their children will develop seizures as they grow older. If a woman's seizures were the result of an acquired disorder such as meningitis or head trauma, you can assure her that her child's risk for seizures is no greater than that for any other child. If the etiology of her seizures is unknown, the chance her child also will develop them is slightly higher than in the

rest of the population. This prediction is only theoretical, however, and cannot be made without a thorough review of the onset and nature of the woman's disorder. Be certain a woman spends enough time with her newborn so she can become acquainted with the sudden jerking motions that occur in newborns such as when a newborn is startled (Moro reflex) or the jaw quivers after prolonged crying so she doesn't interpret these normal movements as seizure activity.

## **A WOMAN WITH MYASTHENIA GRAVIS**

Myasthenia gravis is an autoimmune disorder characterized by the presence of an IgG antibody against acetylcholine receptors in striated muscle. The presence of the antibody causes failure of the striated muscles to contract, particularly those of the oropharyngeal, facial, and extraocular groups. The disorder usually occurs in 20- to 30-year-olds, although it also is seen in young children. Women with the disorder need to be carefully monitored during pregnancy as pregnancy can cause major exacerbations of the disease (Roth, Dent, & McDevitt, 2015).

The disorder is treated with anticholinesterase drugs such as pyridostigmine (Mestinon) or neostigmine (Prostigmin) and possibly a corticosteroid such as prednisone. These medications may be continued during pregnancy, as the fetus will experience no effects from them. Be certain a woman understands atropine is the lifesaving antidote for neostigmine if an overdose should occur. Plasmapheresis (i.e., removal of and replacement of plasma) to remove immune complexes from the bloodstream may be prescribed to reduce symptoms. It must be carried out gradually during pregnancy, however, to reduce the risk of fluid overload or hypotension. Because smooth muscle is not affected by the disease, labor should occur without complications. Magnesium sulfate (administered to halt preterm labor or treat hypertension of pregnancy) should be avoided at any point in pregnancy because it can diminish the acetylcholine effect and therefore increase disease symptoms.

An infant born to a woman with myasthenia gravis may demonstrate disease symptoms at birth because of the transfer of antibodies (see [Chapter 51](#)).

## **A WOMAN WITH MULTIPLE SCLEROSIS**

Multiple sclerosis (MS) occurs predominantly in women of childbearing age, usually between 20 and 40 years of age (Pozzilli & Pugliatti, 2015). With MS, nerve fibers become demyelinated and therefore lose function. Women develop symptoms of fatigue, numbness, blurred vision, and loss of coordination. ACTH (adrenocorticotrophic hormone) or a corticosteroid is commonly given to strengthen nerve conduction and both can be administered safely during pregnancy. In contrast, immunosuppressants such as cyclosporine (Sandimmune), azathioprine (Imuran), and cyclophosphamide (Cytoxan), which are also frequently prescribed, should be used cautiously during pregnancy. Women may continue with plasmapheresis (i.e., withdrawal and replacement of plasma), another treatment regimen, during pregnancy as long as the

volume of exchange is well controlled to prevent hypotension. Although women with the disorder may grow increasingly fatigued as pregnancy progresses, pregnancy does not affect the long-term course of MS. In some women, symptoms may actually improve during pregnancy because of the increased circulating corticosteroid levels. Monitor for UTIs at prenatal visits as these tend to occur as a poorly defined consequence of the illness.

## Musculoskeletal Disorders and Pregnancy

Falls or other unintentional injuries that may lead to bone fractures or muscle sprains in women of childbearing age are discussed in [Chapter 22](#). A chronic musculoskeletal disorder that is first identified during adolescence and so may play a role in childbearing is scoliosis.

### A WOMAN WITH SCOLIOSIS

Scoliosis (i.e., lateral curvature of the spine) begins to be noticed first in girls between 12 and 14 years of age. If it is uncorrected at this time, the curvature progresses until it can interfere with respiration and heart action because of chest compression. Pelvic distortion can interfere with childbirth, especially at the pelvic inlet. If a woman's spine is extremely curved, epidural anesthesia may be difficult to administer for pain management in labor.

Girls with scoliosis may wear a body brace during their adolescent years to maintain an erect posture. Although these braces are not as bulky as they once were, unless they are modified, they cannot be worn during the last half of pregnancy. For surgical correction, girls have stainless steel rods surgically implanted on both sides of their vertebrae to strengthen and straighten their spine. Such rod implantations do not interfere with pregnancy; a woman may notice more than usual back pain, however, from increased tension on back muscles. If a woman's pelvis is distorted, a cesarean birth may be scheduled to ensure a safe birth. Vaginal birth, if permitted, requires the same management as for any woman. With the improved management of scoliosis, the high maternal and perinatal risks associated with the disorder reported in earlier literature no longer exist ([Falick-Michaeli, Schroeder, Barzilay, et al., 2015](#)). Plot the course of labor on a labor graph so an unusually long first stage, suggesting cephalopelvic disproportion, can be recognized. [Chapter 51](#) discusses in detail the nursing care of adolescents following surgery to have rods inserted.

## Endocrine Disorders and Pregnancy

Endocrine disorders have the potential to be serious complications of pregnancy because enzymes and hormones control so many specific body functions ([Krassas, Karras, & Pontikides, 2015](#)).

## A WOMAN WITH A THYROID DYSFUNCTION

As a normal effect of pregnancy, the thyroid gland enlarges (i.e., hypertrophies) slightly because of increased vascularity and blood flow. A woman with a preexisting thyroid illness may have difficulty making this pregnancy transition.

### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for maternal and fetal injury related to preexisting thyroid disorder during pregnancy

**Outcome Evaluation:** No congenital anomalies are present in infant at birth; Apgar score is 7 to 10. Mother continues prepregnancy level of activities.

Thyroid function is necessary for the regulation of almost all body functions. Problems that affect pregnancy are either those of too little thyroid response (i.e., hypothyroidism) or too great a response (i.e., hyperthyroidism).

### A Woman With Hypothyroidism

Hypothyroidism, or underproduction of the thyroid hormone, is a rare condition in late adolescents and especially rare in pregnancy because women with symptoms of untreated hypothyroidism are often anovulatory and unable to conceive. A woman who does conceive can then face another obstacle in that she can have difficulty increasing thyroid functioning to a necessary pregnancy level, which can then lead to early spontaneous miscarriage. Women with hypothyroidism fatigue easily, tend to be obese, their skin is dry (myxedema), and they have little tolerance for cold. It may be associated with an increased incidence of extreme nausea and vomiting (i.e., hyperemesis gravidarum).

Most women with hypothyroidism take levothyroxine (Synthroid) to supplement their lack of thyroid hormone. A woman who is taking levothyroxine needs to consult with her primary care provider when she is planning on becoming pregnant to be certain her dose of this will be high enough to sustain a pregnancy. She needs to come for an early diagnosis and close follow-up as soon as she suspects she is pregnant (1 week past her missed menstrual period). As a rule, her dose of levothyroxine will need to be increased as much as 20% to 30% for the duration of the pregnancy to simulate the increase that would normally occur in pregnancy (Kraut & Farahani, 2015). Be certain a woman realizes the importance of taking this increased dose. Also, caution women that they should take levothyroxine at a different time from any medication containing iron, calcium, or any soy product by about 4 hours to be certain there is no problem with the absorption of the drug (Karch, 2015).

After the pregnancy, the dose of levothyroxine prescribed for pregnancy must be

gradually tapered back to the prepregnancy level for both her health and so she can breastfeed safely. Be certain a woman does not continue to take her pregnancy dose (e.g., in trying to be economical and use up her higher dose pills), or she could pass beyond normal thyroid function and develop hyperthyroidism.

### **A Woman With Hyperthyroidism**

Hyperthyroidism, or overproduction of thyroid hormone, causes symptoms such as a rapid heart rate, exophthalmos (i.e., protruding eyeballs), heat intolerance, heart palpitations, and weight loss. Sometimes called Graves disease, it is more apt to be seen in pregnancy than is hypothyroidism. If undiagnosed, a woman may develop heart failure because her heart, already stressed, cannot manage the increasing blood volume that occurs with pregnancy. She is also more prone than the average woman to symptoms of gestational hypertension, fetal growth restriction, and preterm labor.

Hyperthyroidism is normally diagnosed by a nuclear medicine imaging study involving the radioactive uptake of  $^{131}\text{I}$  subtype. This diagnostic procedure should not be used during pregnancy because the fetal thyroid would also incorporate this drug, possibly resulting in destruction of the fetal thyroid. Treatment for hyperthyroidism is with thioamides (methimazole [Tapazole] or propylthiouracil [PTU]), which reduce thyroid activity. These drugs, unfortunately, cross the placenta and can lead to congenital hypothyroidism and, consequently, an enlarged thyroid gland (i.e., a goiter) in the fetus. Women should be regulated on the lowest possible dose of the drug and cautioned to keep a careful record of doses taken so they do not forget or unintentionally duplicate a dose, because if a goiter in the fetus enlarges enough, it can obstruct the airway and make resuscitation difficult at birth. Methimazole is the preferred drug for pregnant women as it appears to cross the placenta less easily (Andersen, Olsen, & Laurberg, 2016).

If hyperthyroidism is not regulated during pregnancy, an infant may be born with symptoms of hyperthyroidism because of the excess stimulation he or she receives in utero. The newborn may appear jittery with tachypnea and tachycardia. An assay of fetal cord blood will reveal the level of thyroxine ( $\text{T}_4$ ) and thyroid-stimulating hormone and the need for therapy in the infant. Women receiving smaller or minimal doses of antithyroid drugs may breastfeed, although women receiving large doses of these drugs may be advised not to breastfeed because they are excreted in breast milk (Prunty, Heise, & Chaffin, 2016).

Surgical treatment to reduce the functioning of the maternal thyroid gland can be accomplished, but this is generally not the treatment of choice during pregnancy because of the need for general anesthesia. After a pregnancy, if a woman desires other children, the procedure might be suggested as an interpregnancy procedure so she does not enter a second pregnancy with hyperthyroidism.

### **A WOMAN WITH DIABETES MELLITUS**

Diabetes mellitus is an endocrine disorder in which the pancreas cannot produce adequate insulin to regulate body glucose levels. The disorder affects 3% to 5% of all pregnancies and is the most frequently seen medical condition in pregnancy (Bradley, Duprey, & Castorino, 2016). It is increasing in incidence as more and more obese adolescents develop type 2 diabetes (Klingensmith, Pyle, Nadeau, et al., 2016).

Before insulin was produced synthetically in 1921, women with type 1 diabetes (i.e., diabetes acquired in childhood) died before reaching childbearing age, were subfertile, or had spontaneous miscarriages early in pregnancy. Now that both type 1 and type 2 diabetes can be well managed, three new challenges have developed:

- How to manage both type 1 and type 2 diabetes during pregnancy to achieve a healthy glucose/insulin balance during pregnancy
- How to protect an infant in utero from the adverse effects of increased glucose levels
- How to care for the infant in the first 24 hours after birth until the infant's insulin–glucose regulatory mechanism stabilizes

Reproductive planning may be a fourth concern, as women with diabetes may not be good candidates for oral contraceptives because progesterone interferes with insulin activity and therefore increases blood glucose levels.

### **Pathophysiology and Clinical Manifestations**

The possible etiology and pathology of diabetes mellitus are discussed in detail in [Chapter 48](#). The primary concern for any woman with this disorder is controlling the balance between insulin and blood glucose levels to prevent hyperglycemia or hypoglycemia. Both of these conditions are dangerous during pregnancy not only because of long-term effects on the woman's health but also because of the threat to normal fetal growth. Infants of women with unregulated diabetes are five times more apt to be born large for gestational age or with birth anomalies (Ornoy, Reece, Pavlinkova, et al., 2015).

If a woman's insulin production is insufficient, glucose cannot be used by body cells. The cells register the need for glucose, and the liver quickly converts stored glycogen to glucose to increase the serum glucose level. Because insulin is still not available, however, the body cells still cannot use the glucose, so the serum glucose levels rise (i.e., hyperglycemia). When the level of blood glucose reaches 150 mg/100 ml (normal level is 80 to 120 mg/dl), the kidneys begin to excrete quantities of glucose in the urine (i.e., glycosuria) in an attempt to lower the level. This causes large quantities of fluid to be excreted with urine (i.e., polyuria).

As dehydration begins to occur, the blood serum becomes concentrated and the total blood volume decreases. With the reduced blood flow, cells do not receive adequate oxygen, and anaerobic metabolic reactions cause large stores of lactic acid to pour out of muscles into the bloodstream. To replace needed glucose, fat is mobilized from fat stores and metabolized for energy, pouring large amounts of acidic ketone bodies into the bloodstream.

As the process continues, protein stores are tapped in a final attempt to find a source of energy. Utilizing protein for energy this way reduces the supply of protein to body cells. As cells die, they release potassium and sodium, which is lost from the body in the extensive polyuria. These factors combined create an immediate severe metabolic acidosis. Long-term effects are vascular narrowing that leads to kidney, heart, and retinal dysfunction.

## Diabetes During Pregnancy

In type 1 diabetes, which, although unproven, is probably an autoimmune disorder because marker antibodies are present, the pancreas fails to produce adequate insulin for body requirements (Gururaj Setty, Crasto, Jarvis, et al., 2016). In type 2 diabetes, there is a gradual loss of insulin production, but some ability to produce insulin will still be present.

Women with either type 1 or type 2 diabetes who have successful regulation of glucose and insulin metabolism before pregnancy are apt to develop less-than-optimal control during pregnancy because all women experience several changes in the glucose–insulin regulatory system as pregnancy progresses. In all pregnancies, the glomerular filtration of glucose is increased (the glomerular excretion threshold is lowered), causing slight glycosuria. The rate of insulin secretion is increased, and the fasting blood sugar level is lowered. All women appear to develop an insulin resistance as pregnancy progresses or insulin does not seem as effective during pregnancy, a phenomenon that is probably caused by the presence of the hormone human placental lactogen (i.e., chorionic somatomammotropin) and high levels of cortisol, estrogen, progesterone, and catecholamines. This resistance to or destruction of insulin is helpful in a healthy pregnancy because it prevents the maternal blood glucose from falling to dangerous limits. It causes difficulty for a pregnant woman with diabetes because she must then increase her insulin dosage beginning at about week 24 of pregnancy to prevent hyperglycemia.

At the same time, she must guard against **hypoglycemia** (i.e., lowered serum glucose levels) and ketoacidosis caused by the constant use of glucose by the fetus. If a woman has preexisting kidney disease (revealed by proteinuria, decreased creatinine clearance, and hypertension), the risk of hypertension of pregnancy rises markedly (Au, Raynes-Greenow, Turner, et al., 2016).

Infants of women with poorly controlled diabetes tend to be large (>10 lb) because the increased insulin the fetus must produce to counteract the overload of glucose he or she receives acts as a growth stimulant. Hydramnios may develop because a high glucose concentration causes extra fluid to shift and enlarge the amount of amniotic fluid. A macrosomic infant may create birth problems at the end of the pregnancy because of cephalopelvic disproportion. This, combined with an increased risk for shoulder dystocia, may make it necessary for infants of women with diabetes to be born by cesarean birth.

There is also a high incidence of congenital anomaly, especially caudal regression

syndrome (failure of the lower extremities to develop), spontaneous miscarriage, and stillbirth in women with uncontrolled diabetes. At birth, neonates are more prone to hypoglycemia, respiratory distress syndrome, hypocalcemia, and hyperbilirubinemia. The first trimester of pregnancy is the most important time for fetal development; if a woman can be kept from becoming hyperglycemic during this time, the chances of a congenital anomaly are greatly lessened (Box 20.6) (Ornoy et al., 2015).

**BOX 20.6**

**Nursing Care Planning Using Assessment**

**ASSESSING A PREGNANT WOMAN WITH DIABETES MELLITUS**

**Classification of Diabetes Mellitus**

Diabetes is divided into various categories that can be used to predict a pregnancy outcome (Table 20.2). Approximately 2% to 3% of all women who do not begin a

pregnancy with diabetes develop the condition during pregnancy, usually at the midpoint of pregnancy when insulin resistance becomes most noticeable. This is termed *gestational diabetes mellitus* (Landon, Catalano, & Gabbe, 2012). The symptoms fade again at the completion of pregnancy, but the risk of developing type 2 diabetes later in life may be as high as 50% to 60%. It is unknown whether gestational diabetes results from inadequate insulin response to carbohydrate, from excessive resistance to insulin, or from a combination of both. Risk factors for developing gestational diabetes include:

- Obesity
- Age over 25 years
- History of large babies (10 lb or more)
- History of unexplained fetal or perinatal loss
- History of congenital anomalies in previous pregnancies
- History of polycystic ovary syndrome
- Family history of diabetes (one close relative or two distant ones)
- Member of a population with a high risk for diabetes (Native American, Hispanic, Asian)

**TABLE 20.2 CLASSIFICATION OF DIABETES MELLITUS**

Class	Description
Type 1	A state characterized by the destruction of the beta cells in the pancreas that usually leads to absolute insulin deficiency. <ul style="list-style-type: none"> <li>a. Immune-mediated diabetes mellitus results from autoimmune destruction of the beta cells.</li> <li>b. Idiopathic type 1 refers to forms that have no known cause.</li> </ul>
Type 2	A state that usually arises because of insulin resistance combined with a relative deficiency in the production of insulin.
Gestational diabetes	A condition of abnormal glucose metabolism that arises during pregnancy. Possible signal of an increased risk for type 2 diabetes later in life.
Impaired glucose homeostasis	A state between “normal” and “diabetes” in which the body is no longer using and/or secreting insulin properly. <ul style="list-style-type: none"> <li>a. Impaired fasting glucose: a state when fasting plasma glucose is at least 110 but under 126 mg/dl</li> <li>b. Impaired glucose tolerance: a state when results of the oral glucose tolerance test are at least 140 but under 200 mg/dl in the 1-hour sample</li> </ul>

From American Diabetes Association. (2011). Summary of revisions to the 2011 clinical practice recommendations. *Diabetes Care*, 34(Suppl. 1), S3.

### Assessment

Because diabetes is such a serious complication in pregnancy, all women should be

screened during pregnancy for gestational diabetes. A fasting plasma glucose greater than or equal to 126 mg/dl or a nonfasting plasma glucose greater than or equal to 200 mg/dl meets the threshold for the diagnosis of diabetes and does not need confirmation. It is recommended that all pregnant women receive a 50-g **glucose challenge test** between 24 and 28 weeks gestation to determine if they are at risk for gestational diabetes. If the result of that test is 140 mg/dl (some providers use 130 mg/dl as the cutoff), then the woman will need to do a three hour glucose tolerance test.

For this, after a fasting glucose sample is obtained, the woman drinks an oral 100-g glucose solution; a venous blood sample is then taken for glucose determination at 1, 2, and 3 hours later. If two of the four blood samples collected for this test are abnormal or the fasting value is above 95 mg/dl, a diagnosis of diabetes is made. The values that confirm diabetes are reviewed in [Table 20.3](#).

**TABLE 20.3 ORAL GLUCOSE CHALLENGE TEST VALUES (FASTING PLASMA GLUCOSE VALUES) FOR PREGNANCY FOLLOWING A 100-g GLUCOSE SOLUTION**

Test Type	Pregnant Glucose Level (mg/dl)
Fasting	95
1 hr	180
2 hr	155
3 hr	140

### Monitoring a Woman With Diabetes

A woman with diabetes (type 1 or type 2) before pregnancy should meet with her primary healthcare provider prior to becoming pregnant; during this period, her condition can be well regulated so that hyperglycemia does not develop during the early weeks of pregnancy, when the tendency for congenital anomalies in the fetus is highest. A woman should use a home test kit to determine she is pregnant so she knows this at the earliest possible time. The best insulin control program for her during pregnancy can then be determined. The measurement of **glycosylated hemoglobin (HbA1c)**, a measure of the amount of glucose attached to hemoglobin, is used to detect the degree of hyperglycemia present. Measuring HbA1c is advantageous not just because it offers a present value of glucose, but because it reflects the average blood glucose level over the past 4 to 6 weeks (i.e., the time the hemoglobin in red blood cells were picking up the glucose). The upper normal level of HbA1c is 6% of total hemoglobin.

A urine culture may be done each trimester to detect asymptomatic UTIs as the increased glucose concentration in urine may lead to increased infection. An ophthalmic examination should be done once during the pregnancy for a woman with gestational diabetes and at each trimester for women with known diabetes because common background retinal changes that are common in diabetes, such as increased exudate

(Fig. 20.4), dot hemorrhage, and macular edema, can progress or originate during pregnancy. Laser therapy to halt these changes can be done during pregnancy without risk to the fetus.

**Figure 20.4** Increased exudate in the retina can occur with progressing diabetes during pregnancy. It appears as a “cloud-like” finding obscuring a retinal vessel.

## Nursing Diagnoses and Related Interventions

Because diabetes is such a complex disorder, associated nursing diagnoses are many and varied. Examples include:

- Risk for ineffective tissue perfusion related to reduced vascular flow
- Imbalanced nutrition, less than body requirements, related to inability to use glucose
- Risk for ineffective coping related to required change in lifestyle
- Risk for infection related to impaired healing accompanying condition
- Deficient fluid volume related to polyuria accompanying the disorder
- Deficient knowledge related to complex health problem
- Health-seeking behaviors related to voiced need to learn home glucose monitoring

The following nursing diagnosis and related interventions illustrate one of the most important facets of the nurse’s role in caring for the pregnant woman with diabetes: health teaching. Important topics include nutrition, exercise, insulin administration, blood glucose monitoring, and explanations of the various fetal assessment tests that will be done. [Box 20.7](#) shows an interprofessional care map illustrating both nursing and team planning for a woman with diabetes.

**AN INTERPROFESSIONAL CARE MAP FOR A WOMAN WITH MULTIPLE THREATS TO PREGNANCY**

Angelina Gomez, 22 years old, is pregnant with her first child. She fainted this afternoon while participating in an aerobics class.

**Family Assessment:** Patient lives with the 30-year-old father of her child, Josh. She works as a fundraiser for a movie producer. Josh works as an animation artist. Finances are rated as “workable.” She fainted this afternoon while participating in her weekly hour-long aerobics class.

**Patient Assessment:** Patient had rheumatic fever with mitral stenosis as a child. She developed gestational diabetes early in this pregnancy. Her serum glucose level is 207 mg/dl; her blood pressure (BP) is 100/60 mmHg. A uterine monitor shows moderate-strength uterine contractions 7 minutes apart; fetal heart rate (FHR) is 167 beats/min. She asks you, “If exercise is supposed to be good for you, why did this happen?”

**Nursing Diagnosis:** Risk for ineffective tissue perfusion (peripheral) related to lowered blood pressure secondary to mitral stenosis and gestational diabetes

**Outcome Criteria:** BP returns to 120/70 mmHg; pulse rate at 70 to 90 beats/min; fetal heart rate at 110 to 160 beats/min. Serum glucose is less than 126 mg/dl; labor is halted.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse/primary care provider	Assess whether patient understands it is healthy for her to exercise regularly.	Review with patient the need for consistent diet and exercise to regulate glucose during pregnancy.	Strenuous exercise increases cardiac output, placing additional workload on the heart.	Patient describes a more consistent exercise program to use during pregnancy rather than a once-per-week aerobics class.
<i>Teamwork and Collaboration</i>				
Nurse/emergency room medical care provider	Telephone pregnancy and cardiac care	Coordinate care with pregnancy and cardiac	Collaboration with pregnancy	Both pregnancy and cardiac care providers

	providers and alert them to patient's admission.	healthcare providers who know patient best.	and cardiac healthcare providers helps ensure a healthy outcome for the woman and fetus.	contact emergency staff to coordinate care.
--	--	---	--	---

*Procedures/Medications for Quality Improvement*

Nurse/emergency room medical care provider	Monitor patient's BP, pulse rate, FHR, and uterine contractions by continuous monitoring.	Determine patient progress by monitor and physical exam. Inform patient of signs of beginning labor.	Increased FHR (tachycardia) is a sign of possible fetal distress. Uterine contractions could mark the beginning of preterm labor.	Patient voices an understanding labor may be beginning; has confidence in emergency room (ER) staff to manage her condition until her primary care provider arrives.
Nurse/cardiac ultrasound technician/consulting medical care provider	Explain process of echocardiogram to document mitral valve function.	Assure patient echocardiogram is safe during pregnancy. Assist as necessary.	Mitral valve stenosis can lower blood pressure by not allowing adequate blood flow to aorta.	Echocardiogram is recorded in an expedient manner.

*Nutrition*

Nurse	Assess serum glucose every 15 minutes by finger stick.	Document pattern of blood glucose. Administer intravenous (IV) fluid, insulin additive as prescribed.	Correcting blood glucose is vital to both maternal and fetal well-being.	Patient's serum glucose is maintained within normal level within 45 minutes.
-------	--	---	--	--

*Patient-Centered Care*

Nurse	Assess patient's understanding that her complex situation (both cardiac and diabetes disorders) could be compromising her pregnancy.	Educate patient about need for rest in lateral recumbent position until condition is stabilized.	Activity restriction can help prevent uteroplacental insufficiency and supine hypotension syndrome.	Patient voices she understands need for continuous monitoring and rest. Complies with position for rest.
-------	--	--	---	--

*Psychosocial/Spiritual/Emotional Needs*

Nurse	Assess the patient's main support person and ask if she would like him or her notified.	Locate support person and invite him or her to join patient in emergency department.	Anxiety and stressors can increase the workload of the heart. Support person can be instrumental in reducing stress.	Support person arrives and works with staff to alleviate anxiety.
-------	---	--	--	---

*Informatics for Seamless Healthcare Planning*

Nurse/primary care provider	Assess if patient is aware of need for admittance to hospital to continue monitoring.	Assist patient in transfer to hospital unit.	Continuous monitoring is necessary to detect if uterine contractions and preterm birth were halted.	Patient is satisfactorily transferred to hospital unit for further monitoring and care.
-----------------------------	---	--	---	---

**Nursing Diagnosis:** Deficient knowledge related to a therapeutic regimen necessary during pregnancy

**Outcome Evaluation:** Patient states importance of careful attention to nutrition, exercise, and home monitoring of glucose levels during pregnancy; describes nutrition and exercise program; states intention to keep nutrition and exercise constant.

*Education Regarding Nutrition During Pregnancy.* Women with diabetes need to be aware of how much carbohydrate they eat daily by estimating the total carbohydrate each anticipated meal will contain and then administer a number of units of insulin prior to that based on a predetermined insulin-to-carbohydrate ratio. As children also need to adjust insulin amounts to carbohydrate ratios, carbohydrate counting is discussed in [Chapter 48](#).

Dietary control, or maintaining an adequate glucose intake so hypoglycemia does not occur, may be extremely difficult early in pregnancy because of nausea and vomiting. A 1,800- to 2,400-calorie diet (or one calculated at 30 kcal/kg of ideal weight), divided into three meals and three snacks to try and keep carbohydrate evenly distributed during the day so the glucose level remains constant, is a typical nutrition regimen during pregnancy. Ideally, 20% of dietary calories should be from protein, 40% to 50% from carbohydrate, and up to 30% from fat ([Dornhorst & Williamson, 2012](#)).

In addition, a woman's diet should be certain to include a reduced amount of saturated fats and cholesterol and an increased amount of dietary fiber. Increasing fiber decreases postprandial hyperglycemia and so lowers insulin requirements. Women are extremely vulnerable to hypoglycemia at night during pregnancy because of the continuous fetal use of glucose during the time they sleep. Urge a woman to make her final snack of the day one of protein and a complex carbohydrate (e.g., an egg and whole grain toast, hummus and whole grain crackers) to allow slow digestion during the night. If a woman cannot eat because of vomiting or nausea early in pregnancy or heartburn in later pregnancy, she should immediately notify her healthcare provider as she may need temporary intravenous fluid and glucose supplementation. Later in pregnancy, she must be extremely nutrition conscious to maintain good control of glucose levels and to keep her weight gain to a suitable amount (approximately 25 to 30 lb) in the hope of limiting the size of her infant and making a vaginal birth possible. Urge women, however, not to reduce their intake to below 1,800 calories during pregnancy as an intake this low in carbohydrates can lead to fat breakdown and acidosis.

### *What If... 20.3*

**Angelina develops gestational diabetes. She's resistant to learn much about her condition, though, because she knows her symptoms are only temporary and will fade at the end of pregnancy. What type of teaching plan would the nurse devise to help her learn in the face of this attitude?**

*Education Regarding Exercise During Pregnancy.* Exercise is another mechanism that lowers serum glucose levels and, therefore, the need for insulin. If a woman begins an exercise program for the first time during pregnancy, she may notice

excessive glucose fluctuations at first. Therefore, it's best if she begins her exercise program before pregnancy, when glucose fluctuation can be evaluated and food and snacks adjusted accordingly before a fetus is involved.

With exercise, blood glucose levels decrease because the muscles increase their need for glucose, an effect which lasts for at least 12 hours after exercise. If the arm in which a woman injected insulin is actively exercised, the insulin is released so quickly that it can cause hypoglycemia. To avoid this phenomenon, a woman should eat a snack consisting of a protein or complex carbohydrate before exercise and should maintain a consistent exercise program—she should not do aerobic exercises one day and then none the next, but rather, do 30 minutes of walking every day. In a woman with poor blood glucose control, extreme exercise will cause hyperglycemia and ketoacidosis as the liver both releases glucose and breaks down fatty acids in an attempt to supply enough energy for the exercise, yet the body cannot use them because of inadequate insulin.

## Unfolding Patient Stories: Amelia Sung • Part 2

Think back to **Amelia Sung**, who, as you learned in **Chapter 8**, is 36 years old and gravida 2 para 1. She is diagnosed with gestational diabetes mellitus at 26 weeks. Explain the areas of education the nurse should provide on diabetes management. How does the nurse evaluate Amelia's understanding of the information provided and her ability to manage diabetes and maintain normal glucose levels?

Care for Amelia and other patients in a realistic virtual environment: *vSim for Nursing* ([thepoint.lww.com/vSimMaternityPed](http://thepoint.lww.com/vSimMaternityPed)). Practice documenting these patients' care in DocuCare ([thepoint.lww.com/DocuCareEHR](http://thepoint.lww.com/DocuCareEHR)).

### Therapeutic Management

Because blood glucose levels near normal help minimize the risk of maternal and fetal complications, both women with gestational diabetes and those with overt diabetes need more frequent prenatal visits than usual to ensure close monitoring of their condition and that of the fetus (**Table 20.4**).

**TABLE 20.4 THERAPEUTIC MANAGEMENT OF DIABETES DURING PREGNANCY**

	Description	Methods	Precautions
Insulin therapy	Needed by pregestational and gestational diabetics who are	Short-acting insulin may be used alone or with an intermediate type. Two thirds of daily	Early in pregnancy, insulin needs may be less. Later in pregnancy,

	uncontrolled with diet or oral therapy. Necessary for the cells to take glucose from the bloodstream	insulin needs are given before breakfast and one third before dinner. Insulin should be given subcutaneously and at a 90-degree angle to the skin. The injection site should generally be the same each injection (arms OR legs OR abdomen).	increased insulin may be needed. Women should eat immediately after injecting insulin to avoid hypoglycemia. Different body areas take up insulin at different rates. Rotate within the same type of injection site.
Blood glucose monitoring	Completed four times a day by the patient. The patient pricks her finger and uses a glucometer to determine her blood glucose. She should track these numbers with a chart and bring it to her OB visits. Her provider will determine if any adjustments in her insulin or oral diabetic regimen are needed.	The patient should obtain fasting and 1-hour postprandial values. Her goals include fasting numbers that are 90 and below and postprandial values that are less than 140.	If the patient is hypoglycemic, she should have some carbohydrate rich food, like crackers, and a protein, like milk. Simple sugars can create hyperglycemia and rebound hypoglycemia.
Insulin pump therapy (Fig. 20.5)	An insulin pump is an automatic pump with thin tubing, which is placed subcutaneously, most often on the woman's abdomen. Insulin is given through this tube and injection of insulin is therefore eliminated.	A continuous rate (basal) of insulin is given to the patient through the pump, and the patient can program the pump to give extra doses as boluses prior to meals or correctional doses related to her blood glucose values after meals.	The patient should clean the site daily and cover it with a dressing to keep it clean. The site also needs to be changed every 24–48 hr to ensure optimal absorption and decrease infection.

**Figure 20.5** Using an insulin pump during pregnancy is the best assurance that insulin levels will remain constant.

### Tests for Placental Function and Fetal Well-Being

Monitoring of fetal well-being will be individualized depending on the woman's overall health. Because women with diabetes tend to have infants with a higher than normal incidence of birth anomalies, a woman will have a serum  $\alpha$ -fetoprotein level obtained at 15 to 17 weeks to assess for a neural tube defect and an ultrasound examination performed at approximately 18 to 20 weeks to detect gross abnormalities. A creatinine clearance test may be ordered each trimester. A normal creatinine clearance rate suggests a woman's vascular system is intact because kidney function is normal. By default, this also implies uterine perfusion is also adequate. Placental functioning may also be assessed by a weekly nonstress test or biophysical profile during the last trimester of pregnancy (see [Chapter 9](#)) if a woman is in good control, or a daily nonstress test if her regulation is poor.

In addition, a woman may be asked to self-monitor fetal well-being by recording how many movements occur an hour (usually about 10 fetal kicks) (see [Chapter 9](#)). Be certain she understands that fetal activity varies depending on her activity and meal patterns to prevent her from becoming frightened by normal variations. An ultrasound examination may be taken at week 28 and then again at weeks 36 to 38 to determine fetal growth, amniotic fluid volume, placental location, and biparietal diameter. Oligohydramnios (i.e., a small amount of amniotic fluid) may indicate fetal growth restriction or a fetal renal abnormality, whereas polyhydramnios (i.e., an excessive amount of amniotic fluid) may indicate gastrointestinal malformation or poorly controlled disease. A lecithin/sphingomyelin ratio by amniocentesis is usually performed by week 36 of pregnancy to assess fetal maturity. In pregnancies complicated

by diabetes, this ratio tends not to show maturity as early as in other pregnancies probably because the synthesis of phosphatidylglycerol, the compound that stabilizes surfactant, is delayed if hyperglycemia is present.

Because lung surfactant does not appear to form as early in these fetuses as in others, the presence of phosphatidylglycerol, an ingredient of surfactant, at amniocentesis is used to indicate lung maturity for these infants. Although it is known that administering corticosteroids to the mother during the last week of pregnancy can hasten lung maturity, corticosteroids may also impair fetal insulin release and perhaps fetal pancreatic islet development. Therefore, with a fetus who already has a risk at birth from poor glucose control, corticosteroid use to improve lung maturity is not usually recommended.

Fetal surveillance can be both difficult and time-consuming for a woman. Having to wait during each weekly test to hear how her fetus is doing is emotionally draining, especially for a woman who believes it is somehow her fault all the tests are necessary (it is, after all, her diabetes). She needs support people with her to minimize the feeling she is alone and without support in this crisis.

### **Timing for Birth**

Among the most hazardous times for a fetus during a diabetes-involved pregnancy are weeks 36 to 40 of pregnancy, when the fetus is drawing large stores of maternal nutrients because of his or her large size. In the past, many infants were birthed early by routine cesarean birth at 37 weeks gestation to prevent fetal loss from placental insufficiency during these final weeks; unfortunately, if the fetus was still immature, this relieved one concern but created another, such as respiratory distress syndrome in the infant (infants of women with diabetes may be more prone to this than usual because surfactant is not as mature).

Cesarean birth was chosen because it is difficult to induce labor this early in pregnancy because the cervix is not yet ripe or responsive to labor contractions; babies of women with diabetes are large, making vaginal birth difficult; and a fetus suffering placental dysfunction or insufficiency did not do well in labor.

Today, when an accurate assessment of fetal age is available by amniocentesis and the pregnancy can be maintained within safe limits by the use of nonstress testing for a longer period, the last weeks of pregnancy are not as hazardous as before, and the timing and type of birth is much more individualized.

If at all possible, vaginal birth is preferred. Labor may be induced by rupture of the membranes or an oxytocin infusion after measures to induce cervical ripening (see [Chapter 23](#)). Both labor contractions and fetal heart sounds need to be conscientiously monitored during labor to ensure early detection of placental dysfunction. A woman's glucose level is regulated during labor by an intravenous infusion of short-acting or regular insulin with frequent blood glucose assays to prevent hypoglycemia in the mother or rebound hypoglycemia in the newborn (see [Chapter 26](#) for care of the infant of a woman with diabetes at birth).

If a woman will be given an epidural anesthetic, use of an intravenous glucose solution as a plasma volume expander should be avoided to prevent hyperglycemia from developing; Ringer's lactate or 0.9% saline is infused instead.

## Postpartum Adjustment

During the postpartum period, a woman who came into pregnancy with diabetes must undergo yet another readjustment to insulin regulation. With insulin resistance gone, often she needs no insulin during the immediate postpartum period; in another few days, however, she will return to her prepregnant insulin requirements. One- or 2-hour postprandial blood glucose determinations help to regulate how much insulin she needs during this adjustment period. A woman with gestational diabetes usually demonstrates normal glucose values by 24 hours after birth and then will need no further diet or insulin therapy. She requires careful observation, however, during the immediate postpartum period because if polyhydramnios was present during pregnancy, she is at risk of hemorrhage from poor uterine contraction. Women with diabetes may breastfeed because insulin is one of the few substances that does not pass into breast milk from the bloodstream (Gururaj Setty et al., 2016).

Because a woman who has had gestational diabetes is at risk for developing type 2 diabetes later in life, she should have glucose testing done during health maintenance visits throughout life. Be certain that women receive contraceptive information as appropriate. Remind women with ongoing diabetes before they plan a second pregnancy that they will need to be certain their disease is stabilized and in good control.

### QSEN Checkpoint Question 20.5

#### INFORMATICS

Angelina is prescribed an insulin pump to administer insulin for her gestational diabetes. What patient education would the nurse want to provide to explain why nighttime is a particularly hazardous time for her fetus during pump therapy?

- The fetus can develop hyperglycemia from excessive insulin administration.
- Continuous insulin administration with no food intake can lead to hypoglycemia.
- Her lack of exercise at night tends to lead to hypercalcemia from muscle disuse.
- Her lack of fluid intake during the night causes a relative increase in serum insulin levels.

Look in *Appendix A* for the best answer and rationale.

## Mental Illness and Pregnancy

Mental illness may precede or occur with pregnancy the same as it can at any point in life. Schizophrenia tends to have its highest incidence in adolescents and late

adolescents and so may occur in young pregnant women. Depression occurs almost four times more commonly in women than in men and often in late adolescents, making it the most common mental illness seen in pregnant women.

Even normal levels of stress make it difficult to use effective coping mechanisms, so pregnancy or childbirth may be the additional stress that reveals mental illness for the first time. Because of this, a woman with a psychiatric disorder is best cared for by a team approach, including both a psychiatric care team and a prenatal care group, to ensure the stress of pregnancy is not exacerbating the mental illness and that distorted perceptions or depression do not complicate the pregnancy. Any psychotropic medication taken by a pregnant woman should be evaluated before pregnancy for possible fetal harm (Urato, 2015). For example, lithium, a mainstay of therapy for mood disorders such as bipolar disorder, and serotonin-reuptake inhibitors used to counteract depression, are potentially teratogenic (Karch, 2015).

As the care of a newborn requires such a major life change, mental illness may also occur in the postpartum period (postpartum depression or psychosis are discussed in Chapter 25).

### *QSEN Checkpoint Question 20.6*

#### **EVIDENCE-BASED PRACTICE**

Women who have had a complication of pregnancy have the potential to develop depression in the postpartal period because their pregnancy did not go the way they wanted or imagined. To see what factors tend to be associated with depression in women who develop gestational diabetes, researchers administered a questionnaire to 71 women at 4 to 15 weeks postpartum. Results of the study showed that 34% of the women who developed gestational diabetes showed depressive symptoms; factors most associated with depression were cesarean birth and more weight gain than expected during pregnancy (Nicklas, Miller, Zera, et al., 2013).

Based on the previous study, which statement by Angelina would worry the nurse most that she might develop postpartum depression?

- a. “I want to shed some pounds so I’ll fit into the new dress I bought for New Year’s Eve.”
- b. “I hated giving insulin to myself; I’m relieved to not be doing that anymore.”
- c. “My baby is bigger than I expected, but his eyes are beautiful and he’s cute.”
- d. “I think my husband adjusted better to my having diabetes than I did.”

*Look in Appendix A for the best answer and rationale.*

## **Cancer and Pregnancy**

The malignancies most commonly seen with pregnancy are those that occur most frequently in women during childbearing years such as ovarian cancer, uterine cancer, cervical cancer, breast cancer, thyroid cancer, leukemia, melanoma, and Hodgkin

lymphoma (Basta, Bak, & Roszkowski, 2015). Although immunologic mechanisms are altered during pregnancy, there is no evidence that pregnant women are more prone to cancer or that pregnancy changes the course of an existing disease.

If a woman is in the first trimester of pregnancy when a malignancy is diagnosed, she and her partner are asked to make a difficult decision: to delay treatment to avoid teratogenic risks to a fetus from treatment (possibly increasing a woman's risk), to end the pregnancy to allow chemotherapy or radiation treatment to be initiated, or to choose chemotherapy or radiation treatment with the knowledge they may cause birth anomalies in the fetus (Karunaratne, Premaratne, Hapuachchige, et al., 2016).

As a rule, women can receive chemotherapy in the second and third trimesters without adverse fetal effects. In contrast, radiation therapy, another modality that is a mainstay of cancer therapy, puts the fetus at risk throughout pregnancy if the fetus is directly exposed.

A biopsy to confirm the diagnosis or surgery to remove a tumor can be completed during pregnancy with the understanding the fetus is at some risk for anoxia if a general anesthesia is used. Cervical conization for cervical cancer has a particularly high fetal risk because the surgery may directly disrupt the pregnancy. With a vaccine against human papillomavirus (HPV) now available, cervical cancer incidence should be seen much less in the future (Luckett & Feldman, 2016). Following surgery of any kind, a woman is at a higher risk of thrombus formation because of the increased coagulation process accompanying pregnancy.

Cancer in a woman does not appear to metastasize to the fetus. This is because the placenta serves as a barrier against this spread and also because the fetus may be capable of resisting the invasion of the foreign cells. Melanoma is the exception to this, as this does seem capable of spreading to the fetus (Jeremić, Jeremić, Stefanović, et al., 2015).

#### *What If . . . 20.4*

**The nurse is interested in exploring one of the 2020 National Health Goals related to acquired health disorders and pregnancy (see Box 20.1). Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to Angelina's family and that would also advance evidence-based practice?**

## **KEY POINTS FOR REVIEW**

- When women with a preexisting disease become pregnant, it is crucial to obtain a thorough history and physical examination at the first prenatal visit to establish a baseline of information on the condition. Documentation by a medication reconciliation form of any medication being taken is important to protect against

adverse drug interactions and the possibility of teratogenic effects on the fetus.

- Teaching is an important nursing intervention because a woman with a preexisting illness must modify her usual therapy to adjust to pregnancy. Health teaching and how it affects women's overall health helps in planning nursing care that not only meets QSEN competencies but also best meets the family's total needs.
- Because blood volume increases by as much as 50% during pregnancy, cardiac function may become inadequate if cardiovascular disease is present. Cardiac illnesses that cause difficulty can be either acquired disorders such as Kawasaki disease and rheumatic fever or congenital disorders such as mitral valve stenosis and coarctation of the aorta.
- Iron-deficiency anemia, sickle-cell anemia, and folic acid-deficiency anemia are examples of various forms of anemia that can also cause complications of pregnancy. Such anemias can result in fetal distress because of inadequate oxygen transport.
- Urinary tract disorders can lead to pregnancy complications because pregnancy increases the workload of the kidneys. UTIs and chronic renal disease are two disorders that may lead to early pregnancy loss.
- Acute nasopharyngitis, asthma, pneumonia, influenza, and tuberculosis are common respiratory disorders seen in pregnancy. The incidence of tuberculosis is on the increase and special assessments and care are needed for these women.
- Juvenile rheumatoid arthritis and systemic lupus erythematosus are examples of rheumatic disorders seen in pregnancy. These disorders generally require large doses of NSAIDs for therapy. Women taking salicylates are advised to decrease use 2 weeks before birth to avoid bleeding disorders in the newborn and premature closure of the ductus arteriosus.
- Some gastrointestinal illnesses that occur with pregnancy are hiatal hernia, cholecystitis, viral hepatitis, inflammatory bowel disease, and appendicitis. If surgery is necessary for conditions such as cholecystitis or appendicitis, it can be performed by laparoscopic technique during pregnancy, but this may result in preterm labor.
- Recurrent seizures are the most frequently seen neurologic condition during pregnancy. Many drugs used to control seizures are teratogenic. Women need to have their medical regimen evaluated before pregnancy to be certain they are regulated on the fewest medications and the lowest dosages possible.
- The major endocrine disorder seen during pregnancy is diabetes mellitus. Gestational diabetes is diabetes that occurs only during pregnancy.

### CRITICAL THINKING CARE STUDY

Tawnlee Pawlinsky is a 37-year-old G40030, 30-week pregnant woman who comes to your high-risk prenatal clinic for care. She has chronic hypertension and mitral valve insufficiency, which cause her to be short of breath if she hurries up a ladder at her job as a roofer or runs to catch a bus after work. When you talk about pregnancy nutrition with her, she makes a point that she is a vegan. Her hemoglobin is 9 g/ml;

her red blood cells are microcytic and microchromic.

1. Tawnlee is diagnosed as having iron-deficiency anemia. Because she is a vegan, in addition to taking the iron supplement prescribed for her, what foods would you suggest she include daily in meals? Would you suggest she change her eating philosophy for the remainder of pregnancy to include meat?
2. Suppose Tawnlee ran from the bus stop into the clinic to avoid being late for her appointment. As soon as she reached the reception desk, she fell to the floor. You realize she needs cardiopulmonary resuscitation (CPR). What rate of respiratory/cardiac ratio would you use because she is 30 weeks pregnant?
3. Tawnlee is concerned because she was prescribed enalapril for hypertension before pregnancy but was changed to methyldopa at her prepregnancy consultation. She doesn't feel confident methyldopa will work as well, and she fears she will grow dizzy working on a roof and fall. Would you assure her the medication change was a good one, or urge her to ask her primary care provider to change the prescription back to enalapril so she feels more secure at work?

## 21

# Nursing Care of a Family Experiencing a Sudden Pregnancy Complication

*Beverly Muzuki, a 20-year-old gravida 2, para 0, 30-week pregnant woman, noticed some mild lower abdominal pain but thought it was irritation from a bladder infection and waited to get help until she went to her scheduled appointment at the hospital. During the night, she woke up twice because of a nagging lower backache. This morning, she has intermittent sharp uterine contractions. “Why am I starting labor so early?” she asks you. “Is it because I’m Rh negative?”*

*Previous chapters described normal pregnancies and preexisting and newly acquired conditions that can complicate pregnancies. This chapter adds knowledge about complications directly related to the pregnancy.*

**Were Beverly’s actions as informed as they could have been? What additional health teaching might have helped her recognize the signs of preterm labor earlier?**

## KEY TERMS

abortion  
ankle clonus  
cervical cerclage  
chorioamnionitis  
Couvelaire uterus  
early pregnancy failure  
eclampsia  
ectopic pregnancy  
erythroblastosis fetalis  
gestational trophoblastic disease  
HELLP syndrome  
hemolytic disease of the newborn  
polyhydramnios  
isoimmunization  
miscarriage

**oligohydramnios**  
**placenta previa**  
**postterm pregnancy**  
**preeclampsia**  
**premature cervical dilatation**  
**premature separation of the placenta**  
**preterm labor**  
**preterm rupture of membranes**  
**recurrent pregnancy loss**  
**Rh incompatibility**  
**tocolytic agent**

## **OBJECTIVES**

**After mastering the contents of this chapter, you should be able to:**

1. Describe sudden complications of pregnancy that place a pregnant woman and her fetus at high risk.
2. Identify 2020 National Health Goals related to complications of pregnancy that nurses can help the nation achieve.
3. Assess a woman who is experiencing a complication of pregnancy.
4. Formulate nursing diagnoses that address the needs of a woman and her family experiencing a complication of pregnancy.
5. Identify expected outcomes to minimize the risks to a pregnant woman and her fetus when a sudden complication of pregnancy occurs as well as manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care specific to a woman who has developed a sudden complication of pregnancy, such as teaching her how to recognize the symptoms of preterm labor.
8. Evaluate expected outcomes for effectiveness and achievement of care.
9. Integrate knowledge of complications of pregnancy with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

---

Most women who enter pregnancy in good health expect to complete a pregnancy and birth without complications. In a few women, however, unexpected deviations or complications from the course of normal pregnancy occur, which place a severe burden

on a woman and her family and her healthcare providers. All families benefit from the support and skill of a professional nurse who helps them work through the stages of pregnancy and prepares them to become new parents. For a family who must take special care to ensure the continuation of pregnancy, the support and skills of a professional nurse are essential to help them carry the baby to term. Hospitalization may be necessary. Once stabilized, a woman has to be monitored carefully until the pregnancy reaches term. As this is done on an ambulatory basis, nurses continue to be instrumental in care (DiMiceli-Zsigmond, Williams, & Richardson, 2015).

The leading complications related directly to pregnancy are thromboembolism, hemorrhage, infection, hypertension of pregnancy, and ectopic pregnancy (Mehta & Sokol, 2013). All of these have the potential to threaten both the life of the mother and the fetus. National Health Goals established to help reduce poor outcomes of complications of pregnancy such as these are shown in Box 21.1.

### BOX 21.1

#### Nursing Care Planning Based on 2020 National Health Goals

Preventing complications of pregnancy is viewed as so important this issue is included in the 2020 National Health Goals.

- Reduce the rate of maternal deaths to 11.4 maternal deaths per 100,000 live births from a baseline of 12.7 per 100,000 live births.
- Reduce the rate of maternal illness and complications because of pregnancy to 28 per 100 births from a baseline of 31.1 per 100 births.
- Reduce the proportion of total preterm births to 11.4% from a baseline of 12.7%.
- Reduce the incidence of low birth weight to 7.1% of live births from a baseline of 8.2% of live births (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Encouraging all women to come for prenatal care is the best preventive measure for eliminating complications of pregnancy. Nurses working in prenatal settings can help to ensure women are well informed about the normal course of pregnancy so they can actively participate in risk assessment at prenatal visits and also recognize and alert healthcare providers if a complication begins.

#### *Nursing Process Overview*

### FOR A WOMAN WHO DEVELOPS A COMPLICATION OF PREGNANCY

#### **ASSESSMENT**

Nurses often are the first healthcare providers to discover a complication of pregnancy. Always ask women at prenatal visits about any symptoms that might indicate a complication such as pain or vaginal symptoms (e.g., leaking of fluid or bleeding). Provide enough time for a thorough health history so more subtle problems

such as headache, blurred vision, or back pains can be discovered and investigated thoroughly. In addition, review the danger signs of pregnancy with women and, if appropriate, significant family members or other support people so potential problems can be recognized early and a healthcare provider can be contacted. Assure women they are free to call whenever they are concerned. Otherwise, they may wait until symptoms become acute rather than call when a symptom is first noticed.

### **NURSING DIAGNOSIS**

Nursing diagnoses pertaining to a woman with a pregnancy complication should reflect both the physical problem and the woman's or family's concern. Some examples include:

- Anxiety related to guarded pregnancy outcome
- Fear of preterm labor ending the pregnancy
- Anticipatory grieving related to uncertain pregnancy outcome
- Deficient knowledge related to signs and symptoms of possible complications
- Risk for infection related to incomplete miscarriage
- Deficient fluid volume related to third-trimester bleeding
- Risk for ineffective tissue perfusion related to gestational hypertension

### **OUTCOME IDENTIFICATION AND PLANNING**

Complications of pregnancy produce emergency situations. Be sure outcomes address both fetal and maternal welfare and often total family welfare. Treatment protocols should be regularly updated and maintained so they are current. Be certain they reflect a current nursing management level, so nurses can act swiftly and independently as needed with lifesaving measures. Once a woman's condition stabilizes, outcome identification can then focus on long-term objectives.

Many women who develop a pregnancy complication may spend a few days in the hospital for therapy and monitoring followed by discharge to their homes. Waiting for a pregnancy that has been threatened this way to come to term can be difficult and fraught with anxiety. Readmission to the healthcare facility, especially when a new complication occurs, compounds these feelings. Be certain planning considers the many feelings this experience can cause. Offer referrals for counseling and/or community support groups for both the woman and her family as needed. Refer patients and their families to helpful websites and other resources when appropriate (see [Chapter 20](#)).

### **IMPLEMENTATION**

Interventions for a woman experiencing a complication of pregnancy require an interprofessional approach that speaks to several different areas:

- Continued both healthy maternal and fetal physical growth
- A woman's and family's psychological health
- Continuation of the pregnancy for as long as possible

Maintaining an optimistic attitude of fetal progress is important so a woman does not begin anticipatory grieving for her fetus, which could halt the growth of bonding.

If the complication can be contained and the pregnancy continues uninterrupted, this can help protect the mental health of the whole family. If the pregnancy cannot be continued, be available to offer support as the family grieves for the loss of an unborn child and, in rare instances, the loss of future childbearing potential or the woman herself.

### **OUTCOME EVALUATION**

After a pregnancy with complications, a woman has reason to be especially worried about her infant's health at the time of birth. Even though the woman may still be ill herself, help her spend enough time with her child to see that, although perhaps born before term, her infant is well and healthy. Pointing out the infant's ability to follow a light and respond to a voice can help her begin to view the baby as the healthy one she anticipated having. And even though the success or failure of some nursing interventions cannot be fully evaluated until a child is born or into the postnatal period, outcomes should be evaluated throughout the pregnancy if possible. Be aware that after a complication of early pregnancy, a woman cannot help but worry for the remainder of the pregnancy the complication will recur or the original insult to the fetus was severe enough to cause long-term effects. Evaluate the woman and her family's attitude and the woman's physical status at each healthcare visit to be certain she and her family are coping with the situation and adjusting psychosocially.

Unfortunately, even with sustained care, not all fetal outcomes will be optimal. Evaluation will then include the ability of the family to care for an ill infant or grieve if a newborn dies. Examples of expected outcomes include:

- Patient's blood pressure is maintained within acceptable parameters for remainder of pregnancy.
- Couple states they feel able to cope with anxiety associated with the pregnancy complication.
- Patient's signs and symptoms of hypertension of pregnancy do not progress to eclampsia.
- Patient accurately verbalizes crucial signs and symptoms she should immediately report to her primary healthcare provider.
- Couple expresses feelings of sadness over pregnancy loss.
- Patient is able to adhere to the medical treatment regimen and experiences no adverse effects from the treatment.

## **Bleeding During Pregnancy**

Vaginal bleeding during pregnancy is always a deviation from the normal, is always potentially serious, may occur at any point during pregnancy, and is always frightening. It must always be carefully investigated because it can impair both the outcome of the pregnancy and the woman's health or life. The primary causes of bleeding during pregnancy are summarized in [Table 21.1](#).

**TABLE 21.1 SUMMARY OF PRIMARY CAUSES OF BLEEDING DURING PREGNANCY**

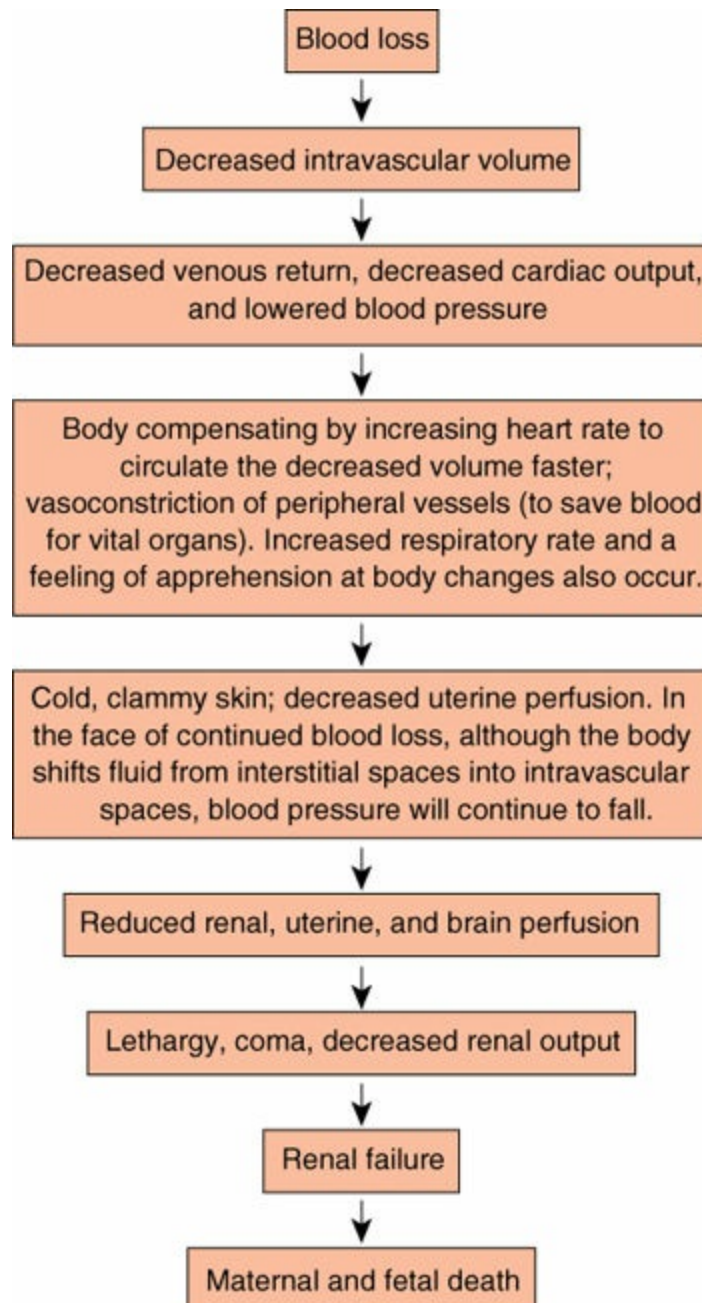

<b>Time</b>	<b>Type</b>	<b>Cause</b>	<b>Assessment</b>	<b>Cautions</b>
First and second trimester	Threatened spontaneous miscarriage (early: under 16 weeks; late: 16 to 24 weeks)	Unknown; possibly chromosomal or uterine abnormalities	Vaginal spotting, perhaps slight cramping	Caution women not to use tampons to halt bleeding as this can lead to infection.
	Imminent (inevitable) miscarriage	Unknown reasons but possibly poor placental attachment	Vaginal spotting, cramping, cervical dilatation	
	Missed miscarriage	Unknown	Vaginal spotting, perhaps slight cramping; no apparent loss of pregnancy	Disseminated intravascular coagulation is associated with missed miscarriage.
	Incomplete spontaneous miscarriage	Unknown; possibly chromosomal or uterine abnormalities	Vaginal spotting, cramping, cervical dilatation, but incomplete expulsion of uterine contents	High risk for uterine infection and hemorrhage
	Complete spontaneous miscarriage	Unknown but possibly chromosomal or uterine abnormalities	Vaginal spotting, cramping, cervical dilatation, and complete expulsion of uterine	

			contents	
	Ectopic (tubal) pregnancy	Implantation of zygote at site other than in uterus, associated with tubal constrictures	Sudden unilateral lower abdominal quadrant pain; minimal vaginal bleeding, possible signs of hypovolemic shock or hemorrhage	May have repeat ectopic pregnancy in future if tubal scarring is bilateral
Second trimester	Gestational trophoblastic disease (hydatidiform mole)	Abnormal proliferation of trophoblast cells; fertilization or division defect	Overgrowth of uterus; highly positive human chorionic gonadotropin (hCG) test; no fetus present on ultrasound; bleeding from vagina of old or fresh blood accompanied by cyst formation	Retained trophoblast tissue may become malignant (choriocarcinoma); follow for 6 months to 1 year with hCG testing
	Premature cervical dilatation	Cervix begins to dilate and pregnancy is lost at about 20 weeks; unknown cause but cervical	Painless bleeding leading to expulsion of fetus	Can have cervical sutures placed to ensure a second pregnancy

		trauma from dilatation and curettage (D&C) may be associated.		
Third trimester	Placenta previa	Low implantation of placenta possibly because of uterine abnormality	Painless bleeding at beginning of cervical dilatation	Don't allow a vaginal examination to minimize placental trauma.
	Premature separation of the placenta (abruptio placentae)	Unknown cause; associated with hypertension; placenta separates from uterus before birth of fetus	Sharp abdominal pain followed by uterine tenderness; vaginal bleeding; signs of maternal hypovolemic shock, fetal distress	Disseminated intravascular coagulation is associated with condition.
	Preterm labor	Many possible etiologic factors such as trauma, substance abuse, hypertension of pregnancy, or cervicitis; increased chance in multiple gestation, maternal	Show (pink-stained vaginal discharge) accompanied by uterine contractions becoming regular and effective	Preterm labor may be halted if the cervix is less than 4 cm dilated and the membranes are intact. Corticosteroids are administered to aid fetal lung maturity.

Although vaginal bleeding may be innocent, any degree of this during pregnancy is a potential emergency because it may mean the placenta has loosened and cut off nourishment to the fetus. Also, the amount of blood visualized may be only a fraction of the blood actually being lost because an undilated cervix and intact membranes contain blood within the uterus. A woman with any degree of bleeding, therefore, needs to be evaluated for the possibility she is experiencing a significant blood loss or is developing hypovolemic shock.

The process of shock due to blood loss is shown in [Figure 21.1](#). Because the uterus is a nonessential body organ, danger to the fetal blood supply occurs when a woman's body begins to decrease blood flow to peripheral organs (although the increased blood volume of pregnancy allows more than normal blood loss before hypovolemic shock processes begin). Signs of hypovolemic shock ([Table 21.2](#)) occur when 10% of blood volume, or approximately 2 units of blood, have been lost; fetal distress occurs when 25% of blood volume is lost ([Box 21.2](#)). Because "normal" blood pressure varies from woman to woman, it is important to know the baseline blood pressure for a pregnant woman when evaluating for hypovolemic shock.

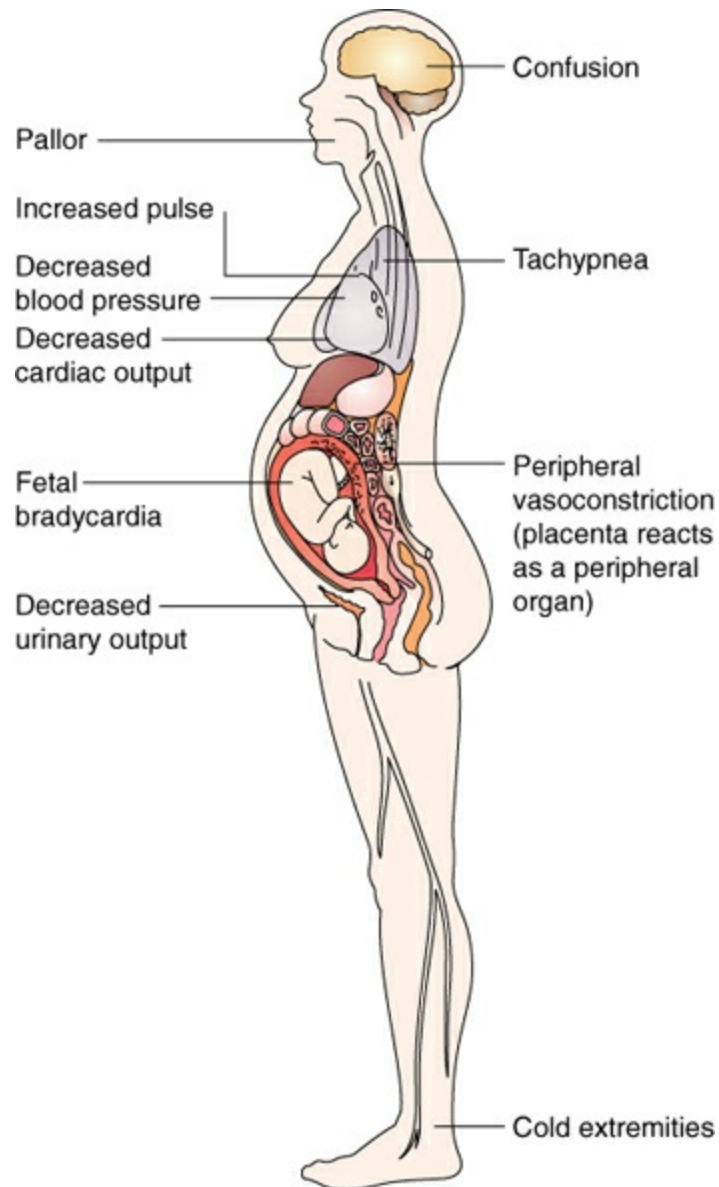

**Figure 21.1** The process of shock because of blood loss (hypovolemia).

BOX 21.2

**Nursing Care Planning Using Assessment**

**ASSESSING A PREGNANT WOMAN WITH HYPOVOLEMIC SHOCK**

**TABLE 21.2 SIGNS AND SYMPTOMS OF HYPOVOLEMIC SHOCK**

Assessment	Significance
Increased pulse rate	Heart attempts to circulate decreased blood volume.
Decreased blood pressure	Less peripheral resistance is present because of decreased blood volume.
Increased respiratory rate	Respiratory system attempts to increase gas exchange to better oxygenate decreased red blood cell volume.
Cold, clammy skin	Vasoconstriction occurs to maintain blood volume in central body core.
Decreased urine output	Inadequate blood is entering kidneys because of decreased blood volume.

Dizziness or decreased level of consciousness	Inadequate blood is reaching cerebrum because of decreased blood volume.
Decreased central venous pressure	Decreased blood is returning to heart because of reduced blood volume.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for deficient fluid volume related to bleeding during pregnancy

**Outcome Evaluation:** Patient's blood pressure is maintained at above 100/60 mmHg; pulse rate is below 100 beats/min; only minimal bleeding is apparent; fetal heart rate (FHR) is maintained at 120 to 160 beats/min with adequate short- and long-term variability; maternal urine output is greater than 30 ml/hr.

Therapy for hypovolemic shock is aimed at restoring blood volume and halting the source of hemorrhage as quickly as possible (Table 21.3). Monitoring urine output is a good gauge of blood loss because kidneys need sufficient arterial blood flow and pressure to function. If they are not producing urine, it suggests the kidneys are not obtaining adequate blood. If the blood deficit continues so blood cannot reach other major organs, multiorgan failure can result. Obtaining hemoglobin and hematocrit levels and securing a blood sample for typing or cross-matching are essential not only to help predict the extent of blood loss but also to prepare for blood replacement. A woman suspected of having serious bleeding will need intravenous fluid replacement, such as Ringer's lactate, as an early intervention. Use a large-gauge Angiocath (16 or 18) for rapid fluid expansion as this will also allow a blood transfusion to be administered through the same site as soon as blood is available. If respirations are rapid, administer oxygen by mask and monitor oxygen saturation levels by pulse oximetry. A woman needs frequent assessments of vital signs and continuous fetal monitoring; therefore, an external monitoring device should be started.

Urge the woman to rest in a side-lying position (left lateral is preferred) to help prevent vena cava compression. If this is not possible, position her on her back, with a wedge under one hip to minimize uterine pressure on the vena cava and prevent blood from being trapped in the lower extremities (supine hypotension syndrome). Continue to provide information about care and emotional support to her and her family members.

A woman may have a central venous pressure catheter (measures the right atrial pressure or the pressure of blood within the vena cava) or a pulmonary capillary wedge catheter (measures the pressure in the left atrium or the filling pressure in the left ventricle) inserted after bleeding is halted (see Chapter 41). During pregnancy, usual values of these measures differ from the average, so they need to be evaluated

in light of the pregnancy. Central venous pressure during pregnancy is 1 to 6 mmHg and pulmonary capillary wedge pressure during pregnancy is 6 to 12 mmHg (Watson & Wilkinson, 2012).

**TABLE 21.3 EMERGENCY INTERVENTIONS FOR BLEEDING IN PREGNANCY**

<b>Intervention</b>	<b>Rationale</b>
Alert healthcare team of emergency situation.	Provides maximum coordination of care
Place woman flat in bed on her side.	Maintains optimal placental and renal function
Begin intravenous fluid such as Ringer's lactate with a 16- or 18-gauge Angiocath.	Replaces intravascular fluid volume; intravenous line is established if blood replacement will be needed
Administer oxygen as necessary at 6–10 L/min by face mask.	Provides adequate fetal oxygenation despite lowered maternal circulating blood volume
Monitor uterine contractions and fetal heart rate by external monitor.	Assesses whether labor is present and fetal status; external system avoids cervical trauma
Omit vaginal examination.	Prevents tearing of placenta if placenta previa is cause of bleeding
Withhold oral fluid.	Anticipates need for emergency surgery
Order type and cross-match of 2 units of whole blood.	Allows for restoring circulating maternal blood volume if needed
Measure intake and output.	Enables assessment of renal function (will decrease to under 30 ml/hr with massive circulating volume loss)
Assess vital signs (pulse, respirations, and blood pressure every 15 min; apply pulse oximeter and automatic blood pressure cuff as necessary).	Provides baseline data on maternal response to blood loss
Assist with placement of central venous pressure or pulmonary artery catheter and blood determinations.	Provides more accurate data on maternal hemodynamic state
Measure maternal blood loss by weighing perineal pads; save any tissue passed.	Provides objective evidence of amount of bleeding; saturating a sanitary pad in less than 1 hr is heavy blood loss; tissue may

Assist with ultrasound examination.	be abnormal trophoblast tissue Supplies information on placental and fetal well-being
Maintain a positive attitude about fetal outcome.	Supports mother–child bonding
Support woman’s self-esteem; provide emotional support to woman and her support person.	Assists problem solving, which is lessened by poor self-esteem.

## SPONTANEOUS MISCARRIAGE

**Abortion** is a medical term for any interruption of a pregnancy before a fetus is viable (i.e., able to survive outside the uterus if born at that time), but it is better to speak of these early pregnancy losses as spontaneous miscarriages to avoid confusion with intentional terminations of pregnancies. A viable fetus is usually defined as a fetus of more than 20 to 24 weeks of gestation or one that weighs at least 500 g. A fetus born before this point is considered a **miscarriage** or is termed a premature or immature birth (Sneider, Langhoff-Roos, Sundtoft, et al., 2015).

Spontaneous miscarriage occurs in 15% to 30% of all pregnancies and arises from natural causes (Seifert & Altman, 2015). A miscarriage is an early miscarriage if it occurs before week 16 of pregnancy and a late miscarriage if it occurs between weeks 16 and 20. For the first 6 weeks of pregnancy, the developing placenta is tentatively attached to the decidua of the uterus; during weeks 6 to 12, it is moderately attached. After week 12, the attachment is penetrating and deep. Because of these degrees of attachment achieved at different weeks of pregnancy, it is important to attempt to establish the week of the pregnancy at which bleeding has become apparent. Bleeding before week 6 is rarely severe; bleeding after week 12 can be profuse because the placenta is implanted so deeply. Fortunately, at this time, with such deep placental implantation, the fetus tends to be expelled as in natural childbirth before the placenta separates. Uterine contractions, however, then help to control placental bleeding as they do postpartally. For some women, then, the stage of attachment between weeks 6 and 12 can lead to the most severe, even life-threatening bleeding.

### Common Causes

The most frequent cause of miscarriage in the first trimester of pregnancy is abnormal fetal development, due either to a teratogenic factor or to a chromosomal aberration. In other miscarriages, immunologic factors may be present or rejection of the embryo through an immune response may occur (Surette & Dunham, 2013). Another common cause of early miscarriage involves implantation abnormalities, as up to 50% of zygotes probably never implant securely because of inadequate endometrial formation or from an inappropriate site of implantation. With inadequate implantation, the placental

circulation does not develop adequately enough to support the pregnancy. Miscarriage may also occur if the corpus luteum on the ovary fails to produce enough progesterone to maintain the decidua basalis. Progesterone therapy may be attempted to prevent this if this cause is documented (Aytac, Bulgan Kilicdag, Haydardedeoglu, et al., 2016).

Ingestion of alcohol at the time of conception or during early pregnancy can contribute to pregnancy loss because of abnormal fetal growth (Bingham, 2015). Urinary tract infections may be a cause but are more strongly associated with preterm birth. Systemic infections such as rubella, syphilis, poliomyelitis, cytomegalovirus, and toxoplasmosis readily cross the placenta and so may also be responsible. With an infection, if the fetus fails to grow, estrogen and progesterone production by the placenta falls and leads to endometrial sloughing. With the sloughing, prostaglandins are released; uterine contractions and cervical dilatation along with expulsion of the products of the pregnancy begin.

Because miscarriage can occur from so many causes and because the cause is often difficult to determine, couples may have difficulty understanding why it happened to them (Box 21.3).

### BOX 21.3

#### Nursing Care Planning to Empower a Family

#### COPING WITH A SPONTANEOUS MISCARRIAGE

**Q.** Beverly Muzuki had a spontaneous miscarriage when she was younger. She asks you, “What did I do wrong that time?”

**A.** Early miscarriage is largely not preventable because it is caused by such things as abnormal chromosome formation or poor uterine implantation—things over which you have no control. Eating a nutritious diet, so you enter a pregnancy in good health and avoiding cigarette smoking or drinking alcohol are sensible recommendations to reduce your risk of miscarriage. If you had extensive blood loss with your miscarriage, be certain to eat iron-rich foods (such as meat and green vegetables) to help restore red blood cells for a second pregnancy.

#### Assessment

The presenting symptom of spontaneous miscarriage is almost always vaginal spotting. At the first indication of this, a woman should contact her healthcare provider and describe how much spotting she is having and its appearance (e.g., dark or fresh blood). Because a nurse often takes this initial call, guidelines to help assess vaginal bleeding quickly are shown in Table 21.4.

**TABLE 21.4 IMMEDIATE ASSESSMENT OF VAGINAL BLEEDING DURING PREGNANCY**

Assessment	Specific Questions to Ask
------------	---------------------------

Factor	
Confirmation of pregnancy	Does the woman know for certain she is pregnant (positive pregnancy test or healthcare provider confirmation)? A woman who has been pregnant before and states she is certain she is pregnant is probably right, even if she has not yet had her pregnancy confirmed.
Pregnancy length	What is the length of the pregnancy in weeks?
Duration	How long did the bleeding episode last? Is it continuing?
Intensity	How much bleeding occurred? (Ask the woman to compare it to a common measure such as a tablespoon or a cup.)
Description	Was blood mixed with amniotic fluid or mucus? Was it bright red (fresh blood) or dark (old blood)? Was it accompanied by tissue fragments? Was it odorous?
Frequency	Steady spotting? A single episode?
Associated symptoms	Cramping? Sharp pain? Dull pain? Has she ever had cervical surgery (to alert healthcare providers the woman may have cervical sutures in place?)
Action	What was happening at the time the bleeding started? What has she done (if anything) to control bleeding? (Caution her not to insert a tampon so the true extent of the bleeding shows.)
Blood type	Does she know this? (Rh-negative women will need Rh immune globulin to prevent Rh isoimmunization.)

The history of the episode is important to help diagnose the cause. Knowledge of a woman's actions is important to ensure she did not attempt an illegal abortion. Asking what she has done, if anything, to halt the bleeding may reveal she inserted a tampon, for example. If she did, although reporting only slight spotting, she actually has an unknown amount of blood loss and might be bleeding much more heavily than she first reported.

### Therapeutic Management

Depending on the symptoms and the description of the bleeding, a woman's primary healthcare provider will decide whether she needs to be seen and, if so, whether she should be seen in an ambulatory setting or the hospital.

### Diagnosis

#### Threatened Miscarriage

Symptoms of a threatened miscarriage begin as vaginal bleeding, initially only scant

and usually bright red. A woman may notice slight cramping, but no cervical dilatation is present on vaginal examination. A woman with an apparent threatened miscarriage may be asked to come to the clinic or office to have fetal heart sounds assessed or an ultrasound performed to evaluate the viability of the fetus. Blood may be drawn to test for human chorionic gonadotropin (hCG) hormone at the start of bleeding and again in 48 hours (if the placenta is still intact, the level in the bloodstream should double in this time). If it does not double, poor placental function is suspected and the pregnancy probably will be lost. Avoidance of strenuous activity for 24 to 48 hours is the key intervention, assuming the threatened miscarriage involves a live fetus and presumed placental bleeding. Complete bed rest is usually not necessary as this may appear to stop the vaginal bleeding but only because blood pools vaginally. When a woman does ambulate again, the vaginal blood collection will drain and bleeding will reappear.

Women are apt to be extremely worried at the sight of bleeding. They need to talk with a sympathetic, supportive person about how distressed they are feeling. Women with threatened miscarriages often look for reasons why this could have happened, such as running up a flight of stairs, forgetting to take an iron pill, or getting angry with an older child. Being assured that none of these events causes miscarriage can help to minimize the guilt a woman may feel.

If the spotting with a threatened miscarriage is going to stop, it usually does so within 24 to 48 hours after a woman reduces her activity. Once bleeding stops, she can gradually resume normal activities. Coitus may be restricted for 2 weeks, however, to prevent infection and to avoid inducing further bleeding. As many as 50% of women with a threatened miscarriage continue the pregnancy; for the other 50%, unfortunately, the threatened miscarriage changes to imminent, or inevitable, miscarriage and the pregnancy ends (Ku, Allen, Malhotra, et al., 2015).

### Imminent (Inevitable) Miscarriage

A threatened miscarriage becomes an imminent (i.e., inevitable) miscarriage if uterine contractions and cervical dilation occur as, with cervical dilation, the loss of the products of conception cannot be halted. A woman who reports cramping or uterine contractions is usually asked to come to the hospital or office, where she is examined. She should save any tissue fragments she has passed and bring them with her so they can be analyzed for an abnormality such as gestational trophoblastic disease (hydatidiform mole; see later). If no fetal heart sounds are detected and an ultrasound reveals an empty gestational sac or nonviable fetus, her primary healthcare provider may offer medication to help the pregnancy pass or perform a dilatation and curettage (D&C) or a dilation and evacuation (D&E) to ensure all the products of conception are removed (Sajan, Pulikkathodi, Vahab, et al., 2015). Be certain the woman has been told the pregnancy was already lost and that all procedures, such as suction curettage, are to clean the uterus and prevent further complications such as infection and not to end the pregnancy. Save any tissue fragments passed in the labor room, along with any brought from home, so it can be established that all the products of conception have been

removed from the uterus. After a woman is discharged, the woman should assess the amount of vaginal bleeding she is having by recording the number of pads she uses; saturating more than one pad per hour is abnormally heavy bleeding.

### Complete Miscarriage

In a complete miscarriage, the entire products of conception (fetus, membranes, and placenta) are expelled spontaneously without any assistance. The bleeding usually slows within 2 hours and then ceases within a few days after passage of the products of conception. Because the process is complete, no therapy other than advising the woman to report heavy bleeding is needed.

### Incomplete Miscarriage

In an incomplete miscarriage, part of the conceptus (usually the fetus) is expelled, but the membranes or placenta are retained in the uterus. The term “incomplete” can be confusing for women as they may interpret it to mean that because the miscarriage was incomplete, it means the pregnancy will continue. With an incomplete miscarriage, there is a danger of maternal hemorrhage as long as part of the conceptus is retained in the uterus because the uterus cannot contract effectively under this condition. The woman will usually have a D&C or suction curettage to evacuate the remainder of the pregnancy. Again, be certain the woman knows the pregnancy is already lost and that these procedures are being done to protect her from hemorrhage and infection, not to end the pregnancy.

### Missed Miscarriage

In a missed miscarriage, also commonly referred to as **early pregnancy failure**, the fetus dies in utero but is not expelled. Women can also find this term misleading because it suggests that if a miscarriage was “missed,” then the pregnancy can continue. A missed miscarriage is usually discovered at a prenatal examination when the fundal height is measured and no increase in size can be demonstrated or when previously heard fetal heart sounds can no longer be heard. A woman may have had symptoms of a threatened miscarriage (e.g., painless vaginal bleeding) or she may have had no prior clinical symptoms.

After an ultrasound establishes the fetus has no heart rate, a D&C or D&E may be done to evacuate the pregnancy. If the pregnancy is over 14 weeks in length and, therefore, these procedures are no longer possible, labor can be induced by a prostaglandin suppository or misoprostol (Cytotec) introduced into the posterior fornix of the vagina to cause dilatation, followed by oxytocin stimulation or administration of mifepristone techniques used for elective termination of pregnancy, which cause contractions and birth (Oman & Burke, 2015). If the pregnancy is not actively terminated this way, miscarriage usually occurs spontaneously within 2 weeks. There is a danger of allowing this normal course to happen, however, because disseminated

intravascular coagulation (DIC), a coagulation defect, may develop if the nonviable (and possibly toxic) fetus remains too long in utero (Zheng, 2012b).

Most women hope, until the moment the ultrasound shows their fetus no longer has a heart rate, that their baby is alive. They may need support in accepting the reality of the situation (Box 21.4) and need counseling to begin a future pregnancy because of fears they may never be able to carry a baby to full term.

#### BOX 21.4

#### Nursing Care Planning Tips for Effective Communication

Beverly's neighbor noticed some vaginal spotting at 10 weeks into her pregnancy. The bleeding stopped spontaneously, but her healthcare provider was unable to hear fetal heart tones. An ultrasound revealed a missed miscarriage. You talk to her neighbor after she has received this news.

*Tip:* Because many women want so badly to be pregnant, it can be easy for them to “miss” bad news about a pregnancy. Actively listen to ensure there are no misunderstandings. It is also difficult for a shocked patient to absorb all the information after being informed about a miscarriage. Repeat information as necessary or ask for the patient to verbalize the plan.

**Nurse:** Hello, Vivian. How are you feeling?

**Vivian:** Fine. I guess this was a small thing.

**Nurse:** I'm sorry it happened. It must be upsetting.

**Vivian:** The bleeding was scary. Made me really nervous something was going wrong with the baby.

**Nurse:** With the baby?

**Vivian:** Yes. I'm really lucky I missed having a miscarriage.

**Nurse:** Let me ask your doctor to reexplain what she meant by a missed miscarriage. That's a term that can be confusing.

### Recurrent Pregnancy Loss

In the past, women who had three spontaneous miscarriages that occurred at the same gestational age were called “habitual aborters.” They were advised they were apparently too “nervous” or that something was so wrong with their hormones that childbearing was not for them. Today, the term **recurrent pregnancy loss** is used to describe this miscarriage pattern, and a thorough investigation is done to discover the cause of the loss and to help ensure the outcome of a future pregnancy. Recurrent pregnancy loss occurs in about 1% of women who want to be pregnant. Although many of these losses occur for unknown reasons, possible causes include:

- Defective spermatozoa or ova
- Endocrine factors such as lowered levels of protein-bound iodine (PBI), butanol-

extractable iodine (BEI), and globulin-bound iodine (GBI); poor thyroid function; or a luteal phase defect

- Deviations of the uterus, such as septate or bicornuate uterus
- Resistance to uterine artery blood flow
- Chorioamnionitis or uterine infection
- Autoimmune disorders such as those involving lupus anticoagulant and antiphospholipid antibodies (Besharat, Tabandeh, Keshtkar, et al., 2015)

## Complications of Miscarriage

As with full-term childbirth, hemorrhage and infection are two of the most likely complications after miscarriage. The risk for Rh isoimmunization and a woman's psychological state also need to be considered.

### Hemorrhage

With a complete spontaneous miscarriage, serious or fatal hemorrhage is rare. With an incomplete miscarriage or in a woman who develops an accompanying coagulation defect (usually DIC), major hemorrhage becomes a possibility. Monitor vital signs for any changes to detect possible hypovolemic shock. If excessive vaginal bleeding occurs, immediately position a woman flat and massage the uterine fundus to try to aid contraction, although this may be impossible with an early pregnancy because the small uterus is not palpable above the symphysis pubis (see [Chapter 17](#)). Applying pneumatic antishock garments can help maintain blood pressure ([FIGO Safe Motherhood and Newborn Health Committee, 2015](#)).

If bleeding doesn't halt, a woman may need a D&C or suction curettage to empty the uterus of the material that is preventing it from contracting and achieving hemostasis. A transfusion may be necessary to replace blood loss. Direct replacement of fibrinogen or another clotting factor may be used to increase coagulation ability.

After a self-limiting complete miscarriage, a woman needs clear instructions on how much bleeding is abnormal (more than one sanitary pad per hour is excessive) and what color changes she should expect in bleeding (gradually changing to a dark color and then to the color of serous fluid as it does with the postpartum woman). Be certain she is aware any unusual odor or passing of large clots is also abnormal. If her primary healthcare provider has prescribed an oral medication such as methylergonovine maleate (Methergine) to aid uterine contraction, review with her why it is being prescribed and the importance of taking it. Some women repress their feelings following a miscarriage, anxious to forget the experience as quickly as possible. Short-term repression this way can be helpful if it helps them with their anger or grief at the loss of the pregnancy. Be careful, however, in repressing the experience a woman does not also repress the memory of her medication and leave herself open to hemorrhage.

### *QSEN Checkpoint Question 21.1*

## PATIENT-CENTERED CARE

Beverly Muzuki had a miscarriage when she was younger. After addressing her immediate psychosocial needs, the nurse identifies which advice as best for a woman who says she is miscarrying?

- a. Lie down and remain on bed rest for 24 hours to stop the bleeding.
- b. Continue light activity as usual because most spotting during pregnancy is harmless.
- c. Save any clots or material passed for your healthcare provider to examine.
- d. Use a tampon to put pressure on your cervix and stop the bleeding.

Look in [Appendix A](#) for the best answer and rationale.

## Infection

The possibility of infection is minimal when pregnancy loss occurs over a short time, bleeding is self-limiting, and instrumentation is limited. However, there is always a possibility it may occur. It tends to develop most often in women who have lost an appreciable amount of blood. Infection is often a reason for excessive blood loss. Observe such women closely to rule out this second and possibly fatal complication. Be certain the woman is familiar with common danger signs of infection, such as fever higher than 100.4°F (38.0°C), abdominal pain or tenderness, and a foul-smelling vaginal discharge. Usually, fever is the most important sign of infection, but it can also be a transient reaction to the period of decreased fluid intake that preceded or shortly followed the miscarriage. Don't dismiss any degree of elevated temperature, however, to avoid overlooking the possibility infection is developing.

The organisms responsible for infection after miscarriage are usually *Escherichia coli* (spread from the rectum forward into the vagina) or group A streptococcus ([Eschenbach, 2015](#)). Caution women to always wipe their perineal area from front to back after voiding and particularly after defecation to prevent the spread of bacteria from the rectal area and to decrease the possibility of this source of infection. Be certain to advise the woman not to use tampons (stasis of any body fluid increases the risk of infection).

Infection usually involves the inner lining of the uterus (endometritis), but it may be more extensive and lead to parametritis, peritonitis, thrombophlebitis, or septicemia. The management of these infections is the same as if they were occurring after the safe birth of a child and so are discussed in [Chapter 25](#).

## Septic Abortion

A septic abortion is an abortion complicated by infection ([Eschenbach, 2015](#)). Infection can occur after a spontaneous miscarriage, but more frequently, it occurs in women who have tried to self-abort or whose pregnancy was aborted illegally using a nonsterile instrument such as a knitting needle. Septic abortion is not common in the United States

due to the legal status of abortion, but it is much more common in areas where abortion is illegal or medical care is not readily available. Because the uterus is a warm, moist, dark cavity, once infectious organisms are introduced, they grow rapidly in this environment, particularly if products of conception such as necrotic membranes are still present.

The woman will have symptoms of fever and crampy abdominal pain; her uterus will feel tender to palpation. Left untreated, such an infection can lead to toxic shock syndrome, septicemia, kidney failure, and death ([Eschenbach, 2015](#)).

Women with a septic abortion need immediate, intensive assessment and therapy. Typically, complete blood count; serum electrolytes; serum creatinine; blood type and cross-match; and cervical, vaginal, and urine cultures are obtained. An indwelling urinary (Foley) catheter may be inserted to monitor urine output hourly to assess kidney function. Intravenous fluid to restore fluid volume and to provide a route for high-dose, broad-spectrum antibiotic therapy is begun. A combination of penicillin (gram-positive coverage), gentamicin (gram-negative aerobic coverage), and clindamycin (gram-negative anaerobic coverage) is commonly prescribed to combat the infection.

A central venous pressure or pulmonary artery catheter may be inserted to monitor left atrial filling pressure and hemodynamic status. The removal of all infected or necrotic tissue from the uterus is important, so a D&C or D&E will be performed. A tetanus toxoid given subcutaneously or a tetanus immune globulin given intramuscularly will be prescribed for prophylaxis against tetanus.

Infection following a septic abortion can be so severe that a woman needs to be admitted to an intensive care setting for continuing care. Dopamine and digitalis may be necessary to maintain sufficient cardiac output. Oxygen and perhaps ventilatory support may be necessary to maintain respiratory function.

Assuming a woman recovers from such an intense episode, a final result may be infertility because of uterine scarring or fibrotic scarring of the fallopian tubes. If the infection was caused by a woman trying to self-abort, she needs follow-up social work counseling to assess her home life and aid in identifying resources that could help her avoid having to make that decision in the future.

## Isoimmunization

Whenever a placenta is dislodged at any point in pregnancy, either by spontaneous birth or by a D&C/D&E, some blood from the placental villi (the fetal blood) is apt to enter the maternal circulation. If the fetus was Rh positive and the woman is Rh negative, enough Rh-positive fetal blood may enter the maternal circulation to cause **isoimmunization**, or the production of antibodies against Rh-positive blood. If the woman's next child should have Rh-positive blood, these antibodies would attempt to destroy the red blood cells of this infant during the months that infant is in utero ([Aitken & Tichy, 2015](#)). Therefore, after a miscarriage, because the blood type of the conceptus is unknown, all women with Rh-negative blood should receive Rh (D antigen) immune globulin (RhIG) to prevent the buildup of antibodies in the event the conceptus was Rh

positive.

### Powerlessness or Anxiety

As with pregnancy loss for any reason, assess a woman's adjustment to a spontaneous miscarriage. Sadness and grief over the loss or the feeling that a woman has lost control of her life is to be expected. Do not forget to assess a partner's or the extended family's feelings as well, or the potential impact of their grief and possible lack of support for the woman over the pregnancy loss can be missed. Spontaneous miscarriage can be particularly heartbreaking for an older woman because she realizes her window of childbearing is limited.

### *QSEN Checkpoint Question 21.2*

#### QUALITY IMPROVEMENT

Beverly Muzuki has an Rh-negative blood type. Her electronic record shows she had a previous miscarriage at 16 weeks into her last pregnancy. What medication should the nurse check she received following the miscarriage to minimize isoimmunization?

- a. Misoprostol (Cytotec)
- b. RhIG (RhoGAM)
- c. Ferrous sulfate
- d. Packed red blood cell transfusion

*Look in [Appendix A](#) for the best answer and rationale.*

### ECTOPIC PREGNANCY

An **ectopic pregnancy** is one in which implantation occurred outside the uterine cavity. The most common site (in approximately 95% of such pregnancies) is in the fallopian tube ([Fig. 21.2](#)). Of these fallopian tube sites, approximately 80% occur in the ampullar portion, 12% occur in the isthmus, and 8% are interstitial or fimbrial ([Jurkovic, 2012](#)).

**Figure 21.2** The sites at which an ectopic pregnancy may occur.

With most ectopic pregnancy, fertilization occurs as usual in the fallopian tube. Unfortunately, because an obstruction is present, such as an adhesion of the fallopian tube from a previous infection (chronic salpingitis or pelvic inflammatory disease), congenital malformations, scars from tubal surgery, or a uterine tumor pressing on the proximal end of the tube, the zygote cannot travel the length of the tube. It lodges at astricted site along the tube and implants there instead of in the uterus.

Approximately 2% of pregnancies are ectopic, and because at least minimal bleeding occurs, it is the second most frequent cause of bleeding early in pregnancy. The incidence of ectopic pregnancy appears to be increasing, possibly because of the increasing rate of pelvic inflammatory disease, which can lead to tubal scarring. The incidence is also increased following in vitro fertilization (a woman might be having the in vitro fertilization because she has tubal scarring) and also in women who smoke.

Women who have one ectopic pregnancy have a higher chance of having a subsequent ectopic pregnancy. This is because salpingitis generally leaves scarring, which is bilateral. Congenital anomalies such as webbing (fibrous bands) that block a fallopian tube may also occur in both tubes. For unknown reasons, oral contraceptives used before pregnancy reduce the incidence of ectopic pregnancy (Li, Zhao, Zhu, et al., 2015).

### Assessment

With an ectopic pregnancy, there are no unusual symptoms at the time of implantation. The corpus luteum of the ovary continues to function as if the implantation were in the uterus, so, often, no menstrual flow occurs. A woman may begin to experience the usual

nausea and vomiting of early pregnancy and a pregnancy test for hCG will be positive. Many ectopic pregnancies are diagnosed because a woman has an early pregnancy ultrasound to date the pregnancy. Magnetic resonance imaging (MRI) is also effective to use for this. If not revealed by an ultrasound, at weeks 6 to 12 of pregnancy (2 to 8 weeks after a missed menstrual period), the zygote grows large enough that it ruptures the slender fallopian tube. Tearing and destruction of blood vessels and bleeding result. If implantation was in the interstitial portion of the tube (where the tube joins the uterus), rupture can cause severe intraperitoneal bleeding because of the large blood vessels in that part of the tube. Fortunately, the incidence of tubal pregnancies is highest in the ampullar area (the distal third), where the blood vessels are smaller and profuse hemorrhage is less likely. Constant, continued bleeding from this area, however, may result in a large amount of blood loss over time. Therefore, a ruptured ectopic pregnancy is serious regardless of the site of implantation.

A woman usually experiences a sharp, stabbing pain in one of her lower abdominal quadrants at the time of rupture, followed by scant vaginal spotting. The amount of bleeding evident with a ruptured ectopic pregnancy usually does not reveal the actual amount present, however, because the products of conception from the ruptured tube and the accompanying blood may be expelled into the pelvic cavity rather than into the uterus. Blood does not reach the vagina to become evident. At the point the placenta dislodges, progesterone secretion will stop and the uterine decidua will begin to slough, causing additional vaginal bleeding. As soon as the woman becomes hypotensive from blood loss, she will experience light-headedness and a rapid pulse, signs of hypovolemic shock.

Because of these symptoms, any woman with sharp abdominal pain and vaginal spotting needs to be evaluated by her healthcare provider to rule out the possibility of ectopic pregnancy. When helping determine whether an ectopic pregnancy is present, ask a woman what she was doing when she felt the pain, if she had pain but no vaginal bleeding. Occasionally, a woman will move suddenly and pull one of her round ligaments, the anterior uterine supports, which causes a sharp but momentary lower quadrant pain, so this must be ruled out. Vaginal spotting or bleeding does rule out round ligament pain as it would be rare for this phenomenon to be reported in connection with vaginal spotting.

By the time a woman arrives at the hospital or primary healthcare provider's office, she may already be in severe shock, as evidenced by a rapid, thready pulse; rapid respirations; and falling blood pressure. Leukocytosis may be present, not from infection but from the trauma. Temperature is usually normal. A transvaginal ultrasound will demonstrate the ruptured tube and blood collecting in the peritoneum. Either a falling hCG or serum progesterone level suggests the pregnancy has ended. If the diagnosis of ectopic pregnancy is in doubt, a primary healthcare provider may insert a needle through the posterior vaginal fornix into the cul-de-sac under sterile conditions to see whether blood can be aspirated. A laparoscopy or culdoscopy can also be used to visualize the fallopian tube if the symptoms alone do not reveal a clear picture of what

has happened. However, ultrasonography alone usually reveals a clear-cut diagnostic picture (Rodgers, Chang, DeBardleben, et al., 2015).

If a woman waits for a time before seeking help, her abdomen gradually becomes rigid from peritoneal irritation. Her umbilicus may develop a bluish-tinged hue (Cullen sign). She may have continuing extensive or dull vaginal and abdominal pain; movement of the cervix on pelvic examination can cause excruciating pain. She may feel pain in her shoulders as well from blood in the peritoneal cavity causing irritation to the phrenic nerve. A tender mass is usually palpable in Douglas cul-de-sac on vaginal examination.

### Therapeutic Management

Some ectopic pregnancies spontaneously end before they rupture and are reabsorbed over the next few days, requiring no treatment. It is difficult to predict when or if this will happen, however, so when an ectopic pregnancy is revealed by an early ultrasound, the woman is shown the sonogram, and after her agreement that therapy could be lifesaving, she is usually medically treated by the intramuscular or less often, oral, administration of methotrexate (Song, Kim, Kim, et al., 2016) (see Chapter 53 for a general discussion of chemotherapy agents of this type). The advantage of this therapy is that the tube is left intact, with no surgical scarring that could cause a second ectopic implantation. Women are treated until a negative hCG titer is achieved. A hysterosalpingogram or ultrasound is usually performed after this to assess that the pregnancy is no longer present and also whether the tube appears fully patent. If an ectopic pregnancy is not discovered early, but rather, only when it ruptures, it creates an emergency situation (Abraham & Seethappan, 2015).

Keep in mind the amount of blood evident with a ruptured ectopic pregnancy is a poor estimate of the actual blood loss. A blood sample needs to be drawn immediately for hemoglobin level, typing and cross-matching, and possibly the hCG level for immediate pregnancy testing, if pregnancy has not yet been confirmed. Intravenous fluid using a large-gauge catheter to restore intravascular volume will be prescribed. Blood then can be administered through this same line as soon as it is matched.

The therapy for ruptured ectopic pregnancy is laparoscopy to ligate the bleeding vessels and to remove or repair the damaged fallopian tube. A rough suture line on a fallopian tube may lead to another tubal pregnancy, so either the tube will be removed or suturing on the tube will be done with microsurgical technique. If a tube is removed, a woman may lose about 5% of her fertility. When she ovulates from either ovary, the egg can be moved into the remaining open tube with the peristaltic motion of that fallopian tube (Talarczyk-Desole, Wróbel, Niepsuj-Biniaś, et al., 2016). As with miscarriage, women with Rh-negative blood should receive RhIG/RhoGAM after an ectopic pregnancy for isoimmunization protection in future childbearing.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Powerlessness related to early loss of pregnancy secondary to ectopic pregnancy

**Outcome Evaluation:** Patient states she feels sad at pregnancy loss but is able to deal with situation; has returned to previous level of activities and has forward-thinking plans.

A woman who has had an ectopic pregnancy not only has grief stages to work through (she has lost a child) but also may have problems of diminished self-image and a sense of powerlessness if surgery included removal of a fallopian tube.

Encourage her to verbalize her concerns about this and her possibly reduced potential for future childbearing. This process of working through grief and role image may take weeks to months, but should begin in the hospital, where a woman has professional people to help her through the first days and to determine whether she will need further counseling.

## ABDOMINAL PREGNANCY

Very rarely after an ectopic pregnancy ruptures—so rarely the instances are difficult to document—the products of conception are expelled into the pelvic cavity with a minimum of bleeding. The placenta continues to grow in the fallopian tube, spreading perhaps into the uterus for a better blood supply; or it may escape into the pelvic cavity and implant on an organ such as an intestine. The fetus will grow in the pelvic cavity (an abdominal pregnancy). This can also occur if a uterus ruptures because an old uterine scar ruptures during pregnancy (Nassali, Benti, Bandani-Ntsabele, et al., 2016).

In an abdominal pregnancy, the fetal outline is usually easily palpable through the abdomen because it is directly below the abdominal wall, not inside the uterus. A woman may either not be as aware of movements as she would be normally or she may experience painful fetal movements and abdominal cramping with fetal movements. She may report she noticed sudden lower quadrant pain earlier in the pregnancy but, because there was no external bleeding, didn't report it. An ultrasound or MRI will reveal the fetus outside the uterus.

The danger of abdominal pregnancy is that the placenta could infiltrate and erode a major blood vessel in the abdomen, leading to hemorrhage. If implanted on the intestine, it may erode so deeply it causes bowel perforation, leaking of intestinal contents, and peritonitis. The fetus is also at high risk (only about 60% come to term) because without a good uterine blood supply, nutrients may not reach the fetus in adequate amounts leading to the threat of fetal deformity or growth restriction.

At term, the infant must be born through laparotomy. The placenta is often difficult to remove after birth if it has implanted onto an abdominal organ such as the intestine. It may, therefore, be left in place and allowed to absorb spontaneously in 2 or 3 months. A follow-up ultrasound can be used to detect whether this has occurred. If not, a woman can be treated with methotrexate to help the placenta absorb, although this therapy may

not be effective because the remaining trophoblasts are no longer fast growing (Nassali et al., 2016).

## GESTATIONAL TROPHOBLASTIC DISEASE (HYDATIDIFORM MOLE)

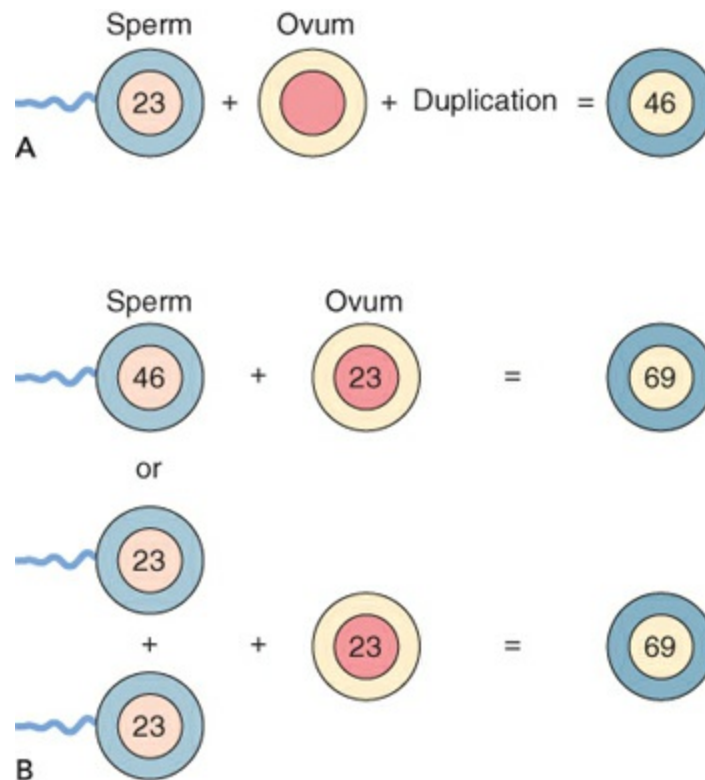

**Gestational trophoblastic disease** is abnormal proliferation and then degeneration of the trophoblastic villi (Jean-Jacques, 2016). As the cells degenerate, they become filled with fluid and appear as clear fluid-filled, grape-sized vesicles. The embryo fails to develop beyond a primitive start. Abnormal trophoblast cells must be identified because they are associated with choriocarcinoma, a rapidly metastasizing malignancy (Fig. 21.3).

**Figure 21.3** Gestational trophoblastic disease (hydatidiform mole). (From Rubin, E., & Farber, J. L. [1994]. *Pathology* [2nd ed.]. Philadelphia, PA: JB Lippincott.)

The incidence of gestational trophoblastic disease is approximately 1 in every 1,500 pregnancies. The condition tends to occur most often in women who have a low-protein intake, in women older than 35 years of age, in women of Asian heritage, and in blood group A women who marry blood group O men (Maestá, Berkowitz, Goldstein, et al., 2015).

Two types of molar growth can be identified by chromosome analysis. With a complete mole, all trophoblastic villi swell and become cystic. If an embryo forms, it dies early at only 1 to 2 mm in size, with no fetal blood present in the villi. On chromosomal analysis, although the karyotype is a normal 46XX or 46XY, this chromosome component was contributed only by the father or an “empty ovum” was fertilized and the chromosome material was duplicated (Fig. 21.4A).

**Figure 21.4** Formation of gestational trophoblastic disease (hydatidiform mole). **(A)** A complete mole. **(B)** A partial mole.

With a partial mole, some of the villi form normally. The syncytiotrophoblastic layer of villi, however, appears swollen and misshapen. The embryo may grow for about 9 weeks but then macerates; some fetal blood may be present in the villi. A partial mole has 69 chromosomes (69XX or 69XY) (a triploid formation in which there are three chromosomes instead of two for every pair: one set supplied by an ovum that apparently was fertilized by two sperm or an ovum fertilized by one sperm in which meiosis or reduction division did not occur). This could also occur if one set of 23 chromosomes was supplied by one sperm and an ovum that did not undergo reduction division supplied 46 (see Fig. 21.4B).

In contrast to complete moles, partial moles rarely lead to choriocarcinoma. Although still above average, hCG titers are lower in partial than in complete moles; titers also return to normal faster after gestational trophoblast evacuation (Savage & Seckl, 2012).

### Assessment

Because proliferation of the abnormal trophoblast cells grow so rapidly, the uterus tends to expand faster than usual or the uterus reaches its landmarks (just over the symphysis brim at 12 weeks, at the umbilicus at 20 to 24 weeks) before the usual time. This rapid development is also diagnostic of multiple pregnancy or a miscalculated due date, however, so this finding must be evaluated carefully. Because hCG is produced by the trophoblast cells that are overgrowing, a serum or urine test of hCG for pregnancy will

be strongly positive (1 to 2 million International Units compared with a normal pregnancy level of 400,000 International Units).

Results continue to be strongly positive after day 100 of pregnancy, when the level of hCG normally begins to decline. This fact must be evaluated carefully also, however, because highly positive test results can be characteristic of multiple pregnancies with more than one placenta or a miscalculated due date. The nausea and vomiting of early pregnancy is usually marked, probably because of the high hCG level present. Symptoms of gestational hypertension, such as increased blood pressure, edema, and proteinuria, are ordinarily not present before week 20 of pregnancy. With gestational trophoblastic disease, they may appear before this time. An ultrasound will show dense growth (typically a snowflake pattern) but no fetal growth in the uterus. No fetal heart sounds can be heard because there is no viable fetus.

At approximately week 16 of pregnancy, if the structure was not identified earlier by ultrasound, it will identify itself with vaginal bleeding. This may begin as spotting of dark-brown blood resembling prune juice or as a profuse fresh flow. As the bleeding progresses, it is accompanied by discharge of the clear fluid-filled vesicles. This is why it is important for any woman who begins to miscarry at home to bring any clots or tissue passed to the hospital with her. The presence of clear fluid-filled cysts changes the diagnosis from a simple miscarriage to gestational trophoblastic disease.

### **Therapeutic Management**

Therapy for gestational trophoblastic disease is suction curettage to evacuate the abnormal trophoblast cells. Following extraction, women should have a baseline pelvic examination and a serum test for the beta subunit of hCG. The hCG is then analyzed every 2 weeks until levels are again normal. The serum hCG level is then assessed every 4 weeks for the next 6 to 12 months to see if it is declining (half of women will still have a positive reading at 3 weeks; one fourth still have a positive test result at 40 days).

If the level plateaus or increases, it suggests a malignant transformation (i.e., choriocarcinoma) is occurring. During the waiting time for the hCG level to decline, a woman should use a reliable contraceptive such as oral estrogen/progesterone so that a positive pregnancy test (the presence of hCG) resulting from a new pregnancy will not be confused with the increasing level that occurs with a developing malignancy. After 6 months, if hCG levels are still negative, a woman is theoretically free of the risk of a malignancy. By 12 months, she could begin to plan a second pregnancy. Although the development of gestational trophoblastic disease means a pregnancy never materialized and a fetus never formed, a woman may experience the same feeling of loss after evacuation that she would have experienced after the loss of a true pregnancy—she did, after all, believe she was pregnant. In addition, she is faced with the possibility a malignancy may develop as well as also delay her childbearing plans for a year. If she had already put off having a child for some time, this may seem to be an unbearably long time.

Some primary healthcare providers give women who have had gestational

trophoblastic disease a prophylactic course of methotrexate. However, because the drug interferes with white blood cell formation (i.e., leukopenia), prophylactic use must be weighed carefully (Stevens, Katzorke, Tempfer, et al., 2015). If malignancy should occur, it can be treated effectively in most instances with methotrexate at that time (Stevens et al., 2015). A second agent such as dactinomycin can be added to the regimen if metastasis occurs.

Women need the opportunity to express their anger and sense of unfairness at this type of event. They may feel inadequate because something went wrong with the pregnancy. They may wonder whether it will happen again in a future pregnancy or whether they will ever be able to have children. Unfortunately, women who have one incidence of gestational trophoblastic disease do have an increased risk of a second molar pregnancy (Maestá et al., 2015). They need early screening with ultrasound during a second pregnancy to be certain this irregular trophoblastic growth is not happening again.

### *What If . . . 21.1*

**After having had a gestational trophoblastic disorder, Beverly Muzuki told the nurse she did not believe in birth control because of religious convictions. She did not intend to take the oral contraceptives prescribed following her mole evacuation. How would the nurse best advise her?**

## **CERVICAL INSUFFICIENCY (PREMATURE CERVICAL DILATATION)**

**Premature cervical dilatation**, previously termed an incompetent cervix, refers to a cervix that dilates prematurely and therefore cannot retain a fetus until term (Roman, 2013). It occurs in about 1% of women. The dilatation usually occurs painlessly, so often the first symptom is show (a pink-stained vaginal discharge) or increased pelvic pressure, which then is followed by rupture of the membranes and discharge of the amniotic fluid. Uterine contractions begin and, after a short labor, the fetus is born. Unfortunately, this commonly occurs at approximately week 20 of pregnancy, when the fetus is still too immature to survive.

It is often difficult to explain in a particular instance what caused premature dilatation, although it is associated with increased maternal age, congenital structural defects, and trauma to the cervix, such as might have occurred with a cone biopsy or repeated D&Cs. Although it may be diagnosed by an early ultrasound before symptoms occur, it is usually diagnosed only after the pregnancy is lost.

After the loss of one child because of premature cervical dilatation, a surgical operation termed **cervical cerclage** can be performed to prevent this from happening in a second pregnancy (Gilner & Biggio, 2016).

As soon as an ultrasound confirms that the fetus of a second pregnancy is healthy at

approximately weeks 12 to 14, purse-string sutures are placed in the cervix by the vaginal route under regional anesthesia. This procedure is called a McDonald or a Shirodkar procedure after the surgeons who perfected the technique. The sutures serve to strengthen the cervix and prevent it from dilating until the end of pregnancy (Fig. 21.5). Still newer techniques allow purse-string sutures to be set before a woman becomes pregnant, providing added assurance she will not begin miscarrying before week 14 of pregnancy. In a McDonald procedure, nylon sutures are placed horizontally and vertically across the cervix and pulled tight to reduce the cervical canal to a few millimeters in diameter. With a Shirodkar technique, sterile tape is threaded in a purse-string manner under the submucous layer of the cervix and sutured in place to achieve a closed cervix. Although routinely accomplished by a vaginal route, sutures may be placed by a transabdominal route.

**Figure 21.5** Shirodkar suture for cervical cerclage.

After cerclage surgery, women remain on bed rest (perhaps in a slight or modified Trendelenburg position) for a few days to decrease pressure on the new sutures. Usual activity and sexual relations can be resumed in most instances after this rest period.

With these procedures, the sutures are removed at weeks 37 to 38 of pregnancy so the fetus can be born vaginally. When a transabdominal approach is used, the sutures must be left in place and a cesarean birth performed.

Women who are discovered to have cervical dilatation but with membranes still intact at a prenatal visit may have emergent cerclage sutures placed in the cervix even at that point as prophylaxis against preterm birth. The success of this procedure is limited, however, compared to preventive suturing (Ragab & Mesbah, 2015).

Be certain to ask women who are reporting painless bleeding (also the symptoms of spontaneous miscarriage) whether they have had past cervical operations to remind them they may have sutures in place. Currently, the prognosis for a successful pregnancy after surgical correction for premature cervical dilatation is very favorable. The success rate with both types of cerclage techniques averages 80% to 90% (Seifert & Altman, 2015).

## PLACENTA PREVIA

**Placenta previa**, a condition of pregnancy in which the placenta is implanted

abnormally in the lower part of the uterus, is the most common cause of painless bleeding in the third trimester of pregnancy ([Mastrolia, Baumfeld, Loverro, et al., 2016](#)) ([Fig. 21.6](#)). It occurs in four degrees: implantation in the lower rather than in the upper portion of the uterus (low-lying placenta), marginal implantation (the placenta edge approaches that of the cervical os), implantation that occludes a portion of the cervical os (partial placenta previa), and implantation that totally obstructs the cervical os (total placenta previa). The degree to which the placenta covers the internal cervical os is generally estimated in percentages: 100%, 75%, 30%, and so forth.

**Figure 21.6** Degrees of placenta previa: (A) low implantation, (B) partial placenta previa, and (C) total placenta previa.

Increased parity, advanced maternal age, past cesarean births, past uterine curettage, multiple gestation, and perhaps a male fetus are all associated with placenta previa. The incidence is approximately 5 per 1,000 pregnancies; it is thought to occur whenever the placenta is forced to spread to find an adequate exchange surface. There is a possibility an increase in congenital fetal anomalies or fetal restricted growth could occur if the low implantation does not allow optimal fetal nutrition or oxygenation, but in actual practice, this rarely happens ([Ahmed, Aitallah, Abdelghafar, et al., 2015](#)).

### Assessment

Placenta previa is often detected during pregnancy through a routine sonogram done to date the pregnancy. Although many low-lying placentas detected on early ultrasounds migrate upward to a noncervical position, the condition is explained to the woman and she is cautioned to call her healthcare provider at any sign of vaginal bleeding. The bleeding with placenta previa doesn't usually begin, however, until the lower uterine segment starts to differentiate from the upper segment late in pregnancy (approximately week 30) and the cervix begins to dilate. At that point, because the placenta is unable to stretch to accommodate the differing shape of the lower uterine segment or the cervix, a small portion loosens and damaged blood vessels begin to bleed. The bleeding is usually abrupt, painless, bright red, and sudden enough to frighten a woman. It is not associated with increased activity or participation in sports and may stop as abruptly as

it began, so that by the time a woman is seen at the healthcare setting, she is no longer bleeding. In other women, it may slow after the initial hemorrhage but linger as continuous spotting.

## Therapeutic Management

The bleeding of placenta previa, like that of ectopic pregnancy, creates an emergency situation as the open vessels of the uterine decidua (maternal blood) place the mother at risk for hemorrhage. Because the placenta is loosened, the fetal oxygen and nutrient supply may also be compromised, placing the fetus at risk as well. With the placental loosening, preterm labor (labor that occurs before the end of week 37 of gestation) may begin, posing the additional threat of preterm birth to the fetus.

### Immediate Care Measures

To ensure an adequate blood supply to a woman and fetus, place the woman immediately on bed rest in a side-lying position. Be certain to assess:

- Duration of the pregnancy
- Time the bleeding began
- Woman's estimation of the amount of blood—ask her to estimate in terms of cups or tablespoons (a cup is 240 ml; a tablespoon is 15 ml)
- Whether there was accompanying pain
- Color of the blood (red blood indicates bleeding is fresh or is continuing)
- What she has done, if anything, for the bleeding (if she inserted a tampon to halt the bleeding, there may be hidden bleeding)
- Whether there were prior episodes of bleeding during the pregnancy
- Whether she had prior cervical surgery for premature cervical dilatation

Inspect the perineum for bleeding and estimate the present rate of blood loss.

Weighing perineal pads before and after use and calculating the difference by subtraction is a good method to determine vaginal blood loss. An Apt or Kleihauer–Betke test (test strip procedures) can be used to detect whether the blood is of fetal or maternal origin. Obtain baseline vital signs to determine whether symptoms of hypovolemic shock are present. Continue to assess blood pressure every 5 to 15 minutes or continuously with an electronic cuff. Never attempt a pelvic or rectal examination with painless bleeding late in pregnancy because any agitation of the cervix when there is a placenta previa might tear the placenta further and initiate massive hemorrhage, possibly fatal to both mother and child.

Attach external monitoring equipment to record fetal heart sounds and uterine contractions (an internal monitor for either fetal or uterine assessment is contraindicated). Hemoglobin, hematocrit, prothrombin time, partial thromboplastin time, fibrinogen, platelet count, type and cross-match, and antibody screen will be assessed to establish baselines, detect a possible clotting disorder, and ready blood for replacement if necessary. Monitor urine output frequently, as often as every hour, as an

indicator her blood volume is remaining adequate to perfuse her kidneys. Administer intravenous fluid as prescribed, preferably with a large-gauge catheter to allow for blood replacement through the same line.

A vaginal birth is always safest for an infant. It is essential, therefore, to determine the placenta's location as accurately as possible in the hope that its position will make vaginal birth feasible. If the previa is under 30% by abdominal or intravaginal ultrasound, it may be possible for the fetus to be born past it. If over 30%, and the fetus is mature, the safest birth method for both mother and baby is often a cesarean birth (Kim, Joung, Lee, et al., 2015).

If only a minimum previa is detected by sonogram, the primary healthcare provider may attempt a careful speculum examination of the vagina and cervix to establish the degree of fetal engagement and to rule out another cause for bleeding, such as ruptured varices or cervical trauma. This should be done in an operating room or a fully equipped birthing room so that if hemorrhage does occur with cervical manipulation, an immediate cesarean birth can be carried out to remove the child and the bleeding placenta and contract the uterus. Have oxygen equipment available in case the fetal heart sounds indicate fetal distress, such as bradycardia or tachycardia, late deceleration, or variable decelerations during the exam.

### Continuing Care Measures

The point at which a diagnosis of placenta previa is made and the age of the gestation dictate the final management. If labor has begun, bleeding is continuing, or the fetus is being compromised (measured by the response of the FHR to contractions), birth must be accomplished regardless of gestational age. If the bleeding has stopped, the fetal heart sounds are of good quality, maternal vital signs are good, and the fetus is not yet 36 weeks of age, a woman is usually managed by expectant watching. Typically, a woman remains in the hospital on bed rest for close observation for 24 to 48 hours. If the bleeding stops, she can be sent home with a referral for bed rest and home care. Assessments of fetal heart sounds and laboratory tests, such as hemoglobin or hematocrit, are obtained frequently. Betamethasone, a steroid that hastens fetal lung maturity, may be prescribed for the mother to encourage the maturity of fetal lungs if the fetus is less than 34 weeks gestation (Box 21.5).

#### BOX 21.5

#### Nursing Care Planning Based on Responsibility for Pharmacology

##### **BETAMETHASONE (CELESTONE)**

**Action:** Betamethasone is a corticosteroid that acts as an anti-inflammatory and immunosuppressive agent. It is given to pregnant women 12 to 24 hours before birth to hasten fetal lung maturity if a fetus is less than 34 weeks gestation and help prevent respiratory distress syndrome in the newborn (Karch, 2015).

**Pregnancy Risk Category: C**

**Dosage:** 12 to 12.5 mg intramuscularly (IM) initially; may be repeated in 24 hours and again in 1 to 2 weeks

**Possible Adverse Effects:** Burning, itching, and irritation at the injection site; swelling, tachycardia, headache, dizziness, weight gain, sodium, and fluid retention; and increased risk of infection if used long term.

**Nursing Implications**

- Explain the purpose of the drug to the patient.
- Administer the initial dose IM. Anticipate the need for repeat dosing within 24 hours and again in 1 to 2 weeks.
- Assist with measures to halt preterm labor if indicated.
- Continue to monitor patient's vital signs and fetal heart rate for changes.
- If patient is also receiving a tocolytic agent, be alert for possible cardiac decompensation as a result of a drug–drug interaction. Observe for signs such as increased pulse, decreased blood pressure, and presence of edema.
- Assess for signs and symptoms of possible infection with long-term use.
- Instruct patient about the possibility that a repeat dose may be necessary.

**Nursing Diagnoses and Related Interventions**

Because the diagnosis of placenta previa with bleeding is an emergency, all goals should reflect the short time frame of the emergency condition.

**Nursing Diagnosis:** Fear related to outcome of pregnancy after episode of placenta previa bleeding

**Outcome Evaluation:** Patient discusses concerns with nurse and other healthcare providers; states hearing fetal heartbeat helps to reassure her about baby's health.

Often, it is difficult for a woman who has experienced bleeding late in a pregnancy to wait for the baby to come to term because she wonders whether her infant will be all right. Regardless of her outward appearance, most likely, she is experiencing severe emotional stress. She cannot help but wonder if the next bleeding she experiences will kill her, the infant, or both. Listening to fetal heart sounds and being reassured they are in a healthy range is helpful, as is having a listening ear she can talk to about her fears for both the pregnancy and herself.

**Birth**

If the pregnancy was past 37 weeks at the time of the initial bleeding, and an amniocentesis analysis for lung maturity shows a positive result (a favorable

lecithin/sphingomyelin ratio), a birth decision will generally be made immediately as it is important birth be in a controlled setting in case more than the usual blood loss occurs with birth. If the fetus is not mature, the pregnancy will be allowed to continue to the point bleeding occurs again, labor begins, the fetus shows symptoms of distress, or the fetus is mature. Offer firm support if the birth will be an emergency situation.

If the placenta previa is found to be total, birth through the cervix which is covered by the placenta is impossible and the baby must be born by cesarean birth. If the placenta previa is partial, the amount of the blood loss, the condition of the fetus, and a woman's parity will influence the birth decision. For cesarean birth, if an ultrasound clearly reveals the placental location, a transverse uterine incision may still be possible, although the uterine cut must be made high, possibly vertically above the low implantation site of the placenta.

After birth, most women inspect their child carefully. They may be worried that because of the problem with placental implantation, there might be something wrong with the baby. During the postpartum period, be sure a woman has adequate time with her child to be certain she feels comfortable giving care before she leaves the healthcare facility.

Any woman who has had a placenta previa is more prone than normal to postpartum hemorrhage because the placental site is in the lower uterine segment, which does not contract as efficiently as the upper segment. Also, because the uterine blood supply is less in the lower segment, the placenta tends to grow larger than it would normally, leaving a larger denuded surface area when it is removed. As a second complication, a woman is more likely to develop endometritis because the placental site is close to the cervix, the portal of entry for pathogens.

### ***QSEN Checkpoint Question 21.3***

#### **SAFETY**

Suppose a sonogram shows Beverly, who is beginning preterm labor, has a placenta previa. The nurse identifies which measure as the priority to ensure her safety?

- a. Keep her physically active to avoid a deep vein thrombosis.
- b. Perform a daily vaginal exam to assess the extent of the previa.
- c. Assess for vaginal bleeding and clear fluid leakage every shift.
- d. Keep her nothing by mouth (NPO) as she will need an emergency cesarean birth.

*Look in Appendix A for the best answer and rationale.*

## **PREMATURE SEPARATION OF THE PLACENTA (ABRUPTIO PLACENTAE)**

Unlike placenta previa, in **premature separation of the placenta** (also called abruptio placentae; Fig. 21.7), the placenta appears to have been implanted correctly. Suddenly,

however, it begins to separate and bleeding results. This occurs in about 10 out of 1,000 pregnancies and, because it can lead to extensive bleeding, is the most frequent cause of perinatal death (Ananth, Lavery, Vintzileos, et al., 2016). The separation generally occurs late in pregnancy; even as late as during the first or second stage of labor. Because premature separation of the placenta may occur during an otherwise normal labor, it is important to always be alert to both the amount and kind of pain and vaginal bleeding a woman is having in labor.

**Figure 21.7** Premature separation of the placenta.

The primary cause of premature separation is unknown, but certain predisposing factors are high parity, advanced maternal age, a short umbilical cord, chronic hypertensive disease, hypertension of pregnancy, direct trauma (as from an automobile accident or intimate partner violence), vasoconstriction from cocaine or cigarette use, and thrombophilic conditions that lead to thrombosis formation (Boisramé, Sananès, Fritz, et al., 2014). It also may be caused by **chorioamnionitis** or infection of the fetal membranes and fluid (Hackney, Kuo, Petersen, et al., 2016).

Yet another possible cause is a rapid decrease in uterine volume, such as occurs with sudden release of amniotic fluid as can happen with polyhydramnios. Usually, the fetal head is low enough in the pelvis that when membranes rupture, this prevents loss of the total volume of the amniotic fluid at one time, so normally a rapid reduction in amniotic fluid does not occur.

### Assessment

A woman experiences a sharp, stabbing pain high in the uterine fundus as the initial separation occurs. If labor begins with the separation, each contraction will be accompanied by pain over and above the pain of the contraction. Tenderness can be felt on uterine palpation.

Heavy bleeding usually accompanies premature separation of the placenta, although it may not be readily apparent. External bleeding will only be evident if the placenta separates first at the edges, so blood escapes freely into the uterus and then the cervix. In contrast, if the center of the placenta separates first, blood can pool under the

placenta, and although bleeding is just as intense, it will be hidden from view. Whether blood is evident or not, signs of hypovolemic shock usually follow quickly. The uterus becomes tense and feels rigid to the touch. If blood infiltrates the uterine musculature, **Couvelaire uterus** or uteroplacental apoplexy, forming a hard, boardlike uterus occurs. As bleeding progresses, a woman's reserve of blood fibrinogen becomes diminished as her body attempts to accomplish effective clot formation, and DIC syndrome can occur (see later).

If a woman is being admitted to the hospital after experiencing symptoms at home, assess when the time the bleeding began, whether pain accompanied it, the amount and kind of bleeding, and her actions to detect if trauma could have led to the placental separation. Initial blood work should include hemoglobin level, typing and cross-matching, and a fibrinogen level and fibrin breakdown products to detect DIC.

### Therapeutic Management

Because of the threat to both the woman and the fetus, separation of the placenta is immediately an emergency situation (Heavey & Dahl Maher, 2015). A woman needs a large-gauge intravenous catheter inserted for fluid replacement and oxygen by mask to limit fetal anoxia. Monitor fetal heart sounds externally and record maternal vital signs every 5 to 15 minutes to establish baselines and observe progress. The baseline fibrinogen determination will be followed by additional determinations up to the time of birth. Keep a woman in a lateral, not supine, position to prevent pressure on the vena cava and additional interference with fetal circulation. It is important not to disturb the injured placenta any further. Therefore, do not perform any abdominal, vaginal, or pelvic examination on a woman with a diagnosed or suspected placental separation.

For better prediction of fetal and maternal outcomes, the degrees of placental separation can be graded (Table 21.5). Unless the separation is minimal (grades 0 and 1), the pregnancy must be ended because the fetus cannot obtain adequate oxygen and nutrients. If vaginal birth does not seem imminent, cesarean birth is the birth method of choice. If DIC has developed, cesarean birth may pose a grave risk because of the possibility of hemorrhage during the surgery and later from the surgical incision. Intravenous administration of fibrinogen or cryoprecipitate (which contains fibrinogen) can be used to elevate a woman's fibrinogen level prior to and concurrently with surgery. With the worst outcome, a hysterectomy might be necessary to prevent exsanguination.

**TABLE 21.5** PREMATURE SEPARATION OF THE PLACENTA: DEGREES OF SEPARATION

Grade	Criteria
0	No symptoms of separation are apparent from maternal or fetal signs; the diagnosis is made after birth, when the placenta is examined and a segment of the placenta shows a recent adherent clot on the maternal surface.

1	Minimal separation, but enough to cause vaginal bleeding and changes in the maternal vital signs; no fetal distress or hemorrhagic shock occurs, however.
2	Moderate separation; there is evidence of fetal distress; the uterus is tense and painful on palpation.
3	Extreme separation; without immediate interventions, maternal hypovolemic shock and fetal death will result.

Fetal prognosis depends on the extent of the placental separation and the degree of fetal hypoxia. Maternal prognosis depends on how promptly treatment can be instituted. Death can occur from massive hemorrhage leading to shock and circulatory collapse or renal failure from circulatory collapse.

Any woman who has had bleeding before birth is more prone to infection after birth than the average woman. A woman with a history of premature separation of the placenta, therefore, needs to be observed closely for the development of infection in the postpartum period.

## **DISSEMINATED INTRAVASCULAR COAGULATION**

DIC is an acquired disorder of blood clotting in which the fibrinogen level falls to below effective limits (Cunningham & Nelson, 2015). Early symptoms include easy bruising or bleeding from an intravenous site. Conditions such as premature separation of the placenta, hypertension of pregnancy, amniotic fluid embolism, placental retention, septic abortion, and retention of a dead fetus are all associated with its development (Cunningham & Nelson, 2015). Normally, platelets quickly form a seal over a point of bleeding to prevent further loss of blood. Intrinsic and extrinsic clotting pathways then activate and strengthen this plug with fibrin threads to produce a firm, fixed structure. To prevent too much clotting from occurring, at the same time the clot is being formed, thrombin activates fibrinolysin, a proteolytic enzyme, which begins digestion of excess fibrin threads (anticoagulation). This lysis results in the release of fibrin degradation products.

DIC occurs when there is such extreme bleeding and so many platelets and fibrin from the general circulation rush to the site that there is not enough left in the rest of the body. This results in a paradox: At one point in the circulatory system, the person has increased coagulation, but throughout the rest of the system, a bleeding defect exists. DIC is an emergency because it can result in extreme blood loss. Goals for care should reflect the presence of the emergency.

Blood needs to be drawn for a platelet count (will be decreased to  $\leq 100,000/\mu\text{l}$ ), prothrombin (will be low because it depends on the conversion of fibrinogen to fibrin), thrombin time (will be elevated because it measures the time necessary for conversion of fibrinogen to fibrin), fibrinogen (will be decreased to  $< 150 \text{ mg/dl}$  because fibrinogen is not available), and fibrin split products (will be  $> 40 \text{ mcg/ml}$  reflecting the destruction of fibrinogen or fibrin). A D-dimer analysis is specific for fibrin (not fibrinogen)

degradation products and will be abnormal in 90% of patients with DIC ([Cunningham & Nelson, 2015](#)).

To stop the process of DIC, the underlying insult that began the phenomenon must be halted. When the insult was a complication of pregnancy, such as premature separation of the placenta, ending the pregnancy by birthing the fetus and delivering the placenta is part of the solution. Next, the marked coagulation must be stopped so that coagulation factors can be freed and normal clotting function can be restored. This is accomplished by the administration of heparin to halt the clotting cascade, first intravenously, then by subcutaneous (SQ) injection. Heparin must be cautiously given close to birth, however, or postpartum hemorrhage could occur from poor clotting after delivery of the placenta. A blood or platelet transfusion may be necessary to replace blood or platelet loss, but this is usually delayed until after heparin therapy so the new blood factors are also not consumed by the coagulation process. Antithrombin III factor, fibrinogen, or cryoprecipitate (which contains fibrinogen) can all be used in place of whole blood for transfusion. If these are not available, fresh frozen plasma or platelets can also aid in restoring clotting function.

It can be confusing for a woman with a disorder such as premature separation of the placenta to have her primary healthcare provider tell her 1-minute bleeding is what he or she is worried about but then hear the next minute an anticoagulant such as heparin has been prescribed. If a woman understands the action of heparin—to discourage blood coagulation—it seems as if this would be exactly the wrong medication. Be certain a woman and her support person have a full explanation of what is happening (i.e., she has an increased risk of hemorrhage because part of her system has tied up coagulation factors; by releasing them, coagulation can be restored throughout the rest of her body) so she can maintain confidence in her caregivers.

Evaluation focuses on determining whether a woman's blood coagulation studies are returning to normal and if any maternal anoxia has occurred, particularly in renal or brain cells from occluded coagulated capillaries. A fetal and newborn assessment is equally important to evaluate the efficiency of the placental circulation in light of the increased clotting (heparin does not cross the placenta so a newborn will not be born with decreased clotting ability).

## Preterm Labor

**Preterm labor** is labor that occurs before the end of week 37 of gestation. It occurs in approximately 9% to 11% of all pregnancies. It is always potentially serious because if it results in the infant's birth, the infant will be immature. Because of this, it is responsible for almost two thirds of all infant deaths in the neonatal period ([American College of Obstetricians and Gynecologists \[ACOG\], 2016a](#)). Any woman having persistent uterine contractions, even if they are mild and widely spaced, should be considered to be in labor. A woman is documented as being in actual labor rather than having false labor contractions if contractions have caused cervical effacement over

80% or dilation over 1 cm.

Maintaining general health during pregnancy is the best preventive measure to avoid preterm birth. Other measures can help prevent an occurrence of preterm birth (Box 21.6). Knowing the signs of labor can help women identify if preterm birth is beginning because some women wait before they seek help for preterm labor because they diagnose back pain or contractions as nothing more than extremely hard Braxton Hicks contractions. Currently, when there is treatment available to delay labor for at least a few days or until a fetus reaches a level of maturity that will allow the newborn to survive in the outside environment, evaluation and the institution of therapy before membranes rupture become vital, as ruptured membranes make it that much more difficult to halt labor.

### BOX 21.6

#### Nursing Care Planning Based on Family Teaching

#### MEASURES TO HELP PREVENT A RECURRENCE OF PRETERM LABOR FOR WOMEN ON BED REST

**Q.** Beverly Muzuki has started preterm labor and so is prescribed bed rest on home care. She asks you, “What else can I do to help prevent having this baby early?”

**A.** Although there are no guarantees, several actions can be helpful to prevent a recurrence of preterm labor:

- Remain on bed rest (a lounge or couch) except to use the bathroom.
  - Drink 8 to 10 glasses of fluids daily (keep a pitcher by your bed so you do not have to get up).
  - Keep mentally active by reading or working on a project to prevent boredom.
  - Avoid activities that could stimulate labor, such as nipple stimulation.
  - Consult your primary care provider regarding whether sexual relations should be restricted.
  - Immediately report signs of ruptured membranes (sudden gush of vaginal fluid) or vaginal bleeding.
  - Report signs of urinary tract or vaginal infection (e.g., burning or frequency of urination, vaginal itching or pain).
  - Keep appointments for prenatal care.
- If uterine contractions recur:*
- Empty your bladder to relieve pressure on the uterus.
  - Lie down on your left or right side to encourage blood return to the uterus.
  - Drink two or three glasses of fluid to increase hydration.
  - Contact your healthcare provider to report the incident and ask for further care measures.

Why labor begins before a fetus is mature is usually unclear. It is associated,

however, with dehydration, urinary tract infection, periodontal disease, chorioamnionitis, and perhaps large fetal size. African American women, adolescents, and those who receive inadequate prenatal care are most susceptible (Parets, Knight, & Smith, 2015). Women who continue to work at strenuous jobs during pregnancy or perform shift work that leads to extreme fatigue may have a higher incidence than others (van Beukering, van Melick, Mol, et al., 2014). Intimate partner violence and the trauma this causes may be yet another cause (Alhusen, Ray, Sharps, et al., 2015).

Common symptoms of early preterm labor women need to identify include a persistent, dull, and low backache; vaginal spotting; a feeling of pelvic pressure or abdominal tightening; menstrual-like cramping; increased vaginal discharge; uterine contractions; and intestinal cramping. Listen carefully to any woman who has these symptoms or believes she is in preterm labor because beginning symptoms of labor are subtle and best recognized by the woman herself.

It is possible to predict which pregnancies will end early by analyzing changes in the length of the cervix by ultrasound exam and analysis of vaginal mucus for the presence of fetal fibronectin, a protein produced by trophoblast cells (Jung, Park, Ryu, et al., 2016). If this is present in vaginal mucus, it predicts that preterm contractions are ready to occur; absence of the protein predicts that labor will not occur for at least 14 days.

## THERAPEUTIC MANAGEMENT

Medical attempts can be made to stop labor if the fetal membranes have not ruptured, fetal distress is absent, there is no evidence that bleeding is occurring, the cervix is not dilated more than 4 to 5 cm, and effacement is not more than 50%.

A woman who is in preterm labor is usually first admitted to the hospital and placed on bed rest to relieve the pressure of the fetus on the cervix. External fetal and uterine contraction monitors are attached to monitor FHR and the intensity of contractions. Intravenous fluid therapy to keep her well hydrated is begun because although not well documented, hydration may help stop contractions. This is thought to be effective because if a woman is dehydrated, the pituitary gland will be activated to secrete antidiuretic hormone, which might cause the pituitary gland to release oxytocin as well, strengthening uterine contractions.

Vaginal and cervical cultures and a clean-catch urine sample are prescribed to rule out infection. If a urinary tract infection is present, the woman will be prescribed an antibiotic that is especially effective for group B streptococcus as this infection can be fatal in a newborn.

## DRUG ADMINISTRATION

Terbutaline is a drug approved to prevent and treat bronchospasm (i.e., narrowing of airways) but may be used, off-label, as a **tocolytic agent** (i.e., an agent to halt labor). Terbutaline carries a “black box” warning, however, that it should not be used for over 48 to 72 hours of therapy because of a potential for serious maternal heart problems and

death. It should not be used in an outpatient or home setting because its administration requires constant professional assessment (Roman, 2013).

Magnesium sulfate, given intravenously, is used primarily to treat preeclampsia and prevent eclamptic seizures. It was traditionally given to prevent preterm labor as well. However, recent research does not support the use of magnesium as a tocolytic. There are no differences seen between those women receiving magnesium and those receiving no treatment in preterm birth outcomes (Navathe & Berghella, 2016). Magnesium sulfate for fetal neuroprotection is used prior to 32 weeks to help prevent cerebral palsy in premature infants (Nijman, van Vliet, Koullali, et al., 2016).

For reasons not clearly understood, if, in the time between when preterm contractions begin and preterm birth occurs, a woman is administered a corticosteroid such as betamethasone the formation of lung surfactant appears to accelerate, thus reducing the possibility of respiratory distress syndrome or bronchopulmonary dysplasia (Msan, Usta, Mirza, et al., 2015). During the time labor is being chemically halted, therefore, if the pregnancy is under 34 weeks, a woman may be given two doses of 12 mg betamethasone intramuscularly 24 hours apart or four doses of 6 mg dexamethasone intramuscularly 12 hours apart.

Although the effect of betamethasone lasts for about 7 days, it takes about 24 hours for the drug to begin its effect, so it is important labor be halted for at least 24 hours. If the fetus is not born within the 7-day time span, the dose of betamethasone may be repeated, but this is controversial because any corticosteroid can interfere with glucose regulation in the woman and potentially in the fetus.

### *What If... 21.2*

**The nurse overhears Beverly tell her mother not to come to the hospital to be with her because her baby is so small that her labor should be quick and easy. Would the nurse investigate further or assume Beverly knows what will be best for herself?**

## FETAL ASSESSMENT

In addition to supervising tocolytic therapy, be certain to assess overall fetal welfare in the woman who is trying to delay or prevent preterm labor by assessing the FHR and activity (Box 21.7, an interprofessional care map for a woman in preterm labor).

### BOX 21.7

#### Nursing Care Planning

### AN INTERPROFESSIONAL CARE MAP FOR A WOMAN IN PRETERM LABOR

Beverly Muzuki is a 20-year-old gravida 2, para 0, 30-week pregnant woman, whom

you see in a prenatal clinic. She has had symptoms of a urinary tract infection for the past few days but didn't call the clinic because she knew she would be in today for her appointment. Yesterday, she noticed some mild lower abdominal pain but thought it was irritation from the bladder infection. During the night, she woke twice because of a nagging lower backache. This morning, she has intermittent sharp uterine contractions. "Why am I starting labor so early?" she asks you. "Is it because I'm Rh negative?"

**Family Assessment:** Patient, 20 years old, lives in a two-bedroom, third-floor apartment and works as a secretary for local construction firm; husband, 26 years old, is a payroll supervisor at the same firm. Finances rated as, "Who couldn't use more money?"

**Patient Assessment:** Gravida 2, para 0, 30-week pregnancy. Heart rate, 88 beats/min; respirations, 22 breaths/min; blood pressure, 130/78 mmHg. Fetal heart rate (FHR), 142 beats/min; reports positive fetal movements. Uterine contractions every 7 minutes lasting 40 seconds. Cervical effacement 30%; dilation: 2–3 cm. Intravenous (IV) therapy with magnesium sulfate and IM corticosteroid prescribed.

**Nursing Diagnosis:** Risk for injury (maternal and fetal) related to preterm labor and tocolytic therapy

**Outcome Criteria:** Contractions halt after treatment with tocolytic; FHR remains within acceptable parameters; patient remains free of signs and symptoms of adverse effects of tocolytic therapy. Patient verbalizes concerns and fears; participates in decision making and relaxation measures.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
-------------------------	------------	--------------	-----------	------------------

*Activities of Daily Living, Including Safety*

Nurse/primary healthcare provider	Attach contraction and FHR monitors for continuous evaluation of contractions and fetal response.	Institute bed rest with patient in side-lying position.	Bed rest relieves pressure of the fetus on the cervix. Side-lying position enhances uterine perfusion. Uterine and fetal monitoring provides evidence of fetal well-being.	Patient will remain on bed rest until labor contractions halt or further action becomes necessary.
-----------------------------------	---	---	--	--

*Teamwork and Collaboration*

Nurse/primary healthcare provider	Contact ultrasound personnel.	Obtain patient consent for ultrasound. Arrange for ultrasound to establish fetal health and cervical length.	An ultrasound can document fetal health and cervical dilation.	Patient agrees to procedure; completes preprocedure readiness actions.
-----------------------------------	-------------------------------	--	--	--

*Procedures/Medications for Quality Improvement*

Nurse	Assess vital signs of patient. Obtain history of events leading up to beginning of labor.	Obtain laboratory studies, including complete blood count, hemoglobin and hematocrit, and serum electrolytes. Obtain clean-catch urine for culture, vaginal and cervical cultures, and fetal fibronectin as ordered.	Assessment provides a baseline for future comparisons. Urine, vaginal, and cervical cultures help to rule out infection as a causative factor for preterm labor. Fetal fibronectin can help predict whether labor is likely to continue.	Specimens are collected and sent to lab promptly to ensure rapid assessment.
-------	---	--	--	--

*Procedures/Medications for Quality Improvement*

Nurse/primary healthcare provider	Assess for contraindications to betamethasone administration. Obtain reports of urine and cervical cultures and fetal fibronectin.	Administer betamethasone to aid fetal lung maturity and an antibiotic for urinary tract infection as prescribed.	Betamethasone, a steroid, helps to decrease the risk of respiratory distress syndrome in the event of premature birth. An antibiotic decreases urinary tract	Patient agrees to betamethasone and antibiotic administration.
-----------------------------------	--	--	--	--

			infection.	
Nurse	Establish strength, duration, and frequency of baseline uterine contractions.	Administer magnesium sulfate as prescribed as an IV piggyback with infusion pump for fetal neuroprotection. Continue infusion for 12–24 hours.	Magnesium sulfate helps protect preterm babies from cerebral palsy.	Premature infant, if born, does not suffer from cerebral palsy.
Nurse	Continue maternal and fetal vital sign assessment.	Monitor patient's vital signs and neurologic status closely. Respirations should be at least 12 breaths/min before each magnesium sulfate dose; FHR, 120–160 beats/min; maternal reflexes, 1+ to 2+.	Decreasing urine output, neurologic changes, or decreased respiration or pulse rate are major indicators of magnesium sulfate toxicity. Decreasing FHR can indicate fetal distress.	Patient's and fetal vital signs, neurologic status, intake and output (renal status), and laboratory values remain within normal parameters during infusion.
Nurse	Assess if calcium gluconate is available.	Keep calcium gluconate available at the bedside.	Calcium gluconate is the antidote for magnesium sulfate toxicity.	Calcium gluconate is prepared by the pharmacy and is readily available.
<i>Nutrition</i>				
Nurse	Obtain hematocrit and serum	Assist with or insert an IV line. Begin IV	Hematocrit, electrolyte levels, and IV	IV fluid improves hydration,

	electrolyte levels every 4 hours or as ordered.	fluid therapy as prescribed.	intake measures the patient's fluid volume status.	which may help to minimize contractions.
--	---	------------------------------	--	--

*Patient-Centered Care*

Nurse	Assess patient's knowledge of preterm labor.	Instruct patient about preterm labor and about steps to be taken to counteract the process.	A well-informed patient can participate more fully in her own care.	Patient states the cause of preterm labor cannot always be identified; describes the part she can play in halting process.
-------	--	---	---	--

*Psychosocial/Spiritual/Emotional Needs*

Nurse	Assess patient's anxiety level over preterm labor. Assess for possible feelings of guilt related to cause of preterm labor.	Help patient to use using relaxation techniques, such as muscle relaxation, breathing, and music. Provide frequent updates about progress. Allow patient to verbalize feelings and concerns.	Relaxation techniques help to decrease anxiety and fear, enhancing feelings of control. Frequent updates about progress help to minimize fear due to the unknown.	Patient verbalizes her feelings about this crisis in her life; demonstrates anxiety but at a level that allows her to cooperate with caregivers.
Nurse	Determine whether patient wants a support person to be with her.	Contact support person as necessary.	The presence of a support person can offer additional comfort to a patient.	Patient names a support person she wants notified about hospital admission.

*Informatics for Seamless Healthcare Planning*

Nurse	Assess patient's home	Contact home care nurse	Monitoring to see if	Patient states she feels her
-------	-----------------------	-------------------------	----------------------	------------------------------

surroundings to determine whether they are appropriate for bed rest and continuing monitoring at home.	service to provide monitoring at home.	contractions return can safely be done at home with a conscientious and well-informed patient.	home and support system will be adequate for home care with self-monitoring; agrees on appointment for first home visit with home care nurse service.
--	--	--	---

Following this initial therapy and if contractions have ceased and there is evidence of fetal well-being, women with arrested preterm labor can be safely cared for at home as long as they can dependably drink enough fluid to remain well hydrated and, although there is little evidence that strict bed rest prevents preterm labor, a woman limits strenuous activities (Sosa, Althabe, Belizán, et al., 2015). It is also important for women to maintain adequate nutrition and to not smoke cigarettes as both poor nutrition and smoking are risks for preterm birth (Moore, Blatt, Chen, et al., 2016). To help with fetal assessment, a woman may be asked to record a daily fetal “kick” count or “count to 10” test (see Chapter 9 for this technique and Chapter 4 for a discussion of home care).

## LABOR THAT CANNOT BE HALTED

In some women, preterm labor is too far advanced (e.g., membranes have ruptured or the cervix is more than 50% effaced and more than 3 to 4 cm dilated) when they are first seen in a healthcare facility for it to be halted. The rupture of membranes, especially, can be thought of as a “point of no return” in stopping or delaying labor because of the increased risk of infection that begins at that point.

If the fetus is very immature at the time labor cannot be halted, a cesarean birth may be planned to reduce pressure on the fetal head and reduce the possibility of subdural or intraventricular hemorrhage from a vaginal birth, although this is controversial because infants born by cesarean birth have a higher incidence of respiratory difficulty, which is already a high risk for a very preterm infant.

Most women assume that if a fetus is preterm, labor for a vaginal birth will be shorter than normal because the infant is still so small. This is not necessarily true, however, because the first stage of labor, the longest stage, proceeds exactly as it would with a term pregnancy. The second stage of labor may be shorter because a small infant can be pushed through the dilated cervix and the birth canal more easily. Because the second stage takes, at most, 1 hour, this means the difference will not be more than 30

minutes to 1 hour. Unless a woman is given this explanation, she may worry not only that her labor is preterm but also that something is going wrong because it is lasting so long. Because of the increased risk for prolapse of the cord around a small head, artificial rupture of the membranes is not done as a rule in preterm labor until the fetal head is firmly engaged.

Analgesic agents are administered with caution because an immature infant will have enough difficulty breathing at birth without the additional burden of being sedated from a drug such as meperidine (Demerol). If a woman wants pharmaceutical pain management for labor, an epidural is preferable.

A woman may feel reassured by having an external fetal monitor during labor because the monitor screen shows evidence that, although her infant is going to be small, heart tones seem to be of good quality and the infant is reacting well to labor. Be certain that if a monitor is attached, the woman rests on her side to help prevent supine hypotension syndrome or an interference with uterine circulation.

Although an episiotomy is not routinely used because the head of a preterm infant is more fragile than that of a mature infant, one may be done to relieve excessive pressure on the head and hopefully reduce the possibility of a subdural or intraventricular hemorrhage. Following birth, the cord of the preterm infant is usually not clamped immediately because this extra amount of blood can help reduce the possibility of preterm anemia and the need for postbirth transfusion (Brocato, Holliday, Whitehurst, et al., 2016).

## Nursing Diagnoses and Related Interventions

Nursing diagnoses for the woman in preterm labor whose labor cannot be halted center around fear for the uncertain outcome of the pregnancy and risk for fetal or newborn injury related to the preterm birth. Be certain these diagnoses and outcomes for care are realistic in light of the threat to fetal and newborn health. Although many measures are available to help the preterm baby adjust to the outside world, a baby born preterm will be at risk for a variety of health problems, especially difficulty with respirations (see [Chapter 26](#)).

**Nursing Diagnosis:** Situational low self-esteem related to feelings of responsibility for preterm labor

**Outcome Evaluation:** Patient expresses feelings and worries to nurse; states she knows she is not responsible for her labor beginning prematurely.

A woman in preterm labor is undergoing an extreme crisis situation. She cannot help asking herself, “What did I do to cause this?” Time spent taking the initial history or timing contractions presents an opportunity to not only bring that concern out in the open but any others she may have as well. She needs a strong support person with her

during labor because if she has not yet taken a preparation for labor class, she may be more concerned than the average woman. Offer frequent assurance during labor that she is breathing well with contractions or just is “doing well.” During the postpartum period, she may need continued reassurance as she is being asked to care for a very small and vulnerable-appearing infant. Helping rebuild self-esteem this way, therefore, not only prepares her better for the stress of labor but also prepares her to be a parent to her preterm infant.

### *QSEN Checkpoint Question 21.4*

#### **TEAMWORK & COLLABORATION**

Beverly’s husband drove her to the emergency room because she was having symptoms of preterm labor. The admitting nurse in the emergency department identifies which action as the priority?

- a. Encourage her to carefully walk so the fetal head maintains pressure on her cervix.
- b. Position her in a side-lying position and assess fetal heart rate and contractions.
- c. Obtain blood for an hCG hormone assessment.
- d. Ensure no one initiates intravenous fluid infusion because hypervolemia exacerbates preterm labor.

*Look in [Appendix A](#) for the best answer and rationale.*

## **Preterm Rupture of Membranes**

**Preterm rupture of membranes** is rupture of fetal membranes with loss of amniotic fluid before 37 weeks of pregnancy (ACOG, 2016b). This occurs in 5% to 10% of pregnancies. The cause of preterm rupture is unknown, but it is strongly associated with infection of the membranes (i.e., chorioamnionitis). If rupture occurs early in pregnancy this way, it poses a major threat to the fetus as, after a rupture, the seal to the fetus is lost and uterine and fetal infections may occur. A second complication that can result is increased pressure on the umbilical cord from the loss of amniotic fluid (thus, inhibiting the fetal nutrient supply) or cord prolapse (extension of the cord out of the uterine cavity into the vagina past the small fetus), a condition that could also interfere with fetal circulation. Yet another risk to the fetus of remaining in a non–fluid-filled environment is the development of a Potter-like syndrome (i.e., distorted facial features and pulmonary hypoplasia from uterine pressure). In many instances, preterm labor follows rupture of the membranes and ends the pregnancy. If neither labor nor an infection begins, the greater the amount of amniotic fluid that remains (revealed by a sonogram), the better will be the pregnancy outcome (Ekin, Gezer, Taner, et al., 2015).

## ASSESSMENT

Rupture of the membranes is suggested by the history. A woman usually describes a sudden gush of clear fluid from her vagina, with continued minimal leakage.

Occasionally, a woman mistakes urinary incontinence caused by exertion for rupture of membranes. Amniotic fluid cannot be differentiated from urine by appearance, so a sterile vaginal speculum examination is done to observe for vaginal pooling of fluid. If the fluid is tested with Nitrazine paper, amniotic fluid causes an alkaline reaction on the paper (appears blue) and urine causes an acidic reaction (remains yellow). The fluid can also be tested for ferning, or the typical appearance of a high-estrogen fluid on microscopic examination (amniotic fluid shows this; urine does not). If there is still a question regarding whether the membranes have ruptured, an ultrasound can be used to assess the amniotic fluid index. Because preterm rupture of membranes is associated with vaginal infection, cultures for *Neisseria gonorrhoeae*, group B streptococcus, and chlamydia are usually obtained. Blood is drawn for white blood cell count and C-reactive protein, both of which increase with membrane rupture. Avoid doing routine vaginal examinations because the risk of infection rises significantly when digital examinations are performed after preterm rupture of membranes.

## THERAPEUTIC MANAGEMENT

A future hope is that by stem cell engineering, ruptured membranes can be repaired. Currently, however, if labor does not begin within 24 hours and the fetus is estimated to be mature enough by amniocentesis to survive in an extrauterine environment, labor contractions may be induced by intravenous administration of oxytocin so the infant can be born before infection can occur.

If the fetus is not at a point of viability, a woman is offered immediate delivery to end the pregnancy or, if she declines delivery, she is placed on bed rest either in the hospital or at home. If she reaches viability, a corticosteroid is administered to hasten fetal lung maturity. Prophylactic administration of broad-spectrum antibiotics effective against group B streptococcus during this period may both delay the onset of labor and reduce the risk of infection in the newborn sufficiently to allow the corticosteroid to have its effect.

A woman with no signs of infection may be administered a tocolytic agent if labor contractions begin. Although its effectiveness is not well documented, a woman might be given an amnioinfusion (see [Chapter 23](#)) to reduce pressure on the fetus or cord and to allow a safer term birth ([Hofmeyr, Eke, Lawrie, et al., 2014](#)).

### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for infection related to preterm rupture of membranes

without accompanying labor

**Outcome Evaluation:** Maternal white blood cell count remains below 20,000/mm<sup>3</sup>; maternal temperature is less than 100.4°F (38.0°C) while awaiting fetal maturity.

An infection can be dangerous for both the mother and fetus; so, if at home, a woman is asked to take her temperature about twice a day and to report a fever (a temperature greater than 100.4°F [38.0°C]), uterine tenderness, or odorous vaginal discharge. She should refrain from tub bathing, douching, and coitus because of the danger of introducing infection. The white blood cell count will need to be assessed frequently. A count of more than 18,000 to 20,000/mm<sup>3</sup> suggests infection, especially if the count is increasing over serial blood draws.

Before a woman is discharged to home care, be certain to ask if she has a thermometer and provide her with specific instructions regarding what degree of temperature she should report and if she understands the level of bed rest expected of her. Help her understand the signs and symptoms of infection so her white blood cell count can be assessed as necessary.

Many misconceptions about the difficulty of labor after preterm rupture of the membranes (i.e., “dry labor”) exist. You can assure a woman that there is no such thing as a dry labor because amniotic fluid is always being formed by the fetus voiding and through production of fluid by the amnion layer of the fetal membranes.

### *What If . . . 21.3*

**Beverly is prescribed bed rest for 24 hours because of preterm contractions, but she tells the nurse she’s too busy to “waste time” on bed rest. How can the nurse empower the patient to ask for help from family and friends so she can achieve bed rest? Are there any other suggestions the nurse could provide to help her maintain bed rest?**

## **Hypertensive Disorders in Pregnancy**

Gestational hypertension is a condition in which vasospasm occurs in both small and large arteries during pregnancy, causing increased blood pressure. **Preeclampsia** is a pregnancy-related disease process evidenced by increased blood pressure and proteinuria. An older term for preeclampsia was toxemia of pregnancy because researchers pictured the symptoms as being caused by women producing a toxin of some kind in response to the foreign protein of the growing fetus. The condition occurs in 5% to 7% of pregnancies. The cause of the disorder is unknown, although women with antiphospholipid syndrome (APS) or the presence of antiphospholipid antibodies in maternal blood are much more likely to develop preeclampsia (van Hoorn, Hague, van Pampus, et al., 2016). The condition tends to occur most frequently in women of

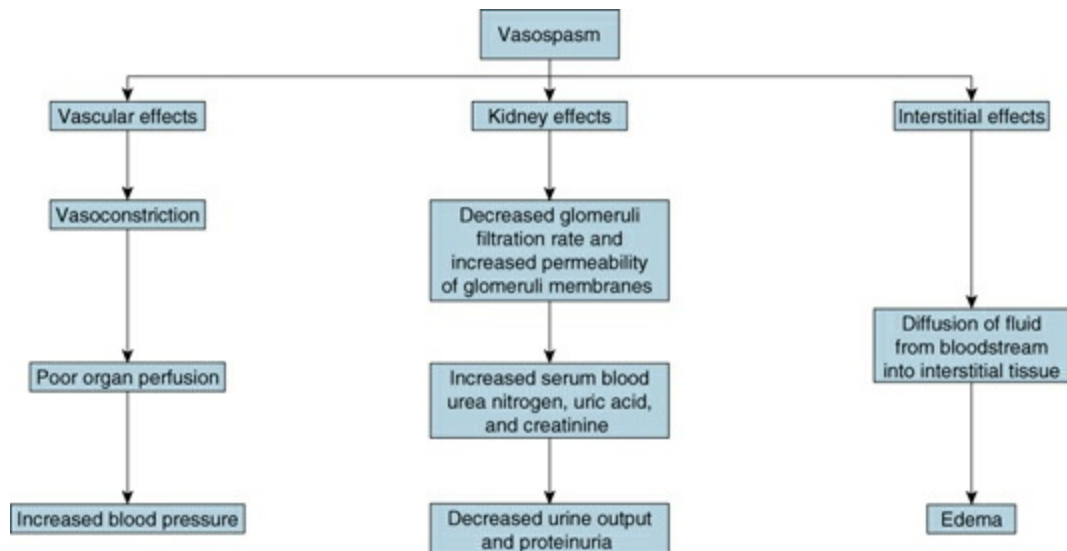

color; those with a multiple pregnancy; primiparas younger than 20 years or older than 40 years of age; women from low socioeconomic backgrounds (perhaps because of poor nutrition); those who have had five or more pregnancies; those who have polyhydramnios (i.e., overproduction of amniotic fluid; refer to later discussion); or those who have an underlying disease such as heart disease, diabetes with vessel or renal involvement, and essential hypertension (Miller, 2012).

## PATHOPHYSIOLOGIC EVENTS

The symptoms of preeclampsia affect almost all organs. The vascular spasm that occurs may be caused by the increased cardiac output required by pregnancy, which injures the endothelial cells of the arteries and reduces the action of prostacyclin—a prostaglandin vasodilator—and excess production of thromboxane—a prostaglandin vasoconstrictor and stimulant of platelet aggregation. Usually during pregnancy, blood vessels are resistant to the effects of pressor substances such as angiotensin and norepinephrine, so even with the increased blood supply, blood pressure remains normal during pregnancy. With gestational hypertension, this reduced responsiveness to blood pressure changes appears to be lost because of the prostaglandin release. Vasoconstriction occurs, and blood pressure increases dramatically.

Beginning about the 20th week of pregnancy, almost all body systems begin to be affected. The cardiac system, for example, can easily become overwhelmed because the heart is forced to pump against rising peripheral resistance. This causes a reduced blood supply to organs, most markedly the kidney, pancreas, liver, brain, and placenta. Poor placental perfusion reduces the fetal nutrient and oxygen supply. Ischemia in the pancreas can result in epigastric pain and an elevated amylase–creatinine ratio. If spasm occurs in the arteries of the retina, vision changes can occur. If this results in retinal hemorrhage, blindness can result.

Vasospasm in the kidney increases blood flow resistance. Degenerative changes then develop in the kidney glomeruli because of back pressure. This leads to increased permeability of the glomerular membrane, allowing the serum proteins albumin and globulin to escape into the urine (i.e., proteinuria). The degenerative changes also result in decreased glomerular filtration, so there is lowered urine output and clearance of creatinine. If increased kidney tubular reabsorption occurs, retention of sodium begins. As sodium retains fluid, edema results. Edema is further increased because, as more protein is lost, the osmotic pressure of the circulating blood falls and fluid diffuses from the circulatory system into the denser interstitial spaces to equalize the pressure (Fig. 21.8). Extreme edema can lead to maternal cerebral and pulmonary edema and seizures (eclampsia).

**Figure 21.8** Physiologic changes with gestational hypertension.

Yet another effect of the condition is that arterial spasm causes the bulk of the blood volume in the maternal circulation to be pooled in the venous circulation, so on assessment, a woman has a deceptively low arterial intravascular volume. In addition, thrombocytopenia or a lowered platelet count occurs as platelets cluster at the sites of endothelial damage. Measuring hematocrit levels helps to assess the extent of plasma loss to the interstitial space or the extent of the edema (the higher the hematocrit, the more is being lost). A hematocrit level above 40% suggests significant fluid loss into interstitial spaces.

## ASSESSMENT

Although women may have additional symptoms such as vision changes, typically hypertension, proteinuria, and edema are considered the classic signs of preeclampsia. Of the three, hypertension and proteinuria are the most significant because extensive edema occurs only after the other two are present (Box 21.8).

### BOX 21.8

#### Nursing Care Planning Using Assessment

#### ASSESSING THE WOMAN WITH GESTATIONAL HYPERTENSION

Preeclampsia is classified as preeclampsia without severe features, preeclampsia with severe features, and eclampsia, depending on how far development of the syndrome has advanced (Table 21.6). Any woman with a high risk of preeclampsia should be observed carefully for symptoms at prenatal visits. She needs instructions about what symptoms to watch for so she can alert her healthcare provider if symptoms begin to occur between visits.

**TABLE 21.6 SYMPTOMS OF GESTATIONAL HYPERTENSION**

Hypertension Type	Symptoms
Gestational hypertension	Blood pressure is 140/90 mmHg or systolic pressure elevated 30 mmHg or diastolic pressure elevated 15 mmHg above prepregnancy level; no proteinuria or edema; blood pressure

	returns to normal after birth
Preeclampsia without severe features	Blood pressure is 140/90 mmHg or systolic pressure elevated 30 mmHg or diastolic pressure elevated 15 mmHg above prepregnancy level; proteinuria of 1+ to 2+ on a random sample; weight gain over 2 lb/week in second trimester and 1 lb/week in third trimester; mild edema in upper extremities or face
Preeclampsia with severe features	Blood pressure is 160/110 mmHg; proteinuria 3+ to 4+ on a random sample and 5 g on a 24-hour sample; oliguria (500 ml or less in 24 hours or altered renal function tests; elevated serum creatinine more than 1.2 mg/dl); cerebral or visual disturbances (headache, blurred vision); pulmonary or cardiac involvement; extensive peripheral edema; hepatic dysfunction; thrombocytopenia; epigastric pain
Eclampsia	Either seizure or coma accompanied by signs and symptoms of preeclampsia are present.

## GESTATIONAL HYPERTENSION

A woman is said to have gestational hypertension when she develops an elevated blood pressure (140/90 mmHg) but has no proteinuria or edema. Perinatal mortality is not increased with simple gestational hypertension, so careful observation but no drug therapy is necessary.

## PREECLAMPSIA WITHOUT SEVERE FEATURES

If a seizure from preeclampsia occurs, a woman now has eclampsia, but any status above gestational hypertension and below a point of seizures is preeclampsia. A woman is said to be preeclamptic without severe features when she has proteinuria (1+ on a urine dip or 300 mg in a 24-hour urine protein collection or 0.3 or higher on a urine protein-creatinine ratio) and a blood pressure rise to 140/90 mmHg, taken on two occasions at least 6 hours apart. The diastolic value of blood pressure is extremely important to document because it is this pressure that best indicates the degree of peripheral arterial spasm present.

A second criterion for evaluating blood pressure is a systolic blood pressure greater than 30 mmHg and a diastolic pressure greater than 15 mmHg above prepregnancy values. This rule is helpful for a woman with preexisting hypertension, but the value of 140/90 mmHg is a more useful cutoff point when there are no baseline data available, such as when a woman seeks prenatal care late in pregnancy.

Average blood pressures in American women are available at <http://thePoint.lww.com/Flagg8e>. According to these averages, a woman younger than 20 years could have a blood pressure of 98/61 mmHg and still be within normal limits. If her blood pressure was elevated 30 mmHg systolic and 15 mmHg diastolic, it would

be only 128/76 mmHg. This is well beneath the traditional warning point of 140/90 mmHg but would represent hypertension for her.

Many women show a trace of protein during pregnancy. Actual proteinuria is said to exist when it registers as 1+ or more (this represents a loss of 1 g/L). A woman with preeclampsia will begin to show proteinuria of 1+ or 2+ on a reagent test strip on a random sample.

Occasionally, women have orthostatic proteinuria (i.e., on long periods of standing, they excrete protein; on bed rest, they do not). If proteinuria is present without other signs of gestational hypertension (no hypertension and no edema), check to see when the specimen was obtained. Ask her to bring in a first morning urine sample next time as that may reveal that orthostatic proteinuria, not preeclampsia, is the cause of protein in her urine.

Edema develops, as mentioned, because of the protein loss, sodium retention, and lowered glomerular filtration rate. The edema can be separated from the typical ankle edema of pregnancy because it begins to accumulate in the upper part of the body as well. A weight gain of more than 2 lb/week in the second trimester or 1 lb/week in the third trimester usually indicates abnormal tissue fluid retention is occurring. No noticeable edema may be present when this sudden increase in weight first occurs or it will be the first symptom a woman notices.

## **PREECLAMPSIA WITH SEVERE FEATURES**

A woman has passed to preeclampsia with severe features when her blood pressure rises to 160 mmHg systolic and 110 mmHg diastolic or above on at least two occasions 6 hours apart at bed rest (the position in which blood pressure is lowest) or her diastolic pressure is 30 mmHg above her prepregnancy level. Marked proteinuria, 3+ or 4+ on a random urine sample or more than 5 g in a 24-hour sample ([Olson-Chen & Seligman, 2016](#)).

With preeclampsia with severe features, extreme edema is most readily palpated over bony surfaces, such as over the tibia on the anterior leg, the ulnar surface of the forearm, and the cheekbones, where the sponginess of fluid-filled tissue can be palpated against bone. If there is swelling or puffiness at these points to a palpating finger but the swelling cannot be indented with finger pressure, the edema is described as nonpitting. If the tissue can be indented slightly, this is 1+ pitting edema; moderate indentation is 2+; deep indentation is 3+; and indentation so deep it remains after removal of the finger is 4+ pitting edema. This accumulating edema will reduce a woman's urine output to approximately 400 to 600 ml per 24 hours.

It's helpful to further assess edema by asking a woman if she has noticed any swelling anywhere in her body. Women commonly report upper extremity edema as "My rings are so tight I can't get them off" and facial edema as "When I wake in the morning, my eyes are swollen shut" or "My tongue is so swollen I can't talk until I walk around awhile."

Some women report severe epigastric pain and nausea or vomiting, possibly because

abdominal edema or ischemia to the pancreas and liver has occurred. If pulmonary edema has developed, a woman may report feeling short of breath. If cerebral edema has occurred, reports of visual disturbances such as blurred vision or seeing spots before the eyes may be reported. Cerebral edema also produces symptoms of severe headache and marked hyperreflexia and perhaps **ankle clonus** (i.e., a pulsed motion of the foot after flexion) (Box 21.9).

## BOX 21.9

### Nursing Care Planning Using Procedures

#### ELICITING A PATELLAR REFLEX AND ANKLE CLONUS

##### Patellar Reflex

With the woman in a supine position, ask her to bend her knee slightly. Place your hand under her knee to support the leg. Locate the patellar tendon in the midline of the anterior leg just below the kneecap. Strike it firmly and quickly with a reflex hammer or the side of your hand. If the leg and foot move, a patellar reflex is present. The reflex is scored as:

- 0 = No response; hypoactive; abnormal
- 1+ = Somewhat diminished response but not abnormal
- 2+ = Average response
- 3+ = Brisker than average but not abnormal
- 4+ = Hyperactive; very brisk; abnormal

##### Ankle Clonus

To elicit ankle clonus, dorsiflex the woman's foot three times in rapid succession. As you take your hand away, observe the foot. If no further motion is present, no ankle clonus is present. If the foot continues to move involuntarily, clonus is present. Although usually just rated as present or absent, it can be rated as:

- Mild = 2 movements
- Moderate = 3–5 movements
- Severe = Over 6 movements

## ECLAMPSIA

**Eclampsia** is the most severe classification of pregnancy-related hypertensive disorders. A woman has passed into this stage when cerebral edema is so acute a grand mal (tonic-clonic) seizure or coma has occurred. With eclampsia, the maternal mortality can be as high as 20% from causes such as cerebral hemorrhage, circulatory collapse, or renal failure (Gongora & Wenger, 2015).

The fetal prognosis with eclampsia is also poor because of hypoxia, possibly caused by the seizure, with consequent fetal acidosis. If premature separation of the placenta from extreme vasospasm occurs, the fetal prognosis becomes even graver. If a fetus must be born before term, all the risks of immaturity will be faced.

### *QSEN Checkpoint Question 21.5*

#### INFORMATICS

The nurse routinely assesses all pregnant women for signs of hypertension while interviewing them at the prenatal clinic and then documents the findings in the electronic health record. Which statement by Beverly would the nurse document as possible evidence that she might be developing gestational hypertension?

- “My feet are so swollen at night I can’t put on my bedroom slippers.”
- “I never guessed I would feel as tired as I do just from being pregnant.”
- “My abdomen feels firm, as if I had a blown-up balloon inside me.”
- “I can live with my puffy feet, but now it’s also my hands and wrists.”

*Look in Appendix A for the best answer and rationale.*

## Nursing Diagnoses and Related Interventions

The nursing diagnoses used with gestational hypertensive disorders are numerous because the disease process has such wide-ranging effects. Some possible nursing diagnoses include:

- Ineffective tissue perfusion related to vasoconstriction of blood vessels
- Deficient fluid volume related to fluid loss to SQ tissue
- Risk for fetal injury related to reduced placental perfusion secondary to vasospasm
- Social isolation related to prescribed bed rest

## NURSING INTERVENTIONS FOR A WOMAN WITH PREECLAMPSIA WITHOUT SEVERE FEATURES

Patients with preeclampsia without severe features prior to full term can be managed at home with frequent follow-up care and fetal testing.

## **Monitor Antiplatelet Therapy**

Because of the increased tendency for platelets to cluster along arterial walls, a mild antiplatelet agent, such as low-dose aspirin, may prevent or delay the development of preeclampsia (Leaf & Connors, 2015). Because aspirin is such a common over-the-counter drug, be certain women appreciate that this is not something to be taken lightly but a serious drug prescription for them. Be certain they purchase low-dose aspirin (81 mg, sold as baby aspirin) as excessive salicylic levels can cause maternal bleeding at the time of birth.

## **Promote Bed Rest**

When the body is in a recumbent position, sodium tends to be excreted at a faster rate than during activity. Bed rest, therefore, is the best method of aiding increased evacuation of sodium and encouraging diuresis of edema fluid. Be certain women know to rest in a lateral recumbent position to avoid uterine pressure on the vena cava and prevent supine hypotension syndrome.

## **Promote Good Nutrition**

A woman needs to continue her usual pregnancy nutrition while on bed rest. At one time, stringent restriction of salt was advised in order to reduce edema. This is no longer true because stringent sodium restriction may activate the renin–angiotensin–aldosterone system and actually result in increased blood pressure, thus compounding the problem.

Assess if a woman has someone to help her prepare food, or either bed rest or nutrition may be compromised.

## **Provide Emotional Support**

It is difficult for a woman with preeclampsia to appreciate the potential seriousness of symptoms because they are so vague; neither high blood pressure nor protein in urine is something she can see or feel. She is aware edema is present, but it seems unrelated to the pregnancy; after all, it is in her hands and face, not a body area near her growing child.

Women are also used to having severe disorders treated with some form of medication. If no other medicine than low-dose aspirin is prescribed, this can make a woman underestimate the severity of her situation, causing her to take instructions such as getting rest lightly. Almost 90% of women of childbearing age work outside their home at least part time today. In addition, most working women make major financial contributions to the running of their households. If a woman is unmarried, her income is probably her sole support. This makes it seem difficult to leave work on the basis of a few vague symptoms—a little swelling or a little headache—unless the woman receives clear information that, if these early symptoms are ignored, they could worsen to the point that they interfere with both her health and that of her fetus.

Healthcare providers cannot solve financial problems, but be certain to ask enough questions at healthcare visits so financial need, if present, can be determined. Questions such as “What will it mean to your family if you have to be on bed rest?” and “How long a maternity leave does your work allow?” will bring concerns to the surface.

Ask if a woman with small children will need to make child care arrangements so she can get sufficient rest. The woman who spends considerable time chauffeuring school-age children to activities may need to investigate carpooling as an alternative. Ask, “What will it mean to your other children or your husband if you have to rest?” to allow her to begin to examine these problems. Remember, having a wife or mother on bed rest is a stress on the total family, so other family members may need support as well.

Women with beginning signs of preeclampsia will be seen approximately weekly or more frequently for the remainder of pregnancy. Be certain a woman understands that if symptoms worsen before her next healthcare visit, she should report them immediately.

## **NURSING INTERVENTIONS FOR A WOMAN WITH PREECLAMPSIA WITH SEVERE FEATURES**

If a woman’s preeclampsia is severe (systolic blood pressure of more than 160 mmHg, diastolic blood pressure of more than 110 mmHg after a woman has been on bed rest; extensive edema; marked proteinuria [3+ to 4+]; cerebral or visual disturbances; marked hyperreflexia; or oliguria [500 ml per 24 hours or less]), a woman may be admitted to a healthcare facility for care. If the pregnancy is greater than 37 weeks, labor can be induced or a cesarean birth performed to end the pregnancy at that point. If the pregnancy is less than 37 weeks, interventions will be instituted to attempt to alleviate the severe symptoms and allow the fetus to come to term. However, if the symptoms persist or worsen, or if the fetal testing shows a compromised fetus, vaginal or cesarean delivery will be necessary even if the pregnancy is preterm.

### **Support Bed Rest**

With preeclampsia with severe features, most women are hospitalized so that bed rest can be enforced and a woman can be observed more closely than she can be on home care. Getting up to use the bathroom is not contraindicated in women with preeclampsia. Visitors are usually restricted to support people such as a partner, father of the child, mother, or older children. Because a loud noise such as a crying baby or a dropped tray of equipment can be sufficient to trigger a seizure that initiates eclampsia, a woman with preeclampsia with severe features is admitted to a private room so she can rest as undisturbed as possible. Raise side rails to help prevent injury if a seizure should occur.

#### *Concept Mastery Alert*

Sudden noises can trigger a seizure in a woman with preeclampsia with severe

features.

Darken the room if possible because a bright light can also trigger seizures. However, the room should not be so dark that caregivers need to use a flashlight to make assessments. Shining a flashlight beam into a woman's eyes is the kind of sudden stimulation to be avoided.

Stress is another stimulus capable of increasing blood pressure and evoking seizures in a woman with severe preeclampsia. Be certain, therefore, the woman receives clear explanations of what is happening and what is planned, especially about the need for visitor restrictions and not to “cheat” on bed rest. Allow her opportunities to express her feelings about what is happening or how bewildered she is because the few simple symptoms she noticed 2 weeks ago (e.g., increase in weight, increasing edema) have now developed into a syndrome that may be lethal to her baby and possibly to herself.

### **Monitor Maternal Well-Being**

Take blood pressure frequently (at least every 4 hours) or with a continuous monitoring device to detect any increase, which is a warning that a woman's condition is worsening. Obtain blood studies such as a complete blood count, platelet count, liver function, blood urea nitrogen, and creatine and fibrin degradation products as ordered by the obstetric team to assess renal and liver function and the development of DIC, which often accompanies severe vasospasm, as well as plasma estriol levels (a test of placenta function), and electrolyte levels. Because a woman is at high risk for premature separation of the placenta and resulting hemorrhage, a blood sample for type and cross-match is usually also obtained.

Daily hematocrit levels are used to monitor blood concentration (this level will rise if increased fluid is leaving the bloodstream for interstitial tissue [edema]).

Obtain daily weights at the same time each day as another evaluation of fluid retention. Ensure a woman is wearing the same amount of clothing at each weighing so any change in weight is not influenced by a change in the weight of her clothing.

An indwelling urinary catheter may be inserted to allow accurate recording of output and comparison with intake. Urinary output should be more than 30 ml/hr; an output lower than this suggests oliguria. Urinary proteins and specific gravity are measured and recorded with voiding or hourly if an indwelling catheter is present. A 24-hour urine sample, or a urine protein–creatinine ratio, may be collected for protein and creatinine clearance determinations to evaluate kidney function. A woman with mild preeclampsia spills between 0.5 and 1 g of protein every 24 hours (1+ on a random sample); a woman with severe preeclampsia spills approximately 5 g per 24 hours (3+ to 4+ on an individual specimen). A urine protein–creatinine ratio is above 0.3 with preeclampsia with mild features.

### **Monitor Fetal Well-Being**

Generally, single Doppler auscultation at approximately 4-hour intervals is sufficient at this stage of management. A woman may have a nonstress test or biophysical profile done daily to assess uteroplacental sufficiency (see [Chapter 9](#)). If fetal bradycardia occurs, oxygen administration to the mother may be necessary to maintain adequate fetal oxygenation.

### Support a Nutritious Intake

A woman needs a diet moderate to high in protein and moderate in sodium to compensate for the protein she is losing in urine. An intravenous fluid line is usually initiated and maintained to serve as an emergency route for drug administration as well as to administer fluid to reduce hemoconcentration and hypovolemia.

### Administer Medications to Prevent Eclampsia

A hypotensive drug such as hydralazine (Apresoline), labetalol (Normodyne), or nifedipine may be prescribed to reduce hypertension. These drugs act to lower blood pressure by peripheral dilatation and thus do not interfere with placental circulation. They can, however, cause maternal tachycardia, so assess pulse and blood pressure before and after administration. Diastolic pressure should not be lowered below 80 to 90 mmHg or inadequate placental perfusion could occur. Even with these new drugs, magnesium sulfate ([Table 21.7](#)) still remains the drug of choice to prevent eclampsia ([ACOG, 2016c](#)). This drug, classified as a cathartic, reduces edema by causing a shift in fluid from the extracellular spaces into the intestine. It also has a central nervous system depressant action (it blocks peripheral neuromuscular transmissions), which lessens the possibility of seizures ([Karch, 2015](#)). To achieve an immediate reduction of blood pressure, magnesium sulfate may first be given intravenously in a loading or bolus dose. The drug begins to act almost immediately; unfortunately, the effect lasts only 30 to 60 minutes, so administration must be continuous.

**TABLE 21.7 DRUGS USED IN PREECLAMPSIA**

Drug	Indication	Dosage	Comments
Magnesium sulfate (pregnancy risk category B)	Muscle relaxant; prevents seizures	Loading dose 4–6 g Maintenance dose 1–2 g/hr IV	Infuse loading dose slowly over 15–30 minutes. Always administer as a piggyback infusion. Assess respiratory rate, urine output, deep tendon reflexes, and clonus every hour. Urine output should be over 30 ml/hr and respiratory rate over 12 breaths/min. Serum magnesium level should

			remain below 7.5 mEq/l. Observe for central nervous system (CNS) depression and hypotonia in infant at birth and calcium deficit in the mother.
Hydralazine (Apresoline) (pregnancy risk category C)	Antihypertensive (peripheral vasodilator); used to decrease hypertension	5–10 mg IV	Administer slowly to avoid sudden fall in blood pressure. Maintain diastolic pressure over 90 mmHg to ensure adequate placental filling.
Diazepam (Valium) (pregnancy risk category D)	Halt seizures	5–10 mg IV	Administer slowly. Dose may be repeated q 5–10 minutes (up to 30 mg/hr). Observe for respiratory depression or hypotension in mother and respiratory depression and hypotonia in infant at birth.
Calcium gluconate (pregnancy risk category C)	Antidote for magnesium intoxication	1 g IV (10 ml of a 10% solution)	Have prepared at bedside as the antidote when administering magnesium sulfate. Administer at 5 ml/min.

Source: Karch, A. M. (2015). *Lippincott's nursing drug guide*. Philadelphia, PA: Lippincott Williams & Wilkins.

The importance of different serum levels of magnesium sulfate is shown in [Box 21.10](#). For the drug to act as an anticonvulsant, blood serum levels must be maintained at 5 to 8 mg per 100 ml. If the blood serum level rises above this, respiratory depression, cardiac arrhythmias, and cardiac arrest can occur.

### BOX 21.10

## Nursing Care Planning Based on Responsibility for Pharmacology

### MAGNESIUM SULFATE

**Action:** Magnesium sulfate is a central nervous system depressant that acts to block neuromuscular transmission of acetylcholine to halt convulsions (Karch, 2015).

**Pregnancy Risk Category:** A

**Dosage:** Initially, 2–6 g IV administered in a 250-ml solution over a 20-minute period, followed by individually calculated IV infusion at a rate to maintain designated serum levels

- Therapeutic range: 5–8 mg/100 ml
- Patellar reflex disappears: 8–10 mg/100 ml
- Respiratory depression occurs: 15–20 mg/100 ml
- Cardiac conduction defects occur: more than 20 mg/100 ml

**Possible Adverse Effects:** Flushing, thirst; with toxicity, absence of deep tendon reflexes, respiratory depression, cardiac arrhythmias, cardiac arrest, and decreased urine output

### **Nursing Implications**

- Administer continuous infusion piggybacked into a main IV line so it can be discontinued immediately without interfering with fluid administration.
- Always use an infusion control device to maintain a regular flow rate.
- Assess maternal blood pressure and fetal heart rate continuously with bolus IV administration.
- Assess deep tendon reflexes every 1–4 hours during continuous infusion. Use the patellar reflex. If patient has received epidural anesthesia, use the biceps reflex.
- Monitor intake and output every hour during continuous infusion. Urine output should be 30 ml/hr or greater.
- Assess patient's level of consciousness, including ability to respond to questions, every hour.
- Obtain serum magnesium levels as indicated, usually every 6–8 hours.
- Keep calcium gluconate, the antidote for toxicity, readily available at the bedside.
- Maintain serum blood levels (for anticonvulsant use) at 5–8 mg/100 ml. If blood serum levels rise above this, respiratory depression, cardiac arrhythmias, and cardiac arrest can occur.
- Do not administer additional doses and stop infusion if deep tendon reflexes are absent or if respiratory rate is less than 12–14 breaths/min or urine output is less than 30 ml/hr.
- This drug may cause respiratory depression in the newborn if administered close to birth. Alert neonatal care personnel about this possibility.
- Magnesium sulfate may cause osteoporosis in the mother if given over a long time.

The most evident symptoms of overdose from magnesium sulfate administration include decreased urine output, depressed respirations, reduced consciousness, and decreased deep tendon reflexes. Because magnesium is excreted from the body almost entirely through the urine, urine output must be monitored closely to ensure adequate elimination. If severe oliguria should occur (less than 100 ml in 4 hours), excessively high serum levels of magnesium can result. Before you administer further magnesium sulfate, therefore, ensure that urine output is at least 30 ml/hr, with a specific gravity of 1.010 or lower. Respirations should be above 12 breaths/min, a woman should be able to answer questions asked of her such as her name or address, ankle clonus should be

minimal, and deep tendon reflexes should be present. Make these assessments every hour if a continuous intravenous infusion is being used.

The easiest deep tendon reflex to assess is the patellar reflex (i.e., knee jerk). Instructions for initiating this reflex and ankle clonus are shown in [Box 21.9](#). If an epidural block has been given for labor anesthesia, assess the biceps or triceps reflex (see [Chapter 34](#)).

In addition to making the previous assessments when magnesium sulfate is being given, a solution of 10 ml of a 10% calcium gluconate solution (1 g) should be kept ready nearby for immediate intravenous administration should a woman develop signs and symptoms of magnesium toxicity, as calcium is the specific antidote for magnesium toxicity.

An FHR monitor during pregnancy may show loss of variability of the heartbeat immediately after magnesium therapy; an ultrasound may reveal reduced fetal breathing movements. Observe carefully for other signs of fetal effects, such as late deceleration with labor contractions. Magnesium sulfate is continued for 12 to 24 hours after birth to prevent eclampsia during this period. The dose is then tapered and discontinued. Breastfeeding does not need to be delayed until the medication is discontinued. A long-term effect of magnesium sulfate therapy is osteoporosis. A woman may be started on a course of calcium postpartally to decrease this problem. On the planned day of birth, the baby's primary care provider should be alerted that the woman has been receiving magnesium sulfate. This is because if magnesium sulfate, which crosses the placenta, is given intravenously within 2 hours of a baby's birth, the baby may be born with severe respiratory depression.

## **NURSING INTERVENTIONS FOR A WOMAN WITH ECLAMPSIA**

Degeneration of a woman's condition from preeclampsia with severe features to eclampsia occurs when cerebral irritation from increasing cerebral edema becomes so acute that a seizure occurs. This usually happens late in pregnancy but can happen up to 48 hours after childbirth. Immediately before a seizure, a woman's blood pressure rises suddenly from additional vasospasm. The increased cerebral pressure causes her temperature to rise sharply to 103° to 104°F (39.4° to 40°C). She notices blurring of vision or severe headache (from the increased cerebral edema), and her reflexes become hyperactive. She may experience a premonition or aura that "something is happening." Vascular congestion of the liver or pancreas can lead to severe epigastric pain and nausea or vomiting. Urinary output may decrease abruptly to less than 30 ml/hr. However, eclampsia has actually occurred, by definition, only when a woman experiences a seizure.

### **Tonic–Clonic Seizures**

An eclamptic seizure is a tonic–clonic type that occurs in stages. After the preliminary signal or aura that something is happening, all the muscles of the woman's body

contract. Her back arches, her arms and legs stiffen, and her jaw closes so abruptly she may bite her tongue. Respirations halt because her thoracic muscles are held in contraction. This phase of the seizure, called the tonic phase, lasts approximately 20 seconds. It may seem longer because a woman may grow slightly cyanotic from the cessation of respirations.

During the second (clonic) stage, the woman's bladder and bowel muscles contract and relax; incontinence of urine and feces may occur. Although a woman begins to breathe during this stage, the breathing is not entirely effective so she may remain cyanotic. The clonic stage of a seizure lasts up to 1 minute. Following this, she will enter an hour long postictal stage, during which she is unconscious.

The priority care for a woman with a tonic-clonic seizure is to maintain a patent airway. To prevent aspiration, turn her onto her side to allow secretions to drain from her mouth. Magnesium sulfate or diazepam (Valium) may be administered intravenously as emergency measures. Assess oxygen saturation via a pulse oximeter. Administer oxygen by face mask as needed to protect fetal oxygenation. Apply an external fetal heart monitor if one is not already in place to assess the FHR. The seizure may announce the beginning of labor, so assess as well for uterine contractions. Check for vaginal bleeding to detect placental separation, although evidence placental separation has occurred will probably appear first on the fetal heart record; vaginal bleeding will strengthen the presumption.

During the postictal stage, a woman cannot be roused except by painful stimuli for 1 to 4 hours. Extremely close observation is therefore as important during this third stage as it was during the first two stages. Be certain to assess for uterine contractions during this stage because if labor begins during this period, the woman will be unable to report the sensation of contractions. Also, the painful stimulus of contractions may initiate another seizure. Be certain to keep the woman on her side so secretions can drain from her mouth. Give her nothing to eat or drink. Remember that with coma, hearing is not necessarily lost, so be certain conversation is limited to those things you would say if she were awake. Continue to check for vaginal bleeding every 15 minutes.

## **Birth**

If the fetus has reached a point of viability, a decision about birth will be made as soon as a woman's condition stabilizes, usually 12 to 24 hours after the seizure. Probably because of the increased stress that has occurred, fetal lung maturity appears to advance rapidly with preeclampsia, so even though the fetus is younger than 37 weeks, the lecithin/sphingomyelin ratio may indicate fetal lung maturity.

Cesarean birth is always more hazardous for the fetus than vaginal birth because of the association of retained lung fluid (see [Chapter 26](#)). Furthermore, a woman with severe high blood pressure is not a good candidate for surgery. An additional problem arises: Because her vascular system is low in volume, she may become hypotensive with regional anesthesia, such as an epidural block. The preferred method for birth, therefore, is vaginal with a minimum of anesthesia. If labor does not begin

spontaneously, rupture of the membranes or induction of labor with intravenous oxytocin may be instituted. If this is ineffective and the fetus appears to be in imminent danger, cesarean birth becomes the birth method of choice.

## NURSING INTERVENTIONS DURING THE POSTPARTUM PERIOD

Postpartum preeclampsia may occur up to 10 to 14 days after birth, although it usually occurs within 48 hours after birth. Therefore, monitoring blood pressure in the postpartum period and at healthcare visits and being alert for preeclampsia, which can occur as late as 2 weeks postbirth, are essential to detect this residual hypertension (Takaoka, Ishii, Taguchi, et al., 2016).

### QSEN Checkpoint Question 21.6

#### EVIDENCE-BASED PRACTICE

Because so many women of childbearing age work at physically demanding occupations, researchers assessed the work lifting requirements of 66,693 pregnant woman when they were at 16 weeks gestational age by phone interview and then analyzed if there was an association between their work lifting characteristics and the development of small-for-gestational-age babies. Results of the study showed no consistent association between the work-related lifting and the incidence of small-for-gestational-age babies (Juhl, Larsen, Anderson, et al., 2014).

Based on the previous study, which statement by Beverly about her job as a secretary at a construction site would give the nurse the most concern regarding fetal health?

- “I think I likely walk at least a mile every work day.”
- “I rarely have time to eat when I’m at work because I get so busy.”
- “Sometimes, I have to move boxes of files around the office.”
- “I usually help my colleague bring boxes of paper up to the office for the photocopier.”

Look in [Appendix A](#) for the best answer and rationale.

## HELLP Syndrome

**HELLP syndrome** is a variation of the gestational hypertensive process named for the common symptoms that occur:

- **Hemolysis** leads to anemia
- **Elevated liver enzymes** lead to epigastric pain
- **Low platelets** lead to abnormal bleeding/clotting (Pourrat, Coudroy, & Pierre, 2015)

The syndrome occurs in 4% to 12% of patients who have elevated blood pressure during pregnancy. It is a serious syndrome because it results in a maternal mortality rate as high as 24% and an infant mortality rate as high as 35%.

Why some women with elevated blood pressure also develop the HELLP syndrome is unknown. It occurs in both primigravidas and multigravidas and is associated with APS or the presence of antiphospholipid antibodies (Tufano, Coppola, Maruotti, et al., 2015).

In addition to proteinuria, edema, and increased blood pressure, additional symptoms of nausea, epigastric pain, general malaise, and right upper quadrant tenderness from liver inflammation occur. Laboratory studies reveal hemolysis of red blood cells (they appear fragmented on a peripheral blood smear), thrombocytopenia (a platelet count  $<100,000/\text{mm}^3$ ), and elevated liver enzyme levels (alanine aminotransferase [ALT] and serum aspartate aminotransferase [AST]), which are all effects of hemorrhage and necrosis of the liver. Because of the low platelet count, women with the HELLP syndrome need extremely close observation for bleeding, in addition to the observations necessary for preeclampsia. Complications associated with the syndrome are subcapsular liver hematoma, hyponatremia, renal failure, and hypoglycemia from poor liver function. Mothers are also at risk for cerebral hemorrhages, aspiration pneumonia, and hypoxic encephalopathy. Fetal complications can include growth restriction and preterm birth (Barnhart, 2015).

Therapy for the condition is transfusion of fresh frozen plasma or platelets in order to improve the platelet count. If hypoglycemia is present, this is corrected by an intravenous glucose infusion. The infant is born as soon as feasible by either vaginal or cesarean birth. Be alert that maternal hemorrhage may occur at birth because of poor clotting ability. Epidural anesthesia may not be possible because of the low platelet count and the high possibility of bleeding at the epidural site. Laboratory results return to normal after birth, the same as preeclamptic symptoms, but the experience of developing the HELLP syndrome is frightening. Women need assurance afterward that symptoms were pregnancy related and so will not return.

## Multiple Pregnancy

Multiple gestation is considered a complication of pregnancy because a woman's body must adjust to the effects of more than one fetus. The incidence of multiple births has increased dramatically because of the use of in vitro fertilization, but still only occurs in 2% to 3% of all births (Bush & Pernoll, 2012).

Identical (i.e., monozygotic) twins begin with a single ovum and spermatozoon. In the process of fusion, or in one of the first cell divisions, the zygote divides into two identical individuals. Single-ovum twins usually have one placenta, one chorion, two amnions, and two umbilical cords. The twins are always of the same sex; they account for one third of twin births. The other two thirds of twins are fraternal (i.e., dizygotic, nonidentical), the result of the fertilization of two separate ova by two separate spermatozoa (possibly not from the same sexual partner). Double-ova twins have two placentas, two chorions, two amnions, and two umbilical cords. The twins may be of the same or a different sex (Fig. 21.9). It is sometimes difficult to determine by ultrasound

or at birth whether twins are identical or fraternal because the two fraternal placentas may fuse and appear as one large placenta.

**Figure 21.9** Multiple gestations. **(A)** Dizygotic twins showing two placentas, two chorions, and two amnions. **(B)** Monozygotic twins with one placenta, one chorion, and two amnions.

Multiple pregnancies of two to eight children may be single-ovum conceptions, multiple-ova conceptions, or a combination of the two types. Most multiple pregnancies today occur from multiple ova being implanted as an in vitro fertility process. Naturally occurring multiple pregnancies are more frequent in Blacks and Hispanics than Whites. The higher a woman's parity and age, the more likely she is to have a multiple gestation. Inheritance appears to play a role in natural dizygotic twinning; this has a familial maternal pattern of occurrence.

## ASSESSMENT

Multiple gestation is suspected early in pregnancy when the uterus begins to increase in size at a rate faster than usual. AFP levels will also be elevated. At the time of quickening, a woman may report flurries of action at different portions of her abdomen rather than at one consistent spot (e.g., where the feet are located). On auscultation of the abdomen, multiple sets of fetal heart sounds can be heard; although if one or more fetus has his or her back positioned toward a woman's back, only one fetal heart sound may be heard.

An ultrasound can reveal multiple gestation sacs early in pregnancy. In some instances, early ultrasound examinations reveal multiple amniotic sacs but then later in pregnancy, in as many as 30% of women, only one fetus remains (i.e., vanishing twin syndrome) (Evron, Sheiner, Friger, et al., 2015). Women who were told they were having twins but then later in pregnancy find out they are having only one child may grieve for a vanished twin as much as if the baby had died at birth. This emotional response is important in an assessment because it could disrupt pregnancy bonding work.

## THERAPEUTIC MANAGEMENT

Women with a multiple gestation are more susceptible to complications of pregnancy such as gestational hypertension, polyhydramnios, placenta previa, preterm labor, and anemia than are women carrying one fetus. Following birth, they are more prone to postpartum bleeding because of the additional uterine stretching that occurred. Because a multiple pregnancy usually ends before term, 25% of low-birth-weight babies are from multiple pregnancies. If monozygotic twins share a common vascular communication, it can lead to overgrowth of one fetus and undergrowth of the second (a twin-to-twin transfusion), resulting in discordant infants (Beauquier-Maccotta, Chalouhi, Picquet, et al., 2016) (see Chapter 26). If a single amnion is present, there can be knotting and twisting of umbilical cords, causing fetal distress or difficulty with birth. Because of the possibility of these complications, a woman with a twin pregnancy needs closer prenatal supervision than a woman with a single gestation to detect these problems as early as possible. A woman carrying more than two fetuses is at greatest risk.

### Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Fatigue related to increased stress on body functioning secondary to multiple gestation

**Outcome Evaluation:** Patient states she is tired but identifies steps she has taken to minimize fatigue.

Although there is little evidence that strict bed rest helps prolong multiple pregnancies (Fuchs & Senat, 2016), spend time at healthcare visits reviewing with a woman with a multiple pregnancy her need for extra rest, especially in a side-lying position during the day, to increase placental perfusion.

Because the woman is carrying double weight during pregnancy, she may notice extreme fatigue and backaches late in the day. She may have more difficulty resting or sleeping than the average woman because of this greater discomfort and increased fetal activity. As the growing uterus compresses her stomach, she may find her appetite decreasing and her intake falling. To compensate and maintain nutrition, a woman may need to eat six small meals a day rather than three large ones. She must also be sure to take her iron, folic acid, and vitamin supplements.

Toward the end of pregnancy, a woman may have extreme difficulty ambulating because of her excess weight. Her abdomen may become so stretched she feels as if she is going to burst.

Beginning with week 28 of pregnancy, a woman may be asked to come to a healthcare facility for monthly ultrasound examinations or weekly nonstress tests to document normal fetal growth, although this may not be necessary if the pregnancy is

going well and the fetuses are growing consistently. If these tests are necessary, be certain that appointments are scheduled to conserve her energy as much as possible.

**Nursing Diagnosis:** Parental role conflict related to recent discovery of multiple (as opposed to single) pregnancy

**Outcome Evaluation:** Patient states she is looking forward to caring for multiple infants (or may express concern about her ability to manage their arrival); patient identifies changes she is making in preparation now that more than one baby is expected.

A woman with a multiple pregnancy has to work through an additional role change during pregnancy. First, she must accept that she is pregnant and then accept that she is having a baby. Then suddenly, at a routine office visit, two or more gestational sacs are seen on ultrasound or two or more sets of heart sounds are heard on auscultation. She is told she is going to have more than one child. Now, she has to work through a second role change—for example, becoming a mother of two, not just of one (or more if she has additional children). This role change takes time and so may be difficult to complete, especially if the pregnancy ends early. A woman may need extra help after birth to form a close mother–child relationship with her newborns.

**Nursing Diagnosis:** Fear concerning her own and the babies' health related to risks of a multiple pregnancy

**Outcome Evaluation:** Patient accurately states risks of a multiple pregnancy; expresses confidence in healthcare team's ability to care for her and her babies through pregnancy and birth.

In addition to having to work through a role change, a woman with a multiple pregnancy has more reason to fear for her life and the life of her babies than does the average woman. Every woman has heard stories about twins being conjoined or born so prematurely they did not survive. If she has not already heard these stories, someone will be sure to mention them to her before her due date. Unfortunately, all these risks cannot simply be filed away under the heading of untrue stories: Both prematurity and high risk status are real hazards in multiple gestation. Help a woman deal with her fears as positively as possible. It can be helpful to tell her there is no indication so far that her babies are in any danger, so right now it is best to continue doing the things that have to be done; if any problems arise, the healthcare team and the woman's family will be there to support her.

Sometimes a woman is so fearful that her infants will be born too small to survive that she makes no preparations for them. She so lacks confidence in herself she cannot imagine she will be lucky enough or “good” enough to be able to carry a multiple pregnancy to term. Give her assurance during prenatal visits she is managing well, so her self-esteem is maintained at as high a level as possible. When her babies are born and all are healthy, the proof she needs she “deserved” this or was capable of it will be present in her arms. Nursing care at the birth of multiple infants is discussed

## Polyhydramnios

Usually, the amniotic fluid volume at term is 500 to 1,000 ml. **Polyhydramnios** occurs when there is excess fluid of more than 2,000 ml or an amniotic fluid index above 24 cm (Wiegand, Beamon, Chescheir, et al., 2016).

Polyhydramnios can cause fetal malpresentation because the additional uterine space can allow the fetus to turn to a transverse lie. It also can lead to premature rupture of the membranes from the increased pressure, which then leads to the additional risks of infection, prolapsed cord, and preterm birth.

### ASSESSMENT

Amniotic fluid is formed by a combination of the cells of the amniotic membrane and from fetal urine. It is evacuated by being swallowed by the fetus, absorbed across the intestinal membrane into the fetal bloodstream, and transferred across the placenta. Although polyhydramnios can occur separate from fetal involvement, accumulation of amniotic fluid suggests difficulty with the fetus's ability to swallow or absorb, or excessive urine production. Inability to swallow occurs in infants who are anencephalic, who have tracheoesophageal fistula with stenosis, or who have intestinal obstruction (Bishop & Ebach, 2015). Excessive urine output occurs in the fetuses of diabetic women (hyperglycemia in the fetus causes increased urine production).

The first sign of polyhydramnios may be unusually rapid enlargement of the uterus. The small parts of the fetus become difficult to palpate because the uterus is unusually tense. Auscultating the FHR can be difficult because of the depth of the increased amount of fluid surrounding the fetus. A woman may begin to notice extreme shortness of breath as the overly distended uterus pushes up against her diaphragm. She may develop lower extremity varicosities and hemorrhoids because good venous return from the lower extremities is blocked by extensive uterine pressure. The increased amount of fluid will cause increased weight gain. Generally, an ultrasound is done to document the presence of polyhydramnios and to discover a reason for the excessive amount of fluid.

### THERAPEUTIC MANAGEMENT

Women with severe polyhydramnios may be admitted to a hospital for bed rest and further evaluation or may be cared for at home. Regardless of the setting, maintaining bed rest helps to increase uteroplacental circulation and reduces pressure on the cervix, which may help prevent preterm labor. Teach a woman that it is vitally important to report any sign of ruptured membranes or uterine contractions. Although not common, there is a possibility that straining to defecate could increase uterine pressure and cause a rupture of membranes. Help her, therefore, avoid constipation by encouraging her to eat a high-fiber diet. Suggest a stool softener if diet alone is ineffective.

Assess vital signs as well as lower extremity edema frequently (the extremely tense uterus puts unusual pressure on both the diaphragm and the vessels of the pelvis). Amniocentesis can be performed to remove some of the extra fluid. Because amniotic fluid is replaced rapidly, however, this has to be repeated almost daily to be effective. Polyhydramnios can also lead to placental separation or rupture of membranes (Zheng, 2012a). If contractions begin, tocolysis may be necessary to prevent or halt preterm labor.

Even with these precautions, in many instances of polyhydramnios, there will be preterm rupture of the membranes because of excessive pressure, followed by preterm birth. To prevent the sudden loss of fluid and the accompanying danger of a prolapsed cord during labor, membranes can be “needled” (a thin needle is inserted vaginally to pierce them) to allow a slow, controlled release of fluid. After birth, the infant must be assessed carefully for factors that may have interfered with the ability to swallow in utero, such as a gastrointestinal blockage.

## Oligohydramnios

**Oligohydramnios** refers to a pregnancy with less than the average amount of amniotic fluid (Kumar, 2012). Because part of the volume of amniotic fluid is formed by the addition of fetal urine, this reduced amount of fluid is usually caused by a bladder or renal disorder in the fetus that is interfering with voiding. It also can occur from severe growth restriction (because of the small size, a fetus is not voiding as much as usual). Because the fetus is so cramped for space, muscles are left weak at birth, lungs can fail to develop (hypoplastic lungs), possibly leading to severe difficulty breathing after birth, and distorted features of the face occur (termed Potter syndrome).

Oligohydramnios is suspected during pregnancy when the uterus fails to meet its expected growth rate. It is confirmed by ultrasound when the pockets of amniotic fluid are less than average. Infants need careful inspection at birth to rule out kidney disease and compromised lung development.

## Postterm Pregnancy

A term pregnancy is 38 to 42 weeks long. A pregnancy that exceeds these limits is prolonged (i.e., postterm pregnancy, postmature, or postdate). The infant of such a pregnancy is considered postmature, or dysmature, if there is evidence that placental insufficiency has occurred and interfered with fetal growth. **Postterm pregnancy** occurs in 3% to 12% of all pregnancies (Kortekaas, Kazemier, Ravelli, et al., 2015).

Included in this group are some pregnancies that appear to extend beyond the due date set for them because of a faulty due date. Women who have long menstrual cycles (e.g., 40 to 45 days) do not ovulate on day 14 as in a typical menstrual cycle. Because they ovulate 14 days from the end of their cycle, or on day 26 or 31, their children will be considered “late” by 12 to 17 days.

In other instances, the pregnancy is truly overdue. For some reason, the trigger that initiates labor did not turn on. Such pregnancies can occur in women receiving a high dose of salicylates (for severe sinus headaches or rheumatoid arthritis) that interferes with the synthesis of prostaglandins, which may be responsible for the initiation of labor. It is also associated with myometrial quiescence, or a uterus that (for unknown reasons) does not respond to normal labor stimulation.

Remaining in utero for longer than 2 weeks beyond term creates a danger to a fetus for several reasons. Meconium aspiration is more apt to occur as fetal intestinal contents are more likely to reach the rectum. If the fetus continues to grow, macrosomia could create a birth problem. However, the usual effect of being postterm is lack of growth because a placenta seems to have adequate functioning ability for only 40 to 42 weeks. After that time, it acquires calcium deposits. This exposes a fetus to decreased blood perfusion and a lack of oxygen, fluid, and nutrients (Mission, Marshall, & Caughey, 2015). If oligohydramnios occurs, it can lead to variable decelerations in the FHR from cord compression.

If labor has not begun by 41 weeks, a nonstress test, and/or a biophysical profile may be done to document the state of placental perfusion and the amount of amniotic fluid present. If these are normal, it suggests the due date was miscalculated. If the test results are abnormal or the physical examination or biparietal diameter measured on ultrasound suggests the fetus is term size, labor will be induced. Prostaglandin gel or misoprostol (Cytotec) applied to the vagina to initiate cervical ripening followed by an oxytocin infusion are common methods used to begin labor. If oxytocin is ineffective, cesarean birth may be necessary. Monitor the FHR closely during labor to be certain placental insufficiency is not occurring from aging of the placenta. Nursing care for the postterm infant at birth is discussed in [Chapter 26](#).

## Isoimmunization (Rh Incompatibility)

Approximately 15% of Whites and 10% of African Americans in the United States are missing the Rh (D) factor in their blood or have an Rh-negative blood type. **Rh incompatibility** occurs when an Rh-negative mother (one negative for a D antigen or one with a dd genotype) carries a fetus with an Rh-positive blood type (DD or Dd genotype). For such a situation to occur, the father of the child must either be homozygous (DD) or heterozygous (Dd) Rh positive. If the father of the child is homozygous (DD) for the factor, 100% of the couple's children will be Rh positive (Dd). If the father is heterozygous for the trait, 50% of their children can be expected to be Rh positive (Dd). Although blood incompatibility is basically a problem that affects the fetus, it can cause such concern and apprehension in a woman during pregnancy that it becomes a maternal problem as well.

Because people who have Rh-positive blood have a protein factor (the D antigen) that Rh-negative people do not, when an Rh-positive fetus begins to grow inside an Rh-negative mother who is sensitized, her body reacts in the same manner it would if the

invading factor were a substance such as a virus—she forms antibodies against the invading substance. The Rh factor exists as a portion of the red blood cell, so these maternal antibodies cross the placenta and cause destruction (i.e., hemolysis) of fetal red blood cells (Fig. 21.10). A fetus can become so deficient in red blood cells from this that a sufficient oxygen transport to body cells cannot be maintained. This condition is termed **hemolytic disease of the newborn** or **erythroblastosis fetalis**. Management of the infant born with this condition is discussed in Chapter 26.

**Figure 21.10** Maternal antibody formation against the Rh antigen.

Theoretically, there is no connection between fetal blood and maternal blood during pregnancy, so the mother should not be exposed to fetal blood. In reality, a small amount of fetal blood does enter maternal circulation (McBain, Crowther, & Middleton, 2015). Procedures such as amniocentesis or percutaneous umbilical blood sampling can allow this to occur. During a first pregnancy, this effect is small. As the placenta separates after birth of the first child, however, there is an active exchange of fetal and maternal blood from damaged villi. This causes most of the maternal antibodies formed against the Rh-positive blood to be formed in the first 72 hours after birth. These become a threat in a second pregnancy.

## ASSESSMENT

All women with Rh-negative blood should have an anti-D antibody titer done at a first pregnancy visit. If the results are normal or the titer is minimal (normal is 0; a ratio below 1:8 is minimal), the test is repeated at week 28 of pregnancy. If this is also normal, no therapy is needed.

If a woman's anti-D antibody titer is elevated at a first assessment (1:16 or greater), showing Rh sensitization, the well-being of the fetus in this potentially toxic environment will be monitored every 2 weeks (or more often) by Doppler velocity of the fetal middle cerebral artery, a technique that can predict when anemia is present or

fetal red cells are being destroyed (Kamei, Yamaguchi, Sato, et al., 2014).

If the artery velocity remains high, a fetus is not developing anemia and most likely is an Rh-negative fetus. If the reading is low, it means a fetus is in danger, and immediate birth will be carried out providing the fetus is near term. If the fetus is not near term, efforts to reduce the number of antibodies in the woman or replace damaged red cells in the fetus are begun.

## **THERAPEUTIC MANAGEMENT**

To reduce the number of maternal Rh (D) antibodies being formed, RhIG, a commercial preparation of passive Rh (D) antibodies against the Rh factor, is administered to women who are Rh negative at 28 weeks of pregnancy. These cannot cross the placenta and destroy fetal red blood cells because the antibodies are not the IgG class, the only type that crosses the placenta. RhIG (RhoGAM) is given again by injection to the mother in the first 72 hours after birth of an Rh-positive child to further prevent the woman from forming natural antibodies. Because RhIG is passive antibody protection, it is transient, and in 2 weeks to 2 months, the passive antibodies are destroyed. Only those few antibodies that were formed during pregnancy are left. For this reason, every pregnancy is like a first pregnancy in terms of the number of antibodies present, ensuring a safe intrauterine environment for any future pregnancies.

After birth, the infant's blood type will be determined from a sample of the cord blood. If it is Rh positive, the mother will receive the RhIG injection. If the newborn's blood type is Rh negative, no antibodies have been formed in the mother's circulation during pregnancy and none will form, so passive antibody injection (RhIG) is unnecessary.

Although in future years, the problem of Rh sensitization will be greatly reduced, it currently remains a complication of pregnancy, particularly in women who gave birth to a first child in an undeveloped nation where they did not receive passive anti-D antibodies. Other women become sensitized because they did not receive an RhIG injection after an induced abortion, miscarriage, ectopic pregnancy, or amniocentesis.

## **INTRAUTERINE TRANSFUSION**

To restore fetal red blood cells, blood transfusion can be performed on the fetus in utero. This is done by injecting red blood cells by amniocentesis technique directly into a vessel in the fetal cord or depositing them in the fetal abdomen where they migrate into the fetal circulation.

Blood used for transfusion in utero is either the fetus's own type (determined by percutaneous blood sampling) or group O negative if the fetal blood type is unknown. From 75 to 150 ml of washed red cells are used, depending on the age of the fetus. After deposition of the blood in the cord or abdomen, the cannula is withdrawn and a woman is urged to rest for approximately 30 minutes while fetal heart sounds and uterine activity are monitored.

Intrauterine transfusion is not without risk. A cord blood vessel could be lacerated by the needle or the uterus could be so irritated by the invasive procedure that labor contractions begin. For the fetus who is severely affected by isoimmunization, however, such a risk is no greater than that of being left untreated in a destructive intrauterine environment. The mother receives an RhIG injection after the transfusion to help reduce increased sensitization from any blood that might have been exchanged. Transfusion is sometimes done only once during pregnancy, or it may be repeated as often as every 2 weeks. As soon as fetal maturity is reached, as shown by a mature lecithin/sphingomyelin ratio, birth will be induced.

After birth, the infant may require therapy with phototherapy lights to reduce the level of bilirubin released from destroyed red blood cells or an exchange transfusion to remove hemolyzed red blood cells and replace them with healthy blood cells (see [Chapter 26](#)). A woman needs to discuss her plans for further childbearing with her healthcare provider and should be provided with contraceptive information if she does not want to undergo the strain of another pregnancy because the constant feeling of wishing that everything was all right but never being certain it was, is more than she may want to endure again.

## Fetal Death

Obviously, one of the most severe complications of pregnancy is fetal death. The most likely causes of this include chromosomal abnormalities, congenital malformations, infections such as hepatitis B, immunologic causes, and complications of maternal disease. If fetal death occurs before the time of quickening, a woman will not be aware the fetus has died because she is not able to feel fetal movements. This type of fetal death may be discovered at a routine prenatal visit when no fetal heartbeat can be heard. An ultrasound will reveal that no fetal heartbeat is present.

That a fetus has died early in intrauterine life may also be revealed first by the miscarriage that occurs. With this, a woman begins painless spotting, gradually accompanied by uterine contractions with cervical effacement and dilatation. The fetus is born lifeless and emaciated. Carefully observe all women who give birth to a fetus who has died for excess bleeding because if the fetus has been dead in utero for any length of time, the risk for the development of DIC increases.

If a fetus dies in utero past the point of quickening, a woman will be very aware that fetal movements are suddenly absent. She may lie down or sit in a position that she knows usually causes fetal movement. Unable to believe something could have happened, she may attribute the lack of movement to “sleeping” or “saving enough strength to be born.” Because she is denying what is happening, it may be a full 24 hours before she calls her healthcare facility to report the apparent lack of fetal movement. On assessment, no fetal heartbeat can be heard. An ultrasound will confirm the absence of a fetal heartbeat.

If labor does not begin spontaneously once the fetal death is confirmed, it will be

induced through a combination of prostaglandin gel or misoprostol (Cytotec) applied to the vagina to effect cervical ripening and oxytocin administration to begin uterine contractions (Abediasl, Sheikh, Pooransari, et al., 2016). Blood for coagulation studies to detect DIC must be obtained to rule out the possibility of this developing.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Powerlessness related to fetal death

**Outcome Evaluation:** Patient and support person express meaning of pregnancy loss; identify support people/family with whom they can share grief.

Going through labor knowing a fetus is dead is difficult. A woman grieves for both her dead child and her inability to carry a pregnancy to term. She may wonder what she had done to cause this, such as forgetting to take an iron supplement, or may worry she is not as good a woman as others. Give her opportunities to express how she feels about this loss. “This must be a very difficult day for you” is the kind of statement that opens up the topic for discussion. If there are older children, it might be a help to explore how a woman plans to explain the fetal death to them.

Ask a couple about their desire for clergy or religious rites, such as baptism. Encourage a support person to remain with a woman during labor but remember that the support person is grieving too. Although this is a difficult time, encouraging them to express their grief can help to make the fact the pregnancy has ended and allows the couple to begin rebuilding their life.

Labor involving a dead fetus is the same as for a live fetus because every fetus is basically a passive participant during labor. It may be difficult for a woman to use controlled breathing exercises, although encouraging her to use them is helpful in making the experience one of controllable pain. If a woman wishes a high level of analgesia, there is no contraindication to this because there is no living fetus to protect from narcotic effects. An epidural is also an option, as this will guard against poor uterine involution in the postpartum period from heavy analgesic sedation.

Ask if the parents wish to see the child after birth. If they do, wash away obvious blood, swaddle the baby as if he or she were a well newborn, and bring the baby to them. Point out particularly endearing features of the child as these can provide a focus for memories. Some parents may want to keep a lock of the child’s hair. Others may want to keep the hospital identification bracelet or take a photograph. Parents may want to name the child. All of these measures are usual responses to grief and help to make the death real to parents, thus letting them begin the healthy process of grieving (Lisy, Peters, Riitano, et al., 2016).

If the child has a congenital anomaly that led to the death, prepare them for this before bringing the child to them and explain how the anomaly affected the child.

Explain hospital procedures such as when the body will be released or what additional permission for autopsy is needed. Different communities have different laws concerning whether burial for an immature fetus is necessary. Consult local health department regulations so you can serve as a resource person for parents about this.

A woman needs to remain for only a few hours in the hospital, assuming no complications with labor developed. Many couples ask how soon it will be safe for them to have another child. They will need to consult with their primary care provider with regard to this, because it depends on why the fetal death occurred and whether the birth was cesarean. For some couples, beginning a second pregnancy immediately is a good recommendation. For others, waiting for an interval of time (perhaps 6 months) is better as this gives them more time to work through their grief before starting a new pregnancy. This helps prevent the new baby from becoming a “replacement baby” or someone to take the place of the dead infant rather than a unique individual in his or her own right. This is important in years to come because replacement children are rarely able to live up to the image of what the deceased baby would have been if only that baby had lived.

Prepare the couple for the possibility that they may feel sad on the day the infant would have been born if the pregnancy had been carried to term, or if they visit a friend’s child of the age their child would have been. Be certain before a woman is discharged from the healthcare facility that she has a support person she can rely on during the following week or month, when the full impact of the fetal loss registers with her. Be certain she has a return appointment for a postpartal checkup so her physiologic and psychological health can be evaluated at that time.

#### *What If . . . 21.4*

**The nurse is interested in exploring one of the 2020 National Health Goals related to complications of pregnancy (see [Box 21.1](#)). Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Muzuki family and that would also advance evidence-based practice?**

### **KEY POINTS FOR REVIEW**

- Vaginal bleeding during pregnancy is always serious until ruled otherwise because it has the potential to diminish the blood supply to both the mother and fetus.
- The amount of bleeding that is evident may not be truly indicative of the amount of bleeding occurring because hidden, internal bleeding may also be happening. As a rule, position women with bleeding during pregnancy on their side to improve placental circulation and prevent supine hypotension syndrome.

- Spontaneous miscarriage is the loss of a pregnancy before viability of the fetus (20 to 24 weeks). The majority of these early pregnancy losses are attributed to chromosomal abnormalities. They are classified as threatened, imminent, complete, incomplete, missed, or recurrent pregnancy loss. Women who have a spontaneous miscarriage at home should bring any tissue passed to the hospital for an analysis for gestational trophoblastic disease. APS is an autoimmune disease that may contribute to recurrent miscarriages; therapy is SQ heparin and low-dose aspirin.
- Ectopic pregnancy is implantation outside the uterus, usually in a fallopian tube. If discovered before the tube ruptures, methotrexate can be administered to cause the conceptus to be reabsorbed. If not discovered early, sharp lower quadrant pain occurs at about 6 to 12 weeks as the tube ruptures. A laparoscopy is necessary to remove the conceptus and repair the tube to halt bleeding.
- Gestational trophoblastic disease is abnormal overgrowth of trophoblast cells. If not discovered by an ultrasound early in pregnancy, bleeding and expulsion of the abnormal growth occur at about the 16th week of pregnancy. Women need close follow-up after this because it can lead to choriocarcinoma, a malignancy.
- Premature cervical dilatation occurs when the cervix dilates early in pregnancy before viability of the fetus. Sutures (cervical cerclage) can be placed to prevent the cervix from dilating prematurely this way again in a second pregnancy.
- Placenta previa is low implantation of the placenta so that it crosses the cervical os. If this is not discovered before labor, cervical dilatation may cause the placenta to tear, causing severe blood loss. Women who have symptoms of placenta previa (i.e., painless vaginal bleeding in the third trimester) should not have vaginal examinations done to prevent disruption of the low-implanted placenta.
- Premature separation of the placenta (i.e., abruptio placentae) or placental separation from the uterus before the fetus is born usually occurs late in pregnancy and cuts off blood supply to the fetus. Women with increased parity, those with previous uterine surgery, and those who are cocaine dependent are at highest risk for this. Often, it is manifested by sudden, sharp fundal pain and then a continuing dull pain and vaginal bleeding.
- DIC is a blood disorder that may occur with any trauma, so it can accompany such conditions as premature separation of the placenta and hypertension of pregnancy. Blood coagulation is so extreme at one point in the circulatory system that clotting factors become diminished, resulting in their absence in the remainder of the system. Beginning symptoms of this include easy bruising, petechiae, and oozing from intravenous sites. Heparin is used to stop the local coagulation and free up clotting factors for systemic use.
- Preterm labor is labor that occurs after 20 weeks and before the end of the 37th week of pregnancy. A woman is said to be in preterm labor when she has had uterine contractions every 10 minutes for 1 hour and cervical dilatation begins. Magnesium sulfate, parentally administered, is the drug of choice to halt preterm labor.
- A corticosteroid is also used in preterm labor management because it appears to

accelerate the formation of lung surfactant in the fetus.

- Preterm rupture of the membranes is tearing of the fetal membranes with loss of amniotic fluid before the pregnancy is at term. After rupture, there is a high risk of fetal and uterine infection (i.e., chorioamnionitis) and preterm birth.
- Preeclampsia is a unique disorder that occurs with three classic symptoms: hypertension, edema, and proteinuria. It is categorized as preeclampsia or eclampsia. If mild (blood pressure not over 140/90 mmHg), treatment is bed rest and perhaps low-dose aspirin. If severe (blood pressure over 160/110 mmHg), bed rest plus administration of magnesium sulfate will be prescribed. If a seizure occurs, the condition becomes eclampsia. Helping prevent the disease from progressing to this stage not only meets QSEN competencies but also can best meet the family's total needs.
- The HELLP syndrome is a unique form of gestational hypertension marked by hemolysis of red blood cells, elevated liver enzymes, and a low platelet count.
- Multiple gestation puts an additional strain on a woman's physical resources and may lead to preterm birth with immaturity of her infants. Helping a woman plan adequate nutrition and rest during pregnancy are nursing responsibilities.
- Postterm pregnancy is pregnancy that extends beyond 42 weeks. Because the placenta deteriorates at this time, it can cause a fetus to receive decreased nutrients.
- Polyhydramnios is overproduction of amniotic fluid (above 2,000 ml) and is a condition that can lead to ruptured membranes and premature birth because of increased intrauterine pressure. Oligohydramnios is characterized by too little amniotic fluid and suggests a renal disorder may exist in the fetus.
- Isoimmunization (Rh incompatibility) is a possibility when a woman who is Rh negative is sensitized and carries a fetus who is Rh positive. Maternal antibodies form and destroy fetal red blood cells, leading to anemia, edema, and jaundice in the newborn. Being certain that women are screened for blood type and antibody titer early in pregnancy is a nursing responsibility.

### CRITICAL THINKING CARE STUDY

Maria Maya is a 37-year-old woman who works part-time in the personnel office at your school. She felt nauseated after receiving the flu vaccine in the health center. Last night, she experienced right-sided lower abdominal pain with scant vaginal spotting. Today, she appears pale. She is diagnosed as having a ruptured ectopic pregnancy. She is scheduled for an emergency laparotomy.

1. Maria questions her diagnosis because she had no idea she was pregnant. How would you respond if she asks you, "Why didn't I have any pregnancy symptoms if I'm really pregnant?"
2. Maria's blood pressure is 90/60 mmHg and she appears very pale. She is refusing, however, to have surgery to end the pregnancy in case there is any chance her baby is still alive. Would you support her decision?

3. Maria's left fallopian tube was so damaged that it was removed in surgery. A week later, she quits her job, sets fire to her apartment, and swallows drain cleaner in a self-injury attempt because "I'm never going to be able to have children, now, am I?" Did Maria receive sound information about what her surgery consisted of?

## Nursing Care of a Pregnant Family With Special Needs

*Mindy Carson, 16 years old and 15 weeks pregnant, received a 4-in. laceration on her leg when she was in an automobile accident on her way into prenatal clinic this morning. The father of Mindy's baby, Carlos, does not want Mindy to keep her baby after the birth because he does not want to get married until he finishes graduate school. Mindy insists she is old enough to be a parent and wants to keep her baby. Mindy's mother has accused Carlos of sharing methamphetamine with Mindy. She's worried Mindy has been working as a prostitute to support a substance abuse habit. Mindy turns to you and asks you what you would recommend she do.*

*Previous chapters discussed high-risk pregnancies for women who are ill when they become pregnant and for those who develop an illness while pregnant. This chapter presents information about women who do not fit the description of the average pregnant woman—a well adult who maintains a healthy lifestyle. Representative of such women who do not fit the description of average pregnant women are very young adolescents, women who have waited until midlife to have their first child, those who are physically or cognitively challenged, those who are unintentionally injured, and those who are substance dependent.*

**What type of immediate assessment does Mindy need? What qualities would you look for to decide if she is ready to be a parent?**

### KEY TERMS

adolescence  
advanced maternal age  
autonomic dysreflexia  
culdocentesis  
emancipated minor  
generativity  
paracentesis  
peritoneal lavage  
substance abuse

## substance dependent

### OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Identify the characteristics and the risks of pregnancy for a pregnant woman who has special needs, such as one who has been injured, an adolescent, a woman over age 40 years, one who is physically or cognitively challenged, or a woman who is substance dependent.
2. Identify 2020 National Health Goals related to women with special needs that nurses can help the nation achieve.
3. Assess a woman with special needs during pregnancy.
4. Formulate nursing diagnoses related to pregnancy for a woman with special needs.
5. Identify expected outcomes for a pregnant woman with special needs to help her manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care for a woman with special needs, such as encouraging her to remain ambulatory during pregnancy.
8. Evaluate outcomes for effectiveness and achievement of care.
9. Integrate knowledge of the risks of pregnancy for women with special needs with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

The National Center for Health Statistics (NCHS) reported in 2014 that the live birth rate, the number of births per 1,000 women aged 15 to 44 years, was 62.9. This was a slight increase from a previous downward trend in birth rates since 2007. The rate of first births to women under 20 years old has declined by 42% between the years 2000 and 2014. In addition, teen birth rates declined for all races, including Hispanics, hitting a historic low live birth rate of 24.2 (Matthews & Hamilton, 2016). Although reasons for the declines are not clear, younger teens appear to be less sexually active and more of those who are sexually active may be using contraception than in previous years. In contrast, more women have delayed beginning a family until their 30s. As a result, birth rates continue to rise for women aged 40 to 44 years (Martin, Hamilton, & Osterman, 2015; Matthews & Hamilton, 2016).

Adolescents require special consideration during pregnancy because they are physically and psychosocially immature. Women over age 40 years may need special consideration also because they can have difficulty adjusting psychosocially to a first

pregnancy and the physical changes that are required (Ben-David, Glasser, Schiff, et al., 2016).

The pregnancy rate is increasing among women who are physically or cognitively challenged as well, including conditions that might have precluded pregnancy a few years ago such as cerebral palsy. Physical and cognitive conditions present a challenge to childbearing and childrearing but do not necessarily prevent women from establishing their own families. Supportive nursing care that considers the limitations imposed by a particular disability while focusing on the normal aspects of childbearing and childrearing combined with a woman's strengths helps to make these pregnancies successful (H. K. Brown, Lunsky, Wilton, et al., 2016).

Women who are substance dependent or who are injured are other high-risk women who require a great deal of nursing support and care. Ideally, a woman should give up substance abuse for the health of a fetus, but that may not be possible. When substance abuse continues, every effort must be made to provide enough prenatal care and attention to protect the fetus in other ways. Women who are injured in automobile accidents or from intimate partner violence can have substantial blood loss that threatens the health of the fetus. They need rapid emergency department assessment and care to be certain fetal health is protected.

Women with special needs have become such a large population of pregnant women that several 2020 National Health Goals have been established in relation to them (Box 22.1).

## BOX 22.1

### Nursing Care Planning Based on 2020 National Health Goals

Several National Health Goals have been formulated to improve the health of women with special needs during pregnancy. These include:

- Reduce the pregnancy rate among adolescent females to no more than 105.9 per 1,000 adolescents from a baseline of 117.7 per 1,000 adolescents.
- Increase abstinence from alcohol, cigarettes, and illicit substances among pregnant women to 98.3% from a baseline of 89.4% (alcohol), 100% from a baseline of 95% (binge drinking), 100% from a baseline of 94.9% (illicit drugs), and 98.6% from a baseline of 89.6% (cigarette smoking) (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by teaching unintentional injury prevention, the dangers and complications of substance dependency, and both the psychological and physical concerns of teenage pregnancy.

### *Nursing Process Overview*

#### FOR CARE OF A PREGNANT WOMAN WITH SPECIAL NEEDS

## **ASSESSMENT**

Assessing the strengths and weaknesses of individual women is always crucial to establish accurate nursing diagnoses and realistic outcomes as well as planning effective nursing care. When a woman has a special need, assessment becomes even more important. Establishing as thorough a database as possible early in pregnancy helps to predict the risks a woman may be exposed to when pregnancy is affected by age extremes, physical or cognitive challenges, an unintentional injury, or an unhealthy lifestyle.

The capacity of a woman with special needs to adapt to pregnancy depends both on her physical capabilities and on her ability to persevere against odds to overcome obstacles. When caring for a woman who is physically challenged, keep in mind physical disabilities occur in degrees; therefore, first establish the impact of the disability on a woman's lifestyle before beginning to offer guidance for care measures during pregnancy. Be certain to assess physical strengths as well as limitations and psychosocial strengths as well as challenges. A woman with a spinal cord injury, for example, is likely to have developed ways of coping in daily life that may never occur to someone who has not experienced that disability.

For some women who are substance dependent, pregnancy may be the impetus they need to stop their substance abuse. Others may only be able to reduce their substance use. In both instances, encourage a woman to keep coming for prenatal care. As long as she feels comfortable with you during regular visits, you may be able to establish a trusting relationship that will eventually provide her with the confidence to try a more healthful pattern of living.

## **NURSING DIAGNOSIS**

Nursing diagnoses established for pregnant women with special needs differ in degree, but not in substance, from the nursing diagnoses established for all pregnant women. For example, if a pregnant adolescent is still growing, sound nutrition is an extremely important issue for both her and her fetus. Examples of nursing diagnoses for women with special needs include:

- Risk for imbalanced nutrition related to combined needs of adolescent and pregnancy
- Risk for fetal injury related to drug and alcohol use
- Impaired physical mobility related to physical disability
- Risk for injury related to unstable balance
- Risk of injury related to potential for unintentional injuries
- Impaired verbal communication related to spastic muscle functioning
- Impaired home maintenance related to a sensory challenge
- Risk for social isolation related to bed rest at home
- Risk for disruption of social interactions related to unclear speech
- Disruption in family dynamics related to serious illness of family's main provider

- Readiness for enhanced family coping related to commitment to have a child in the face of a disabling condition

## OUTCOME IDENTIFICATION AND PLANNING

Be especially careful to establish realistic outcomes given a woman's particular condition or situation. An adolescent, for instance, cannot achieve independent decision making if she is not mature enough to do this. A woman who is visually challenged may not be able to read a digital display on a glucometer or use a wall clock to time contractions no matter how much she would like to do these things.

Often, a pregnant woman with a special need already has significant stressors to deal with in her life. **Adolescence**, for example, is a period of growth and change that can be stressful for both the teenager and her family. The woman who is physically challenged constantly copes with a condition that must be considered in all activities, even if she has adjusted completely to the limitations the disability imposes. The substance-dependent woman is confined by a life-threatening habit. A woman who has an unintentional injury may have to temporarily restructure her life to accommodate a hospital admission. Pregnancy brings with it a whole new set of stressors that can be overwhelming if a woman has no outside support. Planning for a pregnant woman with special needs, therefore, often involves identifying support people to help with this added stress. This support can come from family, friends, a professional organization, or healthcare providers. If a woman is not totally independent in her care, some planning may be required with her support person, who may be the person who actually carries out the proposed action. At the same time, be certain to not ignore a woman and plan around her. Only if she approves of the plan can pregnancy be the enjoyable experience it should be. This principle applies to any woman but especially to one with special needs.

Plans should also include ways to strengthen confidence and self-esteem, crucial attributes for a new mother. These also are areas in which a woman with a special need, especially one who perceives herself as too young or too old or who has experienced a physical dysfunction, may not have developed fully. Substance dependence may also be related to feelings of lowered self-worth, which may have been intensified if the substance-dependent woman has tried unsuccessfully to limit her substance intake in the past.

Being certain that plans are established in a wide range of areas helps to ensure planning is comprehensive. Remember to include safe care of the newborn in plans as well because once an infant is born, it may be too late to make these plans in a comprehensive manner. The U.S. Department of Health and Human Services (DHHS) has initiated a special girls' health program through the Office on Women's Health to help reduce teenage pregnancy, which is helpful to use for referral, along with the Substance Abuse & Mental Health Services. Narcotics Anonymous can be helpful to women who are substance dependent. Alcoholics Anonymous is the standby for women with alcohol dependence. Women who feel they will be injured

by an intimate partner can locate a shelter by calling their local police department. Refer patients and their families to helpful websites and other resources when appropriate (see [Chapter 20](#)).

### **IMPLEMENTATION**

Interventions for the high-risk pregnant woman include promoting a healthy pregnancy and preventing pregnancy complications. Care focuses on teaching and encouraging a woman with any special needs to determine how best to manage her pregnancy according to her particular situation.

A high proportion of adolescents do not seek prenatal care early in pregnancy because they deny they are pregnant. Others may not feel comfortable in a healthcare facility that sees mainly adults. The same may be true of a woman with substance dependency, who fears discrimination from healthcare providers regarding her substance use. A nonjudgmental, welcoming attitude that focuses on the pregnancy and the baby, while avoiding recriminations about a woman's youth or circumstances, is essential to attracting such women to prenatal care and keeping them coming for regular visits. If they hear from a friend that the staff members at the clinic are helpful and not judgmental, they then take the first step into the facility.

### **OUTCOME EVALUATION**

An evaluation of nursing interventions for the care of a pregnant woman with special needs often focuses on a woman's physical and emotional readiness for childbearing, maintenance of fetal health, and a woman's ability to provide a safe and healthy environment for her newborn. Some examples include:

- Patient states she will use walker to maintain balance during pregnancy.
- Adolescent lists a weekly intake of adequate calories, even with frequent meals at fast-food restaurants.
- Family members state they have been able to adjust to changing demands of pregnancy in a mother who is physically challenged.
- Patient reports to methadone maintenance clinic daily and reports no other substance use.
- Patient states she is able to manage a daily rest period even in light of a busy work and travel schedule.
- Patient states she is able to carry out usual lifestyle activities in spite of cast on injured arm.

## **The Pregnant Adolescent**

Adolescent pregnancy is not a new phenomenon. Historically, it was common for women to marry as early as age 12 or 13 years and have their first baby at age 15 years. In today's society, however, marriage and childbearing are life situations thought of as belonging to later years. Reasons for the high number of teenage pregnancies that still continue include:

- Earlier age of menarche in girls (the average age is 12.4 years; many girls begin menstruating at age 9 years and so are ovulating and able to conceive by age 11 years)
- Rates of sexual activity among teenagers
- Lack of knowledge about (or failure to use) contraceptives or abstinence
- Desire by young girls to have a baby

Having an equally young sexual partner can contribute to pregnancy incidence because, in this situation, neither partner may be well versed in contraceptive options (Centers for Disease Control and Prevention [CDC], 2014). In addition, some adolescents become pregnant as the result of rape or incest (Wilson, Casanueva, Smith, et al., 2014).

Failure of adolescents to obtain adequate knowledge of contraceptive measures or abstinence is an issue that can be addressed by healthcare providers. As protective measures are easy to use, the average adolescent should not have difficulty following instructions. Adolescents are also capable of using emergency contraceptive measures correctly and safely. Access to emergency contraception is not associated with increased rates of unprotected intercourse or with higher rates of pregnancy or sexually transmitted infections (STIs) (Potter & Santelli, 2015; Society for Adolescent Health and Medicine, 2016). Unfortunately, providing this type of information does not always resolve the problem because adolescents may lack money to purchase protection such as birth control pills or a diaphragm. In addition, the egocentric phenomenon of adolescence makes a sexually active teenager believe she will not become pregnant (i.e., “It won’t happen to me”). Some adolescent girls actually plan pregnancy because they believe being pregnant will free them from an intolerable school or home situation or give them someone to love who will also love them back. It puts a tremendous responsibility on a newborn to furnish love and change a girl’s life; child maltreatment can occur when the newborn cannot meet such expectations (Seay, Jahromi, Umaña-Taylor, et al., 2016).

As recently as the 1960s, unmarried pregnant girls were sent to a “secret” home or shelter where they would stay throughout their pregnancy, give birth, place the child for adoption, and then return home as if nothing had happened to them. Today, pregnant teenagers typically remain at home, attend prenatal care, and are seen in maternity care facilities the same as older women do. They give birth in birthing rooms at hospitals, and as many as 90% keep their babies (Martin et al., 2015). Few give birth in alternative birth centers because the risk of cephalopelvic disproportion makes adolescent pregnancies high risk. Home birth is not recommended for the same reason. Offering increased guidance during pregnancy and for child care during the following years for adolescents can be an important nursing role.

## **DEVELOPMENTAL TASKS**

Adolescence is a vulnerable time for pregnancy because the developmental tasks of pregnancy are superimposed on those of adolescence. The developmental tasks of the

average adolescent are fourfold: to establish a sense of self-worth or a value system, to emancipate from parents, to adjust to a new body image, and to choose a vocation (Erikson, 1963). A girl in the process of separating from her parents may be devastated by the reality that a baby will soon be dependent on her. She may need her parents' financial help to obtain prenatal care or buy clothing for her new baby. If she must depend on her parents' health insurance, she may feel virtually trapped into dependence. Helping adolescents to make their own healthcare decisions at healthcare visits helps to foster a sense of independence in the middle of this forced dependency. Consider, for example, the decision the adolescent must make about where to place a medication reminder chart: If it hangs in the kitchen, her mother may monitor it; in her bedroom or in her school locker, she alone will monitor it. An adolescent may not be able to choose when she comes for care (her mother has the car to drive her only on Tuesday afternoons), but during a visit, she can do many things to feel independent, such as weigh herself, hold a mirror to view her pelvic examination, or be interviewed apart from her parents.

Parents may have difficulty allowing a daughter to make her own healthcare decisions. Soon, however, she will be caring for an infant, so she needs this practice in independence and responsibility. You may need to remind parents that a pregnant adolescent is regarded as an **emancipated minor** or a *mature minor*—a person capable of making healthcare decisions—and so may sign permission for her own care. In some states, emancipated minors can qualify and are eligible for special health insurance coverage, so issues with privacy, parental permission, and parental notification are avoided. In August 2002, a new federal rule that is based on requirements contained in the Health Insurance Portability and Accountability Act of 1996 (HIPAA) embodies important protections for minors, along with a significant degree of deference to other laws (both state and federal) and to the judgment of healthcare providers. These provisions represent a compromise between competing viewpoints about the importance of parental access to minors' health information and the availability of confidential adolescent healthcare services (Bayer, Santelli, & Klitzman, 2015). The protection of confidentiality for adolescents is based on recognition that some minors would not seek needed health care for such concerns as sexual activity, pregnancy, HIV, STIs, substance abuse, or mental health if they could not receive it confidentially. Forgoing care because of this would have negative health implications for them as well as society. Maintaining privacy for adolescents needs to be especially respected with the introduction of electronic health records (Bayer et al., 2015).

Pregnancy may interfere with the development of a healthy sexual relationship and cause difficulty in establishing future intimate relationships if a girl realizes her current relationship has led to a situation detrimental to her. To prevent this, it is useful to help her view the pregnancy as a growth-producing experience. Most people can point to a day in their life when they “grew up” (perhaps a day a parent became ill or the day they left home for college). This pregnancy can be that “growing up” revelation for a pregnant adolescent.

Establishing a value system or sense of identity can be difficult if healthcare personnel treat a pregnant adolescent as though she is irresponsible. Encouraging her to continue school is crucial to her self-esteem and to her future as well as to the financial future of her unborn child. Many schools have special programs for pregnant adolescents that include aspects of prenatal care to help ensure pregnant adolescents can stay in school.

## PRENATAL ASSESSMENT

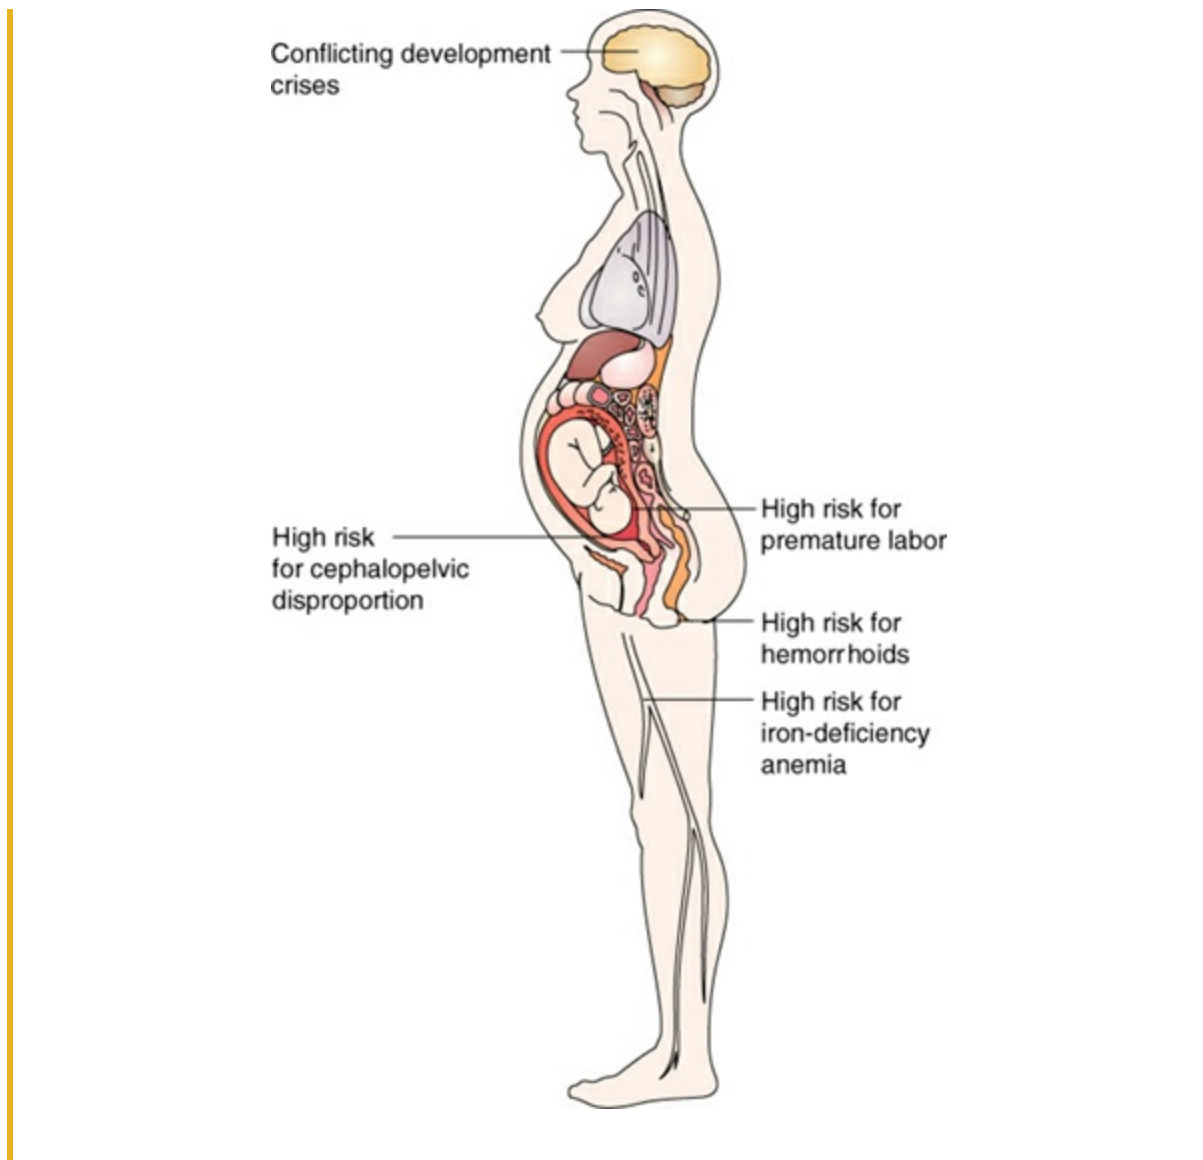

Adolescents are considered high-risk patients because they have a high incidence of iron-deficiency anemia and premature labor (Box 22.2). They also have a higher incidence of low-birth-weight infants, a disproportion between fetal and pelvic size, and a high rate of intimate partner violence (Kirbas, Gulerman, & Daglar, 2016; Willie, Powell, & Kershaw, 2016). Early and consistent prenatal care is essential to their health and the health of their baby.

BOX 22.2

### Nursing Care Planning Using Assessment

#### ASSESSING THE PREGNANT ADOLESCENT FOR COMPLICATION RISK

Unfortunately, many adolescents do not seek prenatal care until late in their pregnancies because they may view not seeking prenatal care as a way of protecting the pregnancy—if they don't tell anyone, no one can suggest they terminate the pregnancy. After the sixth month, abortion is no longer a possibility, so a girl can feel free to come for care without being subjected to this pressure.

Other factors contributing to the lack of prenatal care include:

- Denial she is pregnant
- Lack of knowledge of the importance of prenatal care
- Dependence on others for transportation
- Feeling awkward in a prenatal setting (an adult setting)
- Fear of a first pelvic examination
- Difficulty relating to authority figures

A primary nursing or case management approach that minimizes the number of healthcare providers a teenager is exposed to may be the most effective method for providing care during the prenatal period. Some adolescents do well in group prenatal

care because it allows them to interact with peers the same as they do at school.

## Health History

Take a detailed health history of an adolescent at the first prenatal visit to establish individual risks. This is best done without a parent present. The girl needs practice in being responsible for her own health, and having to account for her health practices can help her do this. It also helps prevent her from fabricating an answer to please a parent.

Some adolescents come to a facility with concerns such as “weight gain” or “feeling tired all the time” rather than saying they are pregnant, hoping healthcare providers will think of pregnancy as a possible reason for their symptoms. This is part denial and part pregnancy protection. Always be alert to the possibility of pregnancy when an adolescent describes symptoms that are vague and hard to define. If the importance of what she is saying when she mentions feeling “tired” or “nauseated” is dismissed, she may ask if someone will feel her stomach. If told this is not necessary for any of the symptoms she has mentioned, she may describe bigger symptoms, such as “terrible stomach pain.” Think of possible pregnancy when you hear such a “growing” history.

Many adolescents want to keep their world totally separate from the adult world, and to do so, they do not voluntarily share information with adults. When interviewing adolescents, be certain to press for the responses needed to allow you to assess them safely. Do not accept statements such as “I eat okay” as a nutrition history or “I’m a very active person” as a history of rest and activity. Ask for details.

If an adolescent delayed seeking health care, ask for the reason for this at her first prenatal visit. Acknowledge that “protecting” the pregnancy is a desirable motive, but continuing with prenatal care will be much more beneficial.

If a parent accompanies a girl, ask the parent separately what, if any, concerns he or she wishes to discuss. A young adolescent is still a daughter, and a parent may be very concerned about her health during this pregnancy, as the parent was at health visits when the girl was being seen for a cold or a sports injury. If the baby’s father attends prenatal care, help him to feel welcome. Because he is not married, he does not have a legal right to participate in decisions concerning the pregnancy, abortion, or adoption, but because he is at the visit, he likely is invested in his partner or the baby (Garfield, Duncan, Rutsohn, et al., 2014). If he is an adolescent, he may feel sorrow that because of his age, he cannot provide adequately. If a complication occurs, he may feel genuine grief things are not going well. Allowing him to offer support in the current pregnancy can help him learn more about himself as well as better define his role. In addition, be sure he receives compassionate education on preventing further pregnancies until he is more mature.

Often, adolescent girls have not talked to other pregnant women, so they may need extra teaching about common pregnancy symptoms such as urinary frequency, fatigue, and breast tenderness. Asking what symptoms an adolescent is having and reassuring her they are part of a normal pregnancy can help prevent her from attempting to treat them with potentially teratogenic over-the-counter medications.

As pregnancy progresses, listen for signs of “nest-building” behavior. An adolescent girl may not have the financial resources to buy clothing or a crib, but she may reveal nest-building feelings by asking an increasing number of questions about newborns or saving money to buy a simple baby article such as a pair of booties. This may seem like small involvement, but for a young girl without financial means, a dollar a week is actually large involvement.

Some adolescents have difficulty telling their parents about the pregnancy. Role-playing or simulation may be an effective technique to help them prepare to do this. Some girls report on a second visit their parents were not nearly as angry as they had anticipated. Instead, their parents reacted as if they had been waiting to hear this news, having accepted it as inevitable months before.

## Family Profile

Adolescents may leave home if their family disapproves of their pregnancy, thus joining the ranks of homeless or adolescent runaways. Others do not leave home, but separate themselves emotionally from their family. Trying to manage by themselves leaves adolescents with a tremendous financial strain and a devastating sense of loneliness. Be sure to ask a girl at prenatal visits where she is living, what the source of her income is, and whom she would call if she suddenly became ill.

Asking about home life may reveal a dysfunctional family or an incest relationship as the cause of the pregnancy. If the girl is under legal age, incest is considered child maltreatment. Know your local and state laws on this topic and make the necessary report.

Because of family relationship problems, a girl may need help in making arrangements for the next few months of her pregnancy and for child care afterward. If she can no longer live at home, is there a relative she may live with? What kind of financial support does she need? Family and social supports for pregnant adolescents have been shown to be important influences on the maintenance of a healthy pregnancy lifestyle and to help prevent low birth weight in their children (Cheng, Rifas-Shiman, Perkins, et al., 2016; Zeiders, Umaña-Taylor, Jahromi, et al., 2015).

Be certain to ask if the girl is planning to continue with school because pregnancy is an egocentric time when outside interests do not always seem important. Help her to see that the months of pregnancy will go by faster if she keeps busy and remaining in school will be a way of doing this. It also is important in preparing for her future because a high school education will be necessary to obtain enough marketable skills to support herself and her baby. Once she has given birth, returning to school may be difficult because she may have child care problems and because she may feel more mature than her classmates (or her classmates may make her feel this way). Any school that obtains federal money cannot discriminate against students because they are physically challenged. Many states interpret pregnancy as physically challenging, so in those states, a girl cannot be forced to leave school (or even asked to go to an alternate school) because of pregnancy. For some girls, you may need to advocate with a school

committee for a proper school placement. [Box 22.3](#) shows an interprofessional care map illustrating both nursing and team planning for a pregnant adolescent.

## BOX 22.3

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR A PREGNANT ADOLESCENT

Mindy Carson, 16 years old and 15 weeks pregnant, received a 4-in. laceration on her leg when she was in an automobile accident on her way to the prenatal clinic this morning. The father of Mindy’s baby, Carlos, is a college student who does not want Mindy to keep her baby after the birth because he does not want to get married until he finishes graduate school. Mindy insists she is old enough to be a parent and wants to keep her baby. Mindy’s mother has accused Carlos of sharing methamphetamine with Mindy. She’s also worried Mindy has been working as a prostitute to support a substance habit.

**Family Assessment:** Lives with family in second-floor apartment above convenience store, which parents own and operate. Is a junior in high school but is “ready to drop out.” Cares for 5-year-old sister after school while parents work downstairs.

**Patient Assessment:** Pale, tired-appearing adolescent female. Failed to come for two previous appointments. Admits to methamphetamine use since becoming pregnant. Hinted she might be using prostitution as income source. Parents want her to end pregnancy; patient wants to continue pregnancy because “Now I can eat anything I want since I’m eating for two.” Unhappy with arguing between parents and boyfriend. States, “I’m coming apart at the seams.”

**Nursing Diagnosis:** Altered family processes related to the stress of adolescent pregnancy

**Outcome Criteria:** Patient and family members demonstrate positive coping mechanisms by communicating effectively; patient identifies plans for self and infant; clarifies relationship desired with father of child. Baby’s father (Carlos) participates in pregnancy activities as desired; patient halts risky, unhealthy practices.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess the reason patient states she is ready to drop out of school.	Discuss with patient advantages of staying in school during	It is difficult for young women to support themselves	Patient contracts to stay in school through graduation if academically possible.

		pregnancy.	and an infant without at least a high school education.
--	--	------------	---

*Teamwork and Collaboration*

Nurse/social worker	Investigate patient’s options for schooling if she no longer feels comfortable in her local public school.	Contact the patient’s school (with her permission) to explore options for her continued school attendance.	Discussion promotes active problem solving and positive adaptation.	Patient and school personnel agree on a course of action that will optimally benefit the patient.
---------------------	--	--	---	---

Nurse/social worker	Assess what community resources are available for withdrawal from methamphetamine.	Discuss the advantages of a withdrawal program during pregnancy.	Almost all substances cross the placenta and reach the fetus.	Patient attends sessions for withdrawal from methamphetamine.
---------------------	--	--	---	---

*Procedures/Medications for Quality Improvement*

Nurse	Assess what patient expects from prenatal care and if she understands the importance of regular attendance.	Discuss that prenatal care is especially important for adolescents as they are prone to complications because of immature body development.	Prenatal care is the best safeguard against complications of pregnancy and can help ensure early, effective intervention if a complication occurs.	Patient attends all future prenatal care appointments; participates in discussions at these times.
-------	---	---	--	--

*Nutrition*

Nurse/nutritionist	Assess 24-hour dietary recall with	Examine food intake to see	“Eating for two” does not	Patient’s 24-hour recall history at

patient.	if it contains all essential nutrients for pregnancy.	mean eating more; it means eating more nutritious foods.	next visit shows improvement in nutrients needed during pregnancy.
----------	---	--	--

*Patient-Centered Care*

Nurse	Assess what patient means by “I’m coming apart at the seams” in reference to her lack of support.	Meet with family members (with patient’s permission) to see if they could offer more emotional support.	Additional emotional help may be required to cope with the added demands of a teenage pregnancy.	Patient states she is receiving adequate support from a combination of her family, her boyfriend, or healthcare providers.
-------	---	---	--	--

*Psychosocial/Spiritual/Emotional Needs*

Nurse	Assess if patient’s disagreement with family over continuing pregnancy is a major stressor.	Assist patient with ways to adapt to changes of pregnancy and responsibility for fetal safety. Support patient’s decision to continue pregnancy.	Adolescence is a highly stressful time, especially without parental support, so change can be difficult if not anticipated.	Patient states she is open to changes she knows will occur with pregnancy; will ask healthcare providers for additional suggestions to handle stress as needed.
-------	---	--	---	---

*Informatics for Seamless Healthcare Planning*

Nurse	Assess the best days for patient and boyfriend to attend prenatal care.	Set up follow-up visits with patient and support	Prenatal care can help detect and prevent complications	Patient attends prenatal care regularly during remainder of pregnancy.

person; plan of pregnancy.  
teaching  
strategies and  
discussion of  
all parties'  
needs and  
concerns as  
appropriate.

## Day History

Adolescents may be unwilling to provide a detailed day history unless its purpose is well explained. Assure a pregnant teenager the purpose of the history is to learn more about her as a whole person, not to discover if she is doing things during the day she should not be doing. Adolescents are private people so to allow you to walk through their adolescent world for a day is a breach of adolescent philosophy. Ask in particular about nutritional practices, sleep, daily activities, use of drugs or alcohol, and whether she has friends who can support her throughout this experience.

Be certain to include questions about her medication history. Ask if she is taking anything over the counter such as cold remedies or herbal supplements. Impress on a girl the importance of not taking any medication—even nonprescription medication—without prior approval from her healthcare provider. It's possible for pregnancy to become an important growth experience if it provides the motivation some adolescents need to withdraw from recreational substance use.

## Physical Examination

Physical examination procedures with pertinent adolescent findings are discussed in [Chapter 34](#). Be certain to explain procedures as you do an examination. A statement such as “Oh, you're starting to have colostrum,” a positive finding of pregnancy, may be frightening to an adolescent who does not know what colostrum is. A better way to phrase such a finding might be, “Your breasts are not only healthy but already beginning to produce early breast milk. Later on, we'll talk about the importance of that for newborns.” This kind of feedback makes a health examination both a learning experience and relieves anxiety for adolescents, who tend to be very concerned about body appearance.

Adolescents may be at an increased risk for gestational hypertension, probably because of immature blood vessels or an immune response to the foreign protein of their fetus ([Waugh & Smith, 2012](#)). Few adolescents know what their blood pressure was prior to pregnancy, so they do not know their nonpregnant pressure. Obtain a baseline pressure at the first prenatal visit and make a point of informing the girl of her reading to encourage active healthcare participation in the future. Adolescents are often active in a waiting room (e.g., walking to get a magazine, returning it, or looking out the

window); be certain the girl has 15 minutes of rest before you take a blood pressure or the recording may be falsely high.

Use a Doppler technique to obtain fetal heart tones, if possible, because hearing the fetal heart helps an adolescent acknowledge the reality of her pregnancy. For the same reason, make a point of assessing fundal height from visit to visit to show the baby is growing.

Adolescents with a substance dependency may be reluctant to supply a urine specimen for testing because they are worried you are secretly looking for evidence of substance use. In these instances, you may receive a cupful of water in place of a urine specimen. If in doubt regarding the substance you are testing, check the specific gravity. The specific gravity of water is 1.000, whereas urine specific gravity ranges from 1.003 to 1.030. Most adolescents like to weigh themselves at prenatal visits because weight gain in early pregnancy is proof they are pregnant. It is good practice to make a note of the clothing a girl is wearing the first time she is weighed, such as jeans and a T-shirt, so later weight determinations can be compared accurately. Be certain teenagers know a healthy weight gain is important for fetal growth and that this weight can be lost afterward.

### ***QSEN Checkpoint Question 22.1***

#### **EVIDENCE-BASED PRACTICE**

To broaden understanding of the reproductive health education needs of adolescent girls, researchers conducted in-depth interviews with 31 adolescent mothers. These interviews included 15 who experienced a second pregnancy within one year of their first birth and 16 who had not had another pregnancy within 1 year. The group who had not had another pregnancy within a year expressed more independent control of their contraceptive choices than those that had a repeat pregnancy within 1 year. Adolescent mothers should be able to independently make decisions about their contraceptive choices (Conroy, Engelhart, Martins, et al., 2015).

Based on the previous study, if Mindy comes to clinic and tells the nurse her mother will not allow her to make independent decisions about her care, what action would be best?

- a. Avoid interfering because the mother is providing helpful input.
- b. Tactfully ask the mother to leave the room and then interview Mindy privately.
- c. Support Mindy in her attempts to take responsibility for her own care.
- d. Supplant Mindy's mother's advice with the nurse's own suggestions that are in Mindy's best interests.

*Look in [Appendix A](#) for the best answer and rationale.*

## **Nursing Diagnoses and Related Interventions**

**Nursing Diagnosis:** Health-seeking behaviors related to special care necessary for healthy adolescent pregnancy

**Outcome Evaluation:** Patient states she feels confident in her ability to follow healthy prenatal guidelines to avoid pregnancy complications; asks questions as needed about her pregnancy.

## Pregnancy Education

Adolescents usually need a great deal of health teaching during pregnancy because they do not know many of the common measures of care older women have learned from experience. They are also often unwilling to follow healthcare advice that makes them feel different in any way from their peers. However, as adolescents often do not have well-established health practices, they may be extremely adaptable and ready to change health habits for a pregnancy.

Adolescent girls may respond to health teaching that is directed to their own health more than to that of a fetus. A statement such as “Eat a high-protein diet because protein makes your hair shiny [or prevents split fingernails]” often leads to better adherence than a reminder that protein is good for the baby. “Taking the iron supplement should make you feel less tired” might be better than, “It will help build the baby’s blood supply,” for the same reason. These are truthful statements, and they appeal to an adolescent’s preoccupation with self. In addition, this type of health teaching is the only form to which an adolescent who is denying her pregnancy can respond.

Adolescents also need instructions about possible discomforts and changes associated with pregnancy and measures to relieve them (see [Chapter 12](#) for a complete discussion). Many pregnant adolescents, for example, develop hemorrhoids because the disproportion of their body size to a fetus puts extra pressure on pelvic vessels, causing blood to pool in rectal veins. You can assure girls this is a pregnancy-related phenomenon that will resolve when the pregnancy is over.

Adolescents may also develop many striae across the sides of their abdomens because so much stretching of the abdominal skin occurs. Assure them, because of skin elasticity, these marks will probably fade after pregnancy. Chloasma, excess pigment deposition on the face and neck, appears at the same rate in adolescents as in older women. Adolescents, however, may be more conscious of this pigment because, overall, they are more conscious and concerned about their facial appearance. Suggesting a cover makeup and offering reassurance the pigmentation will fade after pregnancy may help.

## Nutrition

Good nutrition can be a major problem during an adolescent pregnancy because many girls enter pregnancy with poor nutritional stores from years of eating a less-than-optimal diet. This lack of nutritional stores is serious because, especially in very young

adolescents, it can result in preterm births and low–birth-weight newborns. To prevent these complications, a girl should have an intake that both allows for growth of the fetus and also provides for the needs of her own growing body. Otherwise, protein; iron; folic acid; and vitamins A, C, and D deficiencies may become acute. In order to compensate, she may need to gain more weight than a mature woman to supply adequate pregnancy nutrients.

As more and more teenagers are obese today than ever before because of overeating and lack of exercise, many adolescents enter pregnancy overweight or obese. This can lead to macrosomia or overgrowth in a fetus, a situation that leads to an increase in the number of cesarean births (Houde, Dahdouh, Mongrain, et al., 2015). Such adolescents should not actively restrict nutrients during pregnancy; although they are obese, their body may be deficient in protein and vitamins.

Many adolescent girls do not eat well during pregnancy because they simply do not know what constitutes good nutrition. Some girls have little choice in what foods are prepared at home. To change a dietary pattern for these girls, you may have to talk to the person who does the cooking in the family. Besides eating the right amount of food, a pregnant adolescent may need to abandon a food fad she has been following, such as drinking soda, for a glass of orange juice (difficult to do if no one she knows drinks orange juice). The best you may be able to accomplish in this situation is to secure her agreement to switch to noncaffeinated soft drinks.

Remember, if a girl is attending school, she probably eats at least one meal away from home each day, so be certain nutrition education includes how to “brown bag” or buy a nutritious cafeteria lunch (type A school lunches are discussed in Chapter 32). If she travels by school bus, she may leave home by 6:00 am or 7:00 am, so she needs suggestions on how to construct a quick but healthy breakfast. Leaving so early creates a second problem of having to wait a long space of time until lunchtime. Suggest midmorning snacks, such as fruit, that also supply vitamins, not just empty calories.

Adolescents traditionally do not take medicine conscientiously, so they may need frequent reminders to take their vitamin or iron supplement. Stress that these are intended to complement nutrition during pregnancy so must not only be purchased but also must be swallowed. For a reminder system, girls may need to post a medication reminder chart at home or in her school locker or to set a reminder on her phone in order to increase adherence.

### *What If . . . 22.1*

**Mindy tells the nurse her daily nutrition consists of a liquid diet beverage for breakfast, a salad for lunch, and then cheese pizza for dinner. Will this typical teenage diet be adequate for her during pregnancy?**

## Activity and Rest

Adolescents vary greatly in their levels of activity. Assess a girl’s participation in sports and determine which ones (if any), such as diving, gymnastics, or touch football, may need to be discontinued during pregnancy. Many girls practice sports for the feeling of belonging to a group or for companionship. To prevent her from feeling “shut out” by her friends, you may need to suggest alternative activities such as joining the drama or language club or perhaps inviting friends over once a week to watch a movie so she does not suffer from the loss of companionship.

Planning enough rest time during pregnancy can be yet another area of concern, especially if a girl is acting as if nothing different than usual is happening to her (Box 22.4). If this is so, it may help to explore a typical day and suggest ways to rest without compromising social relationships (e.g., sitting and talking after school rather than walking through the mall).

#### BOX 22.4

#### Nursing Care Planning Tips for Effective Communication

You talk to Mindy at a prenatal clinic. She is 16 years old and 15 weeks pregnant, and there is concern that she is using methamphetamines.

*Tip:* Be careful not to be so intent on giving advice that you forget the first step of effective problem solving: identifying the exact problem that needs solving.

**Nurse:** Hello, Mindy. How are you feeling?

**Mindy:** Good, but always tired. You know.

**Nurse:** Are you getting enough sleep? How about your diet—are you getting enough iron-rich foods?

**Mindy:** How can I? I work every day after school. I don’t always have money for food.

**Nurse:** Is there anyone who could help you out more? Your boyfriend? A friend?

**Mindy:** I’m pretty much alone since I got pregnant.

**Nurse:** As long as you’re coming to this clinic, you’re not alone. Tell me about a typical day and let’s investigate together ways you could get more rest. We can discuss resources to help you get quality food as well.

### Physiologic Changes

A young girl may have little knowledge about body functions, so as a rule, all adolescent girls need substantial education on the physiologic changes that will occur during pregnancy. Despite all the health information given to children in school, it is not uncommon to find an adolescent who thinks her baby is growing in her stomach and so is unable to eat large meals for fear of suffocating or drowning her fetus. In addition,

specific information about labor and delivery is essential to counteract all the “scare stories” girls may be hearing from their peers. Gaining this type of knowledge is another way pregnancy can be a growth experience. At the end of the pregnancy, this adolescent will know a great deal more about her body and her ability to monitor her health than her average classmate.

### Childbirth Preparation

Peer companionship is a strong need for most adolescents. When girls become pregnant, because they are suddenly so different, they may find themselves cut off from fellow classmates. This can make them more inclined, therefore, to join a class of other adolescents in preparation for childbirth. Because being a student is so age appropriate for them, they usually are excellent students in a class. In addition, they have enough childish magical belief operating that they are not skeptical about whether prepared childbirth will work for them. In fact, believing prepared childbirth will work is an important component in a successful prepared childbirth experience, so this becomes a self-fulfilling prophecy.

### Birth Decisions

Pelvic measurements should be taken early and carefully in adolescent girls because cephalopelvic disproportion is a real possibility because of the girl’s incomplete pelvic growth (Timofeev, Reddy, Huang, et al., 2013). Most girls who are told their baby will have to be born by cesarean birth respond well to the news, and some are actually relieved, because surgery seems controlled and simple compared with the agonies of labor they may imagine. Be certain the information a cesarean birth must be scheduled is shared with the girl and her parents as soon as possible as adolescents want to know the truth. They can regard the withholding of information not as protection but as an indication they are being treated as children.

### Plans for the Baby

Adolescents may need additional time at prenatal visits to talk to a good listener about how they feel about being pregnant and becoming a mother. Scared? Bewildered? Numb? Happy? Be certain they know all the options available to them when their baby is born (e.g., keeping the baby, placing the baby in a temporary foster home, adoption). Adolescents, like all women, should be encouraged to breastfeed (Olaiya, Dee, Sharma, et al., 2016). Breast tissue matures with pregnancy, so even very young adolescents are physically capable of breastfeeding.

## COMPLICATIONS OF PREGNANCY

As mentioned earlier, adolescent pregnancy carries the increased incidence of iron-deficiency anemia, preterm labor, and cephalopelvic disproportion (see Box 22.2). Fortunately, with conscientious prenatal care, these complications can be minimized.

## Iron-Deficiency Anemia

Many adolescent girls are deficient in iron because their low intake cannot balance the amount of iron lost with menstrual flows. Deficiency is revealed by chronic fatigue, pale mucous membranes, and a hemoglobin level less than 11 g/dl. Iron-deficiency anemia is associated with pica, or the ingestion of inedible substances such as blackboard chalk (Lumish, Young, Lee, et al., 2014).

A pregnancy compounds iron-deficiency anemia because a girl must now supply enough iron for fetal growth and her increasing blood volume. All pregnant women should take an iron and folic acid supplement (folic acid is important for red blood cell growth and prevention of neural tube defects), but these are especially important for the adolescent (Menon, Ferguson, Thomson, et al., 2016). Like any other medication prescribed for pregnancy, help an adolescent plan a time each day to take her iron supplement. Review with her how many iron-rich foods she needs to eat daily in addition to this. An iron supplement is not a supplement until her dietary intake is already strong in iron-rich foods.

As soon as her body recognizes it has additional iron, she will begin rapidly forming immature red blood cells. To measure whether the supplemental iron is causing this effect, a reticulocyte count may be scheduled after 2 weeks; if the reticulocyte count is not elevated at this time, it implies a secondary problem exists or, more likely, the girl has not been taking the supplement. Taking a stool swab and assessing it for the black tinge of an iron supplement or reassessing her serum iron level are other methods of assessing for adherence.

## Preterm Labor

Adolescents are at high risk for preterm labor, probably because their uteruses are not fully grown (Kirbas et al., 2016). For this reason, review the signs of labor with them by the third month of pregnancy. Stress labor contractions usually begin as only a sweeping contraction no more intense than menstrual cramps. Any vaginal bleeding is suspicious of labor and needs to be reported. Adolescent girls have gained much of their knowledge of labor from television (where a woman suddenly announces she is in labor and within 15 minutes gives birth). Therefore, they may dismiss light contractions as simple discomfort, not realizing they might be the start of labor. If they can recognize labor contractions early, it is more likely premature labor can be halted.

## COMPLICATIONS OF LABOR, BIRTH, AND THE POSTPARTUM PERIOD

### Cephalopelvic Disproportion

Adolescent labor does not differ from labor in the older woman if cephalopelvic disproportion is absent. The presence of cephalopelvic disproportion is suggested by a lack of engagement at the beginning of labor, a prolonged first stage of labor, and poor

fetal descent. Graphing labor progress is an effective way to detect labor that is becoming abnormal or prolonged. Be certain an adolescent has a support person with her in labor so she can relax and breathe effectively with contractions. If this person is also an adolescent, you may need to serve as the true support person, or at least spend considerable time coaching so this person can effectively support the girl in labor.

### **Postpartum Hemorrhage**

Young adolescents are more prone to postpartum hemorrhage than the average woman because, if a girl's uterus is not yet fully developed, it becomes overdistended by pregnancy. An overdistended uterus is more likely not to contract as readily as a normally distended uterus in the postpartum period, thus allowing bleeding to occur (Kawakita, Wilson, Grantz, et al., 2016). Adolescents also may have more frequent or deeper perineal and cervical lacerations than older women because of the size of the infant in relation to their body. Young adolescents, however, are generally healthy and have supple body tissue that allows for adequate perineal stretching. If a laceration does occur, it usually heals readily without complication.

### **Inability to Adapt Postpartally**

Giving birth is such a stress and a major crisis that almost all women have difficulty integrating it into their life. This can make the immediate postpartum period almost an unreal time for an adolescent. A girl may “block out” the hours of labor as if they did not happen. If she was particularly frightened or she received a narcotic for pain, her memory of the labor hours may not be clear. Urge her to talk about labor and birth to make the happening real to her; otherwise, postpartum depression is more apt to occur (Jeha, Usta, Ghulmiyyah, et al., 2015).

### **Lack of Knowledge About Infant Care**

Adolescents show the same positive bonding behavior with their infants as their more mature counterparts (Fig. 22.1). Although they may consider themselves to be knowledgeable in child care because they have babysat for a neighbor's child or a younger sibling, they may lack knowledge of newborn care. They can be overwhelmed in the postpartum period when realizing the baby is their own and child care is not as simple as it seemed. When the child cries, they cannot hand it to someone else; at the end of 4 hours, when they are tired of caring for the baby, they cannot leave and walk away. Although these things were most likely discussed with an adolescent during pregnancy, these feelings may not become prominent until the child is actually born. Spend time with a girl, observing how she handles her infant. Demonstrate bathing and changing the baby as appropriate. Model good parenting behaviors whenever possible by being aware of how you hold and care for the child.

**Figure 22.1** A new adolescent mother begins to bond with her infant.  
(Barbara Sauder/[Shutterstock.com](https://www.shutterstock.com))

Unfortunately, most adolescent mothers choose not to breastfeed. This is probably related to a lack of understanding about the importance of breastfeeding, their perception of breastfeeding as something that will “tie them down,” and anticipating that this will create a time management conflict when returning to school ([Olaiya et al., 2016](#)). Education about the importance of breastfeeding and tips for how to incorporate it into a busy lifestyle can increase the number of adolescents who breastfeed (see [Chapter 19](#)). Help young mothers who do not choose to breastfeed to select a feeding method that is satisfying to them and safe for the infant as part of the process of becoming a young, but effective, new mother.

***QSEN Checkpoint Question 22.2***

**INFORMATICS**

Mindy was placed on an iron supplement because her hemoglobin level was below normal. What would be the best way to determine if Mindy is taking her iron supplement?

- a. Perform a physical assessment noting if her nail beds have deepened in color.
- b. Ask her to describe in her own words why she has been prescribed an iron supplement.
- c. Look up her laboratory results to see if her reticulocyte count has increased since her last visit.
- d. Analyze her urine for color that would reveal the presence of iron deposits.

*Look in [Appendix A](#) for the best answer and rationale.*

## Unfolding Patient Stories: Brenda Patton • Part 2

Recall **Brenda Patton** from [Chapter 9](#), an 18-year-old who is pregnant with her first child. She lives at home with her mother, stepfather, and three siblings (ages 13, 7, and 5 years). She is in a relationship with a boyfriend who is not living in the household. The boyfriend is supportive but uncertain of paternity status. What are the unique family dynamics for a pregnant adolescent and her boyfriend when considering the risks associated with an adolescent pregnancy and the health of the mother and fetus? What assessments and interventions can be incorporated into the nursing plan of care to promote effective prenatal care for an adolescent? What areas of education should the nurse address during prenatal visits?

Care for Brenda and other patients in a realistic virtual environment: *vSim for Nursing* ([thepoint.lww.com/vSimMaternityPed](http://thepoint.lww.com/vSimMaternityPed)). Practice documenting these patients' care in DocuCare ([thepoint.lww.com/DocuCareEHR](http://thepoint.lww.com/DocuCareEHR)).

## The Pregnant Woman Over Age 40 Years

The incidence of women delaying their first pregnancy until their late 30s or early 40s is increasing so much that 12% of births in the United States today are to women age 35 to 39 years and 3% are to women over age 40 years ([Hamilton, Martin, & Osterman, 2015](#)). **Advanced maternal age** is the label for pregnant women 35 years and older at delivery. In the past, it was assumed a woman over 40 years old was past the optimal age for childbearing and so was at risk for many complications. Today, with the exception of a greater incidence of chromosomal abnormality, there is little evidence of serious complications in women older than age 40 years as long as prenatal care is begun early in the pregnancy.

A woman over age 40 years is more likely than a younger woman to enter pregnancy with a previously diagnosed condition, such as hypertension, varicosities, or hemorrhoids. In addition, by age 40 years, a woman usually has a major role change she must undertake during pregnancy, especially if she is well established in a career or has an accustomed routine at home or in her community. During pregnancy, she will need to think through how the pregnancy and childrearing are going to fit into and change her life. Although she may feel rich in the number of support people she perceives around her, she may discover she actually has few “pregnancy support” people because she does not have many friends her age who are also having babies, some even may be close to becoming grandparents. Many of the things these friends remember of pregnancy and labor were their particular highs and lows; the care they received may not reflect current practice. This can leave a woman without access to the daily “shop talk” of other pregnant women or someone to turn to with questions such as whether the backache she is experiencing or frequent need to urinate is normal. On the other hand, because many women delay childbearing today, she may be one of a sizable group of

women in her community experiencing pregnancy at this stage of life. For this reason, be certain to assess each woman individually (Box 22.5).

#### BOX 22.5

### Nursing Care Planning to Respect Cultural Diversity

What is perceived as the best time in life to have children is strongly culturally influenced. In developing countries, for example, many people believe having children while young allows parents to grow with children. In other cultures, such as the United States, many believe delaying childbirth until a family is financially secure is best. Because of these various beliefs, what you believe about the perfect time to have a baby may not be the belief of a family for whom you provide care. What may seem like a catastrophe in timing to you may seem like a blessing to someone else (and vice versa). Assess couples by history and observation to determine if childbearing appears to be timed correctly for them. If not, they may need extra time to accept a pregnancy and adapt to becoming parents.

## DEVELOPMENTAL TASKS AND PREGNANCY

The developmental challenge of the over-40-years-old age group is to expand their awareness or develop **generativity**—that is, a sense of moving away from themselves and becoming involved with the world or community (Erikson, 1963). Some people assume that once they reach adulthood, the way they are is the way they will always be. They are amazed to find not only do their bodies change (men may lose their hair; women and men both gain weight) but so do their interests. They may now find themselves joining committees and clubs, coaching Little League teams, or organizing fundraising or community events—activities they shunned when younger.

This can cause a woman in this age group who is pregnant to begin to feel ambivalent during the pregnancy because she may want to continue with community activities yet also want to concentrate on the baby growing inside her. Encouraging her to discuss how this conflict feels can help her balance her life and manage two life phases this way.

Women who are having a child after age 40 years tend to fall into one of two groups: those who are having their final child and those who have delayed childbearing because of education or a career and are having their first child. Many adults over the age of 40 years care for aging parents and so may also be dealing with the issues of older adults. These additional responsibilities and obligations can make it difficult for a woman to complete the psychological work of pregnancy. It also may create extra strain on her finances and time and it creates a “sandwich generation,” or one pressured by responsibilities by both older and younger family members. Important worries include having enough energy, arranging for child care, and financial and space strains.

## PRENATAL ASSESSMENT

A woman over age 40 years, like all women, should begin prenatal care early in pregnancy. A few mistakenly believe their lack of menstruation is the result of early menopause and so do not seek an early healthcare consultation. Fortunately, most women of this age group recognize what is happening, are well informed about the advisability of early prenatal care, and also have adequate health insurance, so they do seek an early appointment.

### Health History

Ask women in this age group to document their symptoms of pregnancy, how they feel about the pregnancy, and how it fits into their lifestyle. If a woman did not realize she was pregnant, she may have self-medicated. Ask if she has been taking any medication or herbal remedies to relieve symptoms such as nausea or fatigue. Because a woman is functioning well in a business world does not mean she follows a healthy pregnancy lifestyle. Do not accept answers such as “I drink socially” or “I take the usual drugs” without exploring what those phrases specifically mean.

### Family Profile

Some women over age 40 years who are pregnant for the first time have recently changed their life pattern (e.g., become married or became involved in a long-term sexual relationship) or have decided to have a child, perhaps through in vitro fertilization, without a spouse before they are no longer able to conceive. Whereas a younger woman often waits a while after marrying or beginning a relationship with a new partner to become pregnant, a woman over age 40 often plans to become pregnant immediately because she senses her reproductive time clock ticking. Because of this, she may find herself making many adjustments at once (not only to a new life partner, house or apartment, and perhaps community, but also to a pregnancy).

Be certain to identify a woman’s source of income. If she has a well-paying job, stopping work because of a pregnancy complication could greatly reduce her family’s income. Also evaluate how many people are financially or emotionally dependent on her, such as children from a former marriage, elderly parents, an elderly neighbor, or fellow workers who count on her. During pregnancy, when a woman often needs extra emotional support, feeling responsible for so many people can complicate the pregnancy.

### Day History

Ask specifically about a woman’s type of work or home responsibilities and estimate the amount of walking or back strain those entail. Ask about recent diet or exercise programs. If a woman belongs to a health club, remind her the use of saunas and hot tubs for longer than 10 minutes at a time is contraindicated during pregnancy because of possible hyperthermia and teratogenic effects of extreme heat on a developing fetus

(Agopian, Tinker, Lupo, et al., 2013). Identify personal habits, such as cigarette smoking and alcohol consumption, which could be detrimental to a fetus to determine if counseling to halt or decrease these habits is needed.

## Physical Examination

A woman over age 40 years needs a thorough physical examination at her first prenatal visit to establish her general health and to identify any problems, particularly circulatory disturbances, she may have. Inspect her lower extremities thoroughly for varicosities because these are more common in women over age 40 years (Box 22.6). Obtain a urine specimen and test it for specific gravity, glucose, and protein to evaluate overall renal function and the possibility of gestational or type 2 diabetes because older women are more prone than younger women to develop these conditions.

### BOX 22.6

#### Nursing Care Planning Based on Family Teaching

##### TIPS ON PREVENTING VARICOSE VEINS

**Q.** Mindy says to you, “My mother was older when she had me so developed terrible varicose veins. How can I stop that from happening to me?”

**A.** Although the following activities are not foolproof, incorporating them into your day helps prevent the development of varicose veins.

- Find opportunities, such as a class or lunch break, to elevate your legs on a foot stool.
- Be certain your diet includes vitamin C every day because this is important to strengthen vein walls.
- Rest in a side-lying position with your body tipped slightly forward (Sims position) as this allows leg veins to drain and empty.
- Avoid long periods of standing in one place; take “walk breaks” as active muscle contraction help venous return.
- Avoid sitting with your legs crossed.
- Do not wear anything constricting on your lower legs, such as knee-high stockings.
- If you’re prescribed support hose, put them on before you get out of bed in the morning, before veins become swollen, for best results. Don’t be fooled into thinking panty hose marked “strong support” are the same as medically prescribed support stockings.

Assess a woman’s breasts for any abnormalities, as women over age 40 years are in a higher risk group for breast cancer than are younger women. In addition, as gestational trophoblastic disease (hydatidiform mole) is also more common in women over age 40 years (see Chapter 21), assess carefully for fundal height and fetal movement at prenatal

visits.

## Chromosomal Assessment

Because the risk for Down syndrome is higher in older women than in younger women, an incidence of about 1 in 100 compared to 1 in 350 women over 35 years, genetic screening is offered to detect if an open spinal cord or chromosomal defect could be present in the fetus. These tests include an ultrasound to examine for nuchal translucency (seen in chromosomal abnormalities) and an analysis of maternal serum levels of  $\alpha$ -fetoprotein (MSAFP), pregnancy-associated plasma protein A (PAPP-A), and free beta human chorionic gonadotropin (hCG) to evaluate for chromosomal disorders in the fetus. These tests are done at 11 to 13 weeks.

Women over the age of 35 years may be offered a more accurate noninvasive blood test, circulating free DNA (cfDNA) testing, to screen for chromosomal disorders as early as 10 weeks of gestation. Additionally, chorionic villi sampling (CVS) and amniocentesis are both techniques that may be offered to women who are older than 35 years of age to diagnose chromosomal genetic disorders. The CVS and amniocentesis are diagnostic tests (rather than screening tests); they assess the actual karyotype of the fetus to give a definite answer about the presence or absence of chromosomal disorders. Between 15 and 20 weeks gestation, the MSAFP test is repeated to identify if the fetus is at risk for open neural tube defects (Fletcher & Russo, 2015) (see Chapter 8).

Be certain a woman is prepared for these studies and receives support during them. Alert her that false-positive results can occur; to limit these, positive reports will be confirmed through a chromosomal analysis obtained by CVS or amniocentesis. Some women of this age group do not begin nest building until these tests are completed and they've been assured their child will be healthy.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Health-seeking behaviors related to special care necessary for healthy pregnancy

**Outcome Evaluation:** Patient states she feels confident in self-care and her ability to decrease possible complications of pregnancy.

Be certain to adapt prenatal teaching to fit an older woman's lifestyle. If she had not planned on ever being pregnant, she may have isolated herself through the years from "mothering" activities and so, despite her years, may know little about pregnancy and newborn care. Others may have read so extensively that they may know more theoretical information than a woman who has already given birth. Be certain to review information about possible discomforts of pregnancy (see Chapter 12). A pregnant woman over age 40 years, for example, is prone to hemorrhoids because she

may have some rectal varicosities present at the beginning of pregnancy. Pain from rectal distention may, in fact, be one of the primary symptoms she reports at a first visit. Review measures to increase comfort from these (see [Chapter 12](#)).

Varicosities, like hemorrhoids, develop readily in a woman over age 40 years because she may have had some tendency toward these even before the pregnancy. As with hemorrhoids, her best approach during pregnancy is to prevent formation of these. At the time of birth, be certain to document any degree of varicosity formation so nurses caring for her during the postpartum period can take special precautions to prevent thrombophlebitis because, as with venous stasis present after birth, a woman with varicosities is prone to develop this complication immediately postpartum.

## **PREGNANCY EDUCATION**

### **Nutrition**

Assess the number of meals a woman eats outside her home each week, including those she packs for lunch or eats in restaurants. If she enjoys many of these, she may need tips on how to obtain the same nutrition whether she prepares meals at home or eats them at an office or community function. Urge her to substitute a caffeine-free soft drink in place of an alcoholic beverage at social events. In the same way, substitute milk or juice or decaffeinated coffee for regular coffee. Some women this age normally drink little milk. Rather than getting used to milk again, a woman might appreciate suggestions on other ways to ingest calcium, such as puddings or yogurt or ask her healthcare provider for a calcium supplement.

### **Prenatal Classes**

Because a pregnant woman over age 40 years may be unique in her circle of friends, she may be very interested in joining a childbirth preparation or prenatal exercise class where she is “one of the group” ([Fig. 22.2](#)).

**Figure 22.2** Exercise classes during pregnancy can provide women with an opportunity to interact with others like themselves while benefiting from a carefully monitored workout. (wavebreakmedia/[Shutterstock.com](https://www.shutterstock.com))

Such classes for this age group often center on how to avoid complications such as varicosities, how to integrate pregnancy with a full-time work position, and supplying discussion time on how women are reacting to this dramatic life change. Be certain a woman or couple plan to set aside a specific time every day to do breathing exercises to be prepared for labor. Otherwise, a busy woman may never find time to get to them and will find herself unprepared in labor.

## COMPLICATIONS OF PREGNANCY

The complications of pregnancy most likely to occur in a woman over age 40 years—gestational hypertension, preterm or postterm birth, and cesarean birth—are related to the fact that the woman’s circulatory system may not be as competent as when she was younger or her body tissues may not be as elastic as they were once ([Box 22.7](#)).

BOX 22.7

**Nursing Care Planning Using Assessment**

**ASSESSING THE PREGNANT WOMAN OVER 40 YEARS OF AGE FOR COMPLICATIONS**

## Gestational Hypertension

A woman over age 40 years has a higher risk for gestational hypertension than a younger woman because of blood vessel inelasticity, because hypertension tends to occur more frequently in nulliparas than in multiparas, and because some degree of hypertension may already exist before pregnancy (Ben-David et al., 2016). At any age, the best way to reduce the symptoms of gestational hypertension is for women to take in an adequate supply of protein and obtain adequate rest each day. If a woman works full-time, stopping work to obtain more rest may be difficult not only because she believes she may miss out on a promotion or risk losing her job but also because her income is important to her family; she also is used to being productive, not merely resting all day. To allow her to rest effectively, you may need to help her plan activities she can accomplish on bed rest, such as reworking a school course outline or restructuring her office filing system.

## COMPLICATIONS OF LABOR, BIRTH, AND THE POSTPARTUM PERIOD

Complications that occur with a woman over age 40 years related to birth or the immediate period after birth also may be due to the body, which may not be as elastic as it once was.

### Failure to Progress in Labor

Labor in an older primipara may be prolonged because cervical dilatation does not seem to occur as spontaneously as it does in younger women. Graphing labor progress is a good method to use to determine when labor is becoming prolonged. Many women this age may need a cesarean birth if labor becomes so overly prolonged it begins to place a fetus at risk. Encourage a woman to verbalize how she is feeling about her progress throughout labor to allow for reassurance and prompt intervention should problems arise.

### Difficulty Accepting the Event

Women over age 40 years may begin to have second thoughts about childbearing this late in life as the reality of a new baby registers with them during the intrapartal and postpartum periods. Although they may have read a great deal about babies during pregnancy, they may state they wish they had read more or felt as confident with this phase of their life as they are about other areas such as their home, office, or classroom. Review plans for child care and postpartum rest, with an emphasis on helping women learn to balance their lives, especially if they are planning on returning to work soon after the birth. They might appreciate help making child care arrangements. You can assure them well-organized day care programs for preschool children have positive socialization and perhaps nutrition and exercise results ([Santos, Daniel, Fernandes, et al., 2015](#)).

### Postpartum Hemorrhage

Just as the cervix may not dilate as readily during labor due to inelasticity, the uterus may not contract as readily in the postpartum period. The result of this puts women over 40 years of age at higher risk for postpartum hemorrhage ([Debost-Legrand, Rivière, Dossou, et al., 2015](#)). She also may be more prone to perineal–anal tears because her perineum is less supple ([Richards, Flanagan, Littman, et al., 2016](#)). Because a woman over age 40 years may be an independent woman who is interested in self-care, she may ask for little help. Respect her need for independence, but at the same time, don't neglect assessing the amount of lochial flow or potential perineal bleeding to be certain these complications are detected.

### *QSEN Checkpoint Question 22.3*

## QUALITY IMPROVEMENT

Women over the age of 40 years are at increased risk for developing gestational hypertension. As a result, routine screenings for this health problem have been emphasized on the maternal unit for older mothers. What is the rationale for this change in nursing practice?

- a. Many women over 40 years are underweight before they begin pregnancy.
- b. Older women tend to have a higher fluid intake than do younger women.
- c. Many older women are prone to edema due to their lower activity levels.
- d. The blood vessels of older women may not be as elastic as those of younger women.

Look in [Appendix A](#) for the best answer and rationale.

## The Pregnant Woman Who Is Physically or Cognitively Challenged

In the past, women with conditions such as vision, hearing, cognitive, neurologic, or orthopedic challenges were sheltered by their families to such an extent women with even moderately physically challenging conditions could not meet potential sexual or marriage partners and so didn't become pregnant. In addition, many people believed this was right or that these individuals should not become pregnant. Today, women with varying degrees of disability attend public school, work in offices, join community organizations, establish sexual relationships, and plan pregnancies just like everyone else.

It is important to urge women with physical or cognitive disabilities to begin with preconception care so medicines they are taking can be evaluated, and careful planning for safe pregnancy care can be started early (H. K. Brown et al., 2016). Because these women (and in some instances, also their support persons) face special problems related to their conditions, nursing care during pregnancy must be designed with these special concerns in mind so the woman's and her family's challenges and needs can be addressed and met (H. K. Brown et al., 2016).

Table 22.1 lists general areas of care that are important in planning for the pregnant woman who is physically or cognitively challenged.

**TABLE 22.1 AREAS OF PLANNING WITH WOMEN WHO ARE PHYSICALLY OR COGNITIVELY CHALLENGED DURING PREGNANCY**

Area	Assessment and Planning Guidelines
Transportation	Ask if a woman has access to transportation for prenatal care and for emergencies.
Pregnancy counseling	Assess the special modifications of care that will need to be made depending on a woman's special challenge. Use additional visual or

	auditory aids to make your teaching points clear.
Support person	Determine the woman's main support person. In some instances, a woman's condition requires so much assistance during pregnancy you may need to contact community agencies to lend additional support (with her permission).
Health	Do not lose track of a woman's primary health problem. For example, a woman with cerebral palsy may need to continue an active muscle exercise program during pregnancy; a woman with multiple sclerosis may need to change her medication to avoid teratogenic effects.
Work	Assess whether a woman works outside her home and, if work is discontinued during pregnancy, what she could substitute for social contacts.
Recreation	Assess whether a woman's level of activity is adequate, and make concrete suggestions within her limitations if it needs to be increased.
Self-esteem	Assess a woman's level of self-esteem. If it is low, give praise at prenatal visits and help her make pregnancy a growth experience.

## **RIGHTS OF THE PHYSICALLY OR COGNITIVELY CHALLENGED PERSON**

There are ethical and legal considerations related to women with disabilities. By federal law, persons who are physically disabled must have freedom of access to public buildings by means of ramps or handrails ([U.S. Equal Employment Opportunity Commission \[USEEOC\], 1990](#)). All public healthcare facilities must be in compliance with these laws both in terms of physical facilities and in the true spirit of the law; that is, people should be made to feel psychologically welcome as well as physically able to access the inside of the building. Under the same law, a hospital cannot deny care to a person with a disability even though the disabling condition complicates treatment considerably, possibly requiring extra personnel and time. A woman with a disability has full rights to her child, so the baby cannot be taken from her at birth without her full consent. Likewise, she cannot be forced to terminate a pregnancy or undergo sterilization unless that is her informed decision.

## **MODIFICATIONS FOR PREGNANCY**

Explore with women with a disability at a first prenatal visit the exact nature of their disability and their general self-image to identify what modifications they may need you to plan for care during pregnancy. Some women who are physically or cognitively challenged maintain high self-esteem despite severe limitations and are able to modify and grow with a pregnancy, whereas others have a poor sense of self-esteem that could make change particularly difficult for them. However, for most women, pregnancy will

become a special event, a 9-month announcement to everyone that despite their seeming limitations, they are equal to other women and so are capable of participating in one of life's miracles. If a woman is housebound, be certain she is prescribed a prenatal vitamin containing vitamin D and can obtain refills because she is probably not receiving as much sun exposure as those who spend some time outside (Eggemoen, Falk, Knutsen, 2016).

## Safety Measures to Explore

Safety is a key area of concern for a pregnant woman who is physically or cognitively challenged. Be certain to assess areas such as if she has emergency contact persons, suppliers of transportation, and individual considerations such as mobility, elimination, and possible autonomic responses. Be certain a woman reviews any medicine she is taking for her primary condition with her pregnancy care provider to be certain this will continue to be safe during pregnancy. Women with recurrent seizures, for example, may need to have their dose of antiseizure medicine reduced during pregnancy because some of these are teratogenic (Laganà, Triolo, D'Amico, et al., 2015).

### Emergency Contacts

Evaluate the patient's ability to contact someone in case of a pregnancy-related emergency. Does she have a telephone she can reach readily? Does she know how to activate the emergency medical system (911) in her community? If a woman's speech is not clear, evaluate whether she will be understood while using a telephone to call for help in an emergency. Some women with limited mobility, such as those with a spinal cord injury or cerebral palsy, have a specially designed telephone contact system in their home that connects to a paramedic or hospital emergency service through a beeper system. Check that they intend to maintain this throughout pregnancy. Some women who are hearing challenged use a specially equipped telephone (a telecommunications device for the deaf [TDD]) that prints out messages for them.

### Transportation

Assess a patient's ability to come for prenatal care. If a woman depends on a support person for transportation to a healthcare facility, you may have to arrange appointments according to that person's schedule to prevent missed appointments. Ask the woman, in an emergency, if that person is not available, how could she come for care? Women with cognitive or vision challenges, for example, may not qualify for a driver's license and so may need someone, such as a family member or friend, to drive. Women with a mobility challenge may have difficulty transferring into the specially equipped, hand-controlled car they usually drive as pregnancy progresses.

### Mobility

All women who use wheelchairs are taught to press with their hands against the

armrests and lift their buttocks up off the wheelchair seat for 5 seconds every hour to prevent the formation of pressure ulcers on the buttocks and posterior thighs. Encourage pregnant women to continue to perform this maneuver during pregnancy as the increased weight of a fetus increases her risk for pressure ulcer formation from additional compression. In addition, severe hip flexion from sitting in a wheelchair limits venous return from the lower extremities. For at least 1 hour every morning and afternoon, encourage women who ambulate by wheelchair to decrease the sharp bend at their knees and hips that results from sitting in the chair, to promote venous return and help prevent varicosities and thrombi formation. Resting on a couch for a time or adjusting the footrests of the wheelchair so her legs are not as sharply bent accomplishes this.

If maintaining balance is a problem, a woman may need reevaluation at the midpoint of pregnancy because as the weight of her abdomen increases, she becomes less stable. She may need to use crutches if she did not use them before, or use a wheelchair if she was ambulatory with crutches or a walker before pregnancy. Keep in mind a woman who is physically challenged achieved the degree of ambulation with which she first presents usually only after years of physical therapy and strengthening of leg and arm muscles. Help her see that reducing her degree of independence during pregnancy is not a step backward for her but a step forward, allowing her to have a safe pregnancy without the danger of falling ([Fig. 22.3](#)).

**Figure 22.3** During pregnancy, a woman who is physically challenged may need to use a wheelchair to help safeguard herself against injury. Assure her that she may still enjoy her independence and daily activities, such as caring for an older child. (Lorena Fernandez/[Shutterstock.com](https://www.shutterstock.com))

## Elimination

When mobility is an effort, a woman may not drink as much as usual or use a bathroom as frequently as she would if those actions were effortless. Encourage a high fluid intake and frequent voiding, however, to prevent urinary tract infections. Women who use an indwelling catheter are at especially high risk for contracting urinary tract infections at any time and especially during pregnancy. Women who perform self-catheterization or change their own indwelling catheter may be unable to continue to do this late in pregnancy because the increasing size of their abdomen interferes with their ability to see or reach their perineum comfortably. If this happens, it may be necessary for a woman to arrange for a support person, a home care nurse, or a home health aide to do this for her.

## Autonomic Responses

In a woman who has a high spinal cord injury (cervical or high thoracic), observe for **autonomic dysreflexia** during pregnancy, labor, and the immediate postpartum period. This is an exaggerated autonomic response to stimuli. Any irritating condition, such as a distended bladder, increasing uterine size, labor contractions, or breastfeeding, may initiate the response (Castro, Lourenço, & Carrilho, 2014). Without upper motor neuron control to reverse the phenomenon, extreme symptoms such as severe hypertension (300/160 mmHg), throbbing headache, flushing of the skin and profuse diaphoresis above the level of the spinal lesion, nausea, and bradycardia may occur. Immediate action is necessary to protect against a cerebrovascular accident or intraocular damage. Elevate a woman's head to reduce cerebral pressure and locate the irritating stimulus (usually a distended bladder or bowel). If bladder distention is the cause, the woman needs bladder pressure relieved by catheterization if an indwelling catheter is not in place. If a catheter is in place, check to see why it is not draining, then encourage it to drain by unkinking or flushing to allow urine to flow freely again. Anticipate the need for an antihypertensive agent to alleviate the extreme hypertension, although as soon as the source of irritation is removed, symptoms typically fade quickly.

## Prenatal Care Modifications to Meet Specific Needs

Physical examination may need to be modified depending on individual circumstances for women with disabilities (H. K. Brown et al., 2016). Although women with disabilities have been followed by healthcare providers most of their lives, they may never have had a pelvic examination before and so need clear instructions about why it is needed and what it will consist of. Many obstetric examining tables are built for the comfort of the examiner and are too high for a woman to transfer to from a wheelchair by simply sliding onto the table. You may need to secure a ramp from the physical therapy department so the wheelchair can be elevated to the level of the table. Woman with a spinal cord injury or cerebral palsy may be unable to maintain their legs in a lithotomy position because of either hip flexion contracture or laxness of leg support. This means a dorsal recumbent position, rather than a lithotomy position, may be required for a pelvic examination.

Women who are cognitively challenged may not be aware of how they became pregnant. If a woman became pregnant because she was taken advantage of sexually, she may need some time to talk and work through this experience before she can agree to a pelvic examination.

If a woman who is visually challenged brings a guide dog with her to a healthcare visit, remember that although the dog's chief function is to offer direction, its instinct causes it to become a woman's protector. Resist petting guide dogs as this may be interpreted by the dog as a threat because it creates a distraction from safeguarding its owner.

When interviewing or teaching visually challenged women, be certain not to use

your hands to illustrate points (“I’ll need a urine sample of at least this much urine [measured with your fingers]”). Do not use colors as descriptions of objects (“Put on the blue gown”). Use demonstration aids that allow a woman to feel or touch instead. When helping with or performing a physical assessment, let a woman know you are closing the door or drawing a curtain to ensure privacy. Always alert a woman when you are going to touch her, so as not to startle her. Otherwise, you may find yourself facing a growling guide dog that rises to protect her.

If a woman is hearing impaired, she may not be able to see the examiner’s face during a pelvic examination. This means any question asked of her during this time will not be understood because she cannot see the examiner’s lips to lip read (H. L. Brown, Hughes-Bell, & McDuffie, 2015). Stand by the head of the table and repeat instructions or questions as necessary.

### **Pregnancy Education**

Try to modify health teaching to meet each woman’s specific needs. For a woman who is cognitively challenged, for example, instructions about pregnancy may need to be given to her care provider. Those specifically for her might be limited to those few items crucial for safety, such as “Do not drink alcohol or take any medicines except your vitamin pill.”

If a woman and her support person are both visually challenged, pamphlets about pregnancy care will not be useful. If the support person can see, offer the pamphlets to him or her, suggesting the support person read them to the pregnant woman as a shared activity. This will not only be helpful to her but will also make the partner a more informed support person. Many visually challenged women have assistive technology devices such as special audio apps that record and play audio files. Nurses can contact the local branch of the national nonprofit organization Learning Ally (formerly Recording for the Blind and Dyslexic; <http://www.learningally.org/>) and ask if they have any material already recorded on pregnancy or breastfeeding they can supply. If not, you may be able make an audio file on the assistive technology device, including any information you particularly want a woman to remember or that she seems concerned about. Supply the healthcare facility telephone number at the beginning of the recording as an easy reminder for an emergency and perhaps the date of her next visit as well.

Nutritional education is another area that should be designed based on each patient’s specific challenges and usual routine. For example, a woman may only be able to prepare meals that do not require a stove unless her support person is with her. Nutrition counseling, therefore, needs to center on foods that can be prepared without cooking or only microwave warmed.

Activity and exercise, important for any pregnant woman, are just as crucial for a woman who is physically challenged. If exercise is likely to be very reduced in bad weather because she cannot walk safely on slippery snowy sidewalks, be certain a woman understands walking around her home or apartment can provide the same level

of exercise as if she were walking around the block or exercising at a health club. Although labor and her child's birth may be modified somewhat because of a physical condition, gaining general knowledge about labor and birth and participating in a shared experience with her partner in a childbirth preparation class are still valuable. If a woman does not have many outside contacts, she may be the person in the class who has the most time to practice breathing exercises and is able to be the most adept at using such a method to control pain in labor.

The woman who is severely hearing challenged usually has heard the many television announcements on not smoking or drinking alcohol during pregnancy because she uses closed captioning. Be certain, however, that she is as aware of this as others. Likewise, if the woman depends on lip reading, be certain she is deciphering new words such as amniotic, gestation, or edema. It often helps to show her the printed words so she can see what your lip motion represents when presenting new pregnancy terms. If a woman speaks with sign language and brings an interpreter with her to translate, be certain to talk to her, not the interpreter, when interviewing.

## **MODIFICATIONS FOR LABOR AND BIRTH**

Women who are physically or cognitively challenged usually need a few adaptations in preparation for labor and birth. Helpful suggestions include:

- A woman with a spinal cord injury may not be able to feel uterine contractions. Late in pregnancy, she will need to palpate her abdomen periodically for tightening or the presence of contractions so she is aware of beginning labor.
- Women with muscle spasticity or spinal cord injury may not be able to push effectively for the second stage of labor and so may need a cesarean or forceps birth.
- Birth from a Sims or dorsal recumbent position is usually best as this avoids a lithotomy position (true for all women).
- Braille watches used by persons who are visually challenged may not have second hands. This means they may need to time the length of contractions by counting their length rather than timing them by a watch.
- During labor, the woman who is hearing challenged cannot hear information on how she is progressing if you are not directly facing her. If she needs to communicate with her support person in sign language, act as an advocate to keep her hands unencumbered by equipment such as an intravenous line. Remember she cannot hear her infant cry at birth. Hand the infant to her as soon as possible after birth so she can see and feel the baby is crying and breathing well.
- Be certain to identify the usual sounds of birthing rooms (the beeping of a monitor, the swish of a central supply routing system, and so forth) for the visually challenged woman as hearing sounds and not being able to identify them can be frightening.

## MODIFICATIONS FOR POSTPARTUM CARE

After birth, be certain to assess and teach:

- Whether a woman needs additional support to be successful at breastfeeding.
- Whether she has a return appointment for both herself and her infant for follow-up care; also that the arrangements are within her capabilities, transportation, and understanding.
- Whether she desires contraceptive information and what would be best for her individual circumstances.

Women with disabilities generally feel a need to space pregnancies, but their choices of contraceptive methods can vary widely (Fouquier & Camune, 2015). A woman with poor hand control, for example, might not be able to effectively insert a diaphragm; a woman who is cognitively challenged might not understand the importance of taking an oral contraceptive every day.

### Modifications for Planning Child Care

Allow ample time during the first days after birth for mother–child interaction. For example, after birth, a woman who is cognitively challenged may need extra time to understand the transition from “being pregnant” to “having a baby.” She may have difficulty learning to judge when her infant is hungry. She may need extra supervision to be certain she does not leave the baby unprotected on a bed. A woman with a spinal cord disability may be particularly interested in inspecting her baby’s back. A visually challenged woman will probably want to reassure herself her baby can see. Provide generous time during which she can touch her baby and feel for intact body parts. In contrast, a couple who are hearing challenged may not be pleased to learn their baby can hear as they want the child to be as comfortable as they are in their nonhearing world (Paradis & Koester, 2015). Point out other features such as pretty eyes or long hair to help with bonding.

Breastfeeding has special advantages for women who are physically or cognitively challenged because it is the method of feeding that is not only best for the baby but also requires the least preparation effort on a mother’s part. For a woman who is visually challenged and unable to read printed instructions, breastfeeding eliminates formula errors. For a woman who is mobility challenged, it eliminates trips to the refrigerator. Breastfeeding may not be possible for a woman with muscle spasticity, however, because the let-down reflex, which depends on muscle relaxation, may not occur. Be certain women who are cognitively challenged understand they need to feed until the infant is satisfied, not until they are tired of feeding.

Some women will need a referral for home care follow-up and possibly the use of a home health aide to ensure safe child care. Encourage them to think through what baby care equipment will be best for them. Some crib rails lower by pressure on a foot pedal, for example. Others are activated by a waist-high lever. A woman who ambulates by wheelchair usually finds the waist-high lever most convenient because she can reach

this most easily. A woman who is hearing impaired needs a flashing rather than a buzzing baby care monitor.

If a woman has difficulty with mobility, ask how she anticipates carrying her infant. Using an anterior baby sling usually works well for the mother who uses a wheelchair. Women who are mobile by crutches or a walker can place the baby in a small wagon and pull it if a sling makes their balance unstable. Some women lie on their back on the floor, place the baby on their chest, and scoot across the floor. The important point is not how a woman carries her baby but that she has thought through a safe and comfortable way to do this.

All parents need to make eye contact with newborns, so urge a visually challenged woman to remember to do this when talking to her infant. If she ordinarily doesn't turn on the lights in her home, encourage her to develop a habit of doing that after dinner because her infant will need light to develop vision. If her support person is also visually challenged, suggest she check with a close friend or neighbor monthly to ensure that light bulbs have not burned out.

One of the biggest worries for the woman who is hearing impaired is she will not be able to hear her baby crying. Help her plan to bring the infant's crib or bassinet close to her bed so she can feel the vibration of the baby's stirring and waking. If the baby hears, urge her to talk to her infant as she gives care so the baby is introduced to sounds and words. A woman whose speech is severely affected by her hearing disorder may be reluctant to speak to strangers. Assure her that her infant welcomes the sound of her voice and will quiet readily to the sound. The child may develop her speech pattern because of this. Being spoken to and sung to during the first year is important for overall development, however, so this is still preferable to living in a world of silence.

Some women who are cognitively challenged may have been raised in a group home and only recently moved to their own apartment. Unlike those raised at home, they may have unusual difficulty making plans for child care because they have never seen the care of young children. You have a legal obligation to investigate whether a newborn will receive safe care before hospital discharge. Be certain to ask enough questions so you are sure a woman who is severely cognitively challenged, for example, has a responsible friend or partner to help her with child care.

### ***QSEN Checkpoint Question 22.4***

#### **PATIENT-CENTERED CARE**

Mindy makes friends with another adolescent at the prenatal clinic: a 19-year-old who has a cognitive deficit. When planning care for this patient, what would be the best way to meet this woman's educational needs?

- a. Provide simple, written materials rather than providing verbal instructions.
- b. Provide education to the woman's partner or another person with full cognitive function.
- c. Ensure that teaching is appropriate to the woman's level of cognition.

d. Enlist the help of a social worker when teaching the woman.

*Look in Appendix A for the best answer and rationale.*

## A Woman Who Is Substance Dependent

Substance dependence is a growing health problem in women of childbearing age, so its incidence during pregnancy is also increasing. The number of women who use illicit substances during pregnancy is unknown, but as many as 375,000 infants may be affected yearly. As many as 10% to 20% of pregnant women admit using illicit substances during pregnancy (NCHS, 2012). Common illicit substances used are marijuana, cocaine, and methamphetamine. Adolescents have an increased rate of inhalant abuse and binge drinking.

**Substance abuse** is defined as the inability to meet major role obligations, an increase in legal problems or risk-taking behavior, or exposure to hazardous situations because of an addicting substance. A person is **substance dependent** when he or she has withdrawal symptoms following discontinuation of the substance, combined with abandonment of important activities, spending increased time in activities related to the substance use, using substances for a longer time than planned, or continued use despite worsening problems because of substance use. Typically, substance-dependent women are late adolescents as the overall incidence of substance use is highest in this group. Any woman could be substance dependent, however, so all pregnant women need to be assessed for the possibility of substance abuse and dependency.

Many women with substance dependency come late in their pregnancy for prenatal care because they are worried their substance use will be discovered and they will be reported to authorities. If a woman is using a substance that has a short-acting effect, she can have difficulty waiting a long time to be seen for an appointment at a healthcare facility. She may also have difficulty following prenatal instructions for proper nutrition because, although she may desire to eat well, if she only has enough money to buy either drugs or food, she may choose drugs over food as her choice. She may not have money for supplemental vitamins or iron preparations for the same reason.

Illicit substances tend to be of small molecular weight and, therefore, readily cross the placenta. As a result, these substances can lead to fetal effects, and substance dependency can be responsible for fetal abnormalities or preterm birth (Slater, 2015). If a woman uses injected drugs, the risk for hepatitis B or HIV infection increases. Additionally, if a woman earns money to buy illicit substances through prostitution, this increases the risk for STI and poses yet another threat to a fetus.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for injury to self and fetus related to chronic substance dependency

**Outcome Evaluation:** Patient states she has enrolled in a substance-dependency treatment program and consequently has reduced or is no longer abusing any substances.

Women who are substance dependent need anticipatory guidance and nursing support all during pregnancy because this is a long time to remain substance free. Many women who are substance dependent have few effective support people outside their illicit substance culture with whom they feel free to discuss problems or concerns or who could answer their questions about pregnancy. Because of their numerous needs, they require an interprofessional team approach involving both pregnancy healthcare providers and substance-dependency treatment providers. Fortunately, with good support and active participation in a substance treatment program, pregnancy can become a stimulus for substance abuse recovery and a maturing and growth experience for a woman.

If a woman is still abusing a substance by the time she begins labor, her infant may experience substance withdrawal symptoms (i.e., neonatal abstinence syndrome) shortly after birth (usually marked by nervousness, irritability or lethargy, and possibly seizures; see [Chapter 26](#)). Although it varies depending on the substance, breastfeeding is usually not encouraged for women with substance dependency because, just as all medications cross the placenta to some extent, they also are all excreted into breast milk. Women receiving methadone as part of their substance treatment can breastfeed because only a small amount of this medication is excreted in breast milk ([Krans, Cochran, & Bogen, 2015](#)). In some states, because substance dependency has the potential to seriously affect fetal health, women who test positive for illicit substances, either during pregnancy or at the time of birth, must be reported to state child protective agencies; they may be accused of child maltreatment and jailed, with their infant placed in foster care. Be certain you are familiar with agency and state policy concerning these directives ([Miller, Lanham, Welsh, et al., 2014](#)).

### *What If... 22.2*

**Mindy tells the nurse she is not using illicit substances anymore during pregnancy, but when she opens her purse, the nurse notices several packets of white powder inside. What should the nurse do?**

## **COCAINE**

Cocaine is derived from *Erythroxylum coca*, a plant grown almost exclusively in South America. When sniffed into the nose or smoked in a pipe, cocaine is absorbed across the

mucous membranes and affects the central nervous system. As a result, sudden vasoconstriction occurs. Respiratory and cardiac rates and blood pressure all increase rapidly in response to the vasoconstriction. Alkaloidal cocaine (i.e., crack), a concentrated mixture, produces an even more rapid and intense high when inhaled—so dramatic, in fact, that immediate death may result from cardiac failure.

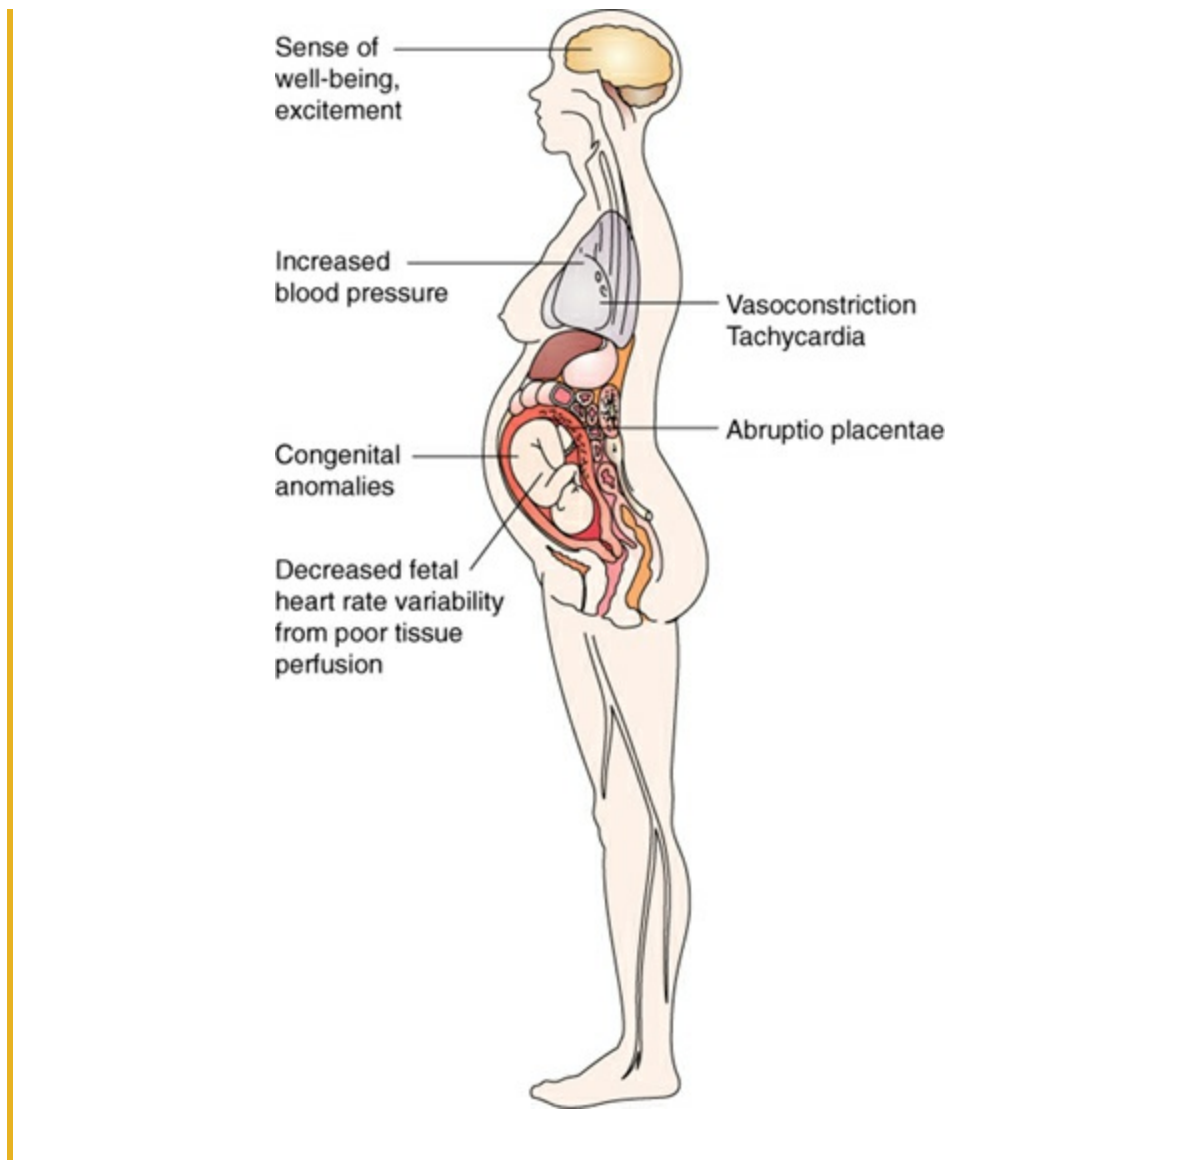

Cocaine is exceptionally harmful during pregnancy because the extreme vasoconstriction can severely compromise placental circulation, leading to premature separation of the placenta, which then results in preterm labor or fetal death (Box 22.8). Infants born to women who are cocaine dependent can suffer the immediate effects of intracranial hemorrhage and an abstinence syndrome of tremulousness, irritability, and muscle rigidity. Long-term effects are not well documented, but learning and social interaction defects are suspected (Messiah, Ludwig, Vidot, et al., 2015).

## BOX 22.8

### Nursing Care Planning Using Assessment

#### ASSESSING THE PREGNANT WOMAN WHO ABUSES COCAINE

Because the effects of cocaine are so intense, counseling women to discontinue using it during pregnancy is often disappointing. Cocaine use can be detected by urinalysis because the metabolites of cocaine can be detected in urine up to 1 week after use.

## AMPHETAMINES

Methamphetamine (i.e., speed) is a neurostimulant and neurotoxin that has a pharmacologic effect similar to cocaine and, in some communities, because it is easily and cheaply manufactured in home labs, can be more commonly used than cocaine (Wright, Schuetter, Tellei, et al., 2015). Ice, a rock type of methamphetamine that is smoked, can produce high concentrations of the substance in the maternal circulation. Women develop blackened and infected teeth. Newborns whose mothers used the substance show jitteriness and poor feeding at birth and may be growth restricted (Wachman & Schiff, 2016).

### **TEAMWORK & COLLABORATION**

Mindy tells the nurse she uses methamphetamine almost daily. What priority nursing intervention should the nurse perform?

- a. Obtain a urine or serum sample for toxicology.
- b. Emphasize the fact that meth is not good for her.
- c. Advise her to stop taking the substance immediately.
- d. Refer Mindy to addictions support services.

*Look in [Appendix A](#) for the best answer and rationale.*

### **MARIJUANA AND HASHISH**

Both marijuana and hashish are obtained from the hemp plant, cannabis. When smoked, they produce tachycardia and a sense of well-being. Although not routinely advised, some women use marijuana to counteract nausea in early pregnancy. With the increase in the legalization of medical marijuana and the more general decriminalization of marijuana in some parts of the United States, there may be an uptick in the number of pregnant women legally using marijuana during pregnancy.

The effect of these substances on fetal development are not well documented because they are frequently part of polysubstance abuse or at the very least cigarette use (Roth, Satran, & Smith, 2015). Marijuana is associated with loss of short-term memory and an increased incidence of respiratory infection in adults. More research is needed about its possible side effects during breastfeeding. A frequent user may be advised not to breastfeed because of reduced milk production and the risk to the newborn from excretion of the substance in breast milk.

### **PHENCYCLIDINE**

Phencyclidine (PCP) was developed in the 1950s as an intravenous anesthetic; it is no longer used that way because, although it creates a sense of euphoria, it also causes irritation and possibly long-term hallucinations (i.e., flashback episodes), and it is now seen most frequently as part of polysubstance use. Because the substance tends to leave the maternal circulation and concentrate in fetal cells, it may be particularly injurious to a fetus.

### **NARCOTIC AGONISTS**

Narcotic agonists (i.e., opiates), used for the relief of pain, such as morphine, oxycodone, meperidine (Demerol), and codeine, are widely abused substances because they can be obtained by prescription and they have a dramatic euphoric effect. Heroin is a raw illicit opiate that is also increasing in incidence in late adolescents. It may be administered intradermally (i.e., “skin popping”), through inhalation (i.e., “snorting”), or intravenously (i.e., “shooting”). It produces an immediate and short-lived feeling of

euphoria immediately followed by sedation. Pregnancy complications related to its use include gestational hypertension and—because the substance is often injected with shared needles—phlebitis, subacute bacterial endocarditis, and hepatitis B and HIV infection may occur.

Abstinence symptoms include nausea, vomiting, diarrhea, abdominal pain, shivering, insomnia, body aches, and muscle jerks. Abstinence symptoms may begin as soon as 6 hours after the last drug dose and can continue for several days. Their severity and duration depend on the amount of substance used daily and the length of the dependence period.

Heroin dependency in the pregnant woman is dangerous because it can result in fetal opiate dependence and severe abstinence symptoms in the infant after birth. Infants tend to be small for gestational age and have an increased incidence of fetal distress and meconium aspiration. They will demonstrate the same abstinence symptoms after birth as the woman would if she abruptly stopped taking the substance.

Because the fetus is exposed to substances that must be processed by the liver, the fetal liver may mature faster than usual. For this reason, newborns of women who are substance abusing can seem better able to cope with bilirubin at birth than other babies. Fetal lung tissue also appears to mature more rapidly than in other infants, apparently from the stress of the intrauterine substance exposure. This means that, although an infant is born preterm, the chance he or she will develop a condition such as respiratory distress syndrome is less than average.

If possible, a woman who is opiate dependent should be enrolled in a substance abuse program—often, a methadone maintenance or buprenorphine (Buprenex) program during pregnancy (Wilder & Winhusen, 2015). Infants of women taking methadone do not escape abstinence symptoms at birth, and some infants appear to have more severe reactions to methadone abstinence than to heroin. Because a woman is being provided an oral medication legally, however, a fetus is at least ensured better nutrition, better prenatal care, and less exposure to pathogens such as hepatitis B and HIV (Wilder & Winhusen, 2015). If a methadone program is not available, women may be treated with buprenorphine (Buprenex). Some women may already be on a buprenorphine/naloxone (Suboxone) combination to treat their substance abuse. Although some providers keep their pregnant patients on this combination, others will try to wean them to a buprenorphine monotherapy.

Narcan (Naloxone) is the medication used to reverse the effects of opioid agents in emergency situations. It is safe to use during pregnancy to treat a pregnant woman who has a respiratory or cardiac code related to opioid overdose. It may cause withdrawal symptoms in the fetus in utero, but the alternative of not treating the pregnant woman who has overdosed is maternal, and then fetal, death. Substance abstinence symptoms in the newborn and accompanying nursing care are discussed in [Chapter 26](#).

## INHALANTS

Inhalant abuse refers to the “sniffing” or “huffing” of aerosol substances. Frequently abused by adolescents, inhalants include model airplane glue, cooking sprays, and computer keyboard cleaner. Most of these substances seem innocent; however, they contain freon as a propellant, which can lead to severe respiratory and cardiac irregularities. The effect of these substances during pregnancy is not well documented, but they appear to have effects similar to alcohol dependency (Boynukalin & Baykal, 2014). The respiratory depression they can cause could be enough to limit fetal oxygen supply to a serious level.

## ALCOHOL

Although alcohol can be legally purchased and is served at social functions, it is just as detrimental to fetal growth as illicit substances. There is little documentation regarding how much alcohol must be ingested before fetal alcohol spectrum disorder, a syndrome with recognizable facial features, possible cognitive challenges, and memory deficits, occurs; therefore, women are advised to drink no alcohol during pregnancy (Green, McKnight-Eily, Tan, et al., 2016). When discussing alcohol ingestion with late adolescents, be certain to mention binge drinking (five or more alcohol drinks on one occasion) to be sure they do not believe this type of occasional drinking is safe during pregnancy.

## Trauma and Pregnancy

Trauma (i.e., injury by force) is a phenomenon that seems remote from pregnancy because pregnant women usually take extra care to protect their body. Even with this, however, trauma in women does occur because the incidence of this is high during the childbearing years. Automobile accidents, homicide, and suicide attempts are among the leading causes of death. During pregnancy, the incidence of trauma is 6% to 7% (as many as 250,000 pregnant women experience trauma per year) (NCHS, 2012). Higher incidences of trauma may occur during the last trimester because of poor balance and fainting from hyperventilation. Orthopedic injuries such as broken wrists or sprained ankles occur because a pregnant woman’s sense of balance is altered and she can fall easily (Box 22.9). In an automobile accident, a pregnant woman is often the front-seat passenger and, in most instances, is also the passenger who receives the most severe injury. Other women seen in emergency departments have suffered intimate partner violence, which increases in pregnancy (Jain, Chari, Maslovitz, et al., 2015).

### BOX 22.9

#### Nursing Care Planning to Empower a Family

#### PREVENTIVE MEASURES TO REDUCE UNINTENTIONAL INJURY DURING PREGNANCY

**Q.** Mindy tells you, “I feel so clumsy since I’m pregnant. What can I do to make sure I don’t hurt my baby?”

**A.** The following guidelines can be helpful:

- Do not stand on stepstools or stepladders (it is difficult to maintain balance on a narrow base).
- Keep small items such as footstools out of pathways (later in pregnancy, it’s difficult to see your feet).
- Avoid throw rugs without a nonskid backing so you don’t slip on these.
- Use caution stepping in and out of a bathtub.
- Do not overload electrical circuits (it is difficult for a pregnant woman to escape a fire because of poor mobility).
- Do not smoke, so falling asleep with a cigarette will not be a concern.
- Do not take medicine in the dark, so you can clearly read the label.
- Avoid working to a point of fatigue, as fatigue lowers judgment.
- Avoid long periods of standing because this can lead to a drop in your blood pressure, causing you to feel dizzy and faint.
- Always use a seat belt while driving or as a passenger in an automobile.
- Refuse to ride with anyone in an automobile who has been drinking alcohol or whose judgment might be impaired in some other way.

## PREVENTING UNINTENTIONAL INJURIES

Unintentional injuries occur more frequently in people under stress than in those with little stress because, in these situations, people concentrate on the stressor, not their immediate surroundings. Because pregnancy is a life event that may cause stress in a family, a woman and her family should take extra precautions for safety. Pregnancy counseling should include education about ways to avoid unintentional injuries by means such as using automobile seat belts (Auriault, Brandt, Chopin, et al., 2016).

## PHYSIOLOGIC CHANGES IN PREGNANCY THAT AFFECT TRAUMA CARE

In an emergency situation, for a physical assessment to be meaningful, consider the physiologic changes that normally occur with pregnancy. A primary rule to remember is that after a traumatic injury, a woman’s body will maintain her own homeostasis at the expense of the fetus. To maintain blood pressure in the face of hemorrhage, for example, a woman’s body will use peripheral vasoconstriction. Because the uterus is a peripheral organ in a shock response, the blood supply to the uterus can be greatly diminished and the nutrient supply to the fetus can be greatly compromised when this happens (see Chapter 21, Fig. 21.1).

A woman’s total plasma volume increases during pregnancy from approximately 2,600 to 4,000 ml at term. This increase serves as a safeguard to a woman if trauma with

bleeding should occur because a woman can lose more blood than usual (up to 30% of her blood volume) before hypovolemia becomes clinically evident. This also means, however, that fluid replacement volume will undoubtedly have to be higher because a pregnant woman needs more fluid than a nonpregnant woman to restore her circulatory volume. Central venous pressure (normal is 0 to 5 cm H<sub>2</sub>O in a nonpregnant state) is increased to 2 to 7 cm H<sub>2</sub>O during pregnancy. Although a woman needs a large amount of replacement fluid, this increased venous pressure means it must not be given too rapidly because her circulation can be overwhelmed more easily than usual by a rapid fluid infusion.

To accommodate the increased vascular load of pregnancy, cardiac output increases from 1 L/min early in pregnancy to 6 to 7 L/min in the second trimester. This volume circulates through the placenta at a rapid rate—approximately one sixth of the total blood volume is present in the placenta at all times. This fact makes a uterine laceration always potentially serious because up to one sixth of a woman's blood volume can be quickly lost.

To move this increased blood volume adequately through the body, a woman's heart rate increases 15 to 20 beats above normal, so a pulse rate of 80 to 95 beats/min is not unusual. Based on this, do not assume a rapid pulse rate indicates hemorrhage following an unintentional injury during pregnancy. In addition, because the heart is displaced by the elevated diaphragm, an electrocardiogram may show a left-axis deviation or the pattern may look distorted from the usual during pregnancy.

Peripheral venous pressure in the pregnant woman is unchanged. However, it tends to be higher in the lower extremities because of compression by the uterus on the vena cava, which causes back pressure. As a result, lacerations of the legs or perineum bleed much more profusely in the pregnant woman. In general, peripheral blood flow is increased because of decreased peripheral vascular resistance (the effect of estrogen and decreased sympathetic activity all through pregnancy). As a result, the pregnant woman can be in severe shock; yet, her extremities will still not feel cold and clammy.

During pregnancy, the leukocyte count rises to 20,000 cells/mm<sup>3</sup> at term, so using this measure as a sign of infection after an open wound is yet another way an assessment can be problematic. The serum albumin level decreases during pregnancy, making the large loss that normally occurs with burns a more serious response than usual. Serum liver enzyme levels such as aspartate aminotransferase, alanine aminotransferase, and lactate dehydrogenase, remain the same during pregnancy. This means, that if these are elevated after an injury, liver trauma can still be detected. Because alkaline phosphatase, a substance also usually helpful in detecting liver trauma, is three to four times greater in the pregnant woman at term than usual (from placental origin), this marker loses its importance. Pancreatic amylase levels remain unchanged during pregnancy, so the pancreas can be evaluated as usual.

Abdominal pain is difficult to localize during pregnancy because organs are pushed aside by the growing uterus. The abdomen often feels tense during pregnancy, so the important findings of guarding and rigidity of the abdominal wall may be lost. Bleeding

into the abdominal cavity with an abdominal injury is apt to be forceful and extreme because of the increased pressure in the pelvic vessels. A procedure such as a needle **paracentesis** (needle aspiration) to assess for bleeding into the abdominal cavity must be done carefully because the bowel, dislocated from its usual position, can be easily punctured. **Culdocentesis**, or needle aspiration through the posterior vaginal fornix into the peritoneal cavity, may be done instead. **Peritoneal lavage** (the process of inserting a peritoneal dialysis catheter into the abdominal cavity, adding a quantity of an isotonic solution, aspirating it again, and analyzing it for blood or urine) may reveal bleeding or bladder rupture best.

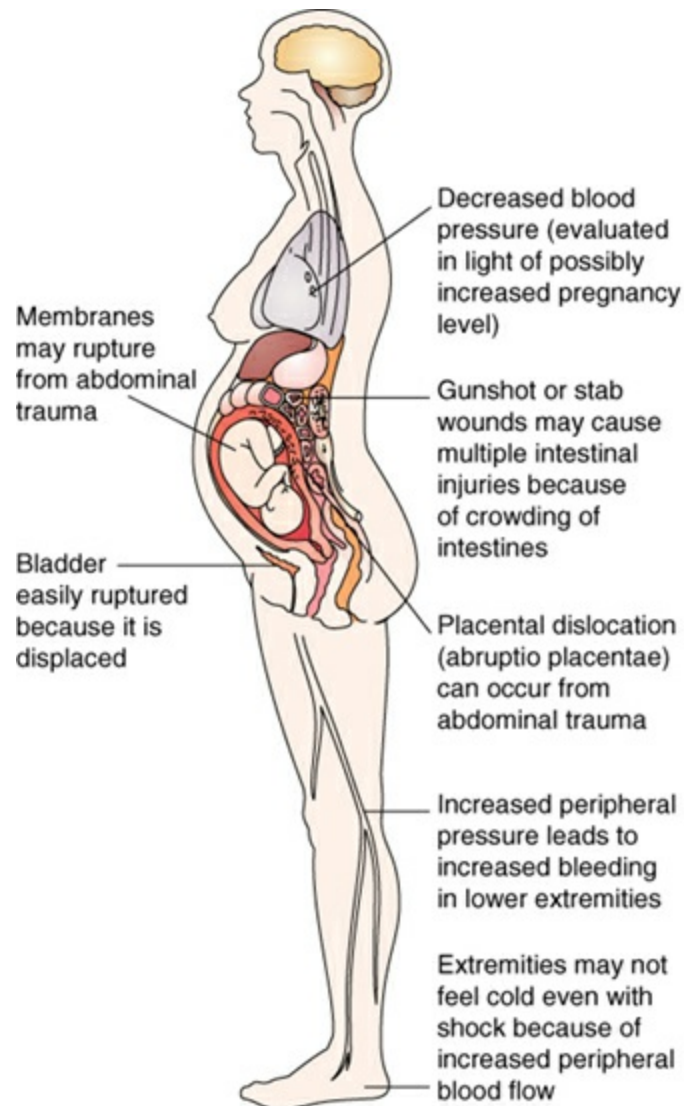

The bladder of a pregnant woman is extremely susceptible to rupture because it is the most anterior organ and is elevated abnormally (Dorairaj, Sagili, Rani, et al., 2012). After abdominal trauma, an indwelling bladder catheter is often inserted to assess for blood in the urine (Box 22.10).

BOX 22.10

### Nursing Care Planning Using Assessment

#### ASSESSING THE EFFECTS OF TRAUMA IN THE PREGNANT WOMAN

## PSYCHOSOCIAL CONSIDERATIONS

When a pregnant woman is seen at a healthcare facility after any type of unintentional injury, she is apt to be apprehensive and frightened, both for herself and for her fetus. She worries not only about what has happened to her but also about what could have happened (if the knife had slipped an inch farther, if the automobile had been moving faster, if she had fallen from further up the stepladder) as well as what medical care will be required. (Does she need an X-ray? Will this be safe for the fetus?)

A second emotion she may feel is guilt about her carelessness (e.g., if she were really a good mother, she would have had her seat belt fastened or would not have tried to stand on a stepladder to hang drapes alone). A feeling of guilt lowers her self-esteem and can increase her level of stress. Remember, people under stress do not process information well and may not perceive correctly the information given to them. Always try to review information with a woman before discharge from an emergency department to be certain she has the facts of her injury and understands the necessary

follow-up.

## ASSESSMENT

Assessment of an injured pregnant woman must be done quickly yet thoroughly and should include both her psychological and physical status. Some women are so concerned with their fetus they do not realize they are injured. Other women might not even consider the possibility that the fetus could be injured until someone asks if she has felt the fetus move since the injury. Assessment, therefore, should be done concurrently with supportive reassurance (e.g., “Your blood pressure is low, but the fetal heartbeat sounds good”) to try to relieve her fear of fetal damage. Use a Doppler to assess fetal heart tones if possible to demonstrate to a woman as well as to yourself that the fetus still appears to be well. Attaching an external monitor to record the fetal heart rate and uterine contractions may be the best way to rule out fetal distress or preterm labor.

Following a serious injury, a woman needs her support people around her. Locate them as necessary and assess their reaction to the trauma as well.

## Health History

In an emergency situation, a few minutes spent attempting to calm a woman and move her past her initial fright is time well spent because reducing a woman’s level of anxiety can enhance her ability to cooperate with a history and physical assessment. This is true unless symptoms of major body system disturbances require immediate efforts to be directed elsewhere.

Take a brief pregnancy history as well as a trauma history, such as the length of pregnancy or any complications. Ask specifically if fetal heart tones have been heard by an examiner during the pregnancy, if she has felt the fetus move since her injury, if she has any sensation of tightening or pain in her abdomen or back that could be uterine contractions, and if she knows what her prepregnancy and pregnancy blood pressures have been to help evaluate the extent of blood loss from the trauma.

Document the circumstances of the trauma: what happened, the time of the injury, signs and symptoms of injury she is experiencing, and actions she has taken to counteract these. If a woman fell, for example, how far was the fall? (A fall from the top of a stepladder is more likely to be serious than a fall from a low rung.) What body part did she land on? (Striking her abdomen may be very serious, although she may be in less pain than if she injured a wrist in the fall.) For an automobile accident, ask how fast the car was traveling, if she was thrown from the car, or if the windshield broke (windshields are usually broken from the impact of a head striking the windshield so the woman will need to be assessed for a head injury).

As a final measure, evaluate whether a woman’s degree of injury is in proportion to the history. Injuries out of proportion (e.g., a woman states she tripped on her front steps, but you notice all her extremities are ecchymotic and her jaw is broken) suggest

intimate partner violence, which is known to increase in pregnancy rather than a simple unintentional injury (Jain et al., 2015). It is important to identify such women not only to stop the abuse but also because they can have an increased incidence of postpartal depression and perhaps an increased risk of wanting to harm themselves (Burnett, Schminkey, Milburn, et al., 2016) (see Chapter 55). Also analyze whether a woman seemed to be using a sensible degree of caution for the circumstances. If not, assess how aware she is of common safety measures. In rare situations, such questions may reveal a woman who self-inflicted an injury in an attempt to end an unwanted pregnancy. A naive adolescent, for example, may attempt to fall down a flight of stairs or to poison herself, which she then reports as an unintentional injury.

### Physical Examination

Unintentional injuries become fatal when lung, heart, kidney, or brain functions fail. Fetal health falls into jeopardy when uteroplacental function becomes impaired. Following trauma, therefore, it's important to evaluate these body systems first (Table 22.2). All women who receive a blow to their abdomen need to be evaluated for direct insults to fetal health, such as premature separation of the placenta, although the incidence of this occurring from abdominal injury is actually small (Jain et al., 2015).

**TABLE 22.2 INITIAL ASSESSMENTS NECESSARY AFTER TRAUMA DURING PREGNANCY**

Body System	Assessment
Respiratory system	<p>What is the quality of respirations (labored or even)?</p> <p>What is the respiration rate?</p> <p>Are there sounds of obstruction (wheezing, retractions, coughing)?</p> <p>Does the woman have cyanosis?</p> <p>Does the woman demonstrate oxygen hunger (inability to lie flat, nasal flaring)?</p>
Cardiovascular system	<p>Is her color pale, which could be from hemorrhage?</p> <p>Is there gross bleeding?</p> <p>What is the pulse rate? Increased, which could identify hemorrhage? Or absent, which identifies heart failure?</p> <p>What is the blood pressure (decreases with hemorrhage)?</p> <p>Does the woman feel apprehensive, which can occur with altered vascular pressure?</p>
Neurologic system	<p>Is the woman conscious (able to answer questions coherently)?</p> <p>Are pupils equal and react to light?</p> <p>Are there bruises or bumps on the head or spinal column?</p> <p>Is there loss of motion or sensory function in a body part?</p>
Renal system	<p>Is there bruising over the bladder or on the back over kidneys?</p>

Uterine–fetal system	Is the urine pink or red, which could identify fresh blood in urine? Or black, which could identify old blood?
	Is there bruising on the abdomen over the uterus?
	Is there bradycardia, tachycardia, or absence of fetal heart tones? Is there loss of variability on a fetal monitor?
	Is there evidence of vaginal bleeding?
	Is there clear fluid leaking from the vagina, which could identify ruptured membranes?

With multiple trauma, a nasogastric tube is usually passed to empty the stomach. A Foley catheter is inserted to assess urine output and to rule out a ruptured bladder (blood would return or urine would be blood-tinged if bleeding were occurring).

To prevent supine hypotension syndrome, be certain a woman does not lie supine for an examination. If she must lie on her back, place a rolled towel or blanket under her right side to tip her body approximately 15 degrees to the side and manually displace her uterus off the vena cava. If surgery is necessary, the operating room table can be tipped to achieve this same effect.

## Nursing Diagnoses and Related Interventions

Planning in an emergency always involves two phases: planning for immediate care to stabilize body systems and protect the fetus and planning for ongoing care to bring the woman back to wellness. Examples of nursing diagnoses include:

- Fear related to threat of injury to the fetus
- Risk for fetal injury related to apparent self-harm attempt
- Ineffective tissue perfusion related to severed artery
- Ineffective breathing pattern related to lung laceration by gunshot wound

Once the immediate emergency phase has passed, nursing diagnoses focus on preventing additional injuries or alleviating emotional distress. Examples include:

- Risk for infection related to loss of skin integrity from knife wound
- Situational low self-esteem related to occurrence of unintentional injury
- Powerlessness related to seriousness of the injury sustained or inability to prevent an unintentional injury from occurring

## THERAPEUTIC MANAGEMENT

Implementations in emergency situations must be done quickly while always remembering a woman’s primary health condition is that she is pregnant.

- For “hands only” cardiopulmonary resuscitation (CPR): Check for unresponsiveness. If the woman is not responsive and not breathing, call for help

or dial 911.

- Begin heart compressions at a rate of at least 100 per minute, depressing the chest at least 2 in. each time. Cardiac massage this way may be awkward late in pregnancy because of the size of the uterus, but undue pressure should not be necessary to create heart action.
- Continue chest compressions at this rate until additional help arrives ([American Heart Association \[AHA\], 2015](#)).
- When help arrives, ask a person to place a rolled towel or blanket under the woman's right side to relieve uterine pressure on the vena cava and help prevent supine hypotension syndrome.

In a health agency setting, CPR should follow agency guidelines. If there has been blood loss, a central line may need to be inserted and lactated Ringer's or another isotonic solution infused to restore fluid volume as well as to provide an open line for emergency medication.

If hypotension is present, it must be corrected quickly to maintain a pressure gradient across the placenta. However, any antihypotensive agent that achieves increased blood pressure by causing peripheral vasoconstriction is contraindicated (vessels in the uterus would constrict and cut off the fetal blood supply). Ephedrine is the medication of choice for a pregnant woman to restore blood pressure because it has a minimal peripheral vasoconstrictive effect. Following emergency interventions, care depends on the specific injury or trauma present ([Jeejeebhoy, Zelop, Lipman, et al., 2015](#)).

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for ineffective tissue perfusion related to blood loss from trauma

**Outcome Evaluation:** Patient's blood pressure remains above 100/60 mmHg, pulse rate below 100 beats/min, fetal heart rate is 120 to 160 beats/min; nonstress test shows good variability; no signs of labor contractions are present.

### Open Wounds

Open wounds vary from simple lacerations to more serious puncture wounds. Because the white blood cell count is normally elevated during pregnancy, a single count is a poor indicator of the presence or extent of infection for these injuries. Serial measurements can be used, however, to assess if infection is occurring.

#### Lacerations

A laceration (e.g., a jagged cut) may involve only the skin layer or may penetrate to deeper subcutaneous tissue and even tendons. Lacerations generally bleed profusely. Halt bleeding by putting pressure on the edges of the laceration; this may be difficult to achieve in the lower extremities because venous pressure is so greatly increased in the legs during pregnancy. After cleaning, the area is then sutured through each layer of tissue involved to approximate the edges. A local anesthetic such as lidocaine (Xylocaine) is necessary for suturing. Because this has only a local effect, you can assure a woman that this will be safe to use during pregnancy. If the laceration is superficial and a woman is worried about the use of an anesthetic, the edges can be approximated with a butterfly strip. This will allow it to heal, although with a slightly more noticeable scar.

### ***QSEN Checkpoint Question 22.6***

#### **SAFETY**

Mindy has a laceration on her leg from her automobile accident. What priority nursing action should the nurse initiate?

- a. Keep the laceration clean by irrigating it with hydrogen peroxide.
- b. Control bleeding by applying a pressure dressing to the wound.
- c. Administer a nonsteroidal anti-inflammatory medication for pain relief.
- d. Obtain written consent for surgery from Mindy.

*Look in [Appendix A](#) for the best answer and rationale.*

## **Puncture Wounds**

A puncture wound results from the penetration of a sharp object such as a nail, splinter, nail file, or knife. Puncture wounds bleed little—an advantage in terms of minimizing blood loss but not in terms of wound cleaning. A puncture wound is usually not sutured because suturing would create a sealed, unoxygenated cavity below the sutures or a space where a tetanus bacilli infection could grow. If a woman has had a tetanus immunization within the past 10 years, tetanus toxoid (Tdap) is administered. If a woman has not had a tetanus immunization within 10 years (the usual condition), both tetanus toxoid (Tdap) and immune tetanus globulin (Tig) are administered. Both of these are safe to administer during pregnancy ([Sukumaran, McCarthy, Kharbanda, et al., 2015](#)).

Puncture wounds are usually frightening because it's difficult to tell how deep they are. They also usually occur with the added association of violence. Knife wounds cause deep penetration puncture wounds and are often directed into the abdomen. Even a paring knife may easily reach the depth of the uterus, possibly directly cutting the fetus. Most stab wounds of the abdomen, however, occur in the upper quadrants of the abdomen, above the uterus, and are more apt to strike the liver or pancreas. To determine the depth and extent of a wound, a fistulogram may be done. This is done by

inserting a thin catheter into the wound and filling the wound with a radiopaque solution that outlines the depth of the wound on x-ray. If the peritoneal cavity was perforated, dye will be shown outlining the intestines. If there is a suspicion of bleeding into the abdominal cavity, a laparoscopy or celiotomy (exploratory surgical procedures into the abdominal cavity) may be performed. Although a frightening procedure for the woman, surgery this close to the uterus usually does not result in disruption of the pregnancy.

If the diaphragm was cut, the intestines may herniate into the chest cavity (diaphragmatic hernia) because of the increased abdominal pressure from the enlarged uterus, causing acute shortness of breath. After surgical repair of an injured diaphragm, cesarean birth is usually planned to avoid strain on the newly repaired diaphragm during labor. The uterus appears to have a natural resistance to infection, so even if it is punctured, infection in the uterus rarely occurs.

### Animal or Snake Bites

Pregnant women are occasionally bitten by venomous snakes but are rarely bitten by any animal but a dog. Animal bites produce a form of puncture wound, so if the rabies immunization status of the dog is known to be up to date, the wound is washed and treated as a puncture wound. If the dog cannot be located or is proved to be rabid after 48 hours of observation, a woman must be administered rabies immune globulin and vaccine. Pregnancy is not a contraindication to rabies immunization because contracting the disease would be fatal (Huang, Liu, Cao, et al., 2013). It has not yet been decided if antivenom or supportive therapy is the optimal management for snake bites (Ishikawa, Ohsaka, Omori, et al., 2015).

To prevent bites, caution pregnant women to avoid contact with unfamiliar dogs. If she will be camping in a remote location, caution her to avoid feeding any wild animals such as squirrels and raccoons for the same reason.

### Blunt Abdominal Trauma

Blunt trauma generally occurs from automobile accidents, when a woman's abdomen strikes the steering wheel or dashboard, or occurs from someone kicking or punching her abdomen. No visible break is present in the skin. Following the injury, however, the underlying tissue becomes edematous; broken underlying blood vessels ooze and form ecchymoses or a hematoma at the site. If the bruise is over the abdomen, to assess if there is internal bleeding, a diagnostic peritoneal lavage may be done by introducing a small amount of normal saline by a syringe into the peritoneum and then withdrawing it to see if blood is evident. Ultrasound may also be used to detect this.

Careful assessment that the pregnancy has not been harmed must be made following blunt trauma because a forceful blow to the abdomen could dislodge the placenta (i.e., abruptio placentae), which would then begin preterm labor. Palpate the uterus for any abnormal contours that would suggest edema or internal bleeding; listen and record fetal heart tones. Use a Doppler not only for easy assessment but also to help assure a woman

the fetal heartbeat is good. Real-time ultrasound may also be helpful in showing that the uterus and placenta are intact. A pelvic examination is usually performed to assess for vaginal bleeding or seepage of clear fluid that would suggest rupture of the amniotic membranes. If a woman reports uterine contractions, attach uterine and fetal monitors so you can estimate the strength and effect of contractions on the fetal heart rate and determine if preterm labor has begun. A tocolytic such as terbutaline will probably be prescribed to halt preterm labor once it is established the uterine environment is still intact (see [Chapter 21](#) for a full discussion of tocolysis).

The possibility some placental blood will enter the maternal circulation with uterine trauma is a real possibility. Rh-negative women, therefore, are typically administered Rh immune globulin after abdominal trauma. That fetal blood cells are present in the maternal bloodstream can be documented by a Kleihauer–Betke test (in a sample of maternal blood, maternal cells remain colorless on staining, whereas fetal cells turn purple-pink).

## **Gunshot Wounds**

A woman may receive a gunshot wound because she was an intended victim or because she was an innocent bystander. Occasionally, a woman attempts to harm herself by a gunshot wound. Assessment of the wound includes inspection for the point where the bullet entered the body as well as the point where it exited (the entry wound is smaller than the exit wound because, as a bullet slows, it begins to tumble, enlarging the space it occupies). The uterine wall is so thick during pregnancy that it may trap a bullet, so there may be no exit point from a woman's body if the uterus was punctured. If the bullet entered high in the abdomen, the intestines will surely be injured because so many intestinal loops are compressed above the uterus.

Gunshot wounds are surgically cleaned and debrided, and a woman is prescribed a high dose of an antibiotic such as ampicillin. If the bullet entered the uterus, the incidence of fetal mortality is high, especially if the placenta was torn by the bullet. After providing emergency care to a woman for the injury, remember to carefully investigate the circumstances of the injury. Since President Lincoln's assassination, gunshot wounds in the United States must be reported to the police. Stay with a woman as necessary while she recounts her history of the incident for law enforcement officers.

## **Poisoning**

Pregnant women are not apt to swallow a poison, although poisoning can occur unintentionally, for instance, from inadequately refrigerated or undercooked foods or if a woman wakes at night and attempts to take medicine in the dark. There is also the possibility a woman might poison herself as a self-harm attempt.

Poisoning in the pregnant woman is managed the same as in a nonpregnant woman. The woman should telephone the National Poison Control Center (1-800-222-1222), state she is pregnant and what she unintentionally swallowed, then follow the specific

recommendation of personnel at the poison control center. When seen in an emergency department, oral activated charcoal is safe during pregnancy and so is the medication of choice to neutralize stomach poison (Karch, 2015).

After a woman has been treated and the emergency of the poisoning is over, carefully investigate the circumstances of the poisoning to help a woman learn about safety with medications or food.

## Choking

If a pregnant woman chokes on a piece of food or a foreign object blocks her airway, attempting to dislodge the object with a sudden upward thrust to the upper abdomen can be difficult because there is a lack of space between the uterus and the end of the sternum. Also, the average person may not be able to reach around a woman's enlarged abdomen to perform a usual chest thrust. Box 22.11 describes how to perform chest thrusts for a pregnant woman.

### BOX 22.11

#### Nursing Care Planning Using Procedures

#### CHEST THRUSTS FOR A PREGNANT WOMAN

**Purpose:** To relieve tracheal aspiration

##### Plan

##### Principle

*For Conscious Victim in Standing Position*

1. Stand behind the woman and encircle her chest with your arms.

1. Proper positioning ensures proper placement for chest pressure and prevents inadvertent injury to underlying body structures.

2. Place the thumb side of your fist on the middle of the woman's sternum.

2. Placement of fist against the chest ensures a solid structure for compression.

3. Grab the fist with the other hand and perform backward thrusts until the foreign body is expelled.

3. Pressure on the chest compresses the ribs, increasing chest and lung pressure. This increased pressure forces an object lodged in the airway to move upward.

---

*For Unconscious Victim in Supine Position*

---

1. Place the woman in the same position as for external heart compressions (heel of the hand on the lower sternum).

1. Loss of consciousness interferes with the woman's ability to maintain an upright position.

2. Follow steps 2 and 3 as with a conscious victim.

2. Chest compression can be as effective in the supine position as in the standing position.

## Orthopedic Injuries

Because women have poor balance late in pregnancy, it is easy for them to trip; when they fall, they almost automatically reach out a hand to prevent landing on their abdomen. Because of extra pregnancy weight, this can cause a serious wrist injury (a Colles fracture). Apply ice to the area to decrease swelling as an immediate first-aid measure. If limited motion is present, an X-ray may be necessary to determine whether a fracture is present. Assure a woman an X-ray of an extremity is safe during pregnancy as long as her abdomen is shielded during the procedure. Be certain to delegate someone to accompany her to the X-ray department and remain with her (outside the actual X-ray room) to ensure lead protection is offered and to remain alert for signs of preterm labor that could suddenly develop as a result of a yet undetected injury.

Because women of childbearing age are usually healthy, fractures or torn ligaments generally heal rapidly without complications. Be certain a woman can identify good calcium food sources if she has a fracture so both she and the fetus can obtain adequate calcium for new bone growth.

Because many more adolescent girls and young adult women participate in sports today than ever before, combined with the cartilage softening and extra weight caused by pregnancy, an increasing number of pregnant women suffer knee cartilage or knee ligament injuries.

Any woman who has had a previous knee injury should have it reevaluated early in the pregnancy because a support device such as a knee immobilizer may be required for the last 3 months of pregnancy to keep the joint from dislocating or the ligament from tearing again. You can assure her having a knee immobilizer in place at the time of birth will not interfere with birth.

The laxness of body cartilage may also cause separation of the symphysis pubis if a woman falls with her legs outspread. Many women experience some nagging suprapubic joint pain during pregnancy. A suture separation is very painful, especially when walking or turning. To avoid pain and allow the cartilage to heal, a woman is usually advised to remain on bed rest at home for 4 to 6 weeks. If separation of the symphysis pubis is still present at the time of birth, this can make labor very painful, especially during the pelvic division of labor as the fetus is pushed through the pelvic ring. She may need additional analgesia at this time.

### *What If . . . 22.3*

**Mindy tore her anterior cruciate ligament (ACL) in an automobile accident and is prescribed a knee immobilizer. She's unable to drive with this in place,**

and her family lives in a second floor walk-up apartment. What factors should the nurse assess with her?

## Burns

Burns are dangerous for the pregnant woman not only because of the thermal injury that occurs but also because inhalation of carbon monoxide gases from the fire can lead to extreme fetal hypoxia because carbon monoxide can cross the placenta in place of oxygen (Wu & Hueppchen, 2015).

In addition, inhaled smoke is extremely irritating to lung tissue and so can result in extensive local lung edema, which can lead to additional fetal hypoxia because of the lack of oxygen–carbon dioxide exchange space in the woman’s lungs. Because fluid and electrolyte losses occur with burns, hypotension from hypovolemia or an electrolyte imbalance can occur. Yet another concern, in response to a severe trauma such as a burn, is that prostaglandins are produced, possibly causing preterm labor. The more extensive the burned area, the poorer the prognosis for both the woman and fetus. Interestingly, burn tissue heals more quickly than usual during pregnancy, probably related to the overall increased metabolism and the increased corticosteroid serum level, which prevents inflammation and damage to tissue from the pressure of edema. Care of burns is discussed in Chapter 52.

## POSTMORTEM CESAREAN BIRTH

If a pregnant woman does not survive serious trauma, it may still be possible for her child to be born safely by a postmortem cesarean birth (Drukker, Hants, Sharon, et al., 2014). This is usually attempted if the fetus is past 24 weeks and less than 20 minutes has passed since the mother died (preferably 5 minutes). By general practice, no consent is necessary for the procedure because the fetus is assumed to want to live but cannot give consent. A classic cesarean incision is used. Personnel should be available to resuscitate the newborn immediately.

### *What If . . . 22.4*

**The nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to women with special needs during pregnancy (see Box 22.1). Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Carson family and that would also advance evidence-based practice?**

## KEY POINTS FOR REVIEW

- Adolescent pregnancy is a major concern because although it is decreasing in

incidence, it still occurs at a high rate and can interfere with the development of both an adolescent and fetus. Nursing care needs to be individualized to meet the prepartal, intrapartal, and postpartum needs of this age group. Planning nursing care that helps adolescents view a pregnancy as a growth experience not only meets QSEN competencies but can also best help a girl mature to be an effective parent.

- Women who delay childbearing until age 40 years may need additional discussion time at prenatal visits to help them incorporate a pregnancy into their lifestyle. They may need reminders to save time during the day for rest, particularly if at risk for gestational hypertension or varicosities.
- Women who are physically, cognitively, visually, mobility, or hearing challenged are apt to have special needs during pregnancy that must be addressed by healthcare providers so adjustments to ensure a safe outcome can be made during pregnancy. Providing time for discussion early in pregnancy so these needs can be identified and anticipated is an important role for nurses.
- Women who are physically or cognitively challenged may need help adjusting their usual regimen to pregnancy. Be certain they are aware of how to contact help in an emergency. Ensure all medications they are taking for their primary disorder are safe for use during pregnancy.
- A woman who is substance dependent presents a unique challenge for healthcare providers during pregnancy. Encouraging her to decrease or halt her substance intake to safeguard the health of a fetus is a short-term goal. Addressing her need to decrease her substance intake for the remainder of her life so she can be a quality parent is a long-term goal.
- The fetus of a woman who is substance dependent is at high risk because of the direct effects of the substance and the indirect effects of an unhealthy lifestyle. Women should be encouraged to join substance reduction/maintenance programs if possible to reduce fetal risk.
- Trauma in pregnancy results from sources such as violence, automobile accidents, and falls. Women with traumatic injuries need to be carefully assessed to be certain their fetus is unhurt and to determine if intimate partner violence could have been the cause of the trauma.

### CRITICAL THINKING CARE STUDY

Anifisa Alkaev is a 42-year-old Russian Catholic woman who, after several fertility treatments, is 10 weeks pregnant. She lived with her parents in Russia until 1 year ago, and she speaks almost no English. She met her partner, a U.S. citizen, approximately 1 year ago. She began living with him 6 months ago in a conservative Jewish community. In Russia, Anifisa was a lawyer but is currently not working because of her language barrier. Her partner's 90-year-old mother has just moved in with them. A 15-year-old niece whom Anifisa does not know well will also be staying with them until she finishes high school. You notice Anifisa is both

hypertensive and overweight.

1. Analyzing Anifisa's situation, what needs would you identify?
2. What nursing interventions would you implement?
3. What complications of pregnancy could Anifisa be at a high risk for that you would want to especially assess for during her pregnancy?

## 23

# Nursing Care of a Family Experiencing a Complication of Labor or Birth

*You admit Rosann Bigalow, a 28-year-old woman about to give birth to her first baby, to a birthing room. Her contractions have been 5 minutes apart for 10 hours. She feels more pain in her back than in her abdomen, saying it feels “like my spine is tearing apart.” A contraction monitor shows contractions are hypotonic. A sonogram shows her fetus is “borderline” large for gestation and in an occipitoposterior position. Her husband asks you if the reason Rosann’s labor is taking so long is because she’s overweight.*

*Previous chapters discussed uncomplicated pregnancy and labor and birth. This chapter adds information about what happens when complications of labor occur. Nurses play a vital role in making any labor safe. They play an even greater role when a complication arises. The sooner a complication in labor is recognized, the better the chance the situation can be corrected, the concern resolved, and both fetal and maternal health can be protected.*

**How would you answer Mr. Bigalow?**

## KEY TERMS

**amnioinfusion**

**amniotic fluid embolism**

**augmentation of labor**

**battledore placenta**

**dysfunctional labor**

**dystocia**

**external cephalic version**

**hypertonic uterine contraction**

**hypotonic uterine contraction**

**induction of labor**

**oxytocin**

**placenta accreta**

**placenta circumvallata**

**placenta marginata**  
**placenta succenturiata**  
**precipitate labor**  
**umbilical cord prolapse**  
**uterine inversion**  
**vacuum extraction**

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe the common deviations in the power (i.e., force of labor), the passage, or the passenger that can cause complications during labor or birth.
2. Identify the 2020 National Health Goals related to complications of labor that nurses can help the nation achieve.
3. Assess a woman in labor and during birth for deviations from the usual labor process.
4. Formulate nursing diagnoses related to deviations in labor and birth.
5. Identify expected outcomes associated with deviations from usual labor and birth such as induction of labor as well as help couples manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care related to complications of labor or birth, such as preparing the family for a cesarean birth.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of deviations from normal labor and birth with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

---

Although labor often proceeds without any deviation from the normal, many potential complications can occur. A difficult labor—**dystocia**—can arise from any of the four main components of the labor process: (a) the power, or the force that propels the fetus (uterine contractions); (b) the passenger (the fetus); (c) the passageway (the birth canal); or (d) the psyche (the woman’s and family’s perception of the event) (Neal, Ryan, Lowe, et al., 2015).

Because complications can occur at any point in labor, a continuous assessment of a laboring woman and her fetus as well as providing emotional support for her and her family are essential. The hours of labor are stressful even when everything is proceeding

normally. Be certain to reassure all women in labor that everything is going smoothly and both she and her fetus appear to be doing well. If a complication arises and assurances cannot be given as freely, it is doubly important that a woman has someone who is both knowledgeable about the deviation and what measures need to be taken as well as able to feel empathetic to her sense of helplessness and the necessary change in her birth plan (Zielinski, Brody, & Low, 2016). Nurses are able to play a key role in providing this type of care because they are skilled practitioners of both physical and emotional care.

The National 2020 Health Goals that relate to attempts to decrease maternal complications and prevent infant injury related to birth are shown in [Box 23.1](#).

### BOX 23.1

#### Nursing Care Planning Based on 2020 National Health Goals

A number of 2020 National Health Goals speak directly to complications of labor.

- Reduce the number of cesarean births among low-risk women to no more than 23.9 per 100 births from a baseline of 26.5 per 100 births.
- Reduce the number of cesarean births among women who have had a previous cesarean birth to no more than 61.7 per 100 births from a baseline of 90.8 per 100 births.
- Reduce the maternal mortality rate to no more than 11.4 per 100,000 live births from a baseline of 12.7 per 100,000 live births.
- Reduce the rate of maternal complications during hospitalized labor and birth to no more than 28 per 100 births from a baseline of 31.1 per 100 births (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by helping identify women in labor who are developing a complication; by assisting with cesarean births and careful assessment during labor; and by being alert to the preliminary symptoms of uterine rupture, which accounts for a substantial number of maternal deaths during labor.

### *Nursing Process Overview*

#### FOR A WOMAN WITH A LABOR OR BIRTH COMPLICATION

##### **ASSESSMENT**

One of the major nursing roles with a woman who is having a variation in labor is a conscientious assessment of labor progress. One of the major assessment tools used to detect deviations is a fetal and uterine monitor. Because such equipment can limit a woman's ability to walk about or even turn freely, thus making labor different than anticipated, a woman in labor may not be totally accepting of technologic or pharmacologic intervention. This calls for frequent adjustment of the equipment to achieve a clear tracing. Caring for a woman with such an apparatus in place involves

explaining its importance to both a woman and her partner, winning their cooperation, and using judgment in reading the various patterns.

### **NURSING DIAGNOSIS**

Common nursing diagnoses specific to a woman experiencing a complication during labor or birth refer to specific problems. Some examples might include:

- Pain related to induction and labor procedures
- Fear related to uncertainty of pregnancy outcome
- Anxiety related to medical procedures and apparatus necessary to ensure health of woman and fetus
- Fatigue related to loss of glucose stores through work and duration of labor
- Ineffective coping related to lack of knowledge or lack of preparation for labor
- Fatigue related to prolonged labor
- Risk for ineffective tissue perfusion related to excessive loss of blood with complication of labor
- Risk for injury (maternal or fetal) related to effect on woman and fetus of a labor complication and treatment required
- Risk for injury (maternal or fetal) related to labor involving a multiple gestation pregnancy
- Anticipatory grieving related to nonviable monitoring pattern of fetus

### **OUTCOME IDENTIFICATION AND PLANNING**

If a complication of labor or childbirth occurs, identification of expected outcomes can be difficult because an outcome that must be included in planning may not be what the woman desires. Encouraging a couple to clarify their priorities when a complication occurs is helpful. For example, early in labor, a woman's birth plan might state her chief goal is to avoid monitoring equipment or any analgesia. If fetal bradycardia occurs, however, monitoring and a cesarean birth may become necessary. If this happens, reminding the woman her primary goal is really to have a healthy baby, not to avoid specific interventions, can help her accept these changes. Refer patients and their partners to helpful websites and other resources when appropriate (see [Chapter 20](#)).

### **IMPLEMENTATION**

If a woman develops a complication of labor or birth, actions to increase the fetal heart rate (FHR) or to strengthen uterine contractions are a priority and possibly an emergency. Interventions must be planned and performed efficiently and effectively, based on the individual circumstances. Be certain to provide psychological reassurance to accompany actions to fully safeguard both the woman and her fetus.

### **OUTCOME EVALUATION**

An evaluation of proposed outcomes may reveal unhappiness because not every woman who experiences a deviation from the normal in labor and birth will be able to give birth to a healthy child. Some deviations will be too great; some interventions

will not be maximally effective because of individual circumstances. Some infants will die; a few women may be left unable to bear future children. An evaluation may lead to a new analysis that the couple's chief need at that point is to grieve for the child or for a lifestyle that can no longer be theirs. If the outcome is more positive, evaluate the couple for signs that they are able to begin interacting with their child after their harrowing experience.

Examples of outcome achievement might include:

- Patient voices confidence she can cope with the fear she feels about her fetus's welfare.
- Patient demonstrates adequate energy during course of labor to maintain effective breathing patterns.
- Patient's blood pressure does not drop below 90/50 mmHg despite excessive blood loss with delivery of the placenta.
- Patient begins positive grieving behaviors in response to loss of newborn.

## Complications With the Power (The Force of Labor)

*Inertia* is a time-honored term to denote sluggishness of contractions, or that the force of labor, is less than usual. A more current term is **dysfunctional labor** (Neal, Lowe, Schorn, et al., 2015). Dysfunction can occur at any point in labor, but it is generally classified as primary (i.e., occurring at the onset of labor) or secondary (i.e., occurring later in labor). The risk of maternal postpartal infection, hemorrhage, and infant mortality is higher in women who have a prolonged labor than in those who do not. Therefore, it is vital to recognize and prevent dysfunctional labor to the extent possible (Hunt & Menticoglou, 2015).

Prolonged labor appears to result from several factors but is most likely to occur if a fetus is large or if the contractions are hypotonic, hypertonic, or uncoordinated contractions occur (Box 23.2).

### BOX 23.2

#### Common Causes of Dysfunctional Labor

- Primigravida status
- Pelvic bone contraction that has narrowed the pelvic diameter so a fetus cannot pass (cephalopelvic disproportion [CPD]) such as could occur in a woman with rickets
- Posterior rather than anterior fetal position or extension rather than flexion of the fetal head
- Failure of the uterine muscle to contract properly or overdistention of the uterus, as with a multiple pregnancy, polyhydramnios, or an excessively oversized fetus
- A nonripe cervix
- Presence of a full rectum or urinary bladder that impedes fetal descent

- A woman becoming exhausted from labor
- Inappropriate use of analgesia (excessive or too early administration)

## INEFFECTIVE UTERINE FORCE

Uterine contractions are the basic force that moves the fetus through the birth canal. They occur because of the interplay of the contractile enzyme adenosine triphosphate and the influence of major electrolytes such as calcium, sodium, and potassium, specific contractile proteins (actin and myosin), epinephrine and norepinephrine, **oxytocin** (a posterior pituitary hormone), estrogen, progesterone, and prostaglandins. In about 95% of labors, contractions follow a predictable, efficient course. When they have less strength than usual or are rapid but ineffective, dysfunctional labor occurs (Neal, Lowe, et al., 2015).

### Hypotonic Contractions

Figure 23.1A illustrates the appearance of normal uterine contractions recorded on a uterine contraction monitor. With **hypotonic uterine contractions**, the number of contractions is unusually infrequent (not more than two or three occurring in a 10-minute period). The resting tone of the uterus remains less than 10 mmHg, and the strength of contractions does not rise above 25 mmHg (Fig. 23.1B). Hypotonic contractions occur during the active phase of labor and tend to occur after the administration of analgesia, especially if the cervix is not dilated to 3 to 4 cm or if bowel or bladder distention is preventing descent or firm engagement. They also may occur in a uterus that is overstretched by a multiple gestation, a larger than usual single fetus, polyhydramnios, or in a uterus that is lax from grand multiparity. Such contractions are not exceedingly painful because of their lack of intensity. Keep in mind, however, that pain is a subjective symptom. Some women, therefore, may interpret these contractions as very painful.

**Figure 23.1** (A) Normal uterine contractions. (B) Hypotonic

contractions; notice that the rise in pressure is no more than 10 mmHg. (C) Hypertonic contractions; notice the high resting pressure (35–40 mmHg).

Hypotonic contractions will increase the length of labor because more of them are necessary to achieve cervical dilatation. If the uterus becomes exhausted, this can cause it to not contract as effectively during the postpartal period, thus increasing a woman’s chance for postpartal hemorrhage. In the first hour after birth following a labor of hypotonic contractions, it is very important to palpate the uterine fundus, obtain the woman’s blood pressure, and assess the amount of lochia every 15 minutes for the first hour to ensure postpartal contractions are not also hypotonic and therefore not adequate to halt postpartal hemorrhage.

### Hypertonic Contractions

**Hypertonic uterine contractions** are marked by an increase in resting tone to more than 15 mmHg (Fig. 23.1C). However, the intensity of the contraction may be no stronger than that associated with hypotonic contractions. In contrast to hypotonic contractions, these occur frequently and are most commonly seen in the latent phase of labor. Hypertonic contractions may occur because more than one uterine pacemaker is stimulating contractions or because the muscle fibers of the myometrium do not repolarize or relax after a contraction, thereby “wiping it clean” to accept a new pacemaker stimulus. They tend to be more painful than usual because the myometrium becomes tender from constant lack of relaxation and the anoxia of uterine cells that results.

A danger of hypertonic contractions is that the lack of relaxation between contractions may not allow optimal uterine artery filling; this can lead to fetal anoxia early in the latent phase of labor. Applying a uterine and a fetal external monitor to any woman whose pain seems out of proportion to the quality of her contractions will help identify that the resting phase between contractions is adequate and that the FHR is not showing late deceleration.

If decelerations in the FHR, an abnormally long first stage of labor, or lack of progress with pushing (i.e., “second-stage arrest”) occurs, cesarean birth may be necessary. Although this is disappointing, be certain the woman and her support person understand that, although contractions are strong, they are ineffective and are not achieving cervical dilatation. To help identify the difference, hypotonic and hypertonic contractions are compared in Table 23.1.

**TABLE 23.1 COMPARISON OF HYPOTONIC AND HYPERTONIC CONTRACTIONS**

Criteria	Hypertonic	Hypotonic
Most common phase of occurrence	Latent	Active

Symptoms	Painful	Limited pain
Medications used		
Oxytocin	Unfavorable reaction	Favorable reaction
Sedation	Helpful	Little value

### Uncoordinated Contractions

Normally, all contractions are initiated at one pacemaker point high in the uterus. A contraction sweeps down over the organ, encircling it; repolarization occurs; relaxation or a low resting tone is achieved; and another pacemaker-activated contraction begins. With uncoordinated contractions, more than one pacemaker may be initiating contractions, or receptor points in the myometrium may be acting independently of the pacemaker. Uncoordinated contractions can occur so closely together that they can interfere with the blood supply to the placenta. Because they occur so erratically, such as one on top of another and then a long period without any, it may be difficult for a woman to rest between contractions or to breathe effectively with contractions.

Applying a fetal and a uterine external monitor and assessing the rate, pattern, resting tone, and fetal response to contractions for 15 minutes (or longer if necessary in early labor) reveals the abnormal pattern. Oxytocin administration may be helpful in uncoordinated labor to stimulate a more effective and consistent pattern of contractions with a better, lower resting tone.

### DYSFUNCTIONAL LABOR AND ASSOCIATED STAGES OF LABOR

For a graphic illustration of the most frequent times dysfunctional labor is apt to occur (Fig. 23.2). Regardless of when dysfunctional labor occurs, the effect on a woman and her support person will be the same: anxiety, fear, or discouragement. A woman needs good explanations of what is happening: “We’re going to take an ultrasound to check the baby’s position.” “This is a drug to make your contractions stronger.” “I know resting is the last thing you feel like doing, but that is what I want you to try to do.”

**Figure 23.2** Graph showing normal and abnormal patterns of labor. (A) Labor curves. (B) Patterns of descent.

### Dysfunction at the First Stage of Labor

Dysfunction that occurs with the first stage of labor involves a prolonged latent phase, protracted active phase, prolonged deceleration phase, and secondary arrest of dilation.

#### Prolonged Latent Phase

When contractions become ineffective during the first stage of labor, a prolonged latent phase can develop. How long the stages of labor take is affected by individual circumstances and whether a woman has received analgesia or an epidural anesthesia (Eggebo, Hassan, Salvesen, et al., 2015). Usual parameters for the stages of labor that can be expected are highlighted in Table 23.2. A prolonged latent phase, as defined by Friedman (1978), is a latent phase that lasts longer than 20 hours in a nullipara or 14 hours in a multipara. This may occur if the cervix is not “ripe” at the beginning of labor. It may occur if there is excessive use of an analgesic early in labor. With a prolonged latent phase, the uterus tends to be in a hypertonic state. Relaxation between contractions is inadequate, and the contractions are only mild (less than 15 mmHg on a monitor printout) and, therefore, ineffective. One segment of the uterus may be contracting with more force than another segment.

**TABLE 23.2** LENGTHS OF PHASES AND STAGES OF NORMAL LABOR IN HOURS

Phase	Nullipara		Multipara	
	Average	Upper Normal	Average	Upper Normal
First stage: time span from beginning of regular contractions to complete cervical dilatation				
Latent phase: onset of labor to 4 cm dilatation	8.6 hr	20.0 hr	5.3 hr	14.0 hr
Active phase: 4 cm to complete dilatation	4.9 hr; minimum rate of dilatation 1.2 cm/hr	12.0 hr	2.5 hr; minimum rate of dilatation 1.5 cm/hr	6.0 hr
Second stage: from full dilatation to birth of infant	1 hr	Under 2 hr without epidural; under 3 hr with epidural	0.5 hr	Under 1 hr without epidural; under 2 hr with epidural
Placenta stage	30 min		30 min	

Management of a prolonged latent phase in labor that has been caused by hypertonic contractions involves helping the uterus to rest, providing adequate fluid for hydration, and pain relief with a drug such as morphine sulfate. Changing the linen and the woman's gown, darkening room lights, and decreasing noise and stimulation can also be helpful. These measures usually combine to allow labor to become effective and begin to progress. If it does not, a cesarean birth or amniotomy (i.e., artificial rupture of membranes) and oxytocin infusion to assist labor may be necessary.

### Protracted Active Phase

A protracted active phase is usually associated with fetal malposition or cephalopelvic disproportion (CPD) (the diameter of the fetal head is larger than the woman's pelvic diameters), although it may reflect ineffective myometrial activity. This phase is prolonged if cervical dilatation does not occur at a rate of at least 1.2 cm/hr in a nullipara or 1.5 cm/hr in a multipara, or if the active phase lasts longer than 12 hours in a primigravida or 6 hours in a multigravida (see [Table 23.2](#)). If the cause of the delay in dilatation is fetal malposition or CPD, cesarean birth may be necessary. Dysfunctional labor during the dilatational division of labor tends to be hypotonic in contrast to the hypertonic action at the beginning of labor. After an ultrasound to show CPD is not present, oxytocin may be prescribed to augment labor (see later discussion on augmentation by oxytocin).

## Prolonged Deceleration Phase

A deceleration phase has become prolonged when it extends beyond 3 hours in a nullipara or 1 hour in a multipara. A prolonged deceleration phase most often results from abnormal fetal head position. A cesarean birth is frequently required.

## Secondary Arrest of Dilatation

A secondary arrest of dilatation has occurred if there is no progress in cervical dilatation for longer than 2 hours. Again, cesarean birth may be necessary (Hamilton, Warrick, Collins, et al., 2015).

## Dysfunction at the Second Stage of Labor

Dysfunction that occurs with the second stage of labor involves prolonged descent and arrest of descent.

### Prolonged Descent

Prolonged descent of the fetus occurs if the rate of descent is less than 1.0 cm/hr in a nullipara or 2.0 cm/hr in a multipara. It can be suspected if the second stage lasts over 2 hours in a multipara (Zheng, 2012).

With both a prolonged active phase of dilatation and prolonged descent, contractions have been of good quality and duration, effacement and beginning dilatation have occurred, but then the contractions become infrequent and of poor quality, and dilatation stops. If everything else is within normal limits except for the suddenly faulty contractions and CPD and poor fetal presentation have been ruled out by ultrasound, then rest and fluid intake, as advocated for hypertonic contractions, also applies. If the membranes have not ruptured, rupturing them at this point may be helpful. Intravenous (IV) oxytocin may be used to induce the uterus to contract effectively (see later discussion on induction of labor by oxytocin). A semi-Fowler's position, squatting, kneeling, or more effective pushing may speed descent.

### Arrest of Descent

*Arrest* of descent results when no descent has occurred for 2 hours in a nullipara or 1 hour in a multipara. *Failure* of descent occurs when expected descent of the fetus does not begin or engagement or movement beyond 0 station does not occur. The most likely cause for arrest of descent during the second stage is CPD. Cesarean birth usually is necessary. If there is no contraindication to vaginal birth, oxytocin may be used to assist labor (Choubey & Werner, 2015).

## Nursing Diagnoses and Related Interventions

It is impossible to prevent all dysfunctional labor, just as it is impossible to predict the functioning of any woman's hormonal system or individual response to labor. However, a number of nursing interventions can contribute to the progression of normal labor and help change a dysfunctional labor to a functional one.

**Nursing Diagnosis:** Fatigue and anxiety related to prolonged labor

**Outcome Evaluation:** Patient states she is able to continue active participation in labor; maintains effective breathing with contractions.

Because labor is work, a woman's glucose stores can deplete over hours of labor. On a woman's admission to a birthing room, assess the likelihood of glucose depletion by asking when she ate her last meal. If she ate breakfast at 8:00 AM and then began labor by 2:00 PM, it has only been 6 hours since her last full meal. However, if she last ate at 5:00 PM the preceding evening and did not eat breakfast because she awoke with labor this morning, it has been 11 hours since a full meal. Alert her primary care provider to this situation. If the woman is still in early labor, she may be encouraged to drink a high-carbohydrate fluid such as a sports drink or to eat a light meal. Sucking on a lollipop or hard candy are enjoyable ways to supply additional glucose.

Although the effect of emotion on labor is difficult to document, for many women, the cervix seems to dilate more rapidly, and therefore, labor is shortened if the woman is neither tense nor frightened. To try to identify stress, ask at a healthcare facility admission if a woman has any special concerns. Offer explanations of all procedures. Help her support person feel welcome and comfortable as well. Allow the woman and her support person as many choices as possible to give them a sense of control. Asking a question such as "Is labor what you thought it would be?" to both the woman and her support person often helps them express their concerns.

Remember that long-term pain is both depressing and exhausting. Encourage a partner to use nonpharmacologic comfort measures such as breathing with the woman, offering a back rub, changing sheets, using cool washcloths, or whatever else seems comforting. An individual woman may find a complementary therapy such as aromatherapy, acupuncture, or music helpful for relaxation (Koyyalamudi, Sidhu, Cornett, et al., 2016).

Be certain that if a woman is in bed to urge her to lie on her side so that the uterus is lifted off the vena cava (to prevent hypotension syndrome). If a woman insists on lying supine, place a hip roll under one or the other of her buttocks to cause her pelvis to "tip" and, at least to some extent, move the uterus to the side.

A full bladder can slow descent of the fetus and may also impede uterine contractions. Urge a woman in labor, therefore, to void every 2 hours to keep the bladder empty so this does not add to the slow progress caused by hypotensive or hypertensive contractions.

**Nursing Diagnosis:** Risk for deficient fluid volume related to length and work of labor

**Outcome Evaluation:** Urine is free of ketones; specific gravity is between 1.003 and 1.030; skin turgor and serum electrolyte levels are within acceptable parameters.

Low levels of serum electrolytes or body fluid can occur in labor for the same reason as a decreased glucose level—there has been a long interval between eating and the end of labor. Additionally, vomiting and diarrhea occasionally accompany labor; if these occur, they can add to fluid and electrolyte losses. Ask if a woman has had any vomiting or diarrhea to determine the possible extent of these because extended vomiting or diarrhea can lead to serious dehydration and electrolyte imbalance. Profuse diaphoresis and hyperventilation that occur with labor are also factors that can further increase fluid and electrolyte loss through insensible water loss.

Test urine each time a woman voids during labor for glucose, protein, ketones, and specific gravity. Ketones in the urine suggest starvation ketosis. A concentrated specific gravity suggests a lack of fluid. Extreme dehydration not only may slow labor but also can lead to increased blood viscosity, possibly increasing the risk for thrombophlebitis during the postpartal period.

Many women react negatively to the idea of IV fluid therapy during labor to restore body fluid, possibly perceiving it as loss of control over their bodies or removal of the “naturalness” of labor and birth. Introduce the idea that IV fluid therapy has been prescribed because of her particular complication before arriving with the bag of fluid and tubing. When inserting the IV catheter, try to use an insertion site in a woman’s nondominant hand and, if necessary, only a small “reminder” hand board. Use long tubing or attach extensions so that the woman can move about freely and her mobility is not limited or restricted by the short length of IV tubing. Assure a woman that being out of bed and walking, turning freely, squatting, sitting, or using whatever position she prefers during labor will not disrupt the IV line or the infusion ([Fig. 23.3](#)).

**Figure 23.3** If intravenous fluid is used for women in labor, it does not need to limit mobility.

**QSEN Checkpoint Question 23.1**

**PATIENT-CENTERED CARE**

Rosann Bigalow states that her contractions are irregular in frequency and short in duration. She screams in pain, however, every time she has a contraction. What action by the nurse would be best?

- a. Recognize that this is a usual response to labor and offer her a back rub.
- b. Notify the anesthesiologist that Rosann needs to have epidural anesthesia.
- c. Obtain a prescription from her primary care provider for an analgesic.
- d. Document/report frequency and duration of contractions plus facilitate pain relief.

Look in *Appendix A* for the best answer and rationale.

**PRECIPITATE LABOR**

*Precipitate dilatation* is cervical dilatation that occurs at a rate of 5 cm or more per hour in a primipara or 10 cm or more per hour in a multipara. *Precipitate birth* occurs when uterine contractions are so strong a woman gives birth with only a few, rapidly occurring contractions, often defined as a labor that is completed in fewer than 3 hours (Suzuki, 2016). Such rapid labor is likely to occur with grand multiparity, or it may occur after induction of labor by oxytocin. Contractions can be so forceful they lead to premature separation of the placenta or lacerations of the perineum, placing the woman at risk for hemorrhage (Kim, Kim, Kim, et al., 2014). Rapid labor also poses a risk to the fetus because subdural hemorrhage may result from the rapid release of pressure on the head. The woman and her support person can feel overwhelmed by the speed of labor.

A **precipitate labor** can be predicted from a labor graph if, during the active phase of dilatation, the rate is greater than 5 cm/hr (1 cm every 12 minutes) in a nullipara or 10 cm/hr (1 cm every 6 minutes) in a multipara.

Caution a multiparous woman by week 28 of pregnancy that because a past labor was so brief, her labor this time also may be brief so that she has time to plan for adequate transportation to the hospital or alternative birthing center. Both grand multiparas and women with histories of precipitate labor should have the birthing room converted to birth readiness before full dilatation is obtained. Then, even if a sudden birth should occur, it can be accomplished in a controlled surrounding.

**What If... 23.1**

**Rosann tells the nurse her sister was only in labor 1 hour when she had her baby. Rosann is planning to spend the last days of this pregnancy camping in a**

mountain cabin 60 miles from the hospital. Would the nurse advise her not to go camping?

## INDUCTION AND AUGMENTATION OF LABOR

When labor contractions are ineffective, several interventions, such as induction and **augmentation of labor** with oxytocin or amniotomy (artificial rupture of the membranes), may be initiated to strengthen them (Gilstrop & Sciscione, 2015).

**Induction of labor** means labor is started artificially. Augmentation of labor refers to assisting labor that has started spontaneously but is not effective. Although induction may be necessary to initiate labor before the time when it would have occurred spontaneously because a fetus is in danger, it is not used as an elective procedure until the fetus is at term (over 39 weeks). At one time, induction could be completed if a fetus was proven to have adequate lung surfactant by amniocentesis at term but less than 39 weeks. However, the American College of Obstetricians and Gynecologists (ACOG) has issued a statement (ACOG, 2013) indicating that fetal lung maturity should not be used and inductions should be avoided until 39 weeks unless medically indicated. Conditions that might make induction necessary before that time include preeclampsia, eclampsia, severe hypertension, diabetes, Rh sensitization, prolonged rupture of the membranes, and intrauterine growth restriction. Postmaturity (a pregnancy lasting beyond 42 weeks) is yet another situation that makes it more potentially dangerous for a fetus to remain in utero than to be born.

Because either augmentation or initiation of labor carries a risk of uterine rupture or premature separation of the placenta, it must be used cautiously in women with multiple gestation, polyhydramnios, grand parity, who are older than 40 years, or have previous uterine scars (Norman, 2012).

Oxytocin is an effective uterine stimulant, but there is a thin line between adequate stimulation and hyperstimulation, so careful observation during the entire infusion time is an important nursing responsibility (Bor, Ledertoug, Boie, et al., 2016). Before induction of labor is begun in term and postterm pregnancies, the following conditions should be present:

- The fetus is in a longitudinal lie.
- The cervix is ripe, or ready for birth.
- The presenting part is the fetal head (vertex) and is engaged.
- There is no CPD.
- The fetus is estimated to be mature by date (over 39 weeks).

### Cervical Ripening

Cervical ripening, or a change in the cervical consistency from firm to soft, is the first change of the uterus in early labor because, until this has happened, dilatation and coordination of uterine contractions will not occur. To determine whether a cervix is “ripe,” or ready for dilatation, Bishop (1964) established criteria for scoring the cervix

(Table 23.3). Using this scale, if a woman’s total score is 8 or greater, the cervix is ready for birth and should respond to induction. To help a cervix “ripen,” a number of methods can be instituted. The simplest method is known as “stripping the membranes,” or separating the membranes from the lower uterine segment manually, using a gloved finger in the cervix. This is an easy procedure performed during an office visit. Possible complications of this mechanical method include bleeding from an undetected low-lying placenta, inadvertent rupture of membranes, and the possibility of infection if membranes should rupture.

**TABLE 23.3 SCORING OF THE CERVIX FOR READINESS FOR ELECTIVE INDUCTION**

Rating Factor	Score			
	0	1	2	3
Dilatation (cm)	0	1–2	3–4	5–6
Effacement (%)	0–30	40–50	60–70	80
Station	–3	–2	–1 to 0	+1 to +2
Consistency	Firm	Medium	Soft	
Position	Posterior	Midposition	Anterior	
A total score of 8 or higher indicates that the cervix is considered ready for birth and should respond to induction.				

Adapted with permission from Bishop, E. H. (1964). Pelvic scoring for elective induction. *Obstetrics and Gynecology*, 24(2), 266.

For a second method, the use of hygroscopic suppositories (suppositories of seaweed that swell on contact with cervical secretions), which gradually and gently urge dilatation (laminaria technique), can be inserted. They can be held in place by gauze sponges saturated with povidone-iodine or an antifungal cream. If sponges are used, documentation of how many were placed is important so it can be documented afterward that none remain.

The most common method used to promote cervical ripening, however, is the insertion of a prostaglandin such as dinoprostone (Prepidil, Cervidil) into the posterior fornix of the vagina, by the cervix (Kunzier, Park, Cioffi, et al., 2016). If the prostaglandin is put in place in the evening, cervical ripening will usually have begun by morning. It’s best if women remain in bed in a side-lying position to prevent loss or leakage of the medication. Monitor the FHR after each application and for side effects such as vomiting, fever, diarrhea, and hypertension in the mother. Oxytocin induction can be started 12 hours after the prostaglandin dose; beginning it sooner might lead to hyperstimulation of the uterus. Even with these side effects, prostaglandins are well accepted by most women as a way to aid cervical ripening (Kunzier et al., 2016). They should be used with caution in women with asthma, renal or cardiovascular disease,

glaucoma, or in those who have had past cesarean births because of the danger of side effects and hyperstimulation (Karch, 2015).

Although not approved for obstetric use by the U.S. Food and Drug Administration (FDA), misoprostol is a drug you may often see used off label to assist in cervical ripening. It is as effective as dinoprostone and requires the same precautions of FHR and maternal vital sign assessments (Kunzier et al., 2016).

### Induction of Labor by Oxytocin

After a cervix is “ripe,” administration of oxytocin (a synthetic form of naturally occurring pituitary hormone) can be used to initiate labor contractions if a pregnancy is at term (Zheng, 2012). Oxytocin is always administered intravenously, so that, if uterine hyperstimulation should occur, it can be quickly discontinued. Because the half-life of oxytocin is approximately 3 minutes, the falling serum level and effects are apparent almost immediately after discontinuation of IV administration.

The danger of hyperstimulation is that a fetus needs 60 to 90 seconds between contractions in order to receive adequate oxygenation from placenta blood vessels. Hyperstimulation (i.e., tachysystole) is usually defined as five or more contractions in a 10-minute period or contractions lasting more than 2 minutes in duration or occurring within 60 seconds of each other, situations that have the potential to interfere with placenta filling and fetal oxygenation. If uterine hyperstimulation should occur, several interventions such as asking the woman to turn onto her left side to improve blood flow to the uterus, administering an IV fluid bolus to dilute the level of oxytocin in the maternal blood stream, and administering oxygen by mask at 8 to 10 L are all helpful. In addition, a primary care provider may prescribe terbutaline to relax the uterus. The surest method to relieve tachysystole, however, is to immediately discontinue the oxytocin infusion. If in doubt, err on the side of stopping the infusion when the action isn’t needed (it can easily be restarted) rather than delaying stopping it so that fetal or maternal harm results.

For administration, oxytocin (Pitocin) is commonly mixed in the proportion of 10 International Units in 1,000 ml of Ringer’s lactate. Ten International Units of oxytocin is the same as 10,000 milliunits, so each milliliter of this solution contains 10 milliunits of oxytocin. An alternative dilution method is to add 15 International Units of oxytocin to 250 ml of an IV solution; this yields a concentration of 60 milliunits per 1 ml. A primary care provider’s prescription for administration of oxytocin for induction usually designates the number of milliunits to be administered per minute such as 1 to 2 milliunits per minute. Be certain you know the dilution prescribed and recognize the concentration in each milliliter (Box 23.3). Don’t increase the rate by more than 2 milliunits at a time.

#### BOX 23.3

#### Nursing Care Planning Based on Responsibility for Pharmacology

## OXYTOCIN FOR LABOR INDUCTION

**Classification:** Oxytocin is a synthetic form of the naturally occurring posterior pituitary hormone.

**Action:** used to initiate uterine contractions in a term pregnancy (over 39 weeks)

**Pregnancy Risk Category:** C

**Dosage:** initially 1–2 milliunits/min by intravenous (IV) infusion, increased at a rate no more than 1–2 milliunits/min at 30- to 60-minute intervals until a contraction pattern similar to normal labor is achieved

**Possible Adverse Effects:** nausea, vomiting, cardiac arrhythmias, uterine hypertonicity, tetanic contractions, uterine rupture (with excessive dosages), severe water intoxication, and fetal bradycardia

### Nursing Implications

- Prepare IV solution by adding 1 ml (10 International Units) to 1,000 ml of designated IV fluid (resulting solution contains 10 milliunits/ml). Obtain an oxytocin infusion solution from pharmacy (30 units/500 ml fluid).
- Use an infusion pump to ensure accurate control of infusion rate.
- Regulate infusion rate to establish uterine contractions similar to a normal labor pattern.
- Monitor frequency, duration, and strength of contractions during infusion.
- Assess maternal pulse and blood pressure, and watch for possible hypotension. If hypotension occurs, discontinue drug and notify primary care provider.
- Continuously monitor fetal heart rate for signs of fetal distress.
- Monitor intake and output and watch for signs of possible water intoxication, such as headache or vomiting. Limit IV fluids to 150 ml/hr.
- Prepare the woman for birth ([Karch, 2015](#)).

When administering the infusion, “piggyback” the oxytocin solution to a maintenance IV solution such as Ringer’s lactate and add the piggyback to the main infusion at the port closest to the woman. Then, if the oxytocin needs to be discontinued quickly during the induction, little solution remains in the tubing to still infuse and the main IV line can still be maintained. Use an infusion pump to regulate the infusion rate, so the rate will not change even if a woman changes position. In addition, a primary care provider should be immediately available during the entire procedure to ensure safety ([Manjula, Bagga, Kalra, et al., 2015](#)).

Infusions are usually begun at a rate of 1 to 2 milliunits/min. If there is no response, the infusion is gradually increased every 30 to 60 minutes by small increments of 1 to 2 milliunits/min until contractions begin. Many women respond with as little as 4 milliunits/min, and most women respond at 16 milliunits/min. Do not increase the rate to more than 30 milliunits/min without checking for further instructions because an administration rate greater than this is likely to cause tetanic contractions.

After cervical dilatation reaches 4 cm, artificial rupture of the membranes may be performed to further induce labor, and the infusion may be discontinued at that point. For other women, the infusion is continued through full dilatation.

A side effect of oxytocin is that it causes peripheral vessel dilation, and peripheral dilation can lead to extreme hypotension. To ensure safe induction, therefore, take the woman's pulse and blood pressure every hour. Monitor uterine contractions and FHR conscientiously. (See [Box 23.4](#) for additional assessments for danger signs of oxytocin administration.)

#### BOX 23.4

### Nursing Care Planning Using Assessment

#### ASSESSING THE PREGNANT WOMAN FOR DANGER SIGNS OF OXYTOCIN ADMINISTRATION

A second side effect of oxytocin is that it can result in decreased urine flow, possibly leading to water intoxication. This is first manifested by headache and vomiting. If you observe these danger signs in a woman during induction of labor, report them immediately and halt the infusion. Water intoxication in its most severe form can lead to seizures, coma, and death because of the large shift in interstitial tissue fluid. Keep an accurate intake and output record and test and record urine specific gravity throughout oxytocin administration to detect fluid retention. Limit the amount of IV fluid being given to that prescribed (usually 150 ml/hr by ensuring the main IV fluid line is infusing at a rate not greater than 2.5 ml/min).

Contractions should occur no more often than every 2 minutes, should not be stronger than 50 mmHg pressure, and should last no longer than 70 seconds. The resting pressure between contractions should not exceed 15 mmHg by monitor (Fig. 23.4). If contractions become more frequent or longer in duration than these safe limits, or if signs of fetal distress occur, stop the IV infusion and seek help immediately. Anticipate oxygen administration may be needed to maintain fetal oxygenation. If stopping the oxytocin infusion does not stop the hyperstimulation, a tocolytic such as terbutaline may be prescribed to decrease myometrial activity. After birth, observe the infant closely for hyperbilirubinemia and jaundice because these are associated with oxytocin induction.

**Figure 23.4** Hypertonic uterine contractions caused by an oxytocin infusion. Contractions are as high as 100 mmHg in intensity. Late decelerations and a fetal heart rate (FHR) of 170 beats/min baseline are present.

Women may worry that induced labor will be more painful or “so different” from normal labor that breathing exercises will be worthless, or that labor will progress so fast it will be harmful to the fetus. Induced labors do tend to have a slightly shorter first stage than the average unassisted labor; however, this can be an advantage not a disadvantage. Once contractions begin by this method, they are basically the same as unassisted contractions. Assure the woman of this so that she does not fight the contractions or become unnecessarily tense, which could prevent her from using her

breathing techniques effectively.

## Augmentation by Oxytocin

Augmentation of labor may be used if labor contractions begin spontaneously but then become weak, irregular, or ineffective (i.e., hypotonic) (Rossen, Østborg, Lindtjorn, et al., 2016).

Precautions regarding oxytocin augmentation are the same as for primary oxytocin induction of labor. Be certain the drug is increased in small increments only and that fetal heart sounds are well monitored during the procedure. Box 23.5 shows an interprofessional care map illustrating both nursing and team planning during an augmented labor.

### BOX 23.5

#### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR A WOMAN EXPERIENCING AUGMENTATION OF LABOR

You admit Rosann Bigalow, a 28-year-old woman about to give birth to her first baby, to a birthing room. Her contractions have been 5 minutes apart for 10 hours. She feels more pain in her back than in her abdomen, “like my spine is tearing apart.” A contraction monitor shows contractions are hypotonic. *A sonogram shows her fetus is “borderline” large for gestation and in an occipitoposterior position.* Her husband asks you if the reason Rosann’s labor is taking so long is because she’s overweight.

**Family Assessment:** Rosann has been married for 2 years. Present pregnancy intended. Husband, 34 years old, owns a car dealership. Rosann works as salesperson in dealership office. Finances rated as “no problem.”

**Patient Assessment:** Patient, gravida 1, para 0, in latent stage of labor. Cervix dilated 4 cm, 80% effaced. Contractions every 5 minutes, with peak strength at 20–25 mmHg and a duration of 10 seconds. Fetal heart rate (FHR) at 130–140 beats/min with beat-to-beat variability present. Patient and partner visibly apprehensive, watching monitor intensely. Patient vital signs within normal parameters. Normal saline IV solution infusing at 150 ml/hr via infusion pump. Patient drinking sports beverage “to keep up strength.” Oxytocin prescribed at 1 milliunits/min; increase 1 milliunits/min at 30-minute intervals.

**Nursing Diagnosis:** Risk for injury (maternal and fetal) related to prolonged labor with ineffective contractions and requiring oxytocin augmentation

**Outcome Criteria:** Patient’s vital signs and FHR remain within acceptable parameters; contractions increase after oxytocin administration without becoming hypertonic; labor progresses without signs and symptoms of maternal or fetal distress. Urine output is at least 30 ml/hr; urine specific gravity, 1.010–1.030.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess what position allows patient the most comfort in light of occipitoposterior fetal position.	Encourage patient to lie on her side or on hands and knees as much as possible. Encourage partner to apply back massage.	A hands and knees position may encourage fetal rotation. Side lying enhances placental perfusion. Back massage can aid comfort.	Patient determines position of comfort. Requests massage if helpful with contractions.
<i>Teamwork and Collaboration</i>				
Nurse/primary care provider	Assess whether healthcare provider coverage will be available for oxytocin administration.	Discuss need for oxytocin administration because of ineffective labor contractions.	Oxytocin administration requires a primary care provider's presence.	Healthcare provider states he or she will be available during oxytocin infusion time.
<i>Procedures/Medications for Quality Improvement</i>				
Nurse/primary care provider	Assess patient's vital signs, FHR, contraction strength, and frequency for baseline values.	Begin piggybacked IV oxytocin administration as prescribed, using an infusion control device.	Oxytocin stimulates uterine contractions. Piggybacking the solution with an infusion control device allows for accurate and safe dosing.	Oxytocin solution infuses at prescribed rate. Patient's blood pressure remains within stated parameters for her; FHR is 120–160 beats/min; no late decelerations occur.
<i>Nutrition</i>				
Nurse	Assess amount	Monitor the IV	Intake and	Patient shows

of intake and output and test urine for specific gravity.	fluid infusion and adjust rate as prescribed. Monitor amount of oral fluid to help prevent water intoxication.	output and urine specific gravity are indicators of fluid volume status. Inadvertent administration of too great an amount of IV or oral fluid can increase the risk of fluid overload.	no water intoxication symptoms: headache, lethargy, confusion, or a change in level of consciousness.
---	--	---	---

*Patient-Centered Care*

Nurse	Explore the meaning of prolonged labor with the couple.	Encourage couple to verbalize feelings and concerns.	Exploration, verbalization, and active questioning provide an outlet for awareness of needs and open lines of communication.	Patient and partner are able to discuss their feelings with caregivers.
-------	---	--	--	---

*Psychosocial/Spiritual/Emotional Needs*

Nurse	Assess what the couple thought labor would be like.	Include couple in the treatment process; provide frequent updates about labor progress.	Frequent updates about progress help to minimize the feelings of fear about the unknown.	Couple state they feel well informed about progress in labor.
-------	---	---	--	---

*Informatics for Seamless Healthcare Planning*

Nurse	Assess whether labor experience was tolerable for couple in light of a complication.	Provide time for couple to “debrief” their labor experience.	Discussing or “putting a fence around” an experience helps to integrate it into other life	Couple state they feel comfortable with labor outcome.
-------	--	--	--	--

events.

### *QSEN Checkpoint Question 23.2*

#### **TEAMWORK & COLLABORATION**

Rosann's primary care provider is considering whether to augment her labor with oxytocin. What would make the nurse question the care provider's use of oxytocin for her?

- Her blood pressure is slightly elevated above normal.
- Her membranes ruptured after only 1 hour of labor.
- Her fetus is large for gestational age by a sonogram.
- She had an amniocentesis performed during pregnancy.

*Look in Appendix A for the best answer and rationale.*

## **Unfolding Patient Stories: Unfolding Patient Stories: Fatime Sanogo • Part 2**

**Fatime Sanogo**, a primiparous 23-year-old who you met in [Chapter 2](#), is now at 41 4/7 weeks gestation and admitted to the hospital for induction of labor. What physical findings should be present before labor is induced? What nursing assessments are performed and what nursing interventions are implemented to safely manage induction of labor with an oxytocin infusion? What assessment data should be documented when artificial rupture of membranes is performed?

Care for Fatime and other patients in a realistic virtual environment: **vSim for Nursing** ([thepoint.lww.com/vSimMaternityPed](http://thepoint.lww.com/vSimMaternityPed)). Practice documenting these patients' care in DocuCare ([thepoint.lww.com/DocuCareEHR](http://thepoint.lww.com/DocuCareEHR)).

## **UTERINE RUPTURE**

Rupture of the uterus during labor, although rare, is always a possibility. It occurs most often in women who have a previous cesarean scar ([Vachon-Marceau, Demers, Goyet, et al., 2016](#)). Contributing factors may include prolonged labor, abnormal presentation, multiple gestation, unwise use of oxytocin, obstructed labor, and traumatic maneuvers of forceps or traction. When uterine rupture occurs, fetal death will follow unless immediate cesarean birth can be accomplished.

If a uterus should rupture, the woman experiences a sudden, severe pain during a strong labor contraction, which she may report as a “tearing” sensation. Rupture can be complete, going through the endometrium, myometrium, and peritoneum layers, or incomplete, leaving the peritoneum intact. With a complete rupture, uterine contractions will immediately stop. Two distinct swellings will be visible on the woman's abdomen: the retracted uterus and the extrauterine fetus. Hemorrhage from the torn uterine arteries

floods into the abdominal cavity and possibly into the vagina. Signs of hypotensive shock begin, including a rapid, weak pulse; falling blood pressure; cold and clammy skin; and dilation of the nostrils from air starvation. Fetal heart sounds fade and then are absent (Box 23.6).

## BOX 22.2

### Nursing Care Planning Using Assessment

#### ASSESSING THE PREGNANT WOMAN WITH COMPLETE UTERINE RUPTURE

If the rupture is incomplete, the signs of rupture are less evident. With an incomplete rupture, a woman may experience only a localized tenderness and a persistent aching pain over the area of the lower uterine segment. However, fetal heart sounds, a lack of contractions, and the changes in the woman's vital signs will gradually reveal fetal and

maternal distress. The rupture can be confirmed by ultrasound (Tauchi, Hasegawa, Oba, et al., 2016).

Because the uterus at the end of pregnancy is such a vascular organ, uterine rupture is an immediate emergency, comparable to splenic or hepatic rupture. Administer emergency fluid replacement therapy as prescribed. Anticipate the use of IV oxytocin to attempt to contract the uterus and minimize bleeding. Prepare the woman for a possible laparotomy as an emergency measure to control bleeding and birth the fetus. The viability of the fetus depends on the extent of the rupture and the time elapsed between rupture and abdominal extraction. A woman's prognosis depends on the extent of the rupture and the blood loss.

Most women are advised not to conceive again after a rupture of the uterus, unless the rupture occurred in the inactive lower segment. At the time of the rupture, the primary care provider, with consent, may perform a cesarean hysterectomy (i.e., removal of the damaged uterus) or tubal ligation, both of which will result in loss of childbearing ability. A woman may have difficulty giving her consent for a hysterectomy because it is unknown whether her present baby will live. If blood loss was acute, she may be nonresponsive because of decreased cerebral perfusion from hypotension. If this has happened, the woman's support person must be the one who gives this consent, relying on the information provided by the primary care provider as to whether a functioning uterus can be saved (Choubey & Werner, 2015).

Be prepared to offer information to the support person and to inform him or her about fetal outcome, the extent of the surgery, and the woman's safety as soon as possible. Initially, a woman and her support person will probably be thankful her life was saved. However, they may become almost immediately angry the rupture occurred, especially if the fetus died and the woman will no longer be able to have children. Allow them time to express these emotions without feeling threatened. They may want to plan a funeral because, oftentimes, the baby is full term. Utilize clergy or counselors as needed to help the couple begin the coping process. They are not only grieving for the loss of a child but also the cost of unexpected surgery and perhaps loss of fertility.

## INVERSION OF THE UTERUS

**Uterine inversion** refers to the uterus turning inside out with either birth of the fetus or delivery of the placenta. It is a rare phenomenon, occurring in about 1 in 20,000 births (Furukawa & Sameshima, 2015). It may occur if traction is applied to the umbilical cord to remove the placenta or if pressure is applied to the uterine fundus when the uterus is not contracted. It may also occur if the placenta is attached at the fundus so that, during birth, the passage of the fetus pulls the fundus downward (Choubey & Werner, 2015).

Because inversion occurs in various degrees, the inverted fundus may lie within the uterine cavity or the vagina, or in total inversion, it may protrude from the vagina. When an inversion occurs, a large amount of blood suddenly gushes from the vagina. The fundus is no longer palpable in the abdomen. The woman begins to show signs of

blood loss: hypotension, dizziness, paleness, or diaphoresis. Because the uterus is not able to contract in this position, bleeding cannot be halted or will continue to such an extent exsanguination could occur within 10 minutes.

Never attempt to replace an inversion because handling of the uterus could increase the bleeding. Never attempt to remove the placenta if it is still attached because this would create a larger surface area for bleeding. Oxytocin, if being used, should be discontinued because it makes the uterus more tense and difficult to replace. An IV fluid line should be inserted if one is not already present (use a large-gauge needle because blood will need to be replaced). If a line is already in place, open it to achieve optimal flow of fluid to restore fluid volume. Administer oxygen by mask, and assess vital signs. Be prepared to perform cardiopulmonary resuscitation (CPR) if the woman's heart should fail from the sudden blood loss. The woman will immediately be given general anesthesia or possibly nitroglycerin or a tocolytic drug by IV to relax the uterus. The primary care provider then replaces the fundus manually. Administration of oxytocin *after* manual replacement helps the uterus to contract and remain in its natural place. Because the uterine endometrium was exposed, a woman will need antibiotic therapy to prevent infection. She needs to be informed that cesarean birth will probably be necessary in any future pregnancy to prevent the possibility of repeat inversion.

### Concept Mastery Alert

*Uterine rupture* occurs during labor. Contractions stop, and bleeding is primarily into the abdominal cavity. *Uterine inversion* occurs following delivery. With uterine inversion, there is a large gush of blood from the vagina, and the uterus is no longer palpable in the abdomen.

### QSEN Checkpoint Question 23.3

#### SAFETY

The nurse notices Rosann's contractions are 70 seconds long and occur every 90 seconds when assessing the frequency of her contractions after she receives oxytocin. What would be the nurse's first action?

- Ask Rosann to turn onto her left side and breathe deeply.
- Increase the rate of Rosann's IV fluid infusion.
- Discontinue the administration of the oxytocin infusion.
- Give an emergency bolus of oxytocin to relax the uterus.

Look in [Appendix A](#) for the best answer and rationale.

## AMNIOTIC FLUID EMBOLISM

**Amniotic fluid embolism** occurs when amniotic fluid is forced into an open maternal uterine blood sinus after a membrane rupture or partial premature separation of the placenta (Balinger, Chu Lam, Hon, et al., 2015).

Previously, it was thought particles such as meconium or shed fetal skin cells in the amniotic fluid entered the maternal circulation and reached the lungs as small emboli. A more likely cause of symptoms is a humoral or anaphylactoid response to amniotic fluid in the maternal circulation. This condition may occur during labor or in the postpartal period. The incidence is about 1 in 20,000 births, and it accounts for at least 10% of maternal deaths in the United States (Balinger et al., 2015). Although it is associated with induction of labor, multiple pregnancy, and perhaps polyhydramnios (i.e., excess amniotic fluid), it is not preventable because it cannot be predicted.

The clinical picture is dramatic. A woman, usually in the active phase of labor, sits up suddenly and grasps her chest because of sharp pain and inability to breathe as pulmonary artery constriction occurs. She becomes pale and then turns the typical bluish gray associated with a pulmonary embolism and lack of blood flow to the lungs. Within minutes, she could be unconscious, and her fetus is put in danger as placenta blood circulation halts. The immediate management is oxygen administration by face mask or cannula. Within minutes, she will need CPR; however, CPR may be ineffective because these procedures (inflating the lungs and massaging the heart) do not relieve the pulmonary constriction. Blood still cannot circulate to the lungs. Death may occur within minutes.

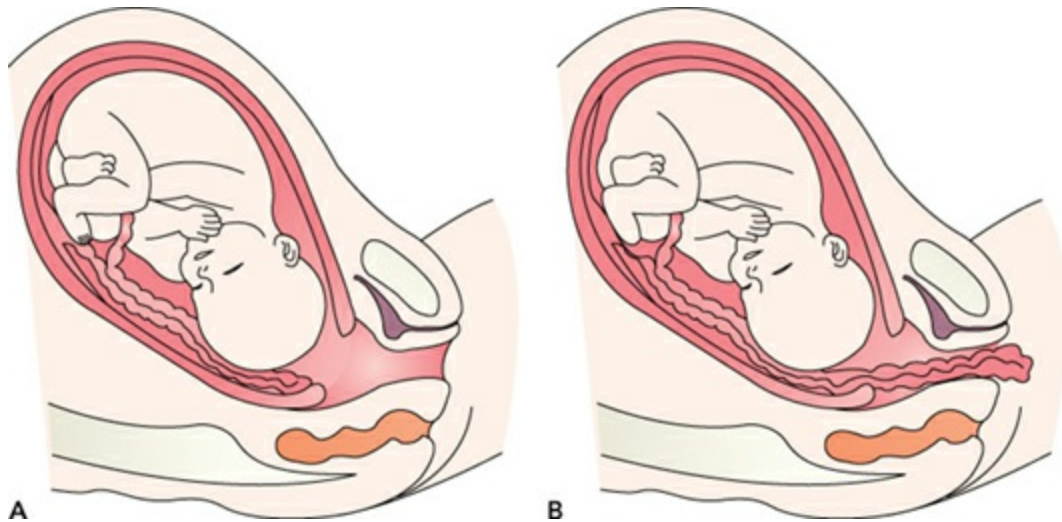

A woman's prognosis depends on the size of the embolism, the speed with which the emergency condition was detected, and the skill and speed of emergency interventions. Even if the woman survives the initial insult, the risk for disseminated intravascular coagulation (DIC) is high, further compounding her condition. In this event, she will need continued management, which includes endotracheal intubation to maintain pulmonary function and therapy with fibrinogen to counteract DIC. Most likely, she will be transferred to an intensive care unit (ICU). The prognosis for the fetus is guarded unless the fetus is born immediately by cesarean birth.

## Problems With the Passenger

Although the fetus is basically passive during birth, complications may arise if an infant is immature or preterm or if the maternal pelvis is so undersized that its diameters are smaller than the fetal skull, such as occurs in early adolescence or in women with altered bone growth from a disease such as rickets. It also can occur if the umbilical cord prolapses, if more than one fetus is present, or if a fetus is malpositioned or too large for the birth canal.

### PROLAPSE OF THE UMBILICAL CORD

In **umbilical cord prolapse**, a loop of the umbilical cord slips down in front of the presenting fetal part (Fig. 23.5). Prolapse may occur at any time after the membranes rupture if the presenting fetal part is not fitted firmly into the cervix. It tends to occur most often with:

**Figure 23.5** Prolapse of the umbilical cord. **(A)** The cord is prolapsed but still within the uterus. **(B)** The cord is visible at the vulva. In both instances, the fetal nutrient supply is being compromised, although only a cord such as that shown in image **B** would be visible. Both prolapses could be detected by fetal monitoring.

- Premature rupture of membranes
- Fetal presentation other than cephalic
- Placenta previa
- Intrauterine tumors preventing the presenting part from engaging
- A small fetus
- CPD preventing firm engagement
- Polyhydramnios
- Multiple gestation

The incidence is about 0.5% of cephalic births but can rise as high as 10% or higher with breech or transverse lies (Kaymak, Iskender, Ibanoglu, et al., 2015).

### Assessment

In rare instances, the cord may be felt as the presenting part on an initial vaginal examination during labor or can be visualized on ultrasound if one of these is taken during labor. More often, however, cord prolapse is first discovered only after the membranes have ruptured, when the FHR is discovered to be unusually slow or a variable deceleration FHR pattern suddenly becomes apparent on a fetal monitor. On inspection, the cord may be visible at the vulva.

To rule out cord prolapse, always assess fetal heart sounds immediately after rupture of the membranes, whether this occurs spontaneously or by amniotomy.

### Therapeutic Management

A prolapsed cord is always an emergency situation because the pressure of the fetal

head against the cord at the pelvic brim leads to cord compression and decreased oxygenation to the fetus. Management is aimed, therefore, at relieving pressure on the cord, thereby relieving the compression and the resulting fetal anoxia. This may be done by placing a gloved hand in the vagina and manually elevating the fetal head off the cord, or by placing the woman in a knee–chest or Trendelenburg position, to cause the fetal head to fall back from the cord. Administering oxygen at 10 L/min by face mask to the woman is also helpful to improve oxygenation to the fetus. A tocolytic agent may be prescribed to reduce uterine activity and pressure on the fetus. Amnioinfusion (see later) is yet another way to relieve pressure on the cord (Hasegawa, Sekizawa, Ikeda, et al., 2016).

If the cord has prolapsed to the extent it is exposed to room air, drying will begin, leading to constriction and atrophy of the umbilical vessels. Do not attempt to push any exposed cord back into the vagina because this could add to the compression by causing knotting or kinking. Instead, cover any exposed portion with a sterile saline compress to prevent drying.

Because cervical dilatation is usually incomplete at the point where the cord prolapse occurred, the birth method of choice is upward pressure on the presenting part, applied by a practitioner's hand in the woman's vagina, to keep pressure off the cord until the baby can be born by cesarean birth.

### Amnioinfusion

**Amnioinfusion** is the addition of a sterile fluid into the uterus to supplement the amniotic fluid and reduce compression on the cord. For this, a sterile double-lumen catheter is introduced through the cervix into the uterus. It is then attached to IV tubing, and a solution of warmed normal saline is rapidly infused. Initially, approximately 500 ml is infused, and then the rate is adjusted to infuse the least amount necessary to maintain an FHR monitor pattern without variable decelerations. Throughout the procedure, urge a woman to lie in a lateral recumbent position to prevent supine hypotension syndrome.

With cord compression, although amnioinfusion is used for only a short time until the cervix is fully dilated or a cesarean birth can be arranged, the procedure can also be performed daily for women with oligohydramnios. Help maintain strict aseptic technique during the catheter insertion and while it remains in place. Continuously monitor FHR and uterine contractions. Record maternal temperature hourly to detect infection. Be certain the solution is warmed to body temperature before the infusion to prevent chilling of the woman and fetus. This can be done by placing the bag of fluid on a radiant heat warmer or by using a blood/fluid warmer before administration.

Because there will be a continuous flow of the infusing solution out of the woman's vagina during the procedure, change her bed frequently. Also assess that there is constant drainage. If vaginal leakage should stop, it usually means the fetal head is firmly engaged and all fluid being infused is being held in the uterus, a potentially dangerous situation because it could lead to polyhydramnios (i.e., presence of excessive

amniotic fluid) and possibly uterine rupture.

## Fetal Blood Sampling

Obtaining the fetal oxygen saturation level by inserting a fetal oximeter into the uterus to rest next to the fetal cheek or obtaining a positive response to scalp stimulation usually supplies the information as to whether a fetus is becoming acidotic (see [Chapter 24](#)); however, this information can also be obtained by scalp blood or fetal blood sampling. Fetal blood sampling, obtaining a sample of blood from the fetal scalp during a vaginal exam, is gradually disappearing from practice due to the difficulty of the procedure and reasonable noninvasive alternatives, such as fetal scalp stimulation ([Chandrabaran, 2016](#)).

## MULTIPLE GESTATION

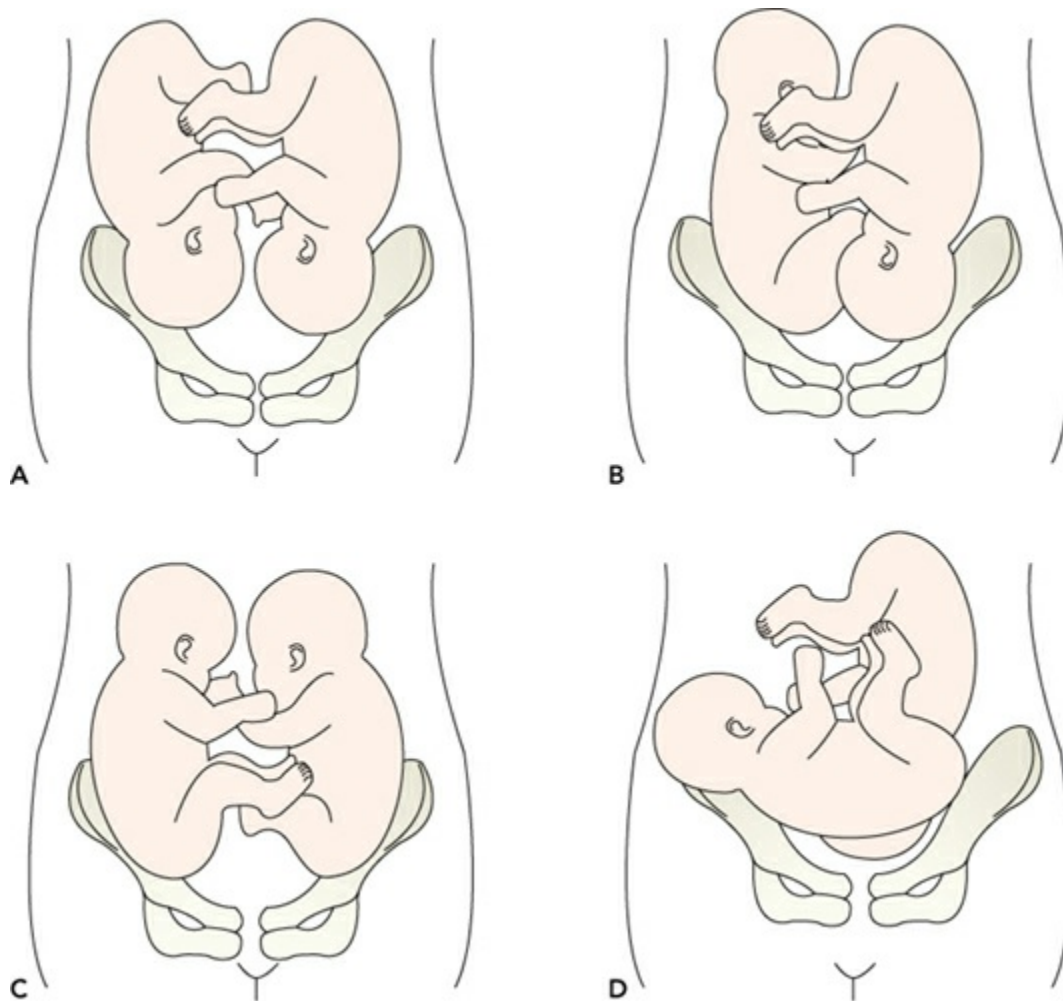

Multiple gestations (i.e., pregnancies with two or more fetuses) have increased substantially over the last several decades as in vitro fertilization has become more popular and often produces a multiple pregnancy ([ACOG, 2014](#)). When a woman with a multiple gestation is admitted to a birthing room, it usually causes a flurry of excitement as additional personnel are needed for the birth, including as many nurses to attend to possibly immature infants as there are infants, plus additional persons skilled in newborn resuscitation. In the middle of all the preparatory activity, it is easy to forget a woman having a multiple birth may be more frightened than excited. Be certain to focus on her needs as well as those of her babies so she isn't neglected. Twins may be born by cesarean birth to decrease the risk the second fetus will experience anoxia; often, this is also the situation in multiple gestations of three or more because of the increased incidence of cord entanglement and premature separation of the placenta ([ACOG, 2014](#)). Anemia and gestational hypertension occur at higher than usual incidences during multiple gestations. To detect these, be certain to assess the woman's hematocrit level and blood pressure closely during labor or while waiting for cesarean arrangements.

If a woman with a multiple gestation will be giving birth vaginally, she is usually instructed to come to the hospital early in labor. The first stage of labor does not differ greatly from that of a woman with a single gestation pregnancy. Coming to a hospital this early in labor, however, will make labor seem long. Urge the woman to spend the early hours of labor engaged in an activity such as playing cards or reading to make the time pass more quickly. Multiple pregnancies often end before full term, so the woman may not yet have practiced breathing exercises. The early hours of labor can be used for this as well. During labor, support the woman's breathing exercises to minimize the need for analgesia or anesthesia; this helps to minimize any respiratory difficulties the infants may have at birth because of their immaturity.

Be certain that when taking FHRs by Doppler or a fetal monitor, you are definitely hearing two separate beats as proof each infant is doing well. Because of the multiple

fetuses, abnormal fetal presentation may occur. Also, because the babies are usually small, firm head engagement may not occur, thus increasing the risk for cord prolapse after rupture of the membranes. Uterine dysfunction from a long labor, an overstretched uterus, unusual presentation, and premature separation of the placenta after the birth of the first child may also be more common.

Most twin pregnancies present with both twins vertex. This is followed in frequency by vertex and breech, breech and vertex, and then breech and breech (Fig. 23.6). Multiple gestations of three or more fetuses have extremely varied presentations. After the first infant is born, both ends of the baby's cord are tied or clamped permanently rather than with cord clamps, which could slip. This prevents hemorrhage through an open cord end if additional infants have shared the placenta. The first infant is identified as *A*, and newborn care is begun. In singleton pregnancies, oxytocin usually is given immediately to contract the uterus and minimize bleeding after an infant is born; with a multiple gestation woman, however, it will not be given to avoid compromising the circulation of the infants not yet born (Barrett, 2014).

**Figure 23.6** Four different twin presentations. (A) Both infants vertex. (B) One infant vertex and one breech. (C) Both infants breech. (D) One infant vertex and one in a transverse lie.

After the birth of the first child, the lie of the second fetus is determined by external abdominal palpation or ultrasound. Evidence shows breech delivery of the second twin is safest if the delivery of the second twin is not imminent. Often an internal podalic version, where the feet are grasped by the delivering provider, is completed to accomplish a breech delivery of the second twin (Barrett, 2014).

Parents usually want to inspect multiple gestation infants thoroughly after birth. The time allowed for this inspection depends on the infants' weights and conditions because, if preterm, cold hypothermia is a concern. Some parents worry the hospital will confuse their infants through improper identification. Review with them the measures used, such as armbands, to ensure this will not happen.

The infants need careful assessment to determine their true gestational age and whether a phenomenon such as twin-to-twin transfusion could have occurred (see Chapter 26). Even though women have known for months they are having multiple infants, many have difficulty believing it has really happened. They feel a need to recount over and over their surprise and to view their infants together to prove to themselves it is true. If parents are unable to inspect their infants thoroughly immediately after birth because of the infants' low birth weights and the danger of chilling, be certain they have an opportunity to do so as soon as possible to dispel any fears they had throughout pregnancy the babies would be born less than perfect.

Assess the woman carefully in the immediate postpartal period because a uterus that was overly distended because of the multiple gestation may have more difficulty contracting than usual, thus placing her at risk for hemorrhage from uterine atony (i.e., lacking normal tone). In addition, the risk for uterine infection increases if labor or birth was prolonged.

## PROBLEMS WITH FETAL POSITION, PRESENTATION, OR SIZE

### Occipitoposterior Position

In approximately one tenth of all labors, the fetal position is posterior rather than anterior. That is, the occiput (assuming the presentation is vertex) is directed diagonally and posteriorly, either to the right (right occipitoposterior [ROP]) or to the left (left occipitoposterior [LOP]). In these positions, during internal rotation, the fetal head must rotate not through a 90-degree arc (Fig. 23.7) but through an arc of approximately 135 degrees (Fig. 23.8). Rotation from a posterior position can be aided by having the woman assume a hands-and-knees position, squatting, or lying on her side (on her left side if the fetus is ROP or on her right side if the fetus is LOP). Theoretically, shifting the weight from right to left or "lunging" or swinging her body right to left while elevating her left foot on a chair widens the pelvic path and makes fetal rotation easier. This is not evidence-based, however, is not proven to be effective, and is tiring for women in labor. Because a high percentage of women choose epidurals for their deliveries, a peanut ball placed between the woman's legs has been found to open the pelvis and reduce total labor time (Roth, Dent, Parfitt, et al., 2016).

**Figure 23.7** Left occipitoanterior (LOA) rotation. **(A)** A fetus in a cephalic presentation, LOA position. View is from the outlet. The fetus rotates 90 degrees from this position. **(B)** Descent and flexion. **(C)** Internal rotation complete. **(D)** Extension; the face and chin are born.

**Figure 23.8** Left occipitoposterior (LOP) rotation. **(A)** Fetus in a cephalic presentation, LOP position. View is from outlet. The fetus rotates 135 degrees from this position. **(B)** Descent and flexion. **(C)** Internal rotation beginning. Because of the posterior position, the head will rotate in a longer arc than if it were in an anterior position. **(D)** Internal rotation complete. **(E)** Extension; the face and chin are born. **(F)** External rotation; the fetus rotates to place the shoulders in an anteroposterior position.

Posterior positions tend to occur in women with android, anthropoid, or contracted pelvises. It is suggested by a dysfunctional labor pattern such as a prolonged active phase, arrested descent, or fetal heart sounds heard best at the lateral sides of the abdomen.

A posteriorly presenting head does not fit the cervix as snugly as one in an anterior position. Because this increases the risk of umbilical cord prolapse, the position of the fetus is confirmed by vaginal examination or ultrasound. The majority of fetuses presenting in posterior positions, if they are of average size, in good flexion, and aided by forceful uterine contractions, rotate through the large arc, arrive at a good birth

position for the pelvic outlet, and are born satisfactorily with only increased molding and caput formation. However, it is not unusual for the labor to be somewhat prolonged because the arc of rotation is greater (Malvasi, Bochicchio, Vaira, et al., 2014).

Because the fetal head rotates against the sacrum, a woman may experience pressure and pain in her lower back because of sacral nerve compression. These sensations may be so intense she asks for medication for relief, not for her contractions but for the intense back pressure and pain. Applying counterpressure on the sacrum by a back rub may be helpful in relieving a portion of the pain (Fig. 23.9). The Rebozo method of jiggling and massaging the uterus may be helpful when assisting the fetus to rotate into a better position (Cohen & Thomas, 2015). During a long labor of this type, be certain a woman voids approximately every 2 hours to keep her bladder empty because a full bladder could further impede descent of the fetus. Be aware of how long it has been since the woman last ate because she may need an oral sports drink or IV glucose solution to replace glucose stores she is using to keep active in labor.

**Figure 23.9** With a posterior fetal position, a woman may feel extensive back pressure. Pressure on her lower back by her support person may help relieve this problem.

If contractions are not effective, or if the fetus is larger than average or not in good flexion, rotation through the 135-degree arc may not be possible. The woman may become exhausted. The fetal head may arrest in the transverse position (i.e., transverse arrest), or rotation may not occur at all (i.e., persistent occipitoposterior position). In these instances, the fetus must be born by cesarean birth. Some women are able to pass a persistent occipitoposterior position through their pelvis. The baby is then born looking at the ceiling or “sunny side up.”

Most women need a great deal of support during such a long labor to prevent them

from becoming worried about the length of labor or that things are not going “by the book.” Provide frequent reassurance that although their pattern of labor is not “textbook,” it is within safe, controlled limits. Although rare, if forceps are used to help the fetus rotate, observe a woman closely for hemorrhage from cervical lacerations or infection in the postpartum period.

### *QSEN Checkpoint Question 23.4*

#### **QUALITY IMPROVEMENT**

Rosann’s baby is not only large but also in an occipitoposterior position. The nurse would want the team members to know which position is best for a woman whose baby is in the occipitoposterior position during labor?

- a. On her right side to stretch the pelvic inlet
- b. Walking about to encourage fetal descent
- c. Sitting in a rocking chair to aid presentation
- d. On her hands and knees to help fetal rotation

*Look in Appendix A for the best answer and rationale.*

### **Breech Presentation**

Most fetuses are in a breech presentation early in pregnancy. By week 38, however, in approximately 97% of all pregnancies, a fetus turns to a cephalic presentation (i.e., head down). This probably happens because, although the fetal head is the widest single diameter, the buttocks (breech) plus the legs of the fetus actually take up more space. As the fundus is the largest part of the uterus, this places the bulkiest parts of the fetus in the fundus.

There are several types of breech presentations: complete, frank, and footling (see [Chapter 15](#)). Examples of why such presentations occur are shown in [Box 23.7](#). Overall, a breech presentation is more hazardous to a fetus than a cephalic presentation because there is a higher risk of the following:

- Developing dysplasia of the hip
- Anoxia from a prolapsed cord
- Traumatic injury to the after-coming head (possibility of intracranial hemorrhage or anoxia)
- Fracture of the spine or arm
- Dysfunctional labor
- Early rupture of the membranes because of the poor fit of the presenting part
- Meconium staining

#### **BOX 23.7**

#### **Causes of Breech Presentation**

- Gestational age less than 40 weeks

- Abnormality in a fetus, such as anencephaly, hydrocephalus, or meningocele (in a fetus with hydrocephalus, the widest fetal diameter is the head, so it retains the most “comfortable” position)
- Polyhydramnios that allows for free fetal movement, so the fetus fits within the uterus in any position
- Congenital anomaly of the uterus, such as a midseptum, that traps the fetus in a breech position
- Any space-occupying mass in the pelvis, such as a fibroid tumor of the uterus or a placenta previa, that does not allow the head to present
- Pendulous abdomen (if the abdominal muscles are lax, the uterus may fall so far forward that the fetal head comes to lie outside the pelvic brim, causing a breech presentation)
- Multiple gestation (the presenting infant cannot turn to a vertex position)

Meconium staining occurs because of cervical pressure on the buttocks and rectum, not because of fetal anoxia, and so is not a sign of fetal distress. Meconium excretion can, however, lead to meconium aspiration if the infant inhales amniotic fluid.

### Assessment

With a breech presentation, fetal heart sounds usually are heard high in the abdomen. Leopold maneuvers and a vaginal examination usually reveal the presentation. If the breech is complete and firmly engaged, the tightly stretched gluteal muscles of the fetus may be mistaken on vaginal examination for a head and the cleft between the buttocks may be mistaken for the sagittal suture line. If the presentation is unclear, ultrasound clearly confirms a breech presentation. Such a study also gives information on pelvic diameters, fetal skull diameters, and evidence of possible placenta previa causing the breech presentation.

In a breech birth, the same stages of flexion, descent, internal rotation, expulsion, and external rotation occur as in a vertex birth. Always monitor FHR and uterine contractions frequently because this allows for early detection of fetal distress from a complication such as prolapsed cord or arrest of descent.

### Birth Technique

If the infant will be born vaginally, a woman is allowed to push after full dilatation is achieved, and the breech, trunk, and shoulders are born (Fig. 23.10A,B). As the breech spontaneously emerges from the birth canal, it is steadied and supported by a sterile towel held against the infant’s inferior surface (Fig. 23.10C). The shoulders present to the outlet with their widest diameter anteroposterior. If they are not born readily, the arm of the posterior shoulder may be drawn downward by passing two fingers over the infant’s shoulder and down the arm to the elbow, then sweeping the flexed arm across the infant’s face and chest and out. The other arm is delivered in the same way. External

rotation is then allowed to occur to bring the head into the best outlet diameter.

**Figure 23.10** (A) Position before labor; left sacroposterior. (B) Descent and internal rotation. (C) Legs being born; the shoulders turn to present to the anteroposterior diameter. (D) The head is born. External rotation has put the anteroposterior diameter of the head in line with the anteroposterior diameter of the woman's pelvis. The head is born by gentle pressure to flex the head fully and by gentle traction to the shoulders upward and outward. Additional pressure might be applied by an assistant to the abdominal wall to ensure head flexion.

Birth of the head is the most hazardous part of a breech birth. Because the umbilicus precedes the head, a loop of cord passes down alongside the head. The pressure of the head against the pelvic brim automatically causes compression on this loop of cord.

A second danger of a breech birth is intracranial hemorrhage. With a cephalic presentation, molding to the confines of the birth canal occurs over hours. With a breech birth, pressure changes occur instantaneously, a situation that can result in tentorial tears leading to gross motor and mental incapacity or lethal damage to the fetus. A danger to the infant who is born gradually to reduce the possibility of intracranial injury is hypoxia. In contrast, the infant who is born suddenly to reduce the duration of cord compression may suffer an intracranial hemorrhage.

To aid in birth of the head, the trunk of the infant is usually straddled over the primary care provider's right forearm (Fig. 23.10D). Two fingers of the right hand are then placed in the infant's mouth. The left hand is slid into the woman's vagina, palm

down, along the infant's back, and pressure is applied to the occiput to flex the head fully. Gentle traction applied to the shoulders (upward and outward) delivers the head. Because of these difficulties with birth of the head is the reason why planned cesarean birth is the usual method of birth for many infants in breech presentation (Berhan & Haileamlak, 2016).

Parents of a breech baby can be worried about their baby's outcome all during labor (Toivonen, Palomäki, Huhtala, et al., 2014). They usually inspect their child a little more closely after birth than do parents whose babies were not breech. They, as well as the person who makes the initial physical assessment of the infant, are looking for a possible reason for the breech presentation. An infant who was born from a frank breech position tends to keep his or her legs extended and at the level of the face for the first 2 or 3 days of life. The infant who was a footling breech may tend to keep the legs extended in a footling position for the first few days. Be sure to point out to the parents that this is normal so that they do not misinterpret the unusual posture of their infant.

### *What If... 23.2*

**Rosann's baby was presenting as breech and the nurse noticed that when her membranes ruptured, the amniotic fluid was green stained. Is this an emergency situation?**

## Face Presentation

A fetal head presenting at a different angle than expected is termed *asynclitism*. Face and brow presentations are examples. Face (chin, or mentum) presentation is rare, but when it does occur, the head diameter the fetus presents to the pelvis is often too large for birth to proceed. A head that feels more prominent than normal, with no engagement apparent on Leopold maneuvers, suggests a face presentation. It is also suggested when the head and back are both felt on the same side of the uterus with Leopold maneuvers. The back is difficult to outline in this presentation because it is concave. If the back is extremely concave, fetal heart tones may be transmitted to the forward-thrust chest and heard on the side of the fetus where feet and arms can be palpated. A face presentation is confirmed by vaginal examination when the nose, mouth, or chin can be felt as the presenting part.

A fetus in a posterior position, instead of flexing the head as labor proceeds, may extend the head, resulting in a face presentation; this usually occurs in a woman with a contracted pelvis or placenta previa. It also may occur in the relaxed uterus of a multipara or with prematurity, polyhydramnios, or fetal malformation. It is a warning signal. Something abnormal is usually causing the face presentation.

When a face presentation is suspected, an ultrasound is done to confirm it; if indicated, the pelvic diameters are measured. If the chin is anterior and the pelvic diameters are within normal limits, it may be possible for the infant to be born without

difficulty (perhaps after a long first stage of labor because the face does not mold well to make a firm engaging part). If the chin is posterior, cesarean birth is usually the method of choice; otherwise, it would be necessary to wait for a long posterior-to-anterior rotation to occur. Such rotation could result in uterine dysfunction or a transverse arrest.

Babies born after a face presentation have a great deal of facial edema and may be purple from ecchymotic bruising. Observe the infant closely for a patent airway. In some infants, lip edema is so severe that they are unable to suck for a day or two. Gavage feedings may be necessary to allow them to obtain enough fluid until they can suck effectively. They may be transferred to a neonatal intensive care unit (NICU) for 24 hours. Reassure the parents that the edema is transient and will disappear in a few days with no aftermath.

### **Brow Presentation**

A brow presentation is the rarest of the presentations. It occurs in a multipara or a woman with relaxed abdominal muscles. It almost invariably results in obstructed labor because the head becomes jammed in the brim of the pelvis as the occipitomenal diameter presents. Unless the presentation spontaneously corrects, cesarean birth will be necessary to birth the infant safely. Brow presentations also leave an infant with extreme ecchymotic bruising on the face. On seeing this bruising over the same area as the anterior fontanelle, or “soft spot,” parents may need additional reassurance that the child is well after birth.

### **Transverse Lie**

Transverse lie occurs in women with pendulous abdomens, with uterine fibroid tumors that obstruct the lower uterine segment, with contraction of the pelvic brim, with congenital abnormalities of the uterus, or with polyhydramnios. It may occur in infants with hydrocephalus or another abnormality that prevents the head from engaging. It may also occur in prematurity if the infant has room for free movement, in multiple gestations (particularly in a second twin), or if there is a short umbilical cord.

A transverse lie usually is obvious on inspection because the ovoid of the uterus is found to be more horizontal than vertical. The abnormal presentation can be confirmed by Leopold maneuvers. An ultrasound may be taken to further confirm the abnormal lie and to provide information on pelvic size.

A mature fetus cannot be born vaginally from this presentation. Often, the membranes rupture at the beginning of labor. Because there is no firm presenting part, the cord or an arm may prolapse, or the shoulder may obstruct the cervix. Cesarean birth is necessary.

### **Oversized Fetus (Macrosomia)**

Size may become a problem in a fetus who weighs more than 4,000 to 4,500 g

(approximately 9 to 10 lb). Babies of this size complicate up to 10% of all births and are most frequently born to women who enter pregnancy with diabetes or who develop gestational diabetes (Ray & Alhusen, 2016). Large babies are also associated with multiparity because each infant born to a woman tends to be slightly heavier and larger than the one born just before.

An oversized infant may cause uterine dysfunction during labor or at birth because of overstretching of the fibers of the myometrium. The wide shoulders may pose a problem at birth because they can cause fetal pelvic disproportion or even uterine rupture from obstruction. A woman may be left with perineal lacerations (Wang, Zhu, Zhang, et al., 2016).

If the infant is so oversized that he or she cannot be born vaginally, a cesarean birth becomes the birth method of choice. The large size of a fetus may be missed in an obese woman because the fetal contours are difficult to palpate and obesity does not necessarily indicate a larger than usual pelvis. Pelvimetry or ultrasound can be used to compare the size of the fetus with the woman's pelvic capacity.

The perinatal mortality rate of larger infants is substantially increased to about 15%, compared with the normal 4%. In addition, a large infant born vaginally has a higher than normal risk of cervical nerve palsy, diaphragmatic nerve injury, or a fractured clavicle because of shoulder dystocia. Postpartally, the woman has an increased risk of hemorrhage because the overdistended uterus may not contract as readily as usual.

### **Shoulder Dystocia**

Shoulder dystocia is a birth problem that is increasing in incidence because the weight and therefore the size of newborns is increasing (McCarthy, Walker, Ugoni, et al., 2016). The problem occurs at the second stage of labor, when the fetal head is born but the shoulders are too broad to enter and be born through the pelvic outlet. This is hazardous to the woman because it can result in vaginal or cervical tears. It is hazardous to the fetus if the cord is compressed between the fetal body and the bony pelvis. In addition, the force of birth can result in a fractured clavicle or a brachial plexus injury for the fetus.

Shoulder dystocia is most apt to occur in women with diabetes, in multiparas, and in postdate pregnancies. The condition may be suspected earlier if the second stage of labor is prolonged, if there is arrest of descent, or if, when the head appears on the perineum (crowning), it retracts instead of protruding with each contraction (a turtle sign). The problem often is not identified, however, until the head has already been born and the wide anterior shoulder locks beneath the symphysis pubis.

Asking or assisting a woman to flex her thighs sharply on her abdomen (McRoberts maneuver) widens the pelvic outlet and may allow the anterior shoulder to be born. Applying suprapubic pressure may also help the shoulder escape from beneath the symphysis pubis and be born. These are the first two of a series of maneuvers that help resolve a shoulder dystocia (Stitely & Gherman, 2014).

### **EVIDENCE-BASED PRACTICE**

To determine which risk factors were associated with shoulder dystocia, researchers studied a cohort of births from 1967 to 2009 in Norway, a sample of 2,014,956 vaginal births. The results of the study found an increased incidence of shoulder dystocia associated with increased fetal weight, maternal diabetes, prolonged labor, instrumental delivery and parity (Øverland, Vatten, & Eskild, 2014).

Based on this study and the fact that a sonogram has shown Rosann's fetus to be extremely large, what assessment would the nurse want to prioritize for Rosann's baby after birth?

- a. If his abdominal wall appears to be ruptured
- b. If his arms feel warm and are the same length
- c. If his buttocks or back have extensive bruising
- d. If his eyes can focus steadily on a nearby object

*Look in [Appendix A](#) for the best answer and rationale.*

### **Fetal Anomalies**

Fetal anomalies of the head such as hydrocephalus (i.e., fluid-filled ventricles) or anencephaly (i.e., absence of the cranium) are a final category of fetal factors that can complicate birth because the fetal presenting part does not engage the cervix well (see [Chapter 27](#)).

### **Problems With the Passage**

Aside from a concern with the power of labor and the passenger, the third reason dystocia can occur is a contraction or narrowing of the passageway or birth canal. This can happen at the inlet, at the midpelvis, or at the outlet. The narrowing causes CPD, or a disproportion between the size of the fetal head and the pelvic diameters, which then results in failure to progress in labor.

#### **INLET CONTRACTION**

Inlet contraction is narrowing of the anteroposterior diameter of the pelvis to less than 11 cm, or of the transverse diameter to 12 cm or less. It usually is caused by rickets in early life or by an inherited small pelvis. Rickets is caused by a lack of calcium and is therefore rare in developed countries but can occur among immigrants who were raised where milk supplies were not plentiful. In primigravidas, the fetal head normally engages between weeks 36 and 38 of pregnancy. If this occurs any time before labor begins, it is proof the pelvic inlet is adequate as lightening, by definition, means the fetal head has sunk below the inlet. Following the general rule that "what goes in, comes out," a head that engages or proves it fits into the pelvic brim will probably also

be able to pass through the midpelvis and through the outlet.

If engagement does not occur in a primigravida, then either a fetal abnormality (larger than usual head) or a pelvic abnormality (smaller than usual pelvis) should be suspected. As a rule, engagement does not occur in multigravidas until labor begins. For these women, previous vaginal birth of a full-term infant without problems is proof their birth canal is adequate.

Every primigravida should have pelvic measurements taken and recorded before week 24 of pregnancy so, based on these measurements and the assumption the fetus will be of average size, a birth decision can be made.

If CPD exists, because the fetus may not engage but instead remains “floating,” the possibility of cord prolapse can lead to a secondary concern.

## OUTLET CONTRACTION

Outlet contraction is a narrowing of the transverse diameter, the distance between the ischial tuberosities at the outlet, to less than 11 cm. This measurement is made by sonogram during pregnancy but can also easily be made manually at a prenatal visit or at the beginning of labor.

## TRIAL LABOR

If a woman has a borderline (just adequate) inlet measurement and the fetal lie and position are good, her primary care provider may allow her a “trial” labor to determine whether labor will progress normally. The trial labor continues as long as descent of the presenting part and dilatation of the cervix continue to occur. With a trial labor, monitor fetal heart sounds and uterine contractions frequently. Urge the woman to void every 2 hours so her urinary bladder is as empty as possible, allowing the fetal head to use all the space available. If, after a definite period (6 to 12 hours), adequate progress in labor cannot be documented, or if at any time fetal distress occurs, the trial labor will be discontinued and the woman will be scheduled for a cesarean birth.

It may be difficult for women to undertake labor they know they may not be able to complete because the effort subjects them needlessly to pain. Emphasize, but do not overstress, that it is best for their baby to be born vaginally. If the trial labor fails and cesarean birth is scheduled, provide an explanation as to why cesarean birth is necessary and why it has become the best route for the birth of their baby ([Box 23.8](#)).

### BOX 23.8

#### Nursing Care Planning Tips for Effective Communication

Rosann Bigalow is having her first baby. Her primary care provider has told her she has a borderline pelvis but she wants her to try a trial labor.

*Tip:* When communicating, avoid making any assumptions. Follow up with additional clarification to ensure the patient understands any procedure she may be

having. If a woman develops a complication of pregnancy, which is referred to by a Latin name, it is generally expected that the couple will not understand the term and so will need to have the complication thoroughly explained. If a condition has a common name, such as protracted pelvis or trial labor, however, it is easy to assume little explanation of the condition is necessary. In reality, couples need explanations about all conditions because what is common to healthcare personnel may not be common to everyone. In this scenario, Rosann was not aware a trial labor might mean she would need surgery.

**Nurse:** Hello, Rosann. Is it all right if I attach a fetal heart rate and uterine contraction monitor so we can observe you closely during labor?

**Rosann:** Sure. Although I should be having this baby any minute. It's already been 10 hours.

**Nurse:** I thought I heard your doctor say she's thinking of this as a trial labor.

**Rosann:** Whatever. I told her anything but surgery would be all right.

**Nurse:** Let's talk about what a trial labor means.

Some women undergoing a trial labor feel as if they themselves are on trial. When dilatation does not occur, they begin to feel discouraged and inadequate, as if they are at fault. A woman may not be aware of how much she wanted the trial labor to work until she is told it is not working. The support person may be as frightened and feel as helpless as she does and so momentarily stops being a support person. You can assure a woman and her support person that a cesarean birth is just an alternative, not an inferior, method of birth for them. Because labor is not progressing, it is the method of choice to allow them to achieve their goal of a healthy mother and healthy child.

## EXTERNAL CEPHALIC VERSION

**External cephalic version** is the turning of a fetus from a breech to a cephalic position before birth. It may be done as early as 34 to 35 weeks, although the usual time is by 37 to 38 weeks of pregnancy (Velzel, de Hundt, Mulder, et al., 2015). For the procedure, FHR and possibly ultrasound are recorded continuously. A tocolytic agent may be administered to help relax the uterus. The breech and vertex of the fetus are located and grasped transabdominally by the examiner's hands on the woman's abdomen. Gentle pressure is then exerted to rotate the fetus in a forward direction to a cephalic lie (Fig. 23.11). Although not always successful, the use of external version can decrease the number of cesarean births necessary from breech presentations (Velzel et al., 2015). Contraindications to the procedure include multiple gestation, severe oligohydramnios, small pelvic diameters, a cord that wraps around the fetal neck, and unexplained third-trimester bleeding, which might be a placenta previa. External version can be uncomfortable for a woman because of the feeling of pressure. Women who are Rh negative should receive Rh immunoglobulin after the procedure in case minimal bleeding occurs.

**Figure 23.11** External cephalic version. The fetus is rotated by external pressure to a cephalic lie. An ultrasound helps guide a safe result.

## FORCEPS BIRTH

Obstetrical forceps are steel instruments constructed of two blades that slide together at their shaft to form a handle. One blade is slipped into the woman's vagina next to the fetal head, and the other is slipped into place on the other side of the head. Next, the shafts of the instrument are brought together in the midline to form the handle. The primary care provider then applies pressure on the handle to manually extract the fetus from the birth canal.

In years past, babies were routinely born with forceps. Today, the technique is rarely used (in only about 4% to 8% of births) because it can lead to rectal sphincter tears in the woman, which can lead to dyspareunia, anal incontinence, or increased urinary stress incontinence (Halscott, Reddy, Landy, et al., 2015). Although no longer used routinely, forceps may be necessary with any of the following conditions:

- A woman is unable to push with contractions in the pelvic division of labor such as might happen with a woman who received regional anesthesia or who has a spinal cord injury.
- Cessation of descent in the second stage of labor occurs.
- A fetus is in an abnormal position.
- A fetus is in distress from a complication such as a prolapsed cord.

Although forceps appear as if they would put forceful pressure on the fetal head, the pressure registers on the steel blades rather than the head so they can actually reduce pressure, thus avoiding a complication such as subdural hemorrhage (Halscott et al., 2015).

Before forceps are applied:

- Membranes must be ruptured.

- CPD must not be present.
- The cervix must be fully dilated.
- The woman's bladder must be empty.

Record the FHR before forceps application. Because there is a danger that the cord could be compressed between the forceps blade and the fetal head, assess FHR again immediately after application. The woman's cervix needs to be carefully assessed after forceps birth to be certain no lacerations have occurred. To rule out bladder injury, record the time and amount of the first voiding. In addition, assess the newborn to be certain no facial palsy exists from pressure. A forceps birth may leave a transient erythematous mark on the newborn's cheek (see [Chapter 18](#)). This mark will fade in 1 to 2 days with no long-term effects.

## VACUUM EXTRACTION

A fetus, if positioned far enough down the birth canal, may be born by **vacuum extraction** ([Fruscalzo, Londero, Calcagno, et al., 2015](#)). With the fetal head at the perineum, a soft, disk-shaped cup is pressed against the fetal scalp and over the posterior fontanelle. When vacuum pressure is applied, air beneath the cup is suctioned out and the cup then adheres so tightly to the fetal scalp that traction on the vacuum cord leading to the cup extracts the fetus ([Fig. 23.12](#)).

**Figure 23.12** Vacuum extraction.

Vacuum extraction has advantages over forceps birth in that little anesthesia is necessary, thus leaving the fetus with less respiratory depression at birth. One disadvantage over natural birth is that more perineal lacerations may occur ([Steinhauer, 2015](#)). Its major disadvantage is that it causes a marked caput on the newborn head that may be noticeable as long as 7 days after birth. Tentorial tears from extreme pressure also have occurred. A woman may need reassurance that the caput swelling is harmless

for her infant and will decrease rapidly. Vacuum extraction should not be used as a method of birth if fetal scalp blood sampling was used because the suction pressure can cause severe bleeding at the sampling site. Moreover, vacuum extraction is not advantageous for preterm infants because of the softness of the preterm skull.

## Anomalies of the Placenta and Cord

The third stage of labor (i.e., delivery of the placenta) can also result in complications; therefore, continued careful observation of the mother is important (Begley, Gyte, Devane, et al., 2015).

### ANOMALIES OF THE PLACENTA

The placenta and cord are always examined for the presence of anomalies after birth. The normal placenta weighs approximately 500 g and is 15 to 20 cm in diameter and 1.5 to 3.0 cm thick. Its weight is approximately one sixth that of the fetus. A placenta may be unusually enlarged in women with diabetes. In certain diseases, such as syphilis or erythroblastosis, the placenta may be so large that it weighs half as much as the fetus. If the uterus has scars or a septum, the placenta may be wide in diameter because it was forced to spread out to find implantation space.

#### Placenta Succenturiata

A **placenta succenturiata** (Fig. 23.13A) is a placenta that has one or more accessory lobes connected to the main placenta by blood vessels. No fetal abnormality is associated with this type. However, it is important it be recognized because the small lobes may be retained in the uterus after birth, leading to severe maternal hemorrhage. On inspection, the placenta appears torn at the edge, or torn blood vessels extend beyond the edge of the placenta. If the remaining lobes are recognized and removed from the uterus manually, the uterus will contract as usual with no adverse maternal effects.

**Figure 23.13** Abnormal placental formation. (A) Placenta succenturiata. (B) Placenta circumvallata. (C) Battledore placenta. (D) Velamentous cord insertion.

#### Placenta Circumvallata

Ordinarily, the chorion membrane begins at the edge of the placenta and spreads to envelop the fetus; no chorion covers the fetal side of the placenta. In **placenta**

**circumvallata**, the fetal side of the placenta is covered to some extent with chorion (Fig. 23.13B). The umbilical cord enters the placenta at the usual midpoint, and large vessels spread out from there. However, they end abruptly at the point where the chorion folds back onto the surface. (In **placenta marginata**, the fold of chorion reaches just to the edge of the placenta.) Although no abnormalities are associated with this type of placenta, its presence should be noted.

### Battledore Placenta

In a **battledore placenta**, the cord is inserted marginally rather than centrally (Fig. 23.13C). This anomaly is rare and has no known clinical significance either.

### Velamentous Insertion of the Cord

Velamentous insertion of the cord is a situation in which the cord, instead of entering the placenta directly, separates into small vessels that reach the placenta by spreading across a fold of amnion (Fig. 23.13D). This form of cord insertion is most frequently found with multiple gestations. Because the fetal blood supply may not be as generous as usual, this type of placenta is associated with fetal anomalies. An infant born with this type of placenta needs to be examined carefully at birth.

### Vasa Previa

In vasa previa, the umbilical vessels of a velamentous cord insertion cross the cervical os and therefore deliver before the fetus (Suzuki & Kato, 2015). The vessels may tear with cervical dilatation, just as a placenta previa may tear. Before inserting any instrument such as an internal fetal monitor, be certain to identify structures to prevent accidental tearing of a vasa previa because tearing would result in sudden fetal blood loss. If sudden, painless bleeding occurs with the beginning of cervical dilatation, either placenta previa or vasa previa is suspected. It can be confirmed by ultrasound. If vasa previa is identified, the infant needs to be born by cesarean birth.

### Placenta Accreta

**Placenta accreta** is an unusually deep attachment of the placenta to the uterine myometrium, so deep that the placenta will not loosen and deliver (Silver, 2015). Attempts to remove it manually may lead to extreme hemorrhage because of the deep attachment. Hysterectomy to remove the uterus or treatment with methotrexate to destroy the still-attached tissue may be necessary.

#### *What If... 23.3*

**While inspecting the placenta, the nurse observe one edge appears torn with torn blood vessels extending beyond its edge. Would the nurse rate the placenta as normal or report its appearance as potentially serious?**

---

## ANOMALIES OF THE CORD

### Two-Vessel Cord

A normal cord contains one vein and two arteries. The absence of one of the umbilical arteries is associated with congenital heart and kidney anomalies because the insult that caused the loss of the vessel may have also affected other mesoderm germ layer structures. Inspection of the cord as to how many vessels are present must be made immediately after birth, before the cord begins to dry, because drying distorts the appearance of the vessels. Document the number of vessels conscientiously because an infant with only two vessels needs to be observed carefully for other anomalies during the newborn period.

### Unusual Cord Length

Although the length of the umbilical cord rarely varies, some abnormal lengths may occur. An unusually short umbilical cord can result in premature separation of the placenta or an abnormal fetal lie. An unusually long cord may be easily compromised because of its tendency to twist or knot. Occasionally, a cord actually forms a knot, but the natural pulsations of the blood through the vessels and the muscular vessel walls usually keep the blood flow adequate. It is not unusual for a cord to wrap once around the fetal neck (nuchal cord) but, again, with no interference to fetal circulation (Zhao, Geng, Kong, et al., 2015).

#### *What If . . . 23.4*

**The nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to complications of labor. What would be a possible research topic to explore pertinent to this goal that would be applicable to the Bigalow family and that would also advance evidence-based practice?**

## KEY POINTS FOR REVIEW

- Complications of labor can arise from problems with the force of labor, the passage, the passenger (the fetus), or the woman's reaction to the experience (the psyche). Hypotonic, hypertonic, and uncoordinated contractions all can occur, resulting in ineffective first or second stages of labor.
- Supporting families who experience a complication of labor is important to not only plan nursing care that meets QSEN competencies but also that best meets a family's total needs.
- Precipitate labor is birth that is completed in less than 3 hours. It can be responsible for subdural hemorrhage in the fetus and cervical or perineal lacerations in the woman.

- Be certain a woman meets the criteria for labor induction before preparing an oxytocin solution. These criteria include engagement of the fetal head, a “ripe” cervix, and absence of CPD. Question if oxytocin should be used if these criteria are not met.
- Always prepare oxytocin as a “piggyback” solution, being extremely careful of the dose used. Both a uterine monitor and an FHR monitor should be used during labor induction to be certain uterine overstimulation does not occur. Observe that contractions occur no less than 2 minutes apart and are no longer than 70 seconds in duration.
- Uterine rupture, although rare, is a complication that is an immediate emergency because of blood loss to the mother and potential anoxia for the fetus.
- Uterine inversion is another rare but grave complication because it leads to inability to control hemorrhage. If the situation is not immediately corrected, emergency hysterectomy may be necessary to save the woman’s life.
- Amniotic fluid embolism occurs when amniotic fluid is forced into an open maternal uterine blood sinus. A woman will notice chest pain and dyspnea. Administer oxygen and notify the woman’s primary care provider of this emergency.
- Prolapse of the umbilical cord is an emergency situation that requires prompt action. Position a woman quickly into either a Trendelenburg or a knee–chest position to relieve cord compression, or apply manual pressure vaginally to lift the fetal head away from the cord. Notify the woman’s primary caregiver of the emergency.
- A multiple gestation can complicate birth. Many infants of multiple gestations are born by cesarean birth to avoid entangled cords or arrest of descent.
- Abnormal position, presentation, or size of the fetus (such as occipitoposterior position; breech, face, or brow presentation; transverse lie) as well as problems of the passage such as inlet and outlet contraction can lead to labor complications.
- Vacuum extraction and forceps are methods that can be used to assist birth. The woman as well as the infant needs special observation after these procedures to detect head trauma or cervical or vaginal tearing.
- Anomalies of the placenta and cord (such as placenta succenturiata, velamentous cord insertion, vasa previa, and two-vessel cord) can lead to birth complications.

### CRITICAL THINKING CARE STUDY

Debbie and Craig O’Hara are a married couple having their first baby. Craig works as a football coach; Debbie is a telemarketer. When you admit them to a birthing room, Debbie tells you, “I’m going to have a terrible labor because something’s wrong with my baby.” On examination, her cervix is 4 cm dilated, 75% effaced; contraction duration is 30 seconds; and frequency is every 5 minutes. Her fetus is in an occipitoposterior position.

1. Would you assume when Debbie said “something’s wrong with my baby” she meant the posterior position? Would you assure her the baby will be fine?

2. Debbie's husband tells you he's proud he's having a boy. You notice he talks to his son all during labor with comments such as "Why aren't you following the playbook?" or "Put your head down and push. The clock is running." Would you be concerned he's coaching his son and not his wife?
3. Debbie's primary care provider wants Debbie to rest between contractions on her hands and knees in the hope that will help her fetus rotate more efficiently and avoid a cesarean birth. Craig tells you he'd rather Debbie have a cesarean than spend so long in labor. How would you respond to him?

## Nursing Care of a Family During a Surgical Intervention for Birth

*Moja Hamma is a 29-year-old woman pregnant with her first baby. Her labor began with ruptured membranes and dark green meconium-stained amniotic fluid. Moja called her nurse-midwife, who instructed her to come to the hospital immediately. Moja drove herself and arrived in 20 minutes. Fetal heart rate (FHR) was 100 beats/min. An obstetrician was consulted, and she scheduled Moja for an immediate cesarean birth. Moja reacted calmly to the news that she needed surgery until she realized her boyfriend would not be able to get to the hospital in time to be with her in surgery. At that point, she refused to sign permission for surgery, saying, "I can't. I just can't go through this alone."*

*Previous chapters described the physiology of labor and the sequence of usual birth. This chapter adds information about surgical interventions for those women who must have a surgical procedure to ensure a safe outcome for themselves or their child.*

**Is Moja's response typical of a woman who is told she needs a surgical procedure for the birth of her baby? What would be your best action to help her accept this procedure?**

### KEY TERMS

**amniotomy**  
**cesarean birth**  
**classic cesarean incision**  
**dehiscence**  
**elective cesarean birth**  
**episiotomy**  
**low segment incision**  
**vaginal birth after cesarean (VBAC)**

### OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe the usual indications for surgical interventions such as amniotomy, episiotomy, and cesarean birth.
2. Identify the 2020 National Health Goals related to cesarean birth that nurses can help the nation achieve.
3. Assess a woman scheduled for a surgical intervention for preoperative, intraoperative, and postoperative needs.
4. Formulate nursing diagnoses related to the family experiencing a surgical intervention for birth.
5. Establish outcomes that meet the needs of a woman requiring a surgical intervention for birth as well as help her manage seamless transitions across different healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement common preoperative and postoperative care for surgical interventions for birth.
8. Evaluate expected outcomes for achievement and effectiveness of care to be certain expected outcomes have been achieved.
9. Integrate knowledge of surgical birth interventions with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to achieve quality maternal and child health nursing care.

---

**Cesarean birth**, or birth accomplished through an abdominal incision into the uterus, is slightly more hazardous than vaginal birth, but compared with other surgical procedures, it is one of the safest types of surgeries and one with few complications (Speichinger & Holschneider, 2013).

The term *cesarean birth*, rather than *cesarean delivery*, is used in nursing literature to accentuate that this is a birth more than it is a surgical procedure. The 2020 National Health Goals related to cesarean birth are shown in [Box 24.1](#).

**BOX 24.1**

**Nursing Care Planning Based on 2020 National Health Goals**

Two National Health Goals speak directly to cesarean birth:

- Reduce the rate of cesarean births among low-risk (full-term, singleton, vertex presentation) women having their first child to 23.9% of live births from a baseline of 26.5%.
- Reduce the rate of cesarean births among women who have had a prior cesarean

birth to 81.7% of live births from a baseline of 90.8% (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by exploring with women who choose elective cesarean birth whether their goals are sound and by encouraging women who fulfill the criteria for vaginal birth after cesarean (VBAC) to attempt a vaginal birth with a second child.

### *Nursing Process Overview*

#### **FOR A WOMAN HAVING A SURGICAL INTERVENTION FOR BIRTH ASSESSMENT**

Some women elect cesarean rather than vaginal birth. Women with smaller than usual pelvic diameters may be informed during pregnancy a cesarean birth will be necessary. Others learn only during labor that a cesarean birth will be necessary because a complication is developing. Surgical interventions such as episiotomy and amniotomy are not usually anticipated before labor. Assessment as to whether a woman will be a good candidate for surgery must include both physiologic and psychological status and the woman's preparedness for the procedure.

#### **NURSING DIAGNOSIS**

Nursing diagnoses specific to surgical interventions are often related to the prevention of common complications or patient/family concerns about the procedure. Specific examples might include:

- Fear related to impending surgery
- Pain related to a surgical incision
- Deficient fluid volume related to blood loss from surgery
- Powerlessness related to medical need for episiotomy or cesarean birth
- Risk for anxiety related to unanticipated circumstances surrounding birth
- Risk for infection related to a surgical incision
- Risk for hemorrhage related to surgical procedure
- Risk for impaired parent–infant attachment related to unplanned method of birth

#### **OUTCOME IDENTIFICATION AND PLANNING**

The same important outcome applies to a woman having a cesarean birth as to a woman giving birth vaginally: a healthy mother and a healthy baby. In either instance, decisions for a method of birth can be made so suddenly, planning is limited to only a few minutes. This means you have only a very short time to organize presurgical steps such as gastrointestinal or anesthesia preparation or to check off a presurgical checklist. Be certain plans afterward include discharge or home care instructions because a woman will remain in the healthcare facility only 2 to 4 days. Refer women who know in advance they will have a cesarean birth to helpful websites and other resources when appropriate (see [Chapter 20](#)).

## IMPLEMENTATION

Every woman is aware childbirth poses some risk to health. When major surgery is superimposed on top of this, it is imperative that a woman and her support person feel confidence in the healthcare personnel who will care for them. When giving care to any woman during labor, be certain to establish early on a helping relationship with both the woman and her support person as this relationship becomes especially advantageous should the birth method need to be altered.

An important intervention includes coordination of healthcare team members such as an anesthesiologist, surgeon, pediatrician or neonatologist, and recovery room or high-risk nursery personnel.

Many interventions focus on teaching and support because the more a woman understands what is happening, the more she can accept and cooperate. After surgery, be certain to provide adequate “talk time” to allow a woman time to review what has happened and integrate the experience with what she and her partner expected would happen.

## OUTCOME EVALUATION

Evaluation of expected outcomes is important in the care of a woman after a surgical intervention to ensure she is not developing a complication and is developing a positive mother–infant (or parent–infant or family–infant) relationship. Examples that would demonstrate successful achievement of outcomes include:

- Patient states she understands the reason for her cesarean birth.
- Patient states she felt well prepared for cesarean birth even in light of an emergency.
- Couple states they feel able to cope with newborn care even with mother recovering from surgery.
- Patient remains free of signs and symptoms of infection after an episiotomy.
- Patient states her incisional pain is controlled and tolerable.
- Patient states birth was a fulfilling experience even in light of the unplanned cesarean birth.

## Surgical Interventions

### AMNIOTOMY

**Amniotomy** is the artificial rupturing of membranes during labor if they do not rupture spontaneously to allow the fetal head to contact the cervix more directly, which possibly increases the efficiency of contractions and therefore increases the speed of labor. There is still conflicting evidence about the risks and benefits of amniotomy with regard to shortening labor duration and risks for cesarean section after amniotomy; therefore, practices may vary widely in how often this technique is used (Jackson & Gregory, 2015). If the procedure is scheduled, a woman is asked to assume a dorsal recumbent position; an amniohook (a long, thin crochet-like instrument) or a hemostat is passed

vaginally. The membranes are torn, and amniotic fluid is allowed to escape. A disadvantage of amniotomy is that it puts a fetus momentarily at risk for cord prolapse if a loop of cord escapes into the vagina with the fluid. It is important to only perform an amniotomy if the fetal head is well applied to the cervix. Always measure the FHR immediately after the rupture of membranes to determine this did not happen ([Maher & Heavey, 2015](#)).

### *QSEN Checkpoint Question 24.1*

#### **SAFETY**

Suppose Moja had an amniotomy during her labor. Immediately after this procedure, which nursing assessment would be most important for the nurse to make?

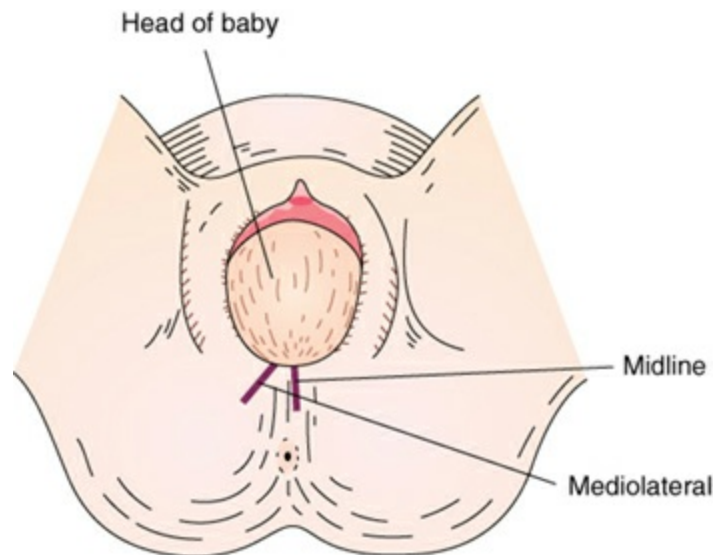

- a. Ask her to rate her pain level after the procedure.
- b. Assess maternal heart rate to detect possible bleeding.
- c. Assess FHR to detect possible cord prolapse.
- d. Document the amount of amniotic fluid that has been lost.

*Look in [Appendix A](#) for the best answer and rationale.*

## **EPISIOTOMY**

An **episiotomy** is a surgical incision of the perineum made to prevent tearing of the perineum, release pressure on the fetal head with birth, and possibly shorten the last portion of the second stage of labor ([Vergheese, Champaneria, Kapoor, et al., 2016](#)).

An episiotomy incision is made with blunt-tipped scissors in the midline of the perineum (i.e., a midline episiotomy) or is begun in the midline but directed laterally away from the rectum (i.e., a mediolateral episiotomy) ([Fig. 24.1](#)). Mediolateral incisions have the advantage over midline cuts in that, if tearing occurs beyond the incision, the tear will not be directed toward the rectum, thus creating less danger of a rectal mucosal tear, which can result in loss of sphincter function and fecal incontinence later in life ([Vergheese et al., 2016](#)). Midline episiotomies, however, heal more easily, cause less blood loss, and result in less postpartal discomfort. The pressure of the fetal head against the perineum as a woman pushes just prior to birth is so intense the nerve endings in the perineum are momentarily deadened, allowing an episiotomy to be done without anesthesia. There is a slight loss of blood, but the pressure of the presenting part immediately seals the cut edges and minimizes bleeding. Episiotomies are sutured after birth.

**Figure 24.1** An episiotomy incision.

Theoretically, if this is done immediately, a woman will still have so much natural-pressure anesthesia of the perineum that she will not require an anesthetic for the repair. In actuality, by the time the placenta is delivered (approximately 5 minutes), enough sensation has returned to the perineum that most women need an injection of a local anesthetic for comfort. Women who received epidural anesthesia will probably not need additional medication.

One instance in which episiotomy (defibulation) may be necessary is in women who have had female circumcision with perineal scarring because their perineum is unable to stretch to allow the vaginal outlet to open for birth ([Abdulcadir, Dugerdil, Yaron, et al., 2016](#)).

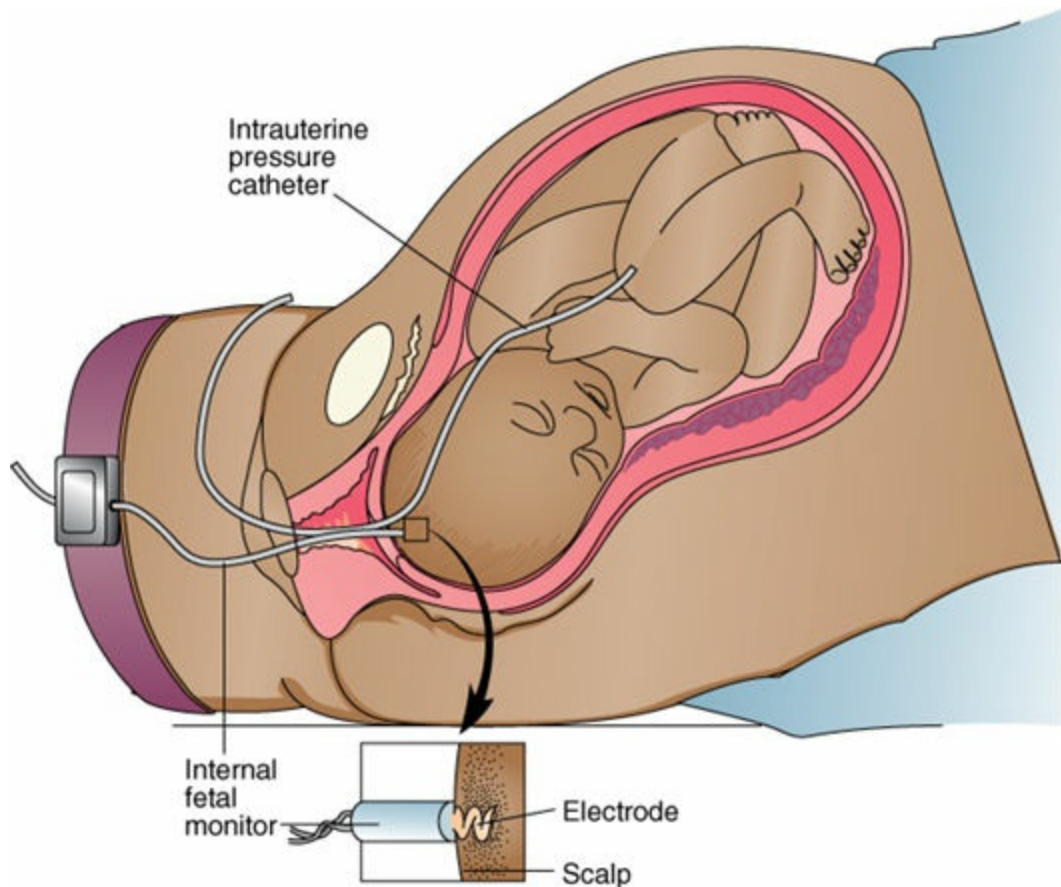

## **PROCEDURES FOR HIGH-RISK PREGNANCIES**

If a woman or fetus is found to be high risk during labor, a number of procedures over and above a usual assessment can become necessary. All these procedures cause increased anxiety for the woman and her family and so need special instructions and supportive reassurance.

### **Internal Electronic Monitoring**

Internal electronic monitoring is the most precise method for assessing FHR and uterine contractions. It is most often used to assess whether contractions are strong enough to cause cervical change in the case of a prolonged labor course. This can be done by wireless telemetry but is usually managed by a pressure-sensing catheter passed through the vagina after the membranes have ruptured, and the cervix has dilated to at least 3 cm. It is then passed into the uterine cavity and alongside the fetus ([Fig. 24.2](#)). The end of the catheter extending from the vagina is attached to a pressure recorder. As each uterine contraction puts pressure on the uterine contents, the pressure exerted on the catheter is recorded. When contractions are monitored by an internal pressure gauge in

this way, the frequency, duration, baseline strength, and peak strength of contractions can all be evaluated. Contraction strength is evaluated by the height of the peak of the contraction on the tracing. Equally important to evaluate is the return of the uterine tone to baseline strength between contractions. This ensures there is placental filling between contractions.

**Figure 24.2** Internal fetal monitoring.

With contractions during the latent phase of labor, the baseline level is usually less than 5 mmHg; with active contractions, it is about 12 mmHg. During the second stage of labor, the baseline may be as high as 20 mmHg. Baseline readings that do not return to 20 mmHg or less following a contraction suggest uterine hypertonia and a possible compromise of fetal well-being.

An accurate FHR recording is obtained from a fetal scalp electrode. This type of monitoring is most useful when babies are difficult to monitor because of maternal habitus or during abnormal tracings due to FHR decelerations. Once the fetal head is engaged, the electrode is inserted vaginally and attached to the fetal scalp with a small puncture of the skin. A fetal electrocardiograph signal is obtained, amplified, and then fed into a cardiometer. The output from the cardiometer is recorded on permanent graph paper.

Although internal monitoring produces clear details of fetal heartbeats, it is invasive, carries the risk of uterine infection, and limits a woman's movement. It is, therefore,

reserved for women whose fetus is at high risk during labor.

### Scalp Stimulation

Although not well studied, if a fetus shows an unresponsive heartbeat during labor, vibroacoustic stimulation can be used the same as is done for nonstress tests during pregnancy to be certain a fetus is responding well to labor (Tan, Smyth, & Wei, 2013). If FHR variability appears to be depressed during labor, the welfare of a fetus can be assessed by scalp stimulation. This is done by applying pressure with the fingers to the fetal scalp through the dilated cervix (Fig. 24.3). This causes a tactile response in the fetus that momentarily increases the FHR. If the fetus is in distress and becoming acidotic, FHR acceleration will not occur. Scalp stimulation, therefore, is an assessment of acid–base balance in a fetus in labor.

**Figure 24.3** Fetal scalp stimulation. (Redrawn from *Journal of Perinatal and Neonatal Nursing*, 16[1]; with permission from Aspen Publishers, Inc.)

### Fetal Oxygen Saturation Level

Fetal oxygen saturation may be measured by an oxygen saturation sensor introduced into the uterus and placed beside the fetus's cheek after membranes have ruptured. Because the procedure creates a small chance of uterine infection, this is generally reserved for women who already have an internal contraction or fetal monitor in place.

### Fetal Blood Sampling

Although not often used anymore, monitoring of the fetal blood composition (obtained from the fetal scalp following cervical dilatation during labor) can reveal hypoxia in a fetus (Chandrahara, 2016). A small laceration will be present on the newborn scalp as a result, which needs to be observed for bleeding or signs of infection following birth.

## Cesarean Birth

Although cesarean birth may be elected by some women, the procedure is used most often as a prophylactic measure to alleviate problems of birth such as cephalopelvic disproportion, breech or multiple fetus births, or failure to progress in labor.

A major concern in maternal and child health nursing is the increasing number of cesarean births being performed annually (Betrán, Ye, Moller, et al., 2016). In 1970, only 5.5% of women in the United States had infants born by cesarean birth. In 2013, the rate had risen by 53% reaching 32%, the highest rate ever reported in the United States (Martin, Hamilton, Osterman, et al., 2015).

This increased rate has resulted from a combination of the increasing safety of cesarean birth, the use of fetal monitors (which provide for early detection of fetal problems), an increased incidence of obese women (Carlson, Hernandez, & Hurt, 2015), and scheduled or **elective cesarean births**, chosen by women for convenience or to prevent potential urinary or anal incontinence later in life (Tähtinen, Cartwright, Tsui, et al., 2016). The increase in rate may also be related to a healthcare provider's fears of malpractice suits should a fetus be allowed to be born vaginally and then be discovered to have suffered anoxia.

Several legal and ethical issues have arisen in recent years when women have refused to undergo cesarean birth after being advised they need one. Because women do have a right to decide whether they will undergo surgery, the right to refuse the procedure must be respected (Box 24.2). In some instances, however, a court order for the procedure has been obtained to save a fetus. Be certain you are aware of the opinion of your agency's ethics committee on this issue.

### BOX 24.2

#### Elective Cesarean Birth

Because about 30% of women have a baby by cesarean birth in the United States today, there is an emerging culture of women who advocate cesarean birth as superior to vaginal birth as a way to eliminate long hours of labor pain. This effect—to make birth a surgical procedure—is in sharp contrast to other efforts to make birth more natural. Because there are added risks to both the woman and her fetus from a cesarean birth, it can cause a nursing care problem if a woman who has no medical reason for a cesarean birth insists on having one. Being certain to explain that a cesarean birth is a method to be used when vaginal birth is not possible, rather than a true option, can help a woman put her choice of type of birth into perspective.

As a rule, nurse-midwifery or interprofessional birthing services have a lower incidence of cesarean births than hospital services even when controlling for a higher incidence of low-risk women in these settings (Rosenstein, Nijagal, Nakagawa, et al., 2015). Continuous support during labor by a concerned healthcare provider (such as a

nurse) appears to decrease the incidence (Cox & King, 2015).

## SCHEDULED CESAREAN BIRTH

Scheduled cesarean births are planned, which means there is time for thorough preparation for the experience throughout the antepartal period. Some women are even able to take a childbirth preparation class specifically for cesarean birth. Women who plan these need to be aware they will need epidural anesthesia, and the risk of injury to them from cesarean birth is higher than that from vaginal birth. Scheduling cesarean births this freely also can result in preterm birth with the accompanying threats to the fetus or newborn (Box 24.3).

### BOX 24.3

#### Nursing Care Planning to Respect Cultural Diversity

Several cultural issues can come into play when planning a cesarean birth. A religious family that was expecting a vaginal birth but needs cesarean birth during labor may ask for time to pray before surgery. If there is no need for an urgent or emergent delivery, it is best to give the family private time to pray. Jehovah's Witnesses cannot accept blood products as a part of their spirituality. If they are at high risk for hemorrhage such as in the case of a placenta previa, it is important for healthcare providers to consider whether this type of high-risk patient should be cared for in a setting where bloodless or transfusion-free medicine is available. These types of specialty groups can help reduce blood loss, increase a patient's ability to make more blood, and circulate a patient's blood back to her, so that she does not need to accept blood from another person.

In the past, many cesarean births were performed because the woman had undergone a cesarean birth with a previous child; with new surgical techniques, particularly the use of a low cervical incision, "once a cesarean, always a cesarean" no longer applies. The majority of women who have had a cesarean birth within the past 10 years are eligible to give birth vaginally in subsequent pregnancies if the circumstances are appropriate for vaginal birth (Iriye, 2015).

Yet, other reasons for scheduled cesarean births are when there is a physical indication such as transverse presentation, an infection that could be contacted by the fetus if born vaginally, or cephalopelvic disproportion (Box 24.4). For instance, cesarean birth reduces the transfer of the herpes type 2 from mother to newborn, so it is recommended for women who have this infection and an active lesion in the vaginal area at the onset of labor (Liu, Li, Chen, et al., 2014). It also can reduce mortality among infants presenting breech (Cunningham, Leveno, Bloom, et al., 2014). It may be advantageous for a preterm birth to avoid pressure on the fetal head (Delnord, Blondel, Drewniak, et al., 2014). It is generally contraindicated when there is a documented dead fetus (labor can be induced to avoid a surgical procedure).

## Selected Indications for Cesarean Birth

### MATERNAL FACTORS

- Active genital herpes or (perhaps) human papillomavirus
- AIDS or (perhaps) HIV-positive status
- Cephalopelvic disproportion
- Cervical cerclage
- Disabling conditions, such as severe gestational hypertension, that would prevent pushing to accomplish the pelvic division of labor
- Failed induction or failure to progress in labor
- An obstructive benign or malignant tumor
- Previous cesarean birth by classic incision
- Fear of birth or wish to help prevent uterine prolapse or urinary incontinence in later years

### PLACENTAL FACTORS

- Placenta previa
- Premature separation of the placenta
- Umbilical cord prolapse

### FETAL FACTORS

- Compound conditions such as macrosomic fetus in a breech lie
- Extreme low birth weight
- Fetal distress
- A major fetal anomaly, such as hydrocephalus
- Multigestation or conjoined twins
- Transverse fetal lie and perhaps breech presentation

## EMERGENT CESAREAN BIRTH

Emergent cesarean births are done for reasons that arise suddenly in labor, such as placenta previa, premature separation of the placenta, fetal distress, or failure to progress. With this second type of cesarean birth, preparation must be done rapidly but with the same concern for fully informing a woman and her support person about what circumstances created the need for the cesarean birth and how the birth will proceed. Cesarean birth is mentioned in most childbirth classes, so any woman who has taken such a class may at least understand that cesarean births are sometimes necessary.

An emergent cesarean birth carries with it the same risks of any emergent surgery: The woman may not be a prime candidate for anesthesia and may be psychologically unprepared for the experience. In addition, the woman may have a fluid and electrolyte imbalance and be both physically and emotionally exhausted from a long labor.

## **Effects of Surgery on a Woman**

Like any surgical procedure, cesarean birth has systemic effects.

### **STRESS RESPONSE**

Whenever the body is subjected to stress, either physical or psychosocial, it responds with measures to preserve the function of major body systems. This results in a release of epinephrine and norepinephrine from the adrenal medulla. Epinephrine increases the heart rate, causes bronchial dilatation, and elevates the blood glucose level. It also leads to peripheral vasoconstriction, which forces blood to the central circulation and increases blood pressure. In the pregnant woman, such responses may minimize blood supply to the lower extremities. Pregnant women are already prone to thrombophlebitis from stasis of blood flow, so these responses compound or greatly increase thrombophlebitis risk.

### **INTERFERENCE WITH BODY DEFENSES**

The skin serves as the primary line of defense against bacterial invasion, so when skin is incised for a surgical procedure, this important line of defense is lost. Strict adherence to aseptic techniques during surgery and in the days following the procedure is necessary to compensate for this impaired defense. If the cesarean birth is performed hours after the membranes rupture, a woman's risk for infection will be higher than if the membranes were still intact. Many women receive prophylactic antibiotics, such as ampicillin (Omnipen) or a cephalosporin, such as cefazolin (Ancef), to ensure protection against postsurgical endometritis, even if the membranes remained intact (Gyte, Dou, & Vazquez, 2014).

### **INTERFERENCE WITH CIRCULATORY FUNCTION**

Although vessels that must be cut for surgery are immediately clamped and ligated, some blood loss occurs with surgery. Compared to other surgeries, the amount of blood lost in a cesarean birth is comparatively high, caused by the fact abdominal and pelvic vessels are congested with blood waiting to supply the placenta. During a vaginal birth, a woman loses 300 to 500 ml of blood. This loss increases to 500 to 1,000 ml with a cesarean birth (Graham, Gimovsky, Roman, et al., 2016).

### **INTERFERENCE WITH BODY ORGAN FUNCTION**

When any body organ is handled, cut, or repaired in surgery, it may respond with a

temporary disruption in function. Therefore, close postoperative assessment, not only of the primary organ involved but also of total body function, is necessary to determine the total degree of disruption present.

Because the uterus is handled during cesarean birth, it may not contract well afterward, which can lead to postpartum hemorrhage. For a healthcare provider to reach the uterus, the bladder must be displaced anteriorly. As a result of this handling, the bladder may not sense filling as well as usual after the procedure (Cordon, Fracchia, & Armenakas, 2014). During surgery, pressure is also felt by the intestine, so a paralytic ileus or halting of intestinal function with obstruction may occur (Sahin & Terzioglu, 2015). As mentioned previously, thrombophlebitis from impaired lower extremity blood flow is yet another possibility. After a cesarean birth, therefore, uterine, bladder, intestinal, and lower extremity circulatory function must all be carefully assessed.

## INTERFERENCE WITH SELF-IMAGE OR SELF-ESTEEM

Surgery always leaves an incisional scar that is noticeable to some extent afterward, and its appearance may cause a woman to feel self-conscious. Although most women accept cesarean birth well, a woman who was intent on having a vaginal birth may feel a loss of self-esteem and depression if she believes the procedure marks her as a woman less capable than others because she was unable to give vaginal birth (Ayers, Bond, Bertullies, et al., 2016).

## Nursing Care for a Woman Anticipating a Cesarean Birth

A woman who is admitted to the hospital for an anticipated cesarean birth may be more worried about the procedure (because she has had more time to worry) than a woman who is told during labor an emergent cesarean is necessary. After the woman is admitted, allow her time to talk about any fears she has. Encourage her to do as much as possible for herself preoperatively to help her feel in control and to diminish her fear (Silva, de Jesus, Merighi, et al., 2014).

Be aware that it is difficult for a woman undergoing surgery to relax as long as her support person remains nervous and worried. Make a point of including this person in all explanations and admission routines to keep his or her anxiety under control as well.

### *What If... 24.1*

**After learning that Moja wanted to wait for her cesarean birth to begin until her boyfriend arrives, the nurse learns the boyfriend has texted to say he cannot possibly stay with Moja in the operating room; he'll feel so nauseated he'll probably faint. Would it be best to plan on supporting Moja yourself or to try to involve the boyfriend?**

## PREOPERATIVE INTERVIEW

Both a woman's primary care provider and the team member who will be administering the anesthesia interview a woman preoperatively to obtain a health history and to make assessments and decisions for safety of the procedure and the use of anesthesia. In addition to these, a nursing assessment is also essential. Be certain to ask about any past surgeries, secondary illnesses, allergies to foods or drugs, reactions to anesthesia, bleeding problems, or current medications to help establish surgical risk, and any body piercings that need to be removed because of the use of electrosurgery or an arterial cauterizing machine. In addition, include questions to discover the woman's knowledge about:

- What the procedure will entail
- Length of hospitalization anticipated
- If she's been told about any postsurgical equipment to be used, such as an indwelling catheter or intravenous (IV) fluid line
- Any special precautions that are being planned for her infant such as high-risk nursery care

## OPERATIVE RISK FOR A WOMAN

Women who are in less than optimal physical or psychological health are at risk for a complicated surgical outcome unless the risk factor is identified, and special precautions are taken.

### Poor Nutritional Status

A woman who is obese because of poor nutrition is at added risk from surgery, because tissue that contains an abundance of fatty cells is difficult to suture, thus causing the surgical incision to take longer to heal. A prolonged healing period increases the risk for infection and rupture of the incision (**dehiscence**) (Ayres-de-Campos, 2015).

Because an obese woman's heart has an increased workload, the physiologic shock of surgery may place greater stress on the already overworked organ. In addition, an obese woman often has more difficulty turning and ambulating postoperatively than does a woman with a lower body mass index (BMI) and therefore has an increased risk for developing respiratory or circulatory complications such as pneumonia or thrombophlebitis (Quinlan & Murphy, 2015).

A woman with a protein or vitamin deficiency is also at risk for poorer healing because protein and vitamins C and D are necessary for new cell formation at the incision site. Vitamin K is necessary to ensure blood clotting after surgery. Pregnant women who are iron deficient (in particular, women with a multiple gestation or women who have not taken supplements), coupled with the blood loss from surgery, are at high risk for extreme fatigue after surgery, which could interfere with parent-child bonding (Drukker, Hants, Farkash, et al., 2015).

## Age Variations

Age affects surgical risk because it can cause both decreased circulatory and renal function. Fortunately, most pregnant women fall within the young adult age group, so are excellent candidates for surgery. A woman older than 40 years falls into a category of slightly higher risk not because of surgery itself but because of associated conditions such as gestational diabetes (Inocêncio, Braga, Lima, et al., 2015).

## Altered General Health

A woman who has a secondary illness such as cardiac disease, diabetes mellitus, anemia, kidney, or liver disease is at greater than usual surgical risk, depending on the extent of her primary disease, because the pathology from the secondary illness may interfere with her ability to physically adjust to the demands of surgery. Therefore, asking if the woman has a secondary illness is an essential component of a preoperative nursing history.

A general medication history also is important because some drugs increase surgical risk by interfering with the effect of an anesthetic or with healing of tissue. Examples of drugs that pregnant women might be taking and their potential complications are shown in Box 24.5.

BOX 24.5

### Nursing Care Planning Based on Responsibility for Pharmacology

#### DRUGS THAT MAY RESULT IN COMPLICATIONS OF CESAREAN BIRTH

Type of Drug	Action
Antibiotics	Specific antibiotics may predispose one to renal insufficiency or increase neuromuscular blockage; can lead to opportunistic infections
Anticoagulants	May cause hemorrhage due to lack of hemostasis during surgery
Anticonvulsants	May increase liver action and metabolism of anesthetic agent
Antihypertensives	May result in hypotension after anesthesia
Corticosteroids	May block body's response to shock and so lead to lack of adrenal function
Insulin	May lead to hypoglycemia during labor

Antianxiety agents

or hyperglycemia if a dextrose solution is administered

May cause hypotension after anesthesia

## Fluid and Electrolyte Imbalance

A woman who enters surgery with a lower than usual blood volume will experience the effect of surgical blood loss more than a woman who has a normal blood volume. A woman who has had a long labor before a cesarean birth is scheduled may fall into this category because she may have had little to eat or drink for almost 24 hours. Recent vomiting, diarrhea, or a chronic poor fluid intake compounds her risk. IV fluid replacement may need to be initiated preoperatively and continued postoperatively to prevent a serious fluid or electrolyte imbalance.

## Fear

Women who are extremely worried about surgery need a very detailed explanation of the procedure in order to reduce their anxiety to a tolerable level. If a woman seems particularly anxious, inform the team member who will administer the anesthesia so that an antianxiety drug can be administered, if necessary, to make the experience less frightening for her.

In many instances, just helping a woman acknowledge that her fear of surgery is a normal reaction can be helpful. This does not make the procedure any less traumatic, but the woman may then view her feelings as expected, which can help to enhance her self-esteem and lower anxiety (Silva et al., 2014).

## OPERATIVE RISK TO THE NEWBORN

Cesarean birth places a newborn at a greater risk than does a vaginal birth. When a fetus is pushed through the birth canal, pressure on the chest helps rid the newborn's lungs of fluid, making it easier for the baby to take a first breath. For this reason, more infants born by cesarean birth develop some degree of respiratory difficulty for a day or two after birth than those born vaginally (Wang, Liu, Zhu, et al., 2015). See Chapter 26 for a discussion of this condition, which is often referred to as transient tachypnea of the newborn.

## PREOPERATIVE DIAGNOSTIC PROCEDURES

Preoperative assessment procedures for a woman who is to have a cesarean birth include documentation of fetal status and presentation and maturity by ultrasound assessment. In addition, assessments also include circulatory and renal function and those for all presurgery patients, including:

- Vital sign determination
- Urinalysis

- Complete blood count
- Coagulation profile (prothrombin time [PT], partial thromboplastin time [PTT])
- Serum electrolytes and pH
- Blood typing and cross-matching

Remember blood values need to be evaluated in light of the changes that occur with pregnancy. During pregnancy, for example, a woman (particularly one who was in prolonged labor) can have an elevated leukocyte count (up to 20,000 cells/mm<sup>3</sup>), so this finding is not as helpful an indicator for the presence of infection in the pregnant woman as it is in others.

## PREOPERATIVE TEACHING

Preoperative teaching is aimed at acquainting a woman with the cesarean procedure and any special equipment to be used so she is as informed as possible.

Before beginning teaching, assess how much a woman knows about her surgery. A woman who has had a cesarean birth for her first child and now is being admitted for a second procedure, for example, already knows many details. Even so, she will undoubtedly appreciate having her memory refreshed and recall confirmed. Answer all specific questions she has and fill in gaps in knowledge as necessary. Be certain all information you offer is accurate. Be certain not to use hospital jargon such as “NPO.” People under stress do not process new information well. They cannot process information at all if they do not understand the terminology.

Be certain to explain the immediate preoperative measures that will be necessary, such as surgical skin preparation, eating nothing before the time of surgery, premedication (if this will be used), and method of transport to surgery. Review the necessity for an indwelling bladder catheter, IV fluid administration, and placement of an epidural catheter (if this will be used for postprocedure pain relief).

For scheduled cesarean births, an explanation of not only what is going to happen immediately but also what activities should be performed to help maintain respiratory and skeletal muscle function and to prevent postsurgical complications (e.g., early ambulation) should also be included in teaching. Women who practice exercises to maintain good respiratory and circulatory function postoperatively tend to experience fewer postoperative respiratory and circulatory complications than those who do not. These preventive exercises are best taught during the preoperative period, when the woman is free of pain and can concentrate on learning. Such teaching also gives a woman a positive outlook on surgery and a sense of control over her situation.

Throughout teaching, use visual aids as necessary. Draw pictures or show illustrations of anatomy, as needed. Be careful, however, not to leave textbooks about cesarean procedure techniques with a woman. Typically, these books also describe complications, and although knowledge of possible complications is necessary for informed consent, reading about complications complete with color illustrations can be overwhelming.

## Deep Breathing

Periodic deep breathing exercises fully aerate the lungs and help prevent stasis of lung mucus from the prolonged time spent in the supine position during surgery. Because stasis always has the potential to cause infection, preventing this helps prevent lung infection such as pneumonia.

A typical exercise is to take 5 to 10 deep breaths every hour. The woman simply inhales as deeply as possible, holds her breath for a second or two, and then exhales as deeply as possible. Be certain she both inhales and exhales fully. Otherwise, she might experience light-headedness from hyperventilation.

## Incentive Spirometry

A common device used three to four times a day postoperatively to encourage deep breathing is an incentive spirometer. These devices, which cause a small ping-pong-like ball to rise in a narrow tube or cause lights to flash, are both easy and fun to operate and give a woman a sense of reward for her effort. The initial impression of most people is that the device works by blowing into it. Because its purpose is to fully aerate lung spaces, however, most models are triggered by *inhalation*, not exhalation. A gauge can be set to monitor levels and tabs to set goals.

## Turning

Be certain women understand that turning postoperatively is important to prevent both respiratory and circulatory stasis.

## Ambulation

The most effective way to stimulate lower extremity circulation after a cesarean birth is by early ambulation. For this reason, most primary healthcare providers prefer a woman to be out of bed and walking as soon as the effect of the epidural anesthesia has worn off. Helping a woman ambulate this early can be difficult because she is both fatigued and has pain from her incision. Help her to understand ambulation is extremely important after cesarean birth because the edema from the low pelvic surgery compresses circulation to the lower extremities, thus increasing the risk for lower extremity circulatory stasis. Some women may be prescribed sequential compression devices (SCDs) or antiembolic stockings (thromboembolic devices [TEDs]) to support and encourage venous return in addition to ambulation.

## IMMEDIATE PREOPERATIVE CARE MEASURES

A number of measures must be taken immediately before surgery to help ensure a safe outcome.

## Informed Consent

Obtaining operative consent is the primary healthcare provider's responsibility, but being certain, it is obtained prior to surgery is everyone's responsibility. You may be asked to witness a woman's signature on such a form. Before signing as a witness, be certain that it was *informed* consent, or one in which the risks and benefits of the procedure were explained in terms the woman could easily understand.

The law differs from state to state with regard to who qualifies to be considered an emancipated or mature minor. Emancipated minors can sign their own permission for a cesarean birth, even though they are legally underage.

## Overall Hygiene

On admission, provide a clean hospital gown. If a woman's hair is long, encourage her to braid it or put it into a ponytail, so it will more easily fit under the surgical cap she will wear; hair contained by a cap is less likely to spread microorganisms during surgery. Follow your institution's procedures with regard to removing nail polish, jewelry, contact lenses, lip or mouth piercings, or hair ornaments before surgery. A growing number of women wear acrylic fingernails and are reluctant to remove them for surgery. If this is the case, ensure that the woman's toenails are free of polish so that toenails can be used to assess capillary refill if this assessment is needed.

### *What If . . . 24.2*

**Moja, who will have epidural anesthesia for her cesarean birth, refuses to remove her contact lenses for surgery even though it is hospital policy for anyone receiving anesthesia to do so. She tells the nurse, "I won't be able to see my baby afterward without them." Would the nurse insist she take them out or ask the anesthesia team member if she could be an exception to a rule?**

## Gastrointestinal Tract Preparation

A gastric emptying agent, such as metoclopramide (Reglan), to speed stomach emptying or a histamine blocker, such as ranitidine (Zantac), to decrease stomach secretions may be prescribed prior to surgery. Yet, another possibility is an oral antacid such as citric acid and sodium citrate (Bicitra), which acts to neutralize acid stomach secretions. These precautions are necessary because the woman will be lying on her back during the procedure, making esophageal reflux and aspiration highly possible.

## Baseline Intake and Output Determinations

To reduce bladder size and keep the bladder away from the surgical field, an indwelling urinary catheter may be prescribed before transport for surgery or after arrival in the surgical suite. Use good lighting so that the woman's perineum is clearly revealed. After catheter insertion, be certain urine drains freely because fetal pressure on the urethra may considerably reduce the flow of urine. During transport, be certain to keep the

drainage bag below the level of the woman's bladder to prevent urine backflow and the possible introduction of microorganisms into the bladder.

If catheterization is difficult before surgery, do not traumatize the urethra by repeated attempts as catheterization can be done in the operating room (OR) after the anesthetic agent is given. If there will be a delay between the time the catheter is inserted and the time of surgery, mark the level of drainage in the bag just before surgery or empty it, so that presurgery urine output can be differentiated from postsurgery urine output. This is because one of the gravest dangers of any surgical procedure is kidney failure from the physiologic stress of surgery or lack of blood flow to the kidneys due to decreased blood pressure. All reproductive tract surgery puts ureter flow at risk as well because the edema that collects in the surgery area can press on the ureters.

## Hydration

Most women have an IV fluid line begun before surgery with a fluid such as lactated Ringer's solution. Doing so helps to ensure a woman will be fully hydrated and will not experience hypotension from epidural anesthesia administration, temporary use of a supine position, or blood loss at birth. Be certain this line is begun in the woman's nondominant hand if possible so she can hold her newborn after surgery without interference. Use a large-size catheter or needle (18 or 20 gauge), so that blood replacement therapy can be administered by the same line if needed.

### *QSEN Checkpoint Question 24.2*

#### **TEAMWORK & COLLABORATION**

The nurse gives a report to an OR nurse prior to a cesarean birth and describes actions she took to reduce the size of the patient's bladder and to keep it away from the surgical field during the procedure. Which action should the nurse describe to her colleague?

- Inserting a Foley catheter to drain the bladder and decrease its size
- Administering an oxytocic drug to cause the bladder to forcefully contract
- Restricting the woman's fluids for at least 16 hours before surgery
- Administering the woman a diuretic to reduce bladder volume

*Look in Appendix A for the best answer and rationale.*

## Preoperative Medication

A minimum of preoperative medication is used with a woman having a cesarean birth to prevent compromising the fetal blood supply and to ensure that the newborn is wide awake at birth and can initiate respirations spontaneously. Be aware if a woman has been in labor, what medications, if any, she has already received to help prevent a drug interaction.

## Patient Chart and Presurgery Checklist

Documentation of nursing care up until the time a woman leaves the nursing care unit or labor room must be completed before a woman leaves for the surgical suite. Many hospitals use an electronic preoperative checklist, such as that shown in Figure 24.4, as a reminder of all necessary measures to be taken. Checking and signing such a form indicates that the specific measures were completed.

Patient concerns	Completed
Skin preparation _____	_____
Identification in place _____	_____
Temperature, pulse, respiration _____	_____
Blood pressure _____	_____
Height _____ Weight _____	_____
Voided _____ Time _____ Amount _____	_____
NPO after _____	_____
Hospital gown _____	_____
Hairpins removed _____	_____
Nail polish removed _____	_____
Jewelry removed _____	_____
Preoperative medication _____	_____
Dentures removed _____ In place _____	_____
Contact lenses removed _____	_____
Prosthetic devices removed _____	_____
Abdominal piercing removed _____	_____
<b>Chart concerns</b>	
Addressograph plate attached _____	_____
Operative permit obtained _____	_____
Urinalysis _____	_____
Hematocrit or CBC _____	_____
Blood order of _____	_____
Signature _____	R.N. _____

**Figure 24.4** A preoperative checklist for cesarean birth. Checklists vary from hospital to hospital.

## Transport to Surgery

A woman may be transferred to surgery in her bed, or she may be helped to move to a stretcher. Urge her to lie on her left side during transport to prevent supine hypotension syndrome. Ensure additional safety by raising the side rails. Cover her with a blanket or sheet to avoid her feeling chilled. Check that her identification is secure before she leaves the patient unit. Make certain, even though steps are being completed rapidly, that her chart or electronic record remains secure and will be available to OR personnel.

### *QSEN Checkpoint Question 24.3*

#### **PATIENT-CENTERED CARE**

Moja Hamma needs to have an IV infusion started prior to her cesarean procedure. Which course of action would be best?

- Introduce the cannula into the back of either hand.
- Begin the IV infusion in the hand nearest to you.
- Ask Moja which hand she would prefer you to use.
- Explain that IVs are typically started in the right hand.

*Look in Appendix A for the best answer and rationale.*

## Role of the Support Person

In most instances, a woman's family can be as involved in a cesarean birth as they would be for a vaginal birth. A support person may need more encouragement to watch a cesarean than a vaginal birth, because he or she may believe the surgery will be much bloodier than it actually is. Helping family members realize cesarean birth is little different from vaginal birth not only allows them to stay with a woman during the procedure but also helps them progress to bonding with the infant and incorporating the new member into their family more easily.

## Nursing Care for a Woman Having an Emergent Cesarean Birth

Many women who will have a cesarean birth have no warning during pregnancy that a cesarean birth will be necessary. Suddenly, during labor, they develop a complication such as prolapsed cord or fetal distress, and surgery becomes necessary.

A woman who has severe pain with labor and is told an emergent procedure is necessary actually may be relieved surgery has been suggested because the surgery will alleviate the pain. In contrast, another woman might feel great disappointment when told her baby must be born by cesarean birth. In many women, both emotions intertwine.

Surgical risk in an emergent situation is determined from the baseline history and physical examination information previously obtained at the beginning of labor. Preoperative preparation measures such as vital signs, urinalysis, and blood work have also already been obtained. An immediate preparation, therefore, involves gaining an informed consent, application of SCDs or elastic stockings (if appropriate), preparing the gastrointestinal tract, adding bladder catheterization, and establishing an IV line. Because, ideally, a cesarean birth should be completed within 30 minutes from the time the procedure was documented to be necessary, teaching about postoperative measures needs to be delayed until after surgery (Lipman, Carvalho, Cohen, et al., 2013).

Available time before the surgery must be spent explaining the immediate procedures to the woman such as transfer, abdominal preparation, and anesthesia. Document carefully what was taught, so that the nurse caring for the woman postoperatively will be aware of the need for additional teaching. At birth, at least one person whose sole responsibility is neonatal resuscitation needs to be present to care for the baby. Some babies born by cesarean birth need assistance to begin breathing at birth, even at full term; about 3% of babies need extensive resuscitation to survive (Konstantelos, Ifflaender, Dinger, et al., 2014).

### *QSEN Checkpoint Question 24.4*

## INFORMATICS

The nurse notices that a colleague who was helping to prepare Moja has left the room to liaise with the OR in anticipation of the cesarean birth. The nurse also notices that the colleague left Moja's electronic health record open and in view of her support people. Which course of action would be best?

- a. Immediately close the record even though all care may not yet be recorded.
- b. Locate the nurse and ask her to come back so she can close the record.
- c. Minimize the record and wait for the nurse to come back and close it.
- d. Report the nurse to the nurse manager for violating confidentiality.

Look in [Appendix A](#) for the best answer and rationale.

## Intraoperative Care Measures

Cesarean birth is most similar to vaginal birth if the woman is awake during the surgery; therefore, after discussion with a woman, the anesthesia of choice is usually a regional block, such as epidural anesthesia ([Box 24.6](#)).

### BOX 24.6

#### Nursing Care Planning Tips for Effective Communication

Moja Hamma has been told she will need a cesarean birth because of fetal distress that has led to meconium staining.

*Tip:* Be certain to ask enough questions so you can learn the importance or meaning of the event to an individual woman. Most women appreciate that cesarean births are done to prevent their infant from being harmed. Others interpret a cesarean birth as being done because the harm has already occurred. Some women interpret a cesarean birth as an announcement they are somehow not as competent as other women. Still, others are relieved labor is being interrupted.

**Nurse:** Moja, can I answer any questions for you?

**Moja:** I want something to put me to sleep so I won't know what's happening.

**Nurse:** Most women want an epidural.

**Moja:** I have to be so sound asleep I won't know what's happening.

**Nurse:** You're not interested in seeing your baby born?

**Moja:** I'm not interested in seeing him born dead.

**Nurse:** Let me find your doctor to explain to you again that you need surgery to prevent something from going wrong, not because something is wrong.

## ADMINISTRATION OF ANESTHESIA

A surgical nurse will assist a woman to move from the transport stretcher or bed to the OR table and will remain with her while anesthesia is administered. If the woman has an epidural catheter in place from labor, be careful not to dislodge it while she is being

moved. During transport and while in surgery, encourage the woman to remain on her side, or place a pillow under her right hip to keep her body slightly tilted to the side, to prevent supine hypotension syndrome. If a spinal anesthetic (which may be used in an emergency) is to be administered, the anesthesiologist usually will do this with the woman sitting up. The anesthesiologist may then ask you to help the woman curve her back to separate the vertebrae and facilitate entry of the spinal needle. Remember, though, that it is difficult for a woman having uterine contractions to remain in this position for long. Talking to her while letting her lean against you is the most effective means of helping her maintain this position. Epidural anesthesia is usually administered with the woman lying on her side. Duramorph is a form of morphine commonly used in addition to a local anesthesia in epidurals. Its effect lasts up to 24 hours, but because it can cause late occurring respiratory depression, respirations should be assessed every 2 hours postsurgery (Butwick, Blumenfeld, Brookfield, et al., 2016).

## SKIN PREPARATION

Reducing the number of bacteria on the skin before surgery automatically reduces the possibility of bacteria entering the incision at the time of surgery. Shaving away abdominal hair, if indicated, and washing the skin area over the incision site with soap and water accomplishes this.

The skin preparation area for a cesarean birth varies among agencies. Be certain to follow agency policy. To avoid being shaved, some women who are scheduled for a planned cesarean birth choose to have a bikini wax done 3 or 4 days before surgery.

## SURGICAL INCISION

After the anesthetic administration, a woman is positioned with a towel under her right hip to move abdominal contents away from the surgical field and to lift her uterus off the vena cava. Be sure the support person is positioned at the woman's head to provide support. Next, a screen is placed at her shoulder level and covered with a sterile drape to block the flow of bacteria from her respiratory tract to the incision site. This also helps block the woman's and the support person's lines of vision, thus preventing additional anxiety caused by the sight of the incision.

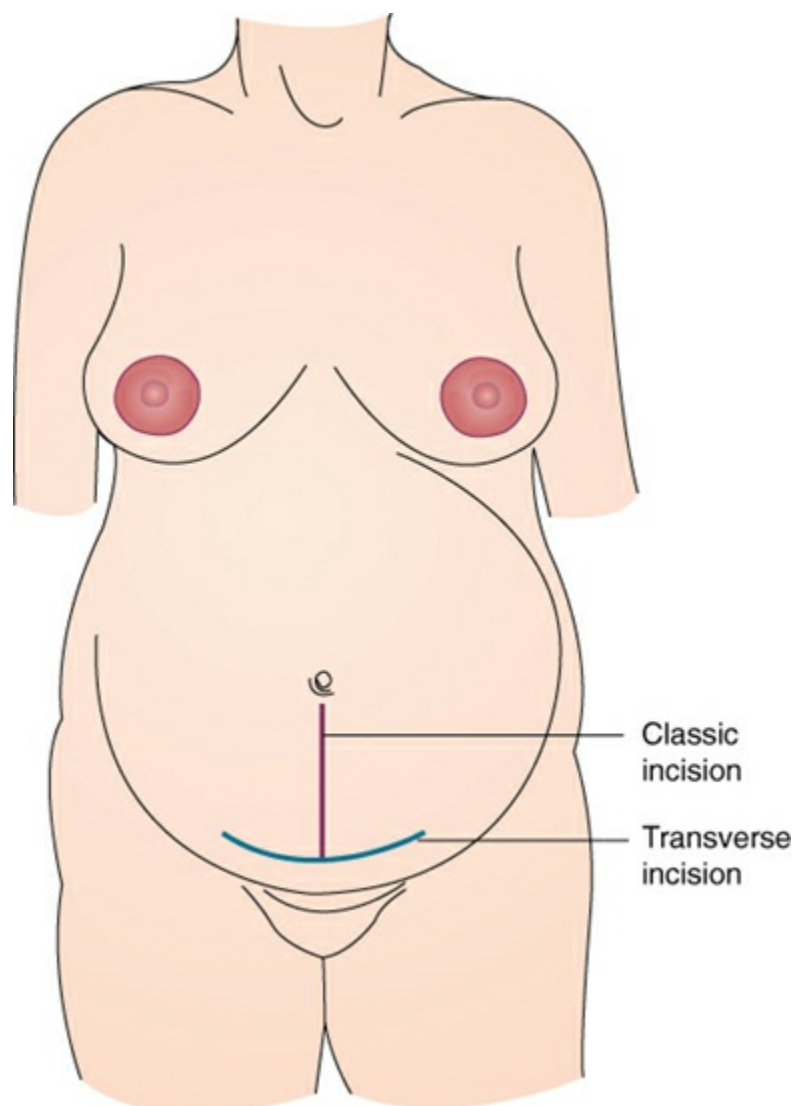

The incision area on the woman's abdomen is then scrubbed with an antiseptic such as iodine, and appropriate drapes are placed around the area so that only a small area of skin is left exposed. Sponge and instrument counts are simplified by the use of prepackaged cesarean birth components. Watching a cesarean birth is usually the first time a father or support person has ever witnessed surgery. Because of this, the person may be too overwhelmed by and interested in the procedure to be of optimum support. Prepare the woman and support person for the sights they might see or help talk them through them as they occur.

Due in part to family and nursing staff pressure, cesarean sections have started to become more family friendly. In the past, babies were often delivered, went to the

warmer for nursing assessments, and were eventually wrapped up and given to the partner to hold near the mother while surgery was finishing. More recently, several interventions have happened to make the experience more “gentle.” There are special sterile drapes that allow for a clear plastic window to be exposed, so the mother and partner can watch the baby being delivered. The opaque drape is lowered just before delivery and replaced after the newborn is delivered, so that the mother and her partner avoid watching both the initial incision and the repair. Additionally, mothers often hold their babies skin to skin after delivery, and they can attempt to breastfeed, even though the position is not ideal for latching. Cesarean sections are often not the ideal solution to delivery, but these changes can help women feel more satisfied with the experience when surgery is necessary.

### Types of Cesarean Incision

There are two types of cesarean incisions. The type chosen depends on the presentation of the fetus and the speed with which the procedure will be performed (Fig. 24.5).

**Figure 24.5** Types of cesarean incisions.

In a **classic cesarean incision**, the incision is made vertically through both the abdominal skin and the uterus. The incision is made high on the uterus, so that it avoids cutting a possible placenta previa. A disadvantage of this type of incision is that it leaves a wide skin scar and also runs through the active contractile portion of the uterus. Because this type of scar could rupture during labor, if this type of incision is used, a woman will be advised not to have a subsequent vaginal birth.

A **low segment incision** (commonly referred to as a low transverse uterine incision and a Pfannenstiel skin incision) is one made horizontally across the abdomen just over the symphysis pubis and also horizontally across the uterus just over the cervix. This is the most common type of cesarean incision used today. It is also referred to as a Misgav-Ladach or a “bikini” incision because even a low-cut bathing suit will cover the scar. Because this type of incision is through the nonactive portion of the uterus (the part that contracts minimally with labor), it is less likely to rupture in subsequent labors, making it possible for a woman to have a **vaginal birth after cesarean (VBAC)** in a subsequent pregnancy (Wu & Chou, 2015). VBAC rates have waxed and waned over the years along with its popularity among patients and providers, but with the recent focus on preventing cesarean births, many institutions are supportive of women who desire VBAC. The low segment incision is preferred because it:

- Results in less blood loss
- Is easier to suture
- Decreases postpartal uterine infections
- Is less likely to cause postpartum gastrointestinal complications (Kawakita, Reddy, Grantz, et al., 2017)

The major disadvantage of this incision is that it takes longer to perform, possibly making it impractical for an emergent cesarean birth. In a few instances, the skin incision is made horizontally (Pfannenstiel) and then the uterine incision is made vertically or vice versa. For this reason, during a future pregnancy, do not assume a woman who has a low transverse skin incision also has had a low transverse uterine incision.

**QSEN Checkpoint Question 24.5**

**EVIDENCE-BASED PRACTICE**

The majority of women who have a cesarean birth are physically eligible to future births vaginally. Researchers examined what influences a woman’s choice in birth mode. They looked at 20 papers reporting views of 507 women who had a previous cesarean section. Women choosing a vaginal birth after cesarean were strongly influenced by a preconceived anticipation of vaginal birth. Women seeking repeat cesarean were often influenced by a prior traumatic birth experience. Women who were open to hearing suggestions had fewer preconceptions about the birth method

and were able to hear a range of options (Black, Entwistle, Bhattacharya, et al., 2016).

Moja tells the nurse, although she knows she will be eligible, she isn't certain if she wants to have a vaginal birth for her next child. Based on the previous study findings, what would be the nurse's best assurance for her?

- a. "It doesn't matter. Once a cesarean, always a cesarean is the rule."
- b. "Birth is such a personal experience it's impossible to say."
- c. "Let's talk about the risks and benefits of both types of deliveries to help you make your decision."
- d. "My coworker had a vaginal birth after a cesarean birth and she was satisfied with her choice."

---

*Look in Appendix A for the best answer and rationale.*

## **BIRTH OF THE INFANT**

Once the surgical incision is complete, the uterus is then cut and the child's head is born manually (Fig. 24.6). The mouth and nose of the baby may be suctioned by a bulb syringe, before the remainder of the child is born. Oxytocin (Pitocin) is administered via IV by the anesthesiologist as the child or placenta is delivered to increase uterine contraction and reduce blood loss. In many instances, a woman's partner may be allowed to cut the umbilical cord the same as in a vaginal birth. After full birth, the uterus is pulled forward onto the abdomen and covered with moist gauze or left in the abdomen for repair. The internal cavity of the uterus is then inspected, and the membranes and placenta manually removed. If the woman wishes to have a tubal ligation or an intrauterine device (IUD) inserted for contraception, either of these can be done at this time (Garcia, Richardson, Gonzalez, et al., 2015; Goldthwaite & Shaw, 2015).

**Figure 24.6** A cesarean birth. **(A)** Positioning for epidural placement. **(B)** Epidural placement. **(C)** Surgical team preparation and sterile draping. **(D–F)** Incision and retraction of skin. **(G)** Birth of the head and posterior shoulder. **(H)** The infant is born. **(I)** Skin closure. **(J)** Mother bonding with newborn. **(A and C.** From Hatfield, N. T. [2014]. *Introductory maternity & pediatric nursing* [3rd ed.]. Philadelphia, PA: Wolters Kluwer. **B.** martin81/shutterstock.com. **D–H.** Chattapat/shutterstock.com. **I.** ARZTSAMUI/shutterstock.com. **J.** VectorDoc/shutterstock.com.)

The uterus, subcutaneous tissues, and skin incisions are then closed. Be sure to remind a woman and her support person that closing the incision can be a long process because many layers of tissue have to be closed so that they do not become concerned something is wrong. Either Dermabond, metal staples, or sutures can be used to close

the exterior skin.

Observing the amount of abdominal manipulation that is involved with surgery helps predict how tender a woman's abdomen will be as well as why she has an overall "aching" feeling after surgery.

## INTRODUCTION OF THE NEWBORN

Once it is determined the newborn is breathing spontaneously, he or she is shown to the mother and support person, just as is done after a vaginal birth (Schorn, Moore, Spetalnick, et al., 2015). Both the support person and the mother may hold the baby immediately. The mother may have some difficulty doing this. Assist her as necessary. Women are able to breastfeed after cesarean births the same as after vaginal births. However, initial breastfeeding may be delayed until the woman has been moved to a recovery room along with her infant because breastfeeding is difficult to do while still in the operating room due to position and monitors or IVs attached to the mother.

## Postpartal Care Measures

Women who have a cesarean birth develop an additional care concern in the immediate postpartal period because they are not only postpartal patients but postsurgical ones. In addition to afterpains from their contracting uterus, they have postsurgical incision pain. A goal of nursing care should be to help women bond successfully with their new infant.

### Nursing Diagnoses and Related Interventions During the Immediate Postpartal Period

Immediately after surgery, a woman is transferred by stretcher from the OR table to the postanesthesia care unit (PACU) or a postpartal room. If spinal anesthesia was used, remember that her legs are fully anesthetized, and she will not be able to help move them.

**Nursing Diagnosis:** Pain related to surgical incision

**Outcome Evaluation:** Patient verbalizes extent of pain (from 1 to 10) and need for relief; states level of pain is tolerable.

In the past, pain control was a major problem after cesarean birth because pain was so intense from either the uterine or abdominal incision that it interfered with a woman's ability to move and deeply breathe. This led to surgical complications such as pneumonia or thrombophlebitis. It also made holding an infant so painful that it

threatened to impair a woman's ability to bond with her newborn. Today, a number of effective types of pain management are available, so this problem is lessened. Always use a pain rating scale to allow a woman to rate her pain. Using a specific tool helps to ensure accuracy of the assessment in light of a woman's overall excitement at having a new child.

Anxiety and fear heighten a pain response. Therefore, a woman who is concerned about her infant may rate pain higher than a woman who feels confident that her infant is doing well. In addition, a tense body posture also causes pressure on sutures. Women who had a long-acting morphine epidural for labor have good pain relief up to 24 hours after birth. Others, who received a shorter acting drug for birth, need additional analgesia to be comfortable. Patient-controlled analgesia (PCA) or continued epidural injections are both effective systems for maximum pain relief. No matter what system of pain relief is used, when administering analgesics after surgery, be certain to supplement them with other comfort measures, such as urging a change of position or straightening bed linen. Always ask a woman what type of pain she is experiencing before administering a new dose of analgesia to be certain she is describing incisional or uterine pain, not pain in some other body part that would suggest a complication of surgery. Check for abdominal distention, which suggests the pain may be caused by intestinal gas rather than incision pain. If this is so, ambulation is often the most effective method to relieve this type of pain.

Urge a woman to continue to take adequate analgesia to effectively manage her pain after she returns home, so she is not so distressed that she cannot nurse her infant or ambulate. Be certain she understands not to use acetylsalicylic acid (aspirin) because this can interfere with blood clotting and uterine healing. Many women who are breastfeeding are reluctant to accept any type of analgesic, especially just before breastfeeding, for fear it will pass into breast milk and to the infant. Although it is true that most analgesics do pass into breast milk, the infant takes such a small amount of breast milk (mainly colostrum) during the first days after surgery, the amount of analgesia received is negligible. Placing a pillow over her lap while the infant nurses can deflect the weight of the infant from her suture line and lessen pain. Encourage the football hold for breastfeeding as another way to keep the infant's weight off her incision (see [Chapter 19](#)).

*Patient-Controlled Analgesia.* With PCA, women administer doses of IV narcotic analgesia, such as morphine, to themselves by means of an IV line as needed. To receive a dose of analgesia, the woman pushes a button similar to a call bell. This alerts the automatic pump to deliver a set amount of narcotic into the IV line. The pump has a "lock-out" setting that prevents a woman from administering a larger dose or doses more frequently than would be safe (e.g., every 8 minutes) ([Fig. 24.7](#)).

**Figure 24.7** Patient-controlled analgesia (PCA) pump. By pushing the button, a patient delivers a bolus of narcotic to herself. (LesPalenik/[shutterstock.com](https://www.shutterstock.com))

With PCA, a fairly constant level of pain relief can be maintained, and pain and fear of injections are eliminated. PCA works well with postcesarean women because they feel overall well and so are interested in self-care and self-administration of analgesia. Because the narcotic is injected in such small amounts, women tend to use less analgesia with a PCA system than they would receive with intramuscular injections.

*Epidural Analgesia.* Today, women who have epidural anesthesia for cesarean birth can have morphine (Duramorph) or fentanyl added to the epidural catheter immediately after surgery, a technique that keeps them pain free for the next 24 hours (see [Chapter 16](#)). Fentanyl creates few side effects. Although epidural morphine offers effective pain relief, side effects of administration, such as intense itching, nausea, and vomiting, can occur. An antihistamine such as diphenhydramine (Benadryl) may be needed to reduce pruritus; an antiemetic such as metoclopramide (Reglan) may be administered to counteract nausea. Even with these annoying side effects, however, epidural analgesia can be a very effective means of pain control after cesarean birth ([Chen, Liu, Cherng, et al., 2014](#)).

On the postpartal unit, an infusion pump is connected to the woman's epidural catheter, and the woman can infuse a bolus of narcotic as additional pain relief as needed. This patient-controlled epidural analgesia (PCEA) not only is an effective means of relieving pain but also omits the problem of infiltration of an IV infusion, which can occur with IV PCA.

*Transcutaneous Electrical Nerve Stimulation.* Transcutaneous electrical nerve

stimulation (TENS) is, as the name implies, the transmission of an electrical current across the skin. Small electrodes are attached to the woman's skin near her incision; when she feels pain, she pushes a transformer button. Irritation or stimulation of large afferent nerve fibers by the electrical stimulation blocks the ability of the smaller, pain-carrying nerve fibers to transmit impulses (as predicted by gating control theory). This is the same phenomenon that rubbing or scratching skin at a point of pain achieves (see [Chapter 16](#)). The use of TENS can provide important pain relief after a cesarean birth because it gives a woman a sense of control over her situation, as does PCA or PCEA ([Kayman-Kose, Ario, Toktas, et al., 2014](#)).

**Nursing Diagnosis:** Risk for deficient fluid volume related to blood loss during surgery

**Outcome Evaluation:** Patient's blood pressure is 100/60 mmHg; pulse remains between 60 and 100 beats/min; scant to no bleeding on surgical dressing is apparent. The potential always exists for deficient fluid volume from surgery due to blood loss until all blood vessels that were cut and ligated during surgery have thrombosed, sclerosed, and permanently sealed closed. The risk of heavy bleeding doubles for the postpartum woman because she may not only hemorrhage vaginally from a noncontracted uterus but also internally from blood vessels not yet securely closed. This danger is most acute during the first hour after surgery; it remains an acute problem for the first 24 hours.

To detect the earliest signs of bleeding, monitor blood pressure, pulse, and respiratory rate approximately every 15 minutes for the first hour after surgery, every 30 minutes for the next 2 hours, every hour for the next 4 hours, or as specifically prescribed. Signs indicative of possible hemorrhage include:

- Falling blood pressure (more than 20 mmHg systolic), a systolic blood pressure less than 80 mmHg, or a drop of 5 to 10 mmHg over several readings
- A change in pulse rate (greater than 110 beats/min or less than 60 beats/min)
- Respirations more rapid and distressed from previous readings
- Restlessness and a sense of thirst

Inspect the dressing over the woman's surgical incision for blood staining each time vital signs are assessed to document there is no incisional bleeding. Observe the perineal pad for lochia flow and palpate the fundal height each time to document uterine contraction. Lochial discharge may be decreased in a woman after a cesarean birth because the uterus was cleaned following the birth, but some lochia will always be present. It will follow a typical rubra, serosa, and alba pattern. Be certain to help a woman turn as you assess for perineal bleeding, so you can look under her body. Blood oozing vaginally or from a surgical wound can pool considerably under a woman before it is otherwise visible.

Oxytocin (Pitocin) may be prescribed to be added to the first 1 or 2 L of IV fluid after surgery to ensure firm uterine contraction. If the rate of fluid administration should fall behind, be careful about "catch-up" administration. Because oxytocin

(Pitocin) can elevate blood pressure by causing vasoconstriction, it may be safer to allow the fluid to remain behind for a time rather than risk elevating blood pressure by a more rapid infusion. Be aware that a woman is very prone to hemorrhage at the point the oxytocin (Pitocin) is discontinued because this is the first time her uterus is asked to maintain contraction on its own. Remember, a minimal but continued change in vital signs (e.g., pulse steadily increasing, blood pressure steadily declining) is as ominous a sign of hemorrhage, as is a sudden alteration in these measurements. Notify a primary care provider of any changes in vital signs that might indicate hemorrhage so that prompt action can be taken.

A woman who has had either spinal or epidural anesthesia usually will not experience pain on uterine palpation until the anesthesia has worn off in approximately 4 to 24 hours. Therefore, uterine palpation should not increase her pain. Once the effect of the anesthesia or analgesia has decreased, palpate gently enough to not cause increased pain but thoroughly enough to determine uterine consistency.

At the same time you assess a woman's uterus for firmness, assess the remainder of her abdomen for softness. A hard, "guarded" abdomen is one of the first signs of peritonitis (i.e., peritoneal infection), a complication that may occur with any abdominal surgical procedure.

### *What If . . . 24.3*

**Moja Hamma refuses to allow the nurse to assess her fundal height after her cesarean birth because she has so much pain. How would the nurse approach this situation?**

## **Nursing Diagnoses and Related Interventions During the Extended Postpartal Period**

The average woman whose child is born by cesarean birth remains in the hospital from 48 hours to 4 days, depending on her preferences and the regulations of her insurance carrier. During this period and until she returns to have her sutures or staples removed, common concerns include pain, fatigue, interference with gastrointestinal function, and reduced activity level.

**Nursing Diagnosis:** Risk for deficient fluid volume related to postsurgical fluid restriction

**Outcome Evaluation:** Patient's urine specific gravity remains between 1.003 and

1.030; weight loss is not more than 5 to 10 lb; fluid intake equals 2 to 3 L/day.

Adequate fluid intake is important after surgery to replace blood loss from surgery and to maintain blood pressure and renal function. Because the intestine is handled during surgery, it takes approximately 24 to 48 hours before full peristaltic function is restored and oral intake is possible. It's important IV fluids be infused during this time at a rate that is not too rapid (which could lead to cardiac overload) or too slow (which could lead to inadequate circulatory compensation). Keep an accurate intake and output record for at least the first 24 hours to be certain an adequate fluid balance has been achieved.

Women are kept nothing by mouth (NPO) for a time after surgery until intestinal peristalsis has returned. To establish this is returning, assess a woman's abdomen at least once every 8 hours for bowel sounds, such as small "pinging" sounds heard on auscultation at a rate of 5 to 10 per minute, as these demonstrate air and fluid are moving through the intestines. Passage of flatus is another indication that intestinal function is again becoming active. As soon as these signs are present, IV fluid therapy is usually discontinued and the woman is allowed sips of fluid. After she begins oral intake, wait 1 hour before removing the IV line. Waiting ensures a woman is not experiencing nausea and vomiting, which might require restarting IV therapy. Introduce oral fluid slowly (e.g., ice chips for the first hour, then sips of clear fluid such as ginger ale, Jell-O, tea, or flavored frozen ice). Gradually advance her diet to a soft and then a regular diet as prescribed.

Teach women to continue to drink large quantities of fluid after they return home (at least six glasses daily), so they have adequate body fluid to make breastfeeding successful.

**Nursing Diagnosis:** Constipation related to effects of abdominal surgery and anesthesia

**Outcome Evaluation:** Woman voices she has a bowel movement every 2 to 3 days or her usual pattern.

Carefully note the time of a woman's first bowel movement following surgery. If she has had no bowel movement by the time of hospital discharge, her primary care provider may prescribe a stool softener, a suppository, or an enema to facilitate stool evacuation. You can reassure a woman who is not receiving much food yet that it is normal not to have bowel movements for 3 or 4 days postoperatively.

Keep women's water pitchers full to remind them to drink fluids. Urge them to eat a diet high in roughage and fluid and to attempt to move their bowels at least every other day to avoid constipation after they return home. Some women may need a stool softener prescribed to manage this because incisional pain interferes with their ability to use their abdominal muscles effectively. Caution them not to strain to pass stools because this puts pressure on their incision.

**Nursing Diagnosis:** Risk for impaired urinary elimination related to surgical

procedure

**Outcome Evaluation:** Urinary output is more than 30 ml/hr; patient reports no pain, frequency, burning, or hesitancy on voiding.

Voiding after surgery provides evidence the woman has adequate renal and circulatory function because the kidneys must have adequate blood flow through them to function. Because the bladder was handled and displaced during surgery, its tone or ability to sense filling may be inadequate to initiate voiding for the first day postsurgery. For this reason, the indwelling catheter placed before surgery is usually left in place for 4 to 24 hours to ensure good urine drainage. Assess that the catheter is draining; a postpartal woman has a urine output of 3,000 to 5,000 ml per 24 hours, so bladder distention can occur rapidly if the catheter becomes blocked.

Before catheter removal, a urine culture may be requested to check for the possibility of a urinary tract infection. After removal of the catheter, the average woman will void in 4 to 8 more hours. Assess for bladder filling at the end of this time by palpation, pressing lightly over the symphysis pubis to assess fullness (Fig. 24.8A), and by percussion. On percussion, an empty bladder sounds dull; a full bladder, resonant; and an extended bladder, hyperresonant (Fig. 24.8B). If a bladder has filled to capacity but cannot empty properly or if the woman is voiding 30 to 60 ml of urine every 15 to 20 minutes, she may have retention with overflow. This voiding pattern is potentially dangerous because it means the woman's bladder is held continuously under tension. This can result in permanent bladder damage if the condition goes undetected. In addition, the constantly full bladder may prevent the uterus from contracting, possibly increasing the risk of postpartal hemorrhage. The woman will need to be catheterized or the urinary catheter to be replaced to avoid these concerns.

**Figure 24.8** (A) Assessing bladder filling by palpation. (B) Assessing bladder filling by percussion. (© Caroline Brown, RNC, MS, DEd.)

To help a woman void, suggest she take her prescribed analgesic to help relax abdominal musculature. In addition, assist the woman to walk to the bathroom at least every 2 hours and provide privacy. Other measures that might be effective include pouring warm water over her vulva (measure the amount of water used, so that it can be differentiated from urine) or running water from a tap within hearing distance.

Teach women to continue to drink adequate fluid (at least five to six glasses daily) to ensure an adequate fluid output and to help prevent urinary tract infection after they return home. Be certain they know to telephone their primary care provider if they should develop symptoms of a urinary tract infection, such as pain with or frequency of voiding or blood in urine.

**Nursing Diagnosis:** Risk for ineffective peripheral tissue perfusion related to immobility during and after surgery

**Outcome Evaluation:** Capillary refill is less than 5 seconds; there is absence of calf pain, redness, edema, or areas of warmth on lower extremities.

Because a woman's abdominal muscles are lax from the stretching that occurred during pregnancy, abdominal contents tend to shift forward and put pressure on the suture line when she is sitting or standing, causing pain and an uncomfortable feeling often described as "everything falling out." A woman usually feels more comfortable turning and sitting up if she supports her abdomen with one hand or splints the

incision with a pillow.

Leg exercises such as flexing and extending her knees and early ambulation are a woman's best safeguards against lower extremity circulatory problems. SCDs may be prescribed to help promote venous return and prevent venous stasis. Always allow a woman to sit on the edge of her bed for a few minutes before helping her to a standing position to prevent orthostatic hypotension (i.e., sudden low blood pressure that occurs with sudden position changes). Assessing that a woman's blood pressure is adequate before she gets out of bed for the first time is an additional safeguard. Before ambulation, also assess the lower extremities for pain in the calf on dorsiflexion of the foot (i.e., Homans sign, which may or may not be reliable) or for pain, edema, warmth, or redness in the calf, to detect the possibility of a thrombus. It is dangerous for a woman to ambulate if signs of a thrombus are present. A thrombus could shift, becoming an embolus, a potentially lethal situation.

Often, it is difficult for women to understand the importance of turning and ambulating as soon as possible after surgery (Fig. 24.9). Still experiencing the "taking in" postpartal phase, they may prefer to spend their first days after surgery just resting quietly in bed. Encourage women to use adequate analgesia during this time, so they can move and ambulate with the least amount of pain. Reinforce the need for continued activity balanced with rest after discharge. Be certain a woman understands the signs and symptoms of complications, such as thrombophlebitis.

**Figure 24.9** (A) Teaching a woman how to support her incision during movement will decrease pain after a cesarean birth. (B) Using an incentive spirometer will promote normal respiratory function. (From Carter, P. J. [2016]. *Lippincott textbook for nursing assistants* [4th ed.]. Philadelphia, PA: Wolters Kluwer.)

**Nursing Diagnosis:** Risk for impaired parenting related to the emergent nature of birth or discomfort from surgery

**Outcome Evaluation:** Parents hold and feed child and voice positive comments about the infant.

When a cesarean birth is unscheduled, a woman does not have much preoperative time to think about how she will feel after surgery. Most women are surprised to

realize not only how well they feel overall but also how quickly they become fatigued and how painful a simple surgical incision can be. Encourage women to breastfeed, although this causes temporary uterine pain as the uterus contracts with breastfeeding.

If the woman's baby was born with a complication or has been placed in an intensive care nursery or transferred to a distant hospital for tertiary care, a woman's postpartal course can be difficult, because she experiences a sense of loss in addition to the pain and fatigue of surgery. Depression, which can slow all body functions and certainly her ability to "take hold" in the postpartal period, can occur.

Unless her baby was transferred to another site, be certain to provide her with ample time to hold and feed her child; assist her to visit in the hospital's high-risk nursery if needed. The average woman can breastfeed satisfactorily after a cesarean birth. She may have some reason to think her baby is not quite perfect—after all, the baby was not born "perfectly"—so she may need additional time to inspect her baby and feel comfortable with him or her (Fig. 24.10).

**Figure 24.10** A mother holds her newborn in the recovery area after a cesarean section.

**Nursing Diagnosis:** Fatigue related to effects of surgery

**Outcome Evaluation:** Patient states she is pleased with level of self-care; ambulates well by 24 hours, and sleeps restfully at night.

Although a woman needs activity and movement after surgery, she also needs adequate rest. Many women attempt to handle their own and their newborn's needs immediately after surgery because their excitement over their baby and their new role as a mother makes them unaware of their underlying fatigue. However, extreme fatigue interferes with healing and possibly increases the risk of infection. A woman

can notice increased uterine bleeding leading to excessive loss of fluid and iron stores and, eventually, interfere with bonding. Help a woman plan a day, therefore, that includes care of her new child as well as periods of rest for herself. Be certain she has adequate analgesic medication at bedtime to allow her to be pain free for the night. Provide a space of time in the middle of the morning and again in the afternoon for uninterrupted rest while she's still in the hospital. Explore her plans for care at home to be certain her plans for rest seem realistic for a postsurgical/postpartal woman (Box 24.7). Once she returns home, rest is often best accomplished if it is scheduled for every time her newborn sleeps.

## BOX 24.7

### Nursing Care Planning Based on Family Teaching

#### MEASURES TO REGAIN ENERGY AFTER A CESAREAN BIRTH

**Q.** Moja tells you, “I am exhausted after my cesarean. What can I do to feel stronger again?”

**A.** Some suggestions to help regain your energy rapidly include:

- Drink adequate fluid daily (at least six glasses). This helps prevent a urinary tract infection and also helps supply all the cells in your body with adequate fluid.
- Rest twice a day for at least one-half hour each time. This helps you get adequate sleep if your baby wakes you at night.
- Do not hesitate to accept help from family and friends for tasks such as house cleaning or grocery shopping.
- Limit the number of stairs you climb daily to one flight once a day. Also limit the amount of weight you lift to the weight of your new baby.
- Do not attempt to be a social hostess as well as a new mom. Put your energy toward relaxing and enjoying your new baby.

**Nursing Diagnosis:** Impaired skin integrity related to surgical incision

**Outcome Evaluation:** Incision line is clean, dry, and intact without erythema; oral temperature is less than 38°C (100.4°F).

Surgical incisions heal by primary intention. Assess the surgical incision once during each nursing shift while a woman is hospitalized to ensure the wound edges are approximated and there are no signs of infection, such as erythema or presence of a discharge. As soon as she can walk steadily, a woman can take a shower (after first removing the dressing) because warm, clean water on the incision feels soothing.

Teach women to continue to observe their incision at least daily at home. Instruct them in signs and symptoms of possible infection and to report any of these signs to their primary care provider. Following a cesarean birth, healing will be adequate enough by day 3 that skin sutures or clamps can be removed, although these may be

left in place until the woman returns for a follow-up appointment in 2 weeks.

### **QSEN Checkpoint Question 24.6**

#### **QUALITY IMPROVEMENT**

Moja tells the nurse she does not intend to continue breastfeeding after she returns home, stating, “My stomach’s too painful.” What action would the nurse add to the plan of care that is most apt to be helpful to Moja?

- a. Insist Moja speak with one of the hospital’s lactation consultants.
- b. Instruct her to take over-the-counter analgesics just before breastfeeding.
- c. Design a study to identify factors that affect breastfeeding success.
- d. Explain that her uterine pain will not last more than a few more days.

*Look in [Appendix A](#) for the best answer and rationale.*

#### **DISCHARGE PLANNING**

A woman being discharged after cesarean birth takes home not only her new baby but also a fair amount of pain and discomfort. Be certain to discuss home care arrangements, emphasizing the need for adequate help with her newborn and other responsibilities at home. Be sure a woman is aware of any restrictions on exercise or activity she needs to follow (common restrictions are not to lift any object heavier than 10 lb or walk upstairs more than once a day for the first 2 weeks). Also teach her to recognize signs of possible complications directly related to the surgery that should be reported to her primary care provider because they may require readmission, including:

- Redness or drainage at the incision line
- Lochia heavier than a normal menstrual period
- Abdominal pain (other than suture line or afterpain discomfort)
- Temperature greater than 38°C (100.4°F)
- Frequency or burning on urination

A woman can plan on resuming coitus as soon as the act is comfortable for her.

Cesarean birth does not interfere with future fertility, so be sure she has contraceptive information, if desired ([Sok, Sanders, Saltzman, et al., 2016](#)). Also ensure she has an appointment for a return visit with her healthcare provider for both herself (usually in 2 to 4 weeks) and her newborn (usually 1 to 2 days).

Unless the reason for the cesarean birth was cephalopelvic disproportion, a woman can probably have her next child vaginally (see [Chapter 15](#)). Being certain the woman is aware of this not only makes her an informed consumer of health care but also can influence whether she plans an additional pregnancy. [Box 24.8](#) shows an interprofessional care map illustrating both nursing and team planning following an emergent cesarean birth.

#### **BOX 24.8**

AN INTERPROFESSIONAL CARE MAP FOR A WOMAN FOLLOWING AN EMERGENT CESAREAN BIRTH

Moja Hamma is a 29-year-old primigravida who underwent an emergent cesarean birth with epidural anesthesia for fetal distress. She gave birth to a healthy 8-lb 2-oz baby girl who breathed immediately. She tells you, "My mouth is dry and my stomach hurts so much I can't move. Don't ask me to hold or feed my baby until the pain goes away."

**Family Assessment:** Patient lives with boyfriend in a westside apartment. Works as a sales clerk in a bridal salon. Boyfriend is currently unemployed. Borrowed money from a friend for hospital bill because Moja has no health insurance.

**Patient Assessment:** Postcesarean birth 4 hours ago. Estimated blood loss of 700 ml. Abdomen soft but tender with low transverse incision. No bowel sounds present. Incisional dressing clean, dry, and intact. Fundus of uterus firm, one fingerbreadth below umbilicus. Minimal lochia rubra vaginal drainage present. Urine output 100 ml in last hour. Skin pink, warm, and dry with good skin turgor. Ringer's lactate infusing at 100 ml/hr. Intravenous site clean, dry, without signs of infiltration. Vital signs slightly elevated above baseline: temperature, 98.4°F; pulse rate, 78 beats/min; respirations, 23 breaths/min and shallow; blood pressure, 130/76 mmHg. States she has abdominal pain, especially at incisional area. Holding hands over abdomen; barely moving in bed. Patient's mother at bedside holding her hand and stroking her forehead. Patient-controlled epidural analgesia (PCEA) pump in place but not being used by patient. When asked why she wasn't using the PCEA pump, she answered, "I don't want to take the chance of being paralyzed forever."

**Nursing Diagnosis:** Pain related to tissue trauma from abdominal incision of cesarean birth

**Outcome Criteria:** Patient identifies pain management measure of choice; reports a decrease in pain with analgesic administration; pulse, respirations, and blood pressure return to baseline.

Patient holds infant warmly, maintains eye contact with infant, and makes positive statements about the newborn prior to discharge.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>

<i>Patient-Centered Care</i>				
Nurse/pain management team	Assess patient's expectations of pain relief measures and safety of PCEA administration.	Review PCEA pump and technique with patient.	Patient cannot have realistic expectations or feel safe with system unless she understands the technique.	Patient states she will use PCEA pump on trial basis for 4 hours. Reevaluate pain relief at that time.
<i>Psychosocial/Spiritual/Emotional Needs</i>				
Nurse	Assess what additional measures patient needs to feel secure after frightening experience of emergent cesarean birth.	Provide reinforcement for positive coping mechanisms that patient demonstrates.	Positive reinforcement enhances self-esteem and control. Praise promotes self-esteem and confidence to manage new situations.	Patient states she feels healthcare providers are providing her support equal to her level of pain and fatigue.
Nurse	Assess patient's expectations of a newborn.	Praise patient for positive behaviors and interactions with the child in light of pain and fatigue level. Encourage patient to keep newborn in the room with her for extended periods as she is able.	Extended contact within the patient's ability to tolerate the activity encourages bonding while minimizing the risk of additional fatigue.	Patient keeps newborn with her in room for the majority of daylight hours. Feeds and interacts actively with child.
<i>Informatics for Seamless Healthcare Planning</i>				
Nurse	Assess the level	Review with	Ambulation and	Patient states

	of support patient will have after she returns home.	patient importance of maintaining a level of pain relief at home so she can ambulate and care for new child.	child care are important for both maternal and child health. Keeping pain to a minimum helps the patient achieve these activities.	she will take enough pain relief at home to allow her to be active and care for newborn. Names at least one person who will serve as her support person
Nurse	Assess whether patient understands signs and symptoms, such as pain on urination, she will need to report after discharge.	Teach signs of all complications she should report to her primary healthcare provider.	Knowing signs and symptoms of complications allows patient to be an informed healthcare consumer.	Patient repeats danger signs she will report to her primary healthcare provider.

### What If . . . 24.4

**The nurse is interested in exploring one of the 2020 National Health Goals related to cesarean birth (see Box 24.1). Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore, pertinent to these goals, that would be applicable to Moja and her family and that would also advance evidence-based practice?**

## KEY POINTS FOR REVIEW

- The term *cesarean birth* is preferred to *cesarean section* or *delivery* because it puts the focus on the childbirth rather than surgical elements of the procedure.
- Cesarean birth may be either a scheduled or an emergent procedure. Because it carries more risk for the woman and infant than does vaginal birth, it is usually undertaken only when medically necessary, although a current trend allows for elective procedures.
- The skin incision may be vertical (i.e., a classic incision), although it is usually a horizontal one just above the pubic hair. The internal incision into the uterus is also usually a horizontal incision into the lower uterine segment.
- Establishing surgical risk, including an assessment of nutritional status, age, general health, fluid and electrolyte balance, and psychological condition, not only meets

QSEN competencies for safety but also best meets a woman's total needs.

- Assessment measures before surgery usually include vital sign determination; urinalysis; blood studies such as complete blood count, electrolytes, blood typing, and cross-matching; and ultrasound.
- Support people can lose a great deal of their ability to support if they feel intimidated, overwhelmed, and out of place in an OR; offer them support as needed to make this a positive experience for them as well.
- Cesarean birth is one of the safest types of surgery performed. To keep a woman safe after the procedure, remember that she is both a postsurgical and a postpartum patient. Make assessments to ensure that neither postpartum nor postsurgical complications occur.
- Adequate pain management is important to allow a woman a sense of control and comfort and bonding with her newborn.
- Women are physically exhausted after cesarean birth and may be psychologically exhausted because of the emergent nature of the experience. Provide rest time to relieve the physical strain and a chance to verbalize the experience to help relieve the psychological strain.
- A major intervention after cesarean birth is early ambulation to prevent complications. Incisional pain may make this difficult, so strong nursing support and adequate pain management are necessary.
- The old saying, "Once a cesarean, always a cesarean," is no longer true as long as cephalopelvic disproportion does not exist and the previous incision was a low transverse one.

### CRITICAL THINKING CARE STUDY

Amy Whithaven is a 38-year-old gravida 4, para 3, who wants to have her fourth child as naturally as possible, the same as she did for her other three children. Her husband, Paul, the chief executive of a public relations firm, is with her in a birthing room as her support person. He assures you Amy is a "veteran" at labor, will use controlled breathing as pain management, and will have no problems. He adds they are especially looking forward to this baby because she will be their first girl. Four hours into labor, Amy experiences sharp abdominal pain and begins to have fresh vaginal bleeding. Amy's blood pressure falls to 100/55 mmHg; the FHR decreases to 80 beats/min. Amy's obstetrician diagnoses placental abruption and asks you to prepare her for an emergent cesarean birth.

1. Because having a cesarean birth is so opposite from what the couple planned for labor, Paul says he wants to investigate Amy's symptoms on the Internet using his laptop or else secure a second opinion from another doctor before surgery can proceed. Would you support him in asking for this?
2. Amy realizes immediately that something is wrong. She asks you if this has something to do with the fact she is having her first girl. Are more girl infants

born by cesarean than male infants?

3. Amy is transported to surgery and, within 20 minutes, a 7-lb 3-oz girl is born. Named Honor, she needs resuscitation to breathe and is transferred immediately afterward to the neonatal intensive care nursery for care. Paul declines to visit Honor in the nursery. He says he'll wait until Amy can be "disappointed" along with him. What actions could you take to help this couple begin bonding with their new daughter?

## Nursing Care of a Family Experiencing a Postpartum Complication

*Bailey Cheshire is a 26-year-old woman who teaches chemistry at a local university. You enter her room 2 hours after she gave birth to an 8-lb girl and find her just finishing breastfeeding. Her face appears abnormally pale. You obtain her vital signs and document her pulse as 90 beats/min and her blood pressure as 90/50 mmHg. When you fold back her bedclothes, you discover her perineal pad is saturated. The capillary refill in her fingers is sluggish. You suspect she is experiencing one of the most serious complications of pregnancy: postpartum hemorrhage.*

*Previous chapters discussed the nursing care for a woman during the typical postpartum period. This chapter contributes information about how to care for a woman and her family when there is a deviation from normal. Comprehensive and recurring nursing care is essential when a postpartum complication develops because it can provide an early alert to conditions that can impact the health of not only the woman but also her child and family.*

**What immediate measures does Ms. Cheshire need? What would be your first action?**

### KEY TERMS

**endometritis**

**mastitis**

**peritonitis**

**postpartum depression**

**postpartal psychosis**

**puerperal infection**

**subinvolution**

**thrombophlebitis**

**uterine atony**

**uterine inversion**

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe a woman at risk for common deviations from the normal that can occur during the puerperium.
2. Identify 2020 National Health Goals related to deviations from the normal in the postpartal period that nurses can help the nation achieve.
3. Assess a woman and her family for deviations from the normal during the puerperium.
4. Formulate nursing diagnoses related to postpartum complications.
5. Establish expected outcomes for a woman and her family experiencing a postpartum complication.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement evidence-based nursing care when a woman and her family experience a postpartum complication.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of postpartum complications with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

---

Although the puerperium is usually a period of health, complications can occur. It's important to be knowledgeable about predisposing factors and clinical manifestations of postpartum complications to ensure the prompt initiation of corrective measures in order to prevent long-term consequences to a woman and her family ([Guntupalli, Karnad, Bandi, et al., 2015](#)).

Postpartum complications are always potentially serious because they can impact so many people. A complication may be so serious it could cause a personal injury, leave a woman with her future fertility impaired, or even result in death. Any complication that affects the health of the mother can also affect her interactions with her newborn, such as causing her to discontinue breastfeeding ([Odom, Li, Scanlon, et al., 2013](#)). Her family can be disrupted because of an extended hospital stay or from an impairment that prevents her from performing her normal family responsibilities. Financial difficulties may arise because of her inability to maintain employment and the need for additional child and health care. Fortunately, most postpartum complications are preventable, and if they do occur, the majority can be treated effectively without long-term complications. Because the health of women and newborns is so important to a nation's health, [Box 25.1](#) describes 2020 National Health Goals that speak to possible

puerperium complications ([Andrighetti, 2013](#)).

## BOX 25.1

### Nursing Care Planning Based on 2020 National Health Goals

The postpartal period is a time when women are very susceptible to hemorrhage and thrombophlebitis and, when these complications develop, women may choose not to breastfeed because of them. The 2020 National Health Goals that speak to this include:

- Reduce the maternal mortality rate to no more than 11.4 per 100,000 live births from a baseline of 12.7 per 100,000.
- Increase the proportion of infants who are breastfed to at least 81.9% from a baseline of 74%.
- Increase the proportion of infants who are breastfed at 6 months from a baseline of 43.5% to 60.6% ([U.S. Department of Health and Human Services, 2010](#); see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by carefully monitoring uterine involution in the postpartal period and by encouraging women to breastfeed even in the face of a postpartal complication.

### *Nursing Process Overview*

#### FOR A WOMAN EXPERIENCING A POSTPARTUM COMPLICATION ASSESSMENT

Women who assume they will immediately return to an active lifestyle after birth of their child may view an extended hospitalization for a postpartum complication as more unsettling than women who view the postpartum period as one in which they are expected to rest. Assess each woman holistically, therefore, to determine how the health problem a woman is experiencing is impacting her and her family.

Assessment findings associated with a postpartum complication may be subtle, such as tenderness in the calf of a leg, an increase in uterine or perineal pain, a slight elevation in temperature, or a small increase in the amount of lochia flow ([Box 25.2](#)). Because the average woman usually has no postpartum complications and the length of stay in the hospital is short, it is easy to overlook these subtle signs, but it is important to be alert to any findings that are unusual because they may be the beginning of a serious concern. To be certain, do not rely solely on a woman's report of perineal healing or amount of lochia; always inspect her perineum and lochia yourself because the report of "I feel fine" or "my bleeding was just a small amount" may be deceptive if she has no familiarity with "normal" lochia, perineal healing, or fundal height against which to accurately compare her own condition.

#### BOX 25.2

## ASSESSING THE POSTPARTAL WOMAN WITH COMPLICATIONS

An increased temperature except during the first 24 hours after birth is a potentially extremely serious finding. Women may try to “explain away” an increased temperature because they know if they have an elevated temperature, they may need to stay longer in the hospital for treatment of an infection. Do not be tempted to rationalize such a finding with explanations such as, “The room was warm,” or “She just drank some hot coffee.” Although these factors may make a slight difference in body temperature, they do not affect it enough to account for an oral temperature greater than 100.4°F (38.0°C).

### NURSING DIAGNOSIS

Nursing diagnoses during this time vary depending on the postpartal complication. Some examples include:

- Deficient fluid volume related to blood loss
- Ineffective breastfeeding related to the development of mastitis

- Risk for impaired parenting related to postpartum depression
- Risk for injury to self and newborn related to postpartal psychosis
- Acute pain related to a collection of blood in traumatized tissue (hematoma) secondary to birth trauma
- Situational low self-esteem related to inability to perform regular tasks
- Social isolation related to precautions necessary to protect infant and others from infection transmission
- Ineffective peripheral tissue perfusion related to interference with circulation secondary to development of thrombophlebitis (blood clot)
- Risk for infection related to microorganism invasion of episiotomy, surgical incision site, or migration of microorganisms from the vagina to the uterus

## **OUTCOME IDENTIFICATION AND PLANNING**

Outcome identification for a woman with a postpartum complication may be particularly difficult, because although a woman wants to do everything necessary to return to health, she also does not want anything to interfere with her ability to bond with and take care of her new child. As a rule, however, never underestimate how much a woman will endure to enable herself to “mother” her new child. This ability of a mother to overcome challenges to meet her child’s needs is the essence of motherhood.

When planning care for a postpartum family, provide for measures that will restore the woman most quickly to health and promote contact among her, her child, and her primary support person. If physical contact between a mother and her newborn is not possible, give the mother frequent reports of her infant’s condition and include her in planning care for her newborn. During her taking-in phase, ask the nursery staff to contact the mother at least once every nursing shift to update her on her infant’s status; during her taking-hold phase, encourage her to contact the nursery. If the infant is being cared for in another facility, ask them to provide photographs of the infant. This provides something tangible to which a new mother can connect with her newborn. Many women respond well to notes written as if they were from her child, for example, “Hi, Mom. I’m drinking well but I miss you and can’t wait for you to get better and take care of me. Love, Kelsey.” Such a note serves to lessen a woman’s concern for her child (because she is doing well) and also helps to promote mother–infant attachment. Because childbirth is generally seen as a happy time, being faced with a postpartal complication can cause a great deal of emotional stress. The risk of both postpartal depression and postpartal psychosis increases when a complication develops. Refer patients to helpful websites and other resources when appropriate (see [Chapter 20](#)).

## **IMPLEMENTATION**

Interventions for a woman with a postpartum complication should include instruction for both self-care and child care (if appropriate) because continuing to review these measures helps a woman accept her situation as temporary, thus reinforcing the idea

she will be able to care for herself and her infant when she is healthy again.

### OUTCOME EVALUATION

An evaluation of a woman with a postpartal complication should address both her and her family's health as well as her family's ability to integrate the new child into the family. The evaluation may suggest the need for home care follow-up to assist a woman in coping with both old and new responsibilities in the face of reduced energy from an illness.

Examples of expected outcomes include:

- Lochia is free of foul odor.
- Fundus remains firm and midline with progressive descent.
- Patient maintains a urinary output greater than 30 ml/hr.
- Lochia discharge amount is 6 in. or less on a perineal pad in 1 hour.
- Patient maintains vital signs and oxygen saturation within defined normal limits.
- Patient identifies signs and symptoms that should be reported.
- Patient demonstrates attachment behaviors with infant despite separation or activity restrictions.

## Postpartum Hemorrhages

Hemorrhage, one of the primary causes of maternal mortality associated with childbearing, is a major threat during pregnancy, throughout labor, and continuing into the postpartum period. Traditionally, postpartum hemorrhage is defined as blood loss of 500 ml or more following a vaginal birth; this occurs in as many as 5% to 15% of postpartal women (Dahlke, Menez-Figueroa, Maggio, et al., 2015). With a cesarean birth, hemorrhage is present when there is a 1,000-ml blood loss or a 10% decrease in the hematocrit level (Pratts & Henderson, 2015). Although hemorrhage may occur either early (within the first 24 hours following birth) or late (from 24 hours to 6 weeks after birth), the greatest danger is in the first 24 hours because of the grossly denuded and unprotected uterine area left after detachment of the placenta.

The four main reasons for postpartum hemorrhage are uterine atony, trauma (lacerations, hematomas, uterine inversion, or uterine rupture), retained placental fragments, and the development of disseminated intravascular coagulation (DIC). These causes are generally referred to as the *four T's* of postpartum hemorrhage: tone, trauma, tissue, and thrombin—a common mnemonic for the etiology of hemorrhage experienced in the puerperium (Fig. 25.1).

**Figure 25.1** The common causes of postpartal hemorrhage.

## UTERINE ATONY

**Uterine atony**, or relaxation of the uterus, is the most frequent cause of postpartum hemorrhage; it tends to occur most often in Asian, Hispanic, and Black woman (Grobman, Bailit, Rice, et al., 2015). Factors that predispose a woman to poor uterine tone or the inability of her uterus to maintain a contracted state are summarized in [Box 25.3](#). When caring for a woman in whom any of these conditions are present, be especially conscientious in your observations and be on guard for signs of uterine bleeding.

### BOX 25.3

#### Conditions That Increase a Woman's Risk for a Postpartal Hemorrhage

Conditions that distend the uterus beyond average capacity	Multiple gestation Polyhydramnios (excessive amount of amniotic fluid) A large baby (>9 lb) The presence of uterine myomas (fibroid tumors)
Conditions that could have caused cervical or uterine lacerations	An operative birth A rapid birth
Conditions with varied placental site or	Placenta previa

attachment	Placenta accreta Premature separation of the placenta Retained placental fragments
Conditions that leave the uterus unable to contract readily	Deep anesthesia or analgesia Labor initiated or assisted with an oxytocin agent High parity or maternal age over 35 years of age Previous uterine surgery Prolonged and difficult labor Chorioamnionitis or endometritis Secondary maternal illness such as anemia Prior history of postpartum hemorrhage Prolonged use of magnesium sulfate or other tocolytic therapy
Conditions that lead to inadequate blood coagulation	Fetal death Disseminated intravascular coagulation (DIC)

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Deficient fluid volume related to excessive blood loss after birth.

**Outcome Evaluation:** Patient's blood pressure and heart rate remains within usual defined limits; lochia flow is less than one saturated perineal pad per hour.

If the uterus suddenly relaxes, there will be an abrupt gush of blood vaginally from the placental site. This can occur immediately after birth but is more likely to occur gradually, over the first postpartum hour, as the uterus slowly loses its tone. If the loss of blood is extremely copious, a woman will quickly begin to exhibit symptoms of hypovolemic shock such as a falling blood pressure; a rapid, weak, or thready pulse; increased and shallow respirations; pale, clammy skin; and increasing anxiety. If the blood loss is unnoticed seepage, there is little change in pulse and blood pressure at first because of circulatory compensation. Suddenly, however, the system is able to compensate no more, and the pulse rate rises rapidly and becomes weak. Blood pressure then drops abruptly. With slow bleeding, a woman develops these symptoms over a period of hours; the end result of continued seepage, however, can be as life threatening as a sudden profuse loss of blood ([Andrighetti, 2013](#)).

It is difficult to estimate the amount of blood a postpartal woman is losing because it is difficult to estimate the amount of blood it takes to saturate a perineal pad (between 25 and 50 ml). By counting the number of perineal pads saturated in given lengths of time, such as half-hour intervals, a rough estimate of the amount of blood loss can be formed. Five pads saturated in half an hour is obviously a different situation from five pads saturated in 8 hours. In either situation, however, a woman will have lost approximately 250 ml of blood, and if either scenario is allowed to continue unattended, she will be in grave danger of hypovolemia. Be certain that when you are counting perineal pads, you differentiate between *saturated* and *used*. Weighing perineal pads before and after use and then subtracting the difference is an accurate technique to measure vaginal discharge: 1 g of weight is comparable to 1 ml of blood volume, so if a pad weights 50 g more after use, the woman has lost 50 ml of blood. Always be sure to turn a woman on her side when inspecting for blood loss to be certain a large amount of blood is not pooling undetected beneath her.

The best safeguard against uterine atony is to palpate a woman's fundus at frequent intervals to be assured her uterus is remaining contracted. Under usual circumstances, a well-contracted uterus feels firm and is easily recognized because it feels like no other abdominal organ. If you are unsure whether you have located a woman's fundus on palpation, it means the uterus is probably in a state of relaxation. Frequent assessments of lochia (to be certain the amount of the flow is under a saturated pad per hour and that any clots are small), as well as vital signs, particularly pulse and blood pressure, are equally important determinations.

## Therapeutic Management

In the event of uterine atony, the first step in controlling hemorrhage is to attempt fundal massage to encourage contraction (Box 25.4). Unless the uterus is extremely lacking in tone, this procedure is usually effective in causing contraction, and, after a few seconds, the uterus assumes its healthy, grapefruit-like feel (World Health Organization [WHO], 2015).

### BOX 25.4

#### Nursing Care Planning Using Procedures

##### FUNDAL MASSAGE

**Purpose:** Helping a woman obtain a clean-catch urine specimen

Procedure	Principle
1. Explain the necessity for the procedure and provide privacy.	1. Explanations help to decrease anxiety, and providing privacy enhances self-esteem.
2. Ask patient to void (unless bleeding is	2. An empty bladder prevents

extensive and more rapid action seems necessary). Ask her to lie supine with knees flexed.

3. Put on gloves. Place one hand on the abdomen just above the symphysis pubis. Place the other hand around the top of the fundus (Fig. A).

4. Rotate the upper hand to massage the uterus until it is firm, being careful not to overmassage (Fig. B).

displacement of the uterus and ensures accurate assessment of uterine tone. Proper positioning enhances visualization and effectiveness of procedure.

3. This anchors the lower uterine segment and allows you to locate and assess the fundus.

4. Massage should be done only when the uterus is not firm, and aggressive massage may lead to a partial or complete uterine prolapse.

- |  |   |
|--|---|
| <p>5. When the uterus is firm, press the fundus between the hands using slight downward pressure against the lower hand.</p> <p>6. Remove and observe the woman's perineum for the passage of clots and the amount of bleeding.</p> <p>7. Massage the uterus one more time to be certain it remains firm, cleanse the perineum, and apply a clean perineal pad. Discard gloves and soiled pads according to agency policy.</p> <p>8. Document the results of the procedure. Continue to assess the fundus and lochia according to agency policy. Notify the primary care provider if the fundus does not remain firm or if bleeding continues.</p> | <p>5. Gently squeezing with downward pressure helps to expel blood or clots collected in the uterine cavity.</p> <p>6. This helps to assess the degree of bleeding.</p> <p>7. This helps to promote comfort and hygiene while reducing the risk for infection.</p> <p>8. Documentation provides a means for evaluation. Continued assessment allows for early identification and prompt intervention with additional measures, such as oxytocin, to prevent hemorrhage.</p> |
|--|---|

With uterine atony, even if the uterus responds well to massage, the problem may not be completely resolved because, as soon as you remove your hand from the fundus, the uterus may relax and the lethal seepage will begin again. To prevent this, remain with a woman after massaging her fundus and assess to be certain her uterus is not relaxing again. Continue to assess carefully for the next 4 hours.

If a woman's uterus does not remain contracted, contact her primary care provider so interventions to increase contraction such as administering a bolus or a dilute intravenous infusion of oxytocin (Pitocin) can be prescribed to help the uterus maintain tone (Lang, Zhao, & Robertson, 2015).

When oxytocin is given intravenously (IV), its action on the uterus is immediate. Be aware, however, that oxytocin has a short duration of action, approximately 1 hour, so symptoms of uterine atony can recur quickly if it is administered only as a single dose (see Chapter 23, Box 23.3 for cautions to be aware of with an oxytocin infusion).

If oxytocin is not effective at maintaining tone, carboprost tromethamine (Hemabate), a prostaglandin F<sub>2a</sub> derivative, or methylergonovine maleate (Methergine), an ergot compound, both given intramuscularly, are second possibilities. Misoprostol (Cytotec), a prostaglandin E<sub>1</sub> analogue, may also be administered rectally to decrease postpartum hemorrhage. Carboprost tromethamine may be repeated every 15 to 90 minutes up to 8 doses; methylergonovine maleate may be repeated every 2 to 4 hours up to 5 doses. A second dose of misoprostol should not be administered unless a minimum of 2 hours has elapsed. It's important to check that all of these drugs are readily available for use on a hospital unit in the event of postpartum hemorrhage. Because prostaglandins tend to cause diarrhea and nausea as side effect, assess for this after administration; some women will need to be administered an antiemetic to limit these side effects (Bateman, Tsen, Liu, et al., 2014).

Be aware that all of these medications can increase blood pressure and so must be used cautiously in women with hypertension. Assess blood pressure prior to administration and about 15 minutes afterward to detect this potentially dangerous side effect.

Additional measures that can be helpful to combat uterine atony include:

- Elevate the woman's lower extremities to improve circulation to essential organs.
- Offer a bedpan or assist the woman to the bathroom at least every 4 hours to be certain her bladder is emptying because a full bladder predisposes a woman to uterine atony. To reduce the possibility of bladder pressure, insertion of a urinary catheter may be prescribed.
- Administer oxygen by face mask at a rate of about 10 to 12 L/min if the woman is experiencing respiratory distress from decreasing blood volume. Position her supine (flat) to allow adequate blood flow to her brain and kidneys.
- Obtain vital signs frequently and assess them for trends such as a continually decreasing blood pressure with a continuously rising pulse rate.

When planning continuing care after sudden blood loss, remember that a woman may be so exhausted from labor and the effect of the blood loss that she resents frequent uterine and blood pressure assessments. Explain that you realize these measures are disturbing, but that they are important for her welfare. Obtain measurements as quickly and gently as possible to cause a minimum of discomfort and disruption, allowing the woman time to rest.

## Bimanual Compression

If fundal massage and administration of uterotonics (drugs to contract the uterus) are not effective at stopping uterine bleeding, a sonogram may be done to detect possible retained placental fragments. The woman's primary care provider may attempt bimanual compression (Weeks & Mallaiah, 2016). With this procedure, the primary care provider inserts one hand into a woman's vagina while pushing against the fundus through the abdominal wall with the other hand. If this is ineffective, the woman may be

returned to the birthing room, so that her uterine cavity can be explored manually. Under sonogram visualization, a balloon catheter may be introduced vaginally and inflated with sterile water until it puts pressure against the bleeding site. Vaginal packing is inserted during this procedure to stabilize the placement of the balloon. Be certain to document the presence of the packing so it can be removed before agency discharge because retained packing serves as a growth medium for microorganisms that could lead to postpartal infection ([Vintejou, Ulrich, Mousty, et al., 2015](#)).

## Blood Replacement

Blood transfusion to replace blood loss with postpartal hemorrhage is often necessary. In most agencies, blood typing and cross-matching is done when a woman is admitted to the labor service so blood can be rapidly cross-matched.

Under usual circumstances, the average woman takes the full postpartal period to regain her strength. Women who experience postpartal hemorrhage tend to have an even longer recovery period, because the physiologic exhaustion of body systems can interfere with recovery. Iron therapy may be prescribed to ensure good hemoglobin formation. Activity level, exertion, and postpartal exercise may be somewhat restricted. Discuss with the woman the possibility of having someone stay with her at home, at least for the first week, to help with the care of her newborn and to prevent exhaustion so childbearing doesn't turn into a less than satisfying event.

Extensive blood loss is one of the precursors of postpartal infection because of the general debilitation that results. Therefore, observe any woman who has experienced more than a normal loss of blood for changes such as scant or odorous lochia discharge. Monitor her temperature closely in the postpartal period to detect the earliest signs of developing infection. Make certain the woman knows how to assess for normal lochia and temperature once she is discharged.

## Hysterectomy or Suturing

Usually, uterine massage and administration of a drug to contract the uterus (uterotonic) are effective to halt bleeding. With extreme bleeding, embolization of pelvic and uterine vessels by angiographic techniques may be necessary. As a last resort, ligation of the uterine arteries or a hysterectomy (removal of the uterus) may be necessary ([Ghosh & Mala, 2015](#)). In this totally unexpected outcome of childbearing, provide comfort and support to both the woman and her support person.

After a hysterectomy, a woman usually wants to talk about what happened, why surgery was necessary, or how she feels now that she can no longer bear children so she can sort through her feelings of "Why me?" She may reveal ambivalent feelings: She wanted to have more children (or at least have the ability to have more), but she is also grateful to be alive. She is both thankful her life has been saved, but she may also feel resentful you couldn't have done more to protect her future childbearing. She may grieve for children who will not be born. If her child was born outside the hospital

(although postpartum hemorrhage is lower during home births than hospital births), she may have a need to talk about her choice of location for childbirth and that she did not choose a higher resource setting for childbirth (Zielinski, Ackerson, & Kane Low, 2015).

Open lines of communication between the couple and healthcare providers that allow a family to vent their feelings are most helpful to a couple in this crisis. Referral to a grief counselor may be necessary because grieving for future children who will not be born can interfere with bonding with the present child.

### ***QSEN Checkpoint Question 25.1***

#### **INFORMATICS**

All postpartum women are at risk for uterine hemorrhage. What assessment data should the nurse first collect when appraising Ms. Cheshire's risk for hemorrhage?

- a. Ask her to describe her perineal care.
- b. Assess the skin integrity of her abdomen.
- c. Assess her oxygen saturation level.
- d. Assess her uterus for height and tone.

*Look in Appendix A for the best answer and rationale.*

## **LACERATIONS**

Small lacerations or tears of the birth canal are common and may be considered a normal consequence of childbearing. Large lacerations, however, can be sources of infection or hemorrhage. They occur most often:

- With difficult or precipitate births
- In primigravidas
- With the birth of a large infant (>9 lb)
- With the use of a lithotomy position and instruments (e.g., forceps, vacuum extraction)

Lacerations may occur in the cervix, the vagina, or the perineum. After birth, anytime a uterus feels firm but bleeding persists, suspect a laceration at one of these three sites is causing the bleeding.

### **Cervical Lacerations**

Lacerations of the cervix are usually found on the sides of the cervix, near the branches of the uterine artery. If the artery is torn, the blood loss may be so great that blood gushes from the vaginal opening. Because this is arterial bleeding, it is a brighter red than the venous blood lost with uterine atony. Fortunately, this bleeding ordinarily occurs immediately after detachment of the placenta, when the primary care provider is still in attendance.

## Therapeutic Management

The repair of a cervical laceration usually requires sutures and can be difficult because, if the bleeding is intense, this obstructs visualization of the area. A woman is not always aware of what is happening at this point, but she quickly senses something is seriously wrong. Try to maintain an air of calm and, if possible, stand beside the woman at the head of the table. She may be worried that the extra activity in the room has something to do with her baby. Assure her of her baby's condition and inform her about the need to stay in the birthing room a little longer than expected while the primary care provider places sutures or packing. Remember, the protective attitude a woman has felt toward her body all during pregnancy now turns toward her baby, so she usually is relieved to learn any problem that may be occurring is hers, not her infant's.

If the cervical laceration appears to be extensive or difficult to repair, it may be necessary for the woman to be given a regional anesthetic to relax the uterine muscle and to prevent pain. Explain the need for an anesthetic and the procedures being carried out. Be certain the primary care provider has adequate space to work, adequate sponges and suture supplies, and a good light source.

## Vaginal Lacerations

Vaginal lacerations are easier to locate and assess than cervical lacerations because they are so much easier to view.

## Therapeutic Management

Unfortunately, vaginal tissue is friable, making vaginal lacerations difficult to suture. A balloon tapenade similar to the type used with a uterine hemorrhage may be effective if suturing does not achieve hemostasis (Atilgan, Ozkan, Orak, et al., 2014). Some oozing often occurs after a vaginal repair, so the vagina may be packed to maintain pressure on the suture line. An indwelling urinary catheter (Foley catheter) may be placed following the repair because the packing causes such pressure on the urethra that it can interfere with voiding. Be certain to document in the woman's electronic record when and where packing was placed so you can be certain it is removed after 24 to 48 hours or before hospital discharge to prevent infection.

## Perineal Lacerations

Lacerations of the perineum are more apt to occur when a woman is placed in a lithotomy position for birth rather than a supine position because a lithotomy position increases tension on the perineum. Perineal lacerations are classified by four categories, depending on the extent and depth of the tissue involved. These categories are shown in Table 25.1.

**TABLE 25.1 CLASSIFICATION OF PERINEAL LACERATIONS**

Classification	Description of Involvement
----------------	----------------------------

First degree	Vaginal mucous membrane and skin of the perineum to the fourchette
Second degree	Vagina, perineal skin, fascia, levator ani muscle, and perineal body
Third degree	Entire perineum, extending to reach the external sphincter of the rectum
Fourth degree	Entire perineum, rectal sphincter, and some of the mucous membrane of the rectum

## Therapeutic Management

Perineal lacerations are sutured and treated the same as an episiotomy repair. Make certain the degree of the laceration is documented because women with fourth-degree lacerations need extra precautions to avoid having sutures loosened or infected. Both sutured lacerations and episiotomy incisions tend to heal in the same length of time. A diet high in fluid and a stool softener may be prescribed for the first week after birth to prevent constipation and hard stools, which could break the new sutures. Any woman who has a third- or fourth-degree laceration should not have an enema or a rectal suppository prescribed or have her temperature taken rectally because the hard tips of equipment could open sutures near to or including those of the rectal sphincter. Although fourth-degree lacerations can lead to long-term dyspareunia, rectal incontinence, or sexual dissatisfaction, they usually heal without further complications.

## RETAINED PLACENTAL FRAGMENTS

Occasionally, a placenta does not detach in its entirety; fragments of it separate and are left still attached to the uterus. Because the portion retained keeps the uterus from contracting fully, uterine bleeding occurs. Although this is most likely to happen with a succenturiate placenta—a placenta with an accessory lobe (see [Chapter 23](#))—it can happen in any instance. Placenta accreta—a placenta that fuses with the myometrium because of an abnormal decidua basalis layer—may also be retained. This is associated with previous cesarean birth and in vitro fertilization and occurs at an incidence of about 1 out of 3,000 births; it can be identified by an ultrasound exam during pregnancy. Removing such a deeply embedded placenta can lead to severe postpartal hemorrhage ([Silver, 2015](#)). To identify the complication of a retained placenta, every placenta should be inspected carefully after birth to be certain it is complete. Retained placental fragments may also be detected by ultrasound. A blood serum sample that contains human chorionic gonadotropin (hCG) hormone also reveals that part of a placenta is still present.

## Assessment

If an undetected retained fragment is large, bleeding will be apparent in the immediate postpartal period because the uterus cannot contract with the fragment in place. If the fragment is small, bleeding may not be detected until postpartum day 6 to 10, when the

woman notices an abrupt discharge and a large amount of vaginal bleeding. On examination, usually the uterus is found to not be fully contracted.

### Therapeutic Management

Removal of the retained placental fragment is necessary to stop the bleeding and can usually be accomplished by a dilatation and curettage (D&C). If it cannot be removed, methotrexate may be prescribed to destroy the retained fragment. Because the hemorrhage from retained fragments may be delayed until after a woman is at home, be certain women know to continue to observe the color of lochia and to report any tendency for the discharge to change from lochia serosa or alba back to rubra. In some instances, placenta accreta is so deeply attached that balloon occlusion and embolization of the internal iliac arteries may be necessary to minimize blood loss. In others, a hysterectomy must be performed (Silver, 2015).

### QSEN Checkpoint Question 25.2

#### TEAMWORK & COLLABORATION

Suppose Bailey Cheshire has a retained placental fragment that is causing extensive postpartal bleeding. Which test prescribed by her primary care provider would best reveal a retained fragment is present?

- a. Placental and cord blood estrogen
- b. Progesterone
- c. Human chorionic gonadotropin hormone
- d. Oxytocin

*Look in Appendix A for the best answer and rationale.*

### UTERINE INVERSION

**Uterine inversion** is a prolapse of the fundus of the uterus through the cervix so that the uterus turns inside out. This usually occurs immediately after birth and so is discussed in [Chapter 23](#).

### DISSEMINATED INTRAVASCULAR COAGULATION

DIC is a deficiency in clotting ability caused by vascular injury. It may occur in any woman in the postpartal period, but it is usually associated with premature separation of the placenta, a missed early miscarriage, or fetal death in utero. DIC is discussed in [Chapter 21](#) along with these disorders.

### SUBINVOLUTION

**Subinvolution** is the incomplete return of the uterus to its prepregnant size and shape. With subinvolution, at a 4- or 6-week postpartal visit, the uterus is still enlarged and soft. Lochial discharge usually is still present. Subinvolution may result from a small

retained placental fragment, a mild endometritis (infection of the endometrium), or an accompanying problem such as a uterine myoma that is interfering with complete contraction.

## Therapeutic Management

Oral administration of methylergonovine, 0.2 mg four times daily, is the usual prescription to improve uterine tone and complete involution. If the uterus feels tender to palpation, suggesting endometritis is present, an oral antibiotic also will be prescribed. Being certain women are able to recognize the normal process of involution and lochia discharge before hospital discharge helps women to be able to identify subinvolution and seek early care if it occurs. A chronic loss of blood from subinvolution will result in anemia and a lack of energy, conditions that possibly could interfere with infant bonding or lead to infection.

### *What If... 25.1*

**Bailey Cheshire tells the nurse she has a PhD in chemistry. She says that based on her background, she knows she is having a normal amount of lochia flow, so there is no need for the nurse to assess her perineum or perineal pad. Would the nurse respect her privacy or would insist the need to assess the amount of her lochia flow?**

## PERINEAL HEMATOMAS

A perineal hematoma is a collection of blood in the subcutaneous layer of tissue of the perineum. The overlying skin, as a rule, is intact with no noticeable trauma. Blood accumulates underneath, however, from injury to blood vessels in the perineum during birth. Hematomas are most likely to occur after rapid, spontaneous births and in women who have perineal varicosities. They may occur at the site of an episiotomy or laceration repair if a vein was punctured during suturing. Although these can cause a woman acute discomfort and concern, they usually represent only minor bleeding.

### Assessment

Perineal sutures almost always give a postpartal woman some discomfort. If a woman reports severe pain in the perineal area or a feeling of pressure between her legs, inspect the perineal area to see if a hematoma could be causing this. If a hematoma is present, it appears as an area of purplish discoloration with obvious swelling. It could be as small as 2 cm or as large as 8 cm in diameter (Fig. 25.2). At first it may feel fluctuant, but as seepage into the area continues and tissue is drawn taut, it palpates as a firm globe and feels tender.

**Figure 25.2** The appearance of a perineal hematoma from a bleeding subcutaneous vessel.

### **Therapeutic Management**

Report the presence of a hematoma, its estimated size, and the degree of the woman's discomfort to her primary care provider. Describe a definite size such as "5 centimeters" or the size of a quarter or a half dollar rather than documenting it as "large" or "small" as this best establishes a baseline and will enable you to assess if it is growing larger.

Administer a mild analgesic as prescribed for pain relief. Applying an ice pack (covered with a towel to prevent thermal injury to the skin) may prevent further bleeding. Usually, a hematoma is absorbed over the next 3 or 4 days. If one is large when discovered or continues to increase in size, the woman may have to be returned to the birthing room to have the site incised and the bleeding vessel ligated under local anesthesia.

You can assure the woman that even though the hematoma is causing her considerable discomfort, it is not a serious complication and will slowly reabsorb over the next 6 weeks, causing no further difficulty. If an episiotomy incision line was opened to drain a hematoma, it may be left open and packed with gauze rather than resutured. Be certain to record this packing was placed so it can be removed in 24 to 48 hours. A suture line opened this way heals by tertiary intention or from the bottom to the top, rather than side to side, so healing will occur more slowly than a usual primary intention suture line. Be certain the woman has clear instructions before discharge regarding necessary suture line care she will need to do at home, such as keeping it clean and dry and perhaps using a sitz bath once or twice a day.

### **Puerperal Infections**

Infection of the reproductive tract in the postpartal period is another major cause of

maternal mortality (Galvão, Braga, Gonçalves, et al., 2016). Factors that predispose women to infection during this time are shown in Box 25.5. When caring for a woman who has any of these circumstances, be aware that the risk for postpartal infection is greatly increased.

### BOX 25.5

#### Conditions That Increase a Woman's Risk for Postpartal Infection

Risk Factor	Basis for Risk
Rupture of the membranes more than 24 hours before birth	Bacteria may have started to invade the uterus while the fetus was still in utero.
Retained placental fragments within the uterus	The tissue necroses and serves as an excellent bed for bacterial growth.
Postpartal hemorrhage	The woman's general condition is weakened.
Preexisting anemia	The woman's general condition is weakened.
Prolonged and difficult labor, particularly with instrument births	Trauma to the tissue may leave lacerations or fissures for easy portals of entry for infection.
Internal fetal heart monitoring electrode	Contamination may have been introduced with placement of the scalp electrodes.
Local vaginal infection present at the time of birth	A direct spread of infection has occurred.
Uterus explored after birth for a retained placenta or abnormal bleeding site	The infection was introduced with exploration.

Theoretically, the uterus is sterile during pregnancy and up until the membranes rupture. After rupture, pathogens can begin to invade; the risk of infection grows even greater if tissue edema and trauma are present. If infection should occur, the prognosis for complete recovery depends on such factors as the woman's general health, virulence of the invading organism and portal of entry, the degree of uterine involution at the time of the invasion, and the presence of lacerations in the reproductive tract.

A **puerperal infection** is always potentially serious, because, although it usually begins as only a local infection, it has the potential to spread to the peritoneum (peritonitis) or the circulatory system (septicemia), conditions that can be fatal in a woman whose body is already stressed from childbirth.

Organisms commonly cultured postpartally include group B streptococci, staphylococci, and aerobic gram-negative bacilli such as *Escherichia coli*. The

management for puerperal infection focuses on the use of an appropriate antibiotic after culture and sensitivity testing of the isolated organism.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for infection related to loss of uterine sterility with childbirth

**Outcome Evaluation:** Patient's temperature remains below 100.4°F (38°C) orally, excluding the first 24 hours after birth; lochia is present without foul odor.

To help prevent an infection, any articles such as gloves or instruments that are introduced into the birth canal during labor, birth, and the postpartal period should be sterile. In addition, adherence to standard infection precautions is essential.

Be certain to instruct a postpartal woman in proper perineal care, including wiping from front to back so that she does not bring *E. coli* organisms forward from the rectum. Use good hand washing technique before, during, and after any patient care to prevent cross-contamination. When giving perineal care, both wash your hands and wear gloves. Each postpartal woman should have her own perineal supplies and should not share them to prevent the transfer of pathogens from one woman to another.

Intravenous antibiotics usually are prescribed for a postpartal infection. Frequently used antibiotics include ampicillin, gentamicin, and third-generation cephalosporins such as cefixime (Suprax). If the woman will be continuing drug therapy at home, stress that she must take the full course to prevent the infection from recurring. Be certain women who are breastfeeding are not prescribed antibiotics incompatible with breastfeeding. Alert them to observe for problems in their infant, such as white plaques or thrush (oral candidiasis) in their infant's mouth that can occur when a portion of the maternal antibiotic passes into breast milk and causes an overgrowth of fungal organisms (i.e., an opportunistic infection) in the infant. The infant also should be assessed for easy bruising because a decrease in microorganisms in the bowel caused by an antibiotic passed in breast milk may lead to insufficient vitamin K formation and, consequently, decreased blood-clotting ability.

**Nursing Diagnosis:** Social isolation related to precautions necessary to protect baby and others from exposure to infectious microorganisms

**Outcome Evaluation:** Patient acknowledges agency policy regarding precautions and a willingness to comply with policies. States plans for diversional activities to pass the time if separated from her newborn; demonstrates bonding behaviors, such as asking about newborn and expressing desire to see infant.

Healthcare agencies have well-defined guidelines on whether a woman who has an

infection should be separated from other women or her newborn. As a general rule, the baby of a mother with an increased temperature (100.4°F [38°C]) for two consecutive 24-hour periods exclusive of the first 24 hours is kept in a closed incubator in her room until the cause of the infection is determined because she may have an upper respiratory or gastrointestinal tract infection unrelated to childbearing that is transmittable to a newborn.

If the cause of the fever is found to be related to childbirth but involves a closed infection, such as thrombophlebitis, there is no danger of the baby contracting the disease, so the woman may care for her child as long as she maintains the degree of prescribed bed rest necessary for her primary condition. If the infection involves drainage such as can occur with endometritis or a perineal abscess, the mother should wash her hands thoroughly before holding her infant and avoid placing her baby on the bottom bed sheet, where there may be some infected drainage from her perineal pad. Instead, furnish a clean sheet for her to spread over the covers.

If the woman develops a high fever, breast milk may become deficient. Fortunately, with modern antimicrobial therapy, the period of high fever usually is transient. If the mother is too ill to nurse her baby during this time or if she is receiving an anticoagulant or antibiotic that would be harmful to the baby, the infant should be fed by a supplementary milk formula. Urge her to manually express or pump breast milk during this time to maintain the production of milk. She may need support to do this because, if she fatigues easily, her energy level may not be enough to support her good intentions.

It's difficult for many women to accomplish their new role change even when things are going well. If a woman is segregated from others, frightened by her condition, and denied the pleasure of holding and feeding her newborn, her situation may seem overwhelming. Women who are isolated this way need friendly, understanding support from hospital personnel during such a stressful time.

## ENDOMETRITIS

**Endometritis** is an infection of the endometrium, the lining of the uterus (Pratts & Henderson, 2015). Bacteria gain access to the uterus through the vagina and enter the uterus either at the time of birth or during the postpartal period. This may occur with any birth, but the infection is usually associated with chorioamnionitis and a cesarean birth (Shanks, Mehra, Gross, et al., 2016).

### Assessment

A benign temperature elevation may occur on the first postpartal day, particularly if a woman is not drinking enough fluid. In contrast, the fever of endometritis usually manifests itself on the third or fourth postpartal day, suggesting that much of the invasion occurred during labor or birth (consistent with the time it takes for infectious organisms to grow).

Normally, the white blood cell count of a postpartal woman is increased to 20,000 to 30,000 cells/mm<sup>3</sup> due to the stress of labor. Because of this increase, the conventional method of detecting infection (elevated white blood cell count) is not of great value in the puerperium. Infection is suspected, instead, in postpartal women who have a temperature over 100.4°F (38°C) for two consecutive 24-hour periods. Because women may be at home when this elevated temperature occurs, be certain they know to take their temperature if they feel it is increased and to notify their primary care provider if it is elevated.

A rise in temperature that occurs on the third or fourth day postpartum occurs coincidentally at the same time as breast filling occurs. Do not be led astray by attributing an elevated temperature at this time to breast filling. Suspect fever on the third or fourth day postpartum as possible endometritis until proven otherwise.

Depending on the severity of the infection, a woman may have accompanying chills, loss of appetite, and general malaise. Her uterus usually is not well contracted and is painful to touch. She may feel strong afterpains. Lochia usually is dark brown and has a foul odor. It may be increased in amount because of poor uterine involution, but if the infection is accompanied by high fever, lochia may, in contrast, be scant or absent. A sonogram may be prescribed to confirm the presence of placental fragments that could be a possible cause of the infection.

### **Therapeutic Management**

When taking a culture to identify the offending organism, be certain to obtain fluid from the vagina using a sterile swab rather than from a perineal pad to ensure you are culturing the endometrial infectious organism and not an unrelated one from the pad. Treatment will consist of the administration of an appropriate antibiotic, such as clindamycin (Cleocin), as determined by the culture. An oxytocic agent such as methylergonovine may also be prescribed to encourage uterine contraction. Urge the woman to drink additional fluid to combat the fever. If strong afterpains and abdominal discomfort are present, ask if she needs an analgesic for pain relief.

Sitting in a semi-Fowler's position or walking encourages lochia drainage by gravity and helps prevent pooling of infected secretions. Because any drainage on perineal pads or bed linens is contaminated, be certain to wear gloves when helping a woman change her perineal pads and changing bed linen. In addition, be certain both you and the woman use good hand washing techniques before and after handling pads.

As with any infection, endometritis can be controlled best if it is discovered early. If you can interpret the normal color, quantity, and odor of lochia discharge and the size, consistency, and tenderness of a normal postpartal uterus, you can be the first person to recognize that an infection is present. Because a woman may be at home when signs of infection occur, be certain you've taught about the signs and symptoms of endometritis before healthcare agency discharge.

If the infection is limited to the endometrium, the course of infection will be about 7

to 10 days. If this occurs while a woman is hospitalized, she may have to make arrangements for her baby's discharge before her own or arrange for help with newborn care when she is discharged. Be certain she knows to take the full course of antibiotics prescribed so the infection is completely eradicated and does not return.

An added danger of endometritis is that it can lead to tubal scarring and interference with future fertility. At a future time, if the woman desires more children, she may need a fertility assessment (including a sonohysterosalpingogram) to determine tubal patency. With mild endometritis, this is usually not a problem, but a woman should be forewarned that it could occur.

### *What If . . . 25.2*

**Just before hospital discharge on her third postpartal day, Bailey Cheshire develops a shaking chill and a fever of 101.5°F (38.6°C). She's already dressed to go home and assures the nurse the temperature elevation is inaccurate because she just drank some hot coffee. On palpation, the nurse notices her abdomen is tender. Would the nurse agree with her that it's safe to be discharged?**

## **INFECTION OF THE PERINEUM**

If a woman has a suture line on her perineum from an episiotomy or a laceration repair, a ready portal of entry exists for bacterial invasion.

### **Assessment**

Infections of the perineum usually remain localized. They are revealed by symptoms similar to those of any suture-line infection, such as pain, heat, and a feeling of pressure. The woman may or may not have an elevated temperature depending on the systemic effect and spread of the infection.

Inspection of the suture line will reveal inflammation. One or two stitches may have sloughed away, so an area of the suture line is open with purulent drainage present (Fig. 25.3). Notify the woman's primary care provider of the localized symptoms, and culture the discharge using a sterile cotton-tipped applicator touched to the secretions.

**Figure 25.3** An infected suture line appears reddened and edematous and often contains infected secretions.

### **Therapeutic Management**

Typically, either a systemic or topical antibiotic is ordered even before the culture report is returned. An analgesic may be prescribed to alleviate discomfort. It may be necessary to remove perineal sutures to open the area and allow for drainage. Sitz baths, moist warm compresses, or Hubbard tank treatments may be prescribed to hasten drainage and cleanse the area. Remind the woman to change perineal pads frequently. Because they are contaminated by drainage, if left in place too long, they might cause vaginal contamination or reinfection. Repeat again that the woman should wipe front to back after urinating or a bowel movement to prevent bringing contamination forward from the rectum onto the healing area.

With a local infection of this nature, a woman is usually discharged with a referral for home care follow-up because the incision site, once opened, must heal by tertiary rather than by primary intention. Infections of this nature are annoying and painful, but fortunately, with improved techniques during birth and the puerperium, perineal infections occur only rarely. Because they are localized, there is no need to restrict the woman from caring for her infant as long as she washes her hands well before holding her newborn. Be certain not to place the infant on the bottom bed sheet of the woman's

bed where the baby could contact pathogenic bacteria. Encourage the woman to ambulate and ask for analgesia as needed. Often, the pain from an infected suture line is severe, and the woman may decrease ambulation unless she is urged to continue.

## PERITONITIS

**Peritonitis**, or infection of the peritoneal cavity, usually occurs as an extension of endometritis. It is one of the gravest complications of childbearing and is a major cause of death from puerperal infection. The infection spreads from the uterus through the lymphatic system or directly through the fallopian tubes or uterine wall to the peritoneal cavity. An abscess may form in the cul-de-sac of Douglas because this is the lowest point of the peritoneal cavity and gravity causes infected material to localize there.

### Assessment

Symptoms are the same as those of a surgical patient in whom a peritoneal infection develops: rigid abdomen, abdominal pain, high fever, rapid pulse, vomiting, and the appearance of being acutely ill. When assessing the abdomen of a postpartal woman, be sure to note not only that her uterus is well contracted but also that the remainder of her abdomen is soft because the occurrence of a rigid abdomen (i.e., guarding) is one of the first symptoms of peritonitis.

### Therapeutic Management

Peritonitis is often accompanied by a paralytic ileus (a blockage of inflamed intestines). This requires insertion of a nasogastric tube to prevent vomiting and to rest the bowel. Intravenous fluid or total parenteral nutrition will then be necessary. A woman will need analgesics for pain relief and intravenous antibiotics to treat the infection. Her hospital stay will be extended, but with effective antibiotic therapy, the outcome should be good. Peritonitis can interfere with future fertility because it can leave scarring and adhesions in the peritoneum, which separate the fallopian tubes from the ovaries to the extent that ova can no longer easily enter the tubes.

### QSEN Checkpoint Question 25.3

#### QUALITY IMPROVEMENT

Bailey Cheshire develops endometritis. When planning nursing care, which activity would be best to advise for Bailey?

- Walking around her room listening to music
- Lying supine with a cold cloth on her forehead
- Reading while resting in a slight Trendelenburg position
- Alternating between prone and supine positions

*Look in [Appendix A](#) for the best answer and rationale.*

## Thrombophlebitis

Phlebitis is inflammation of the lining of a blood vessel. **Thrombophlebitis** is inflammation with the formation of blood clots. Thrombophlebitis is classified as either superficial vein disease (SVD) or deep vein thrombosis (DVT). When either type occurs in the postpartum period, it tends to occur because:

- A woman's fibrinogen level is still elevated from pregnancy, leading to increased blood clotting.
- Dilatation of lower extremity veins is still present as a result of pressure of the fetal head during pregnancy and birth so blood circulation is sluggish.

It tends to occur most often in women who:

- Are relatively inactive in labor and during the early puerperium because this increases the risk of blood clot formation
- Have spent prolonged time in a birthing room with their legs positioned in stirrups
- Have preexistent obesity and a pregnancy weight gain greater than the recommended weight gain, which can lead to inactivity and lack of exercise
- Have preexisting varicose veins
- Develop a postpartal infection
- Have a history of a previous thrombophlebitis
- Are older than age 35 years or have increased parity
- Have a high incidence of thrombophlebitis in their family
- Smoke cigarettes because nicotine causes vasoconstriction and reduces blood flow

### FEMORAL THROMBOPHLEBITIS

With femoral thrombophlebitis, the femoral, saphenous, or popliteal veins are involved. Although the inflammation site in thrombophlebitis is a vein, an accompanying arterial spasm often occurs, diminishing arterial circulation to the leg as well. This decreased circulation, along with edema, gives the leg a white or drained appearance. It was formerly believed that breast milk drained into the leg, giving it its white appearance. The condition was, therefore, formerly called *milk leg* or *phlegmasia alba dolens* ("white inflammation").

Ambulation and limiting the time a woman remains in obstetric stirrups encourages circulation in the lower extremities, promotes venous return, and decreases the possibility of clot formation, thus helping to prevent thrombophlebitis. If stirrups on examining tables or birthing rooms are used, be certain that they are well padded to prevent any sharp pressure against the calves of the legs and that the woman remains in a lithotomy position for as short a period of time as possible. If a woman had varicose veins before or during pregnancy, wearing support stockings for the first 2 weeks after birth can help increase venous circulation and prevent stasis. If these are prescribed, be certain the woman knows to buy medical support stockings, not panty hose advertised

as offering support, and to put them on before she rises in the morning. If she waits until she is already up and walking, venous congestion will have already occurred and the stockings will be less effective. Encourage her to remove the support stockings twice daily and assess her skin underneath for mottling or inflammation that would suggest inflammation of her veins.

Women are not normally prescribed acetylsalicylic acid (aspirin) for pain because aspirin is a mild anticoagulant, which interferes with blood clotting by preventing platelet aggregation and clot formation. However, women who are high risk for thrombophlebitis may be prescribed aspirin every 4 hours as a preventive measure. If this is so, be certain to not interpret aspirin used this way as an as needed (PRN) analgesic order and withhold it depending on the woman's level of pain. Other measures for preventing thrombophlebitis are summarized in [Box 25.6](#).

## BOX 25.6

### Nursing Care Planning Based on Family Teaching

#### PREVENTING THROMBOPHLEBITIS

**Q.** Bailey Cheshire tells you, “My sister developed a thrombophlebitis after the birth of her first baby. How can I prevent that from happening to me?”

**A.** Here are a few helpful hints:

- Ask your primary care provider if you can use a side-lying or back-lying (supine recumbent) position for birth rather than a lithotomy position because a lithotomy position can increase the tendency for pooling of blood in the lower extremities.
- If you will be using a lithotomy position, ask for padding on the stirrups to prevent pressure on the calf of your legs.
- Drink adequate fluids to be certain you're not dehydrated (6 to 8 glasses of fluid per day).
- Do not sit with your knees crossed or bent sharply and avoid wearing constricting clothing such as knee-high stockings.
- Ambulate as soon after birth as possible because walking is the best preventive measure. When resting in bed, wiggle your toes or do leg lifts to improve venous return.
- Ask your primary care provider if he or she recommends support stockings in the immediate postpartal period. Be certain to put these on before ambulating in the morning before leg veins fill.
- Quit smoking because this is associated with the development of thrombophlebitis

#### Assessment

If a pelvic thrombophlebitis develops, a woman will generally have an elevated temperature, a systemic fever, chills, and pain. Comparatively, a woman experiencing a femoral thrombophlebitis will usually have unilateral localized symptoms such as

redness, swelling, warmth, and a hard inflamed vessel in the affected leg. Symptoms for thrombophlebitis usually present about 10 days after birth. The woman's leg begins to swell below the lesion at the point at which venous circulation is blocked. Her skin may become so stretched from swelling that it appears shiny and white. A Homans sign (pain in the calf of the leg on dorsiflexion of the foot) may be positive; however, a negative Homans sign does not rule out obstruction. The diameter of the leg at thigh or calf level may be increased compared with the other leg. Doppler ultrasound or contrast venography will be prescribed to confirm the diagnosis (Al-Thani, El-Menyar, Asim, et al., 2016).

### Therapeutic Management

Treatment consists of the administration of anticoagulants, the application of moist heat (to decrease inflammation), and bed rest with the affected leg elevated. A bed cradle over the leg can lift the pressure of the bedclothes off the affected leg and can both decrease the sensitivity of the leg and improve circulation. Assess the woman for risk of a pressure ulcer and provide good back, buttocks, and heel care for as long as she is on bed rest.

Although simple in theory, application of moist compresses is, unfortunately, one of the most technically difficult treatments to carry out because dressings invariably dry or become cold and dampen bed clothes after only a short time. Compresses and water used in this way do not have to be sterile because with thrombophlebitis, there is no break in the skin. Because of edema in the area, be certain to test water temperature by dipping your inner wrist into it before soaking a dressing to be sure it is not so warm it could cause a burn. Cover wet, warm dressings with a plastic pad to hold in heat and moisture. In addition, position a commercial pad with circulating heating coils or chemical hot packs over the plastic to ensure soaks stay warm. Be certain the weight of a hot pack or pad does not rest on the leg, causing an obstruction to flow of blood.

*Never massage the skin over the clotted area because this could loosen the clot, causing a pulmonary or cerebral embolism.* Check the woman's bed frequently to be certain the mattress does not become wet from seeping water. For compresses to stay in place, a woman must lay with her leg fairly immobile. However, be certain she does not interpret this as meaning she cannot turn or move about. Help her select activities to exercise the other parts of her body or stimulate her mind such as reading a good book or information on newborn care. Women who have been discharged from the hospital may be cared for at home on bed rest or may need to return to the hospital so strict bed rest can be enforced. If infection was the underlying cause of the condition, an antibiotic to treat the initial infection will be prescribed. In order to prevent further blood clotting, an anticoagulant such as unfractionated heparin (given IV) or low-molecular-weight heparin (given subcutaneously) will be prescribed. Thrombolytics (medications that dissolve clots) may also be prescribed; these should be initiated within the first 24 hours for best results. With the use of anticoagulants, a blood coagulation study will be necessary to establish a baseline value followed by sequential tests to determine the

effectiveness of the drug therapy. Heparin therapy is usually continued until symptoms resolve and the international normalized ratio (INR) is  $>2$  for at least 24 hours (Box 25.7). Be certain that protamine sulfate, the antagonist for heparin, and vitamin K, the antagonist for warfarin, are both readily available until the woman's anticoagulation therapy is stabilized.

### BOX 25.7

## Nursing Care Planning Based on Responsibility for Pharmacology

### LOW-MOLECULAR-WEIGHT HEPARIN

**Classification:** Heparin is a common anticoagulant.

**Action:** Heparin blocks the conversion of prothrombin to thrombin and of fibrinogen to fibrin, decreasing clotting ability and resulting in the inhibition of thrombus and clot formation. It is used to prevent and treat thrombosis and pulmonary embolism (Karch, 2015).

**Pregnancy Risk Category:** B

**Dosage:** Dosage is dependent on coagulation studies. Dosage is considered therapeutic when the activated partial thromboplastin time (aPTT) is 1.5 to 3 times the control value. The drug is given by subcutaneous injection.

**Possible Adverse Effects:** Hemorrhage, bruising, thrombocytopenia (lowered platelet count), urticaria (hives and itching)

#### Nursing Implications

- Obtain coagulation studies as prescribed; *adjust dosage as necessary*.
- Heparin is usually injected into subcutaneous tissue of the abdomen. For best absorption, rotate injection sites. Do not aspirate for blood return or massage the injection site afterward to avoid bruising or hematoma formation.
- Avoid any intramuscular injection of other medications because a hematoma may form at the injection site.
- Assess a woman and alert her to self-assess for signs and symptoms of bleeding, such as oozing from the gums, nosebleeds, hematuria, or frank or occult blood in stool.
- Closely monitor patient's lochia, including amount and color. Assess pad count to determine extent of vaginal bleeding.
- Keep protamine sulfate, the antidote, readily available in case of overdose.
- Instruct the woman about antibleeding precautions such as using a soft toothbrush to minimize the risk of bleeding and in the correct injection technique and allow her to demonstrate this before health agency discharge.

Following this initial treatment with heparin, a woman will be discharged on subcutaneous heparin or oral anticoagulation therapy such as warfarin (Coumadin). If

she will be doing her own subcutaneous injections at home, be certain she demonstrates good injection technique before discharge, is aware of complications associated with anticoagulant therapy, and understands the importance of required blood work so she schedules these appropriately.

The woman can continue to breastfeed while receiving heparin. She has to discontinue breastfeeding during therapy with warfarin (Coumadin) because warfarin-derived anticoagulants are passed in breast milk. If the thrombophlebitis does not seem to be severe and the woman wants to restart breastfeeding after the course of warfarin (Coumadin) (about 10 days), encourage her to manually express breast milk at the time of normal feedings so she maintains a good milk supply.

Lochia usually increases in amount in a woman who is receiving an anticoagulant. Be sure to keep a meaningful record of the amount of this discharge, so that it can be estimated; “lochia serosa with scattered pinpoint clots; three perineal pads saturated in 8 hours,” for example, is far more meaningful than “large amount of lochia.” Also assess for other possible signs of bleeding, such as bleeding gums, ecchymotic spots on the skin, or oozing from an episiotomy suture line.

With proper treatment, the acute symptoms of femoral thrombophlebitis last only a few days, but the full course of the disease takes 4 to 6 weeks before it is fully resolved. Anticoagulant therapy may need to be continued for as long as 3 to 6 months. The affected leg may never return to its former size and may always cause discomfort after long periods of standing.

## **PELVIC THROMBOPHLEBITIS**

Pelvic thrombophlebitis involves the ovarian, uterine, or hypogastric veins. It usually follows a mild endometritis and occurs later than femoral thrombophlebitis, often around the 14th or 15th day of the puerperium. Inflammation of the blood vessels in the pelvic area causes a partial obstruction, which leads to slowed blood flow and clots in the stagnant blood in the vessel. Risk factors are the same as for femoral thrombophlebitis. The prevention of endometritis by the use of good aseptic technique during and after birth is important to help prevent the disorder ([Laifer-Narin, Kwak, Kim, et al., 2014](#)).

### **Assessment**

With pelvic thrombophlebitis, a woman suddenly becomes extremely ill, with a high fever, chills, abdominal pain, weakness, and general malaise. Her infection can be so severe it necroses the vein and results in a pelvic abscess. In severe instances, it can become systemic and results in a lung, kidney, or heart valve abscess.

### **Therapeutic Management**

As with femoral thrombophlebitis, therapy involves total bed rest and the administration of analgesics, antibiotics, and anticoagulants.

The disease runs a long course of 6 to 8 weeks. If an abscess forms, it can be located by sonogram and incised by laparotomy. A woman may need surgery to remove the affected vessel before she attempts to become pregnant again.

Regardless of the type of thrombophlebitis, teach women preventive measures to reduce the risk of recurrence with future pregnancies such as wearing nonconstricting clothing on their lower extremities, resting with the feet elevated, and ambulating daily. Caution a woman to tell her primary care provider before her next pregnancy of the difficulty she experienced at this time, so that extra prophylactic precautions can be taken to prevent thrombophlebitis in a future pregnancy.

### ***QSEN Checkpoint Question 25.4***

#### **SAFETY**

Ms. Cheshire has a risk for DVT during the postpartal period. What would be the best suggestion the nurse could make to help prevent this?

- a. Rest in bed as much as possible for the first several days.
- b. Assume a knee–chest position for 15 minutes every day.
- c. Increase fluid intake to reduce blood viscosity.
- d. Ambulate early and consistently to improve circulation.

*Look in Appendix A for the best answer and rationale.*

## **PULMONARY EMBOLUS**

A pulmonary embolus is obstruction of the pulmonary artery by a blood clot; it usually occurs as a complication of thrombophlebitis when a blood clot moves from a leg vein to the pulmonary artery (Konkle, 2015). The signs of pulmonary embolus are sudden, sharp chest pain; tachypnea; tachycardia; orthopnea (inability to breathe except in an upright position); and cyanosis (the blood clot is blocking both blood flow to the lungs and return to the heart). This is an emergency. A woman needs oxygen administered immediately and is at high risk for cardiopulmonary arrest. Her condition is extremely guarded until the clot can be lysed or adheres to the pulmonary artery wall and is reabsorbed. Because of the seriousness of this condition, a woman with a pulmonary embolism commonly is transferred to an intensive care unit for continuing care.

## **Mastitis**

**Mastitis** (infection of the breast) may occur as early as the seventh postpartal day or not until the baby is weeks or months old (Witt, Bolman, Kredit, et al., 2016). The organism causing the infection usually enters through cracked and fissured nipples. Therefore, to prevent mastitis, it's important to prevent nipples from cracking through measures such as:

- Making certain the baby is positioned correctly and grasps the nipple properly, including both the nipple and areola

- Helping a baby release a grasp on the nipple before removing the baby from the breast
- Washing hands between handling perineal pads and touching breasts
- Exposing nipples to air for at least part of every day
- Possibly using a vitamin E ointment daily to soften nipples
- Encouraging women to begin breastfeeding (when the infant sucks most forcefully) on an unaffected nipple (if a woman has one cracked nipple and one well nipple)

Occasionally, the organism that causes mastitis comes from the nasal–oral cavity of the infant. In these instances, the infant has usually acquired *Staphylococcus aureus*, a methicillin-resistant *S. aureus* infection (MRSA), or candidiasis while in the hospital. The infant introduces the organisms into the milk ducts by sucking, where they proliferate (breast milk is an excellent medium for bacterial growth). Because this spreads from one person to another, this is termed *epidemic mastitis* or *epidemic breast abscess*. When it occurs, it is usually discovered that several women discharged from the hospital at the same time have similar infections.

## ASSESSMENT

Mastitis is usually unilateral, although epidemic mastitis, because it originates with the infant, may be bilateral. The affected breast feels painful and appears swollen and reddened. Fever accompanies these first symptoms within hours, and breast milk becomes scant. If the diagnosis is not clear from the typical symptoms, the woman may have a sonogram prescribed to be certain a deep lying breast abscess isn't also present (Irusen, Rohwer, Steyn, et al., 2015).

## THERAPEUTIC MANAGEMENT

Treatment consists of antibiotics effective against penicillin-resistant staphylococci such as dicloxacillin or a cephalosporin, and, because symptoms often appear after a hospital discharge, it is treated on an outpatient basis (Pustotina, 2015). Breastfeeding should be continued if possible because keeping the breast emptied of milk helps to prevent the growth of bacteria. Some women find an infected breast too painful to allow their infant to suck, however, and prefer to express milk manually from the affected breast until their antibiotic has taken effect and the mastitis has diminished (about 3 days). Cold or ice compresses and a good supportive bra help with pain relief until the process improves, although warm, wet compresses can also be helpful because this reduces inflammation and edema.

If therapy is started as soon as symptoms appear, the condition runs a short course of about 2 or 3 days. If left untreated, a breast infection can become a localized abscess. If unrecognized, this can spread to involve a large portion of the breast and even rupture through the skin, with thick, purulent drainage. If an abscess forms, breastfeeding on that breast is discontinued as the abscess may need incision and drainage. Encourage

women to continue to pump breast milk, if possible, until the abscess has resolved in order to preserve breastfeeding. Many women find a breast this infected too tender to do this, however, so instead choose to bottle-feed their infant. Although this is not the outcome she hoped for, you can assure a woman that formula feeding will be an acceptable alternative for this child.

Neither mastitis nor a breast abscess leaves any permanent breast disease. A woman can be assured that such an incident is not associated with the development of breast cancer and does not interfere with future breastfeeding potential. [Box 25.8](#) shows an interprofessional care map illustrating both nursing and team planning for a woman with mastitis.

## BOX 25.8

### Nursing Care Planning

#### AN INTERPROFESSIONAL CARE MAP FOR A WOMAN WITH MASTITIS

Bailey Cheshire calls your clinic 3 weeks after childbirth because she has a fever and swelling and pain in her right breast. She comes into the clinic for an evaluation.

**Family Assessment:** Patient lives in three-bedroom apartment with boyfriend. Employed as a chemistry teacher but has not returned to work. Boyfriend is a short-order cook but is currently unemployed; wants her to stop breastfeeding because of her infection.

**Patient Assessment:** A 30-year-old primipara woman who gave birth vaginally 3 weeks ago and is breastfeeding exclusively. Temperature 101.1°F (38.4°C). Other vital signs within acceptable parameters. Right breast reddened and edematous, tender and warm to touch. Slight fissure noted on right nipple. States, “I hurt too much to breastfeed any longer. How can I be a good mother if I don’t breastfeed my baby?”

**Nursing Diagnosis:** Pain related to development of mastitis

**Outcome Criteria:** Patient states amount of pain is decreasing with prescribed therapy; describes measures used to promote comfort. Breast swelling, redness, fever, and tenderness decrease.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse/primary care provider	Assess extent of mastitis and whether patient could continue breastfeeding with additional	Encourage patient to continue breastfeeding on left breast. Recommend	Milk provides a medium for bacterial growth. Emptying breasts prevents	Patient states she will try to continue breastfeeding even though infection is

	support.	patient try continuing to breastfeed on right breast.	stasis of milk and reduces further infection and pain.	present.
--	----------	---	--	----------

---

*Teamwork and Collaboration*

---

Nurse/lactation specialist	Assess whether patient has a support person she uses for breastfeeding advice or if she would like one.	Suggest patient contact the local La Leche League chapter hotline for consultation and support.	Support from experts in the technique of breastfeeding can offer helpful tips to ensure success.	Patient states she will contact a support service for additional information within 2 days.
----------------------------	---	---	--	---

---

*Procedures/Medications for Quality Improvement*

---

Nurse/primary care provider	Assess what actions patient feels will help relieve her pain best.	Instruct patient in ways to apply warm moist heat, such as with a shower or warm packs, at home.	Moist heat promotes circulation to the area, decreasing inflammation, edema, and pain.	Patient states she understands purpose and techniques of warm, moist heat.
Nurse	Review modifying breastfeeding strategies with mastitis.	Encourage patient to nurse every 2 to 3 hours, wear a support bra, and start each infant feeding on the unaffected breast.	Beginning feeding on the unaffected breast reduces discomfort on infected breast because infant will not suck as hard on affected breast.	Patient states she will try suggested techniques.

---

*Nutrition*

---

Nurse	Assess whether patient understands the importance of good fluid intake for breastfeeding	Advise patient to drink at least 8 glasses of fluid daily.	Fluid is important for breast milk formation and to prevent dehydration with fever.	Patient states she has access to fluid and understands the importance of fluid intake.
-------	--	--	---	--

success.

*Patient-Centered Care*

Nurse/nurse-midwife	Assess patient's knowledge of the cause and therapy for mastitis.	Explain mastitis is not unusual postpartum and should not interfere with continued breastfeeding.	Misconceptions can negatively affect success with breastfeeding.	Patient states the infection is not her fault, and she is not a "bad mother" because of it.
---------------------	---	---	--	---

*Psychosocial/Spiritual/Emotional Needs*

Nurse	Attempt to identify the meaning of breastfeeding to patient.	Encourage patient to express feelings about continuing or not continuing breastfeeding because of mastitis.	Identifying the meaning of breastfeeding assists in determining the effect a diagnosis of mastitis may have on patient.	Patient states she views this event as only a minor setback to her childrearing plans.
-------	--	---	---	--

*Informatics for Seamless Healthcare Planning*

Nurse	Determine whether patient has appointment for follow-up care.	Praise for decision-making ability to foster self-esteem. Urge boyfriend to provide breastfeeding support.	Adequate self-esteem is important to make effective childrearing decisions.	Patient will discuss lack of breastfeeding support with boyfriend and keep follow-up appointment.
-------	---	--	---	---

## Urinary System Disorders

Because a woman's bladder is compressed by the infant's head during birth, several urinary tract disorders can occur.

### URINARY RETENTION

Urinary retention occurs when the bladder is unable to empty completely (Mulder, Oude Rengerink, van der Post, et al., 2016). After childbirth, bladder sensation for voiding is decreased because of bladder edema caused by the pressure of birth. This concern is compounded during prolonged labor, perineal lacerations, and the use of epidural

anesthesia. Unable to empty, the bladder fills to overdistention. When the woman does void, instead of emptying completely, the bladder empties only a small portion of its contents (retention with overflow). As a result, it quickly becomes overdistended again. If it is allowed to continue, bladder overdistention can cause permanent damage to bladder tone, leading to permanent incontinence (Mulder et al., 2016).

## Assessment

In a postpartal woman, urinary retention with overflow may be more difficult to detect than primary or simple overdistention. With primary overdistention, a woman does not void at all. A longer than usual time (>8 hours) passes after birth or between voids. Assessment by percussion or palpation of the bladder reveals bladder distention.

With urinary retention and overflow, a woman is able to void. Voiding is very frequent, however, and in very small amounts, so her overall output is inadequate. Always measure the amount of a woman's first voiding after birth because with diuresis occurring, this should be large. As a rule, if this first voiding is less than 100 ml, suspect urinary retention.

Urinary retention is confirmed by catheterizing a woman immediately after she voids. If the amount of urine left in the bladder after voiding (termed *residual*) is greater than 100 ml, the woman is retaining more than the usual amount of urine. Typically, the prescription for catheterization is written as: "Catheterize for residual urine. If this is greater than 100 ml, leave indwelling catheter in place." Always use an indwelling (Foley) catheter, rather than a temporary one (straight catheter), therefore, to catheterize for residual urine so this can be inflated and left in place. Use strict antiseptic technique to prevent introducing pathogenic bacteria into the sterile urinary tract and causing a urinary tract infection.

Catheterizing a woman during the early postpartal period can be more difficult than usual because vulvar edema often distorts the position and appearance of the urinary meatus. Use a gentle technique, remembering that a woman's perineum is apt to feel tender to touch.

## Therapeutic Management

The amount of urine to remove from an overdistended bladder is controversial. There is a suggestion that removing more than 750 to 1,000 ml of urine at any one time may create such an extreme pressure change in the lower abdomen that it causes blood to flow into the area, causing supine hypotension. There is little evidence of this actually happening, however, and particularly not in the postpartal period, when a bladder is easily distended and the uterus is larger than normal. Although this shift in pressure may not be as important as usual, follow your healthcare agency's policy concerning how much urine to remove from a full bladder at catheterization.

If an indwelling catheter will be left in place, be certain to explain the rationale for its insertion, and how the inflated balloon will hold it in place so the woman does not

limit activity and leave herself open to other complications, such as thrombophlebitis.

After 24 hours, the indwelling catheter is usually clamped for a short time and then removed. Encourage a woman to void by the end of 6 hours after removal of the catheter by offering fluid, administering an analgesic so she can relax, assisting her to the bathroom as necessary, and trying time-tested solutions such as running water at the sink or letting her hold her hand under warm running water. In most women, bladder and vulvar edema have decreased so much by this time that they are able to void without further difficulty. If a woman has not voided by 8 hours after catheter removal, she may need reinsertion of the indwelling catheter for an additional 24 hours.

Difficulty with bladder function after childbirth is becoming less of a problem because less anesthesia and fewer forceps are used at birth, thus decreasing bladder and vulvar pressure. If problems do arise, they may be difficult for a woman to accept because bladder elimination is a basic step of self-care and discouraging for a woman who wants to be able to care not only for herself but also a new infant. You can assure the woman that bladder complications are not uncommon after childbirth. Fortunately, they are usually present for no longer than 48 hours and most likely do not recur.

## URINARY TRACT INFECTIONS

A woman who is catheterized at the time of childbirth or during the postpartal period is prone to the development of a urinary tract infection because bacteria may be introduced into the bladder at the time of catheterization. Pushing with labor may also have allowed some secretions to enter the urinary urethra.

### Assessment

If a urinary tract infection develops, the woman notices symptoms of burning on urination, possibly blood in the urine (hematuria), and a feeling of frequency or that she always has to void. The pain feels so sharp on voiding that she may resist voiding, further compounding the problem of urinary stasis. She may also have a low-grade fever and discomfort from lower abdominal pain.

Obtain a clean-catch urine specimen from any woman with symptoms of a urinary tract infection as an independent nursing action (see Nursing Care Planning Using Procedures in [Chapter 11, Box 11.6](#)). To make sure lochial discharge does not contaminate the specimen, provide a sterile cotton ball for the woman to tuck into her vagina after perineal cleansing. Be certain to ask if she removed the cotton ball after the procedure; otherwise, it could cause stasis of vaginal secretions and increase the possibility of endometritis. Mark the specimen “possibly contaminated by lochia” so that any blood in the specimen will not be overly interpreted by the laboratory technician.

### Therapeutic Management

Although sulfa drugs are usually prescribed for a urinary tract infection, they are

contraindicated for breastfeeding women because they can cause neonatal jaundice. Typically, therefore, a broad-spectrum antibiotic such as amoxicillin or ampicillin will be prescribed to treat a postpartal urinary tract infection. If an antibiotic contraindicated during breastfeeding is prescribed, check with a woman's primary care provider about possibly changing the antibiotic to one that is safe for breastfeeding. Otherwise, once she is home, in order to breastfeed, the woman will not take the prescribed antibiotic.

In addition to the antibiotic, encourage a woman to drink large amounts of fluid (a glass every hour) to help flush the infection from her bladder. She may need an oral analgesic, such as acetaminophen (Tylenol), to reduce the pain of urination for the next few times she voids until the antibiotic begins to have an effect and the burning sensation disappears. Otherwise, because voiding is painful, she may not drink the fluid you suggest, knowing it will increase the number of times she needs to void.

Although symptoms of a urinary tract infection decrease quickly, be certain the woman understands the importance of continuing to take the prescribed antibiotic for the full 5 to 7 days to eradicate the infection completely. Plan with the woman what will be an effective reminder system for her to use, such as a chart on her refrigerator door or a reminder signal on her smartphone because when women are busy—and a woman caring for a newborn is busy—forgetting to take medicine is easy to do. If she stops taking the antibiotic, however, bacteria in the urine will begin to multiply again and, in another week, symptoms and the active infection will recur. Discuss with the woman common methods that all women should use to prevent urinary tract infections such as voiding after intercourse as more assurance that she can remain infection free (see [Chapter 46](#)).

### *What If . . . 25.3*

**Eight hours after birth, Bailey Cheshire tells the nurse that she has frequency and burning on urination. She had a urinary tract infection during pregnancy, so she recognizes the symptoms. Because she has some medicine left from pregnancy, she tells the nurse there's no need to report her symptoms because she will take her unused medicine to cure the infection. What advice would the nurse give her?**

## Cardiovascular System Disorders

Because pregnancy requires major changes in the volume of blood and gestational hypertension may occur, some excess volume and pressure changes can still be present in the postpartal period.

### POSTPARTAL PREECLAMPSIA

Because preeclampsia usually develops during pregnancy, it is discussed in [Chapter 21](#).

Mild preexisting hypertension from this may increase in severity during the first few hours or days after birth. Rarely, it develops for the first time in a woman who has had no prenatal or intranatal symptoms. When this happens, the cardinal symptoms are the same as those of prenatal preeclampsia: proteinuria, edema, and increased blood pressure (Takaoka, Ishii, Taguchi, et al., 2016).

The reason the condition occurs is usually retention of some placental material. The woman may be taken to surgery to have a D&C to be certain all placental fragments have been removed from her uterus. After the D&C, blood pressure often falls dramatically to normal. If not, continued treatment measures are the same as for antepartal preeclampsia: bed rest, a quiet atmosphere, frequent monitoring of vital signs and urine output, and the administration of magnesium sulfate or an antihypertensive agent. Antihypertensive therapy can be administered in higher doses than during pregnancy because there is no longer any risk of injury to a fetus.

Seizures, if they occur postpartally as a symptom of eclampsia, typically develop 6 to 24 hours after birth. Seizures occurring more than 72 hours after birth are probably not the result of eclampsia but the result of some cause unrelated to childbearing.

Women in whom postpartal preeclampsia develops may be bewildered by what has happened to them. If seizures occur, they are frightened to discover how little control they have over their body. They worry they will have a seizure after they are at home while holding their baby. You can assure them that preeclampsia, although it appears late, is a condition of pregnancy, so the symptoms will fade quickly. Women with chronic hypertension need frequent monitoring during a future pregnancy to help detect preeclampsia symptoms should these occur (Anjum, Goel, Sharma, et al., 2016).

## Reproductive System Disorders

Pregnancy has the potential to leave reproductive system organs weakened or displaced, especially in women with grand multiparity or who had an instrument birth.

### REPRODUCTIVE TRACT DISPLACEMENT

If the ligaments of the uterus are weakened because of pregnancy, they may no longer be able to maintain the uterus in its usual position or level after pregnancy, thus creating concerns such as retroflexion, anteflexion, retroversion, and anteversion or prolapse of the uterus. These uterine displacement disorders can interfere with future childbearing and fertility and may cause continued pain or a feeling of lower abdominal heaviness or discomfort.

If the walls of the vagina are weakened, a cystocele (outpouching of the bladder into the vaginal wall) or a rectocele (outpouching of the rectum into the vaginal wall) may occur (see Chapter 5, Figs. 5.7A and B). These are identified on pelvic exam or by sonogram (Lamblin, Delorme, Cosson, et al., 2016). If extensive, surgery to repair such conditions may be necessary. If stress incontinence (involuntary voiding on exertion) occurs, Kegel exercises to strengthen perineal muscles, injection of bulking agents,

pelvic floor physical therapy, or Botox may be helpful (Vitale, Laganà, Gulino, et al., 2016).

## SEPARATION OF THE SYMPHYSIS PUBIS

During pregnancy, many women feel some discomfort at the symphysis pubis because of relaxation of the joint preparatory for birth. If a fetus is unusually large or the fetal position is not optimal, the ligaments of the symphysis pubis may be so stretched by birth they actually tear. After birth, the woman experiences acute pain on turning or walking; her legs tend to rotate externally, giving her a waddling gait. A defect over the symphysis pubis can be palpated: The area is swollen and feels tender to touch (Urraca-Gesto, Plaza-Manzano, Ferragut-Garcías, et al., 2015).

Bed rest and the application of a snug pelvic binder to immobilize the joint may be necessary to relieve pain and allow healing. As with all ligament injuries, a 4- to 6-week period is necessary for healing to be complete. During this time, a woman should avoid heavy lifting; she may need to arrange for a person to help her with child care at home. She may be advised to consider a cesarean birth for any future pregnancy.

## Emotional and Psychological Complications of the Puerperium

Any woman who is extremely stressed or who gives birth to an infant who in any way does not meet her expectations such as being the wrong sex, being physically or cognitively challenged, or being ill may become so depressed she has difficulty bonding with her infant. Both depression and an inability to bond is a postpartal complication with far-reaching implications, possibly affecting the future health of the entire family.

## POSTPARTAL DEPRESSION

Almost every woman notices some immediate (1 to 10 days postpartum) feelings of sadness (postpartal “blues”) after childbirth. This probably occurs as a response to the anticlimactic feeling after birth and also probably is related to hormonal shifts as the levels of estrogen, progesterone, and gonadotropin-releasing hormone in her body decline.

In as many as 20% of women, however, especially in women who are disappointed in some aspect of their newborn or who have poor family support, these normal feelings continue beyond the immediate postpartal period (possibly as long as 1 year) or reflect a more serious problem than usual “baby blues.” They become **postpartum depression** (Box 25.9). Depression of this type, manifested by overwhelming sadness, can occur in both new mothers and fathers (Paulson, Bazemore, Goodman, et al., 2016). The syndrome can interfere with breastfeeding, child care, and returning to a career. Both women and men may notice extreme fatigue, an inability to stop crying, increased anxiety about their own or their infant’s health, insecurity (unwillingness to be left alone

or inability to make decisions), psychosomatic symptoms (nausea and vomiting, diarrhea), and either depressive or extreme mood fluctuations (Paulson et al., 2016) (Table 25.2). Risk factors for postpartal depression include:

- History of depression
- Troubled childhood
- Low self-esteem
- Stress in the home or at work
- Lack of effective support
- Different expectations between partners (e.g., if a woman wants a child and her partner does not)
- Disappointment in the child (e.g., a boy instead of a girl)

### BOX 25.9

#### Nursing Care Planning Tips for Effective Communication

Bailey Cheshire is about to be discharged from the hospital 72 hours after childbirth. You notice that although her boyfriend visited with her, left some baby clothes, and then went downstairs to complete the discharge papers, Bailey has made no attempt to change to street clothes or dress her new baby in the baseball jersey her boyfriend left for the baby.

*Tip:* Be sure to ask enough questions to be certain a woman's sadness is not something more serious than simple "baby blues" before she is discharged from the healthcare facility so she can be referred to the proper professional for help and support. Almost all women experience some fatigue after childbirth. As many as 70% experience a temporary feeling of sadness (baby blues). About 10%, however, develop depression severe enough to need therapy.

**Nurse:** Bailey? Are you ready to leave?

**Bailey:** I feel too tired to go home. Are you sure I can't stay?

**Nurse:** Tell me more about that.

**Bailey:** I'm so tired it feels easier for me to sit here and cry than go home, work full-time, and take care of this baby.

**Nurse:** Is that different from how you thought things would be?

**Bailey:** I thought he'd ask me to marry him if I had a baby. Bet he would have if I'd had a boy instead of a girl.

**Nurse:** I'd like to ask you a few more questions about how you're feeling [this would be a great time to do a depression screen like the PHQ-9 or the EPDS]. I'd also like for our social worker to see you to make sure you have all the information you need about feeling sad after having a baby before you go home.

**TABLE 25.2** COMPARING POSTPARTAL BLUES, DEPRESSION, AND PSYCHOSIS

	<b>Postpartal Blues</b>	<b>Postpartal Depression</b>	<b>Postpartal Psychosis</b>
Onset	1–10 days after birth	1–12 months after birth	Within first year after birth
Symptoms	Sadness, tears	Anxiety, feeling of loss, sadness	Delusions or hallucinations of harming infant or self
Incidence	70% of all births	10% of all births	1%–2% of all births
Etiology (possible)	Probable hormonal changes, stress of life changes	History of previous depression, hormonal response, lack of social support	Possible activation of previous mental illness, hormonal changes, family history of bipolar disorder
Therapy	Support, empathy	Counseling, possibly drug therapy	Psychotherapy, drug therapy
Nursing role	Offer compassion and understanding	Screen for depression and refer to counseling	Refer to psychiatric care, safeguarding mother from injury to self and newborn

American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders* (5th ed.). Arlington, VA: Author; Feingold, S. B. (2013). *Happy endings, new beginnings: Navigating postpartum disorders*. Far Hill, NJ: New Horizon Press.

It is difficult to predict which women will develop postpartal depression before birth because childbirth can result in so many varied reactions. In the postpartal period, discovery of the problem as soon as symptoms develop is a nursing priority. A number of depression scales to help detect postpartum depression are available (such as the Patient Health Questionnaire-9 (PHQ-9) or the Edinburgh Postnatal Depression Scale [EPDS]), but conscientious observation and discussion with women can reveal symptoms as well. The woman may need counseling and possibly antidepressant therapy to integrate the experience of childbirth into her life (O'Connor, Rossom, Henninger, et al., 2016). This is crucial to the development of a healthy maternal–infant bond, to the health of any other children in the family, and to overall family functioning. Ask at postpartal return visits and well-child visits about symptoms that would suggest depression and recommend an appropriate referral. Measures to help prevent depression are shown in [Box 25.10](#).

### BOX 25.10

#### Nursing Care Planning to Empower a Family

**Q.** Bailey asks you, “How can I avoid becoming depressed after I return home with

my new baby?”

A. Some helpful guidelines include:

- Plan a balanced program of nutrition, exercise, and sleep. Plan meals that are easy to prepare, sleep whenever your baby sleeps, and begin a program of walking daily with your baby.
- Share your feelings with a support person. Many communities have postpartum support groups to help with this.
- Take some time every day to do something for yourself (e.g., work on a scrapbook, go shopping) so you have a break from baby care.
- Do not try to be perfect. Analyze what are the important things to do and get them done. Let unimportant things go for another day.
- Do not let yourself be isolated by baby care. Use the Internet or your cell phone to keep in contact with your friends so you are not lonely.

### *QSEN Checkpoint Question 25.5*

#### **EVIDENCE-BASED PRACTICE**

Postpartal depression affects not only the postpartum woman but also her entire family because partners can become depressed during this time as well. To assess developmental impacts on children, researchers assessed 192 fathers, 54 who met criteria for depression, and their interactions with their infants in a play session. Fathers with depression were more likely to be withdrawn in their behavior with their infants, providing less stimulation for their babies (Sethna, Murray, Netsi, et al., 2015). Based on the given study, which statement by Bailey’s boyfriend would concern the nurse he might be as depressed as she seems to be?

- a. “I never guessed I’d ever really be lucky enough to be a father.”
- b. “I don’t like talking to the baby yet. She can’t talk back yet.”
- c. “I didn’t really understand the reason that Bailey bled after the baby was born.”
- d. “No one told me women could become depressed after birth.”

*Look in Appendix A for the best answer and rationale.*

## **POSTPARTAL PSYCHOSIS**

As many as 1 woman in 500 has enough symptoms during the year after the birth of a child to be considered psychiatrically ill (this statistic seems high but represents the current rate of overall mental illness in woman) (American Psychiatric Association [APA], 2013). When the illness coincides with the postpartal period or occurs during the following year, it is termed **postpartal psychosis**. Rather than being a response to the physical aspects of childbearing, it is probably a response to the crisis of childbearing. The majority of these women have had symptoms of mental illness before pregnancy. If the pregnancy had not precipitated the illness, a death in the family, loss

of a job or income, divorce, or some other major life crisis might have precipitated the same recurrence.

A woman with postpartal psychosis usually appears exceptionally sad. By definition, psychosis exists when a person has lost contact with reality. Because of this break with reality, the woman may deny she has had a child and, when the child is brought to her, insist she was never pregnant. She may voice thoughts of infanticide or that her infant is possessed. If observation tells you a woman is not functioning in reality, you cannot improve her concept of reality by simple measures such as explaining what her correct perception should be because her sensory input is too disturbed to comprehend this. In addition, she may interpret your contrasting opinion as threatening and respond with anger or threats. Instead, the woman needs referral to a professional psychiatric counselor and probably antipsychotic medication (Kimmel, Lara-Cinisomo, Melvin, et al., 2016).

While waiting for such a skilled professional to arrive, do not leave the woman alone because her distorted perception might lead her to harm herself. In addition, don't leave her alone with her infant because she could harm the infant as well.

Always keep in mind when evaluating women during pregnancy or the puerperium that postpartal psychosis, although rare, does exist. Remembering childbearing can lead to this degree of mental illness helps you to put childbearing into perspective. Because it can cause such a crisis in a woman's life, it cannot be considered an everyday incident in anyone's life.

### ***QSEN Checkpoint Question 25.6***

#### **PATIENT-CENTERED CARE**

The nurse is making an effort to address Bailey Cheshire's psychosocial health in addition to her physiologic well-being. Which of Bailey's statements would be most suggestive of possible postpartal psychosis?

- a. "I wish my baby had longer hair."
- b. "I've felt exhausted ever since birth."
- c. "I'm happy not to have any children."
- d. "Breastfeeding is way harder than I thought."

*Look in Appendix A for the best answer and rationale.*

## **WOMEN WITH UNIQUE POSTPARTAL CARE NEEDS**

A number of women have unique postpartal needs because of unexpected circumstances.

### **The Woman Whose Child Is Born With an Illness or a Physical Challenge**

Immediately after birth, the average woman often has momentary difficulty believing that her pregnancy is finally over, and her child has been born. This difficulty can be

compounded for a woman whose child is challenged in some way because she must not only grasp the fact that her baby has been born but also that her baby is different from the one she envisioned (Riley & Baas, 2015).

During pregnancy, most women say they do not care about the sex of their child as long as the child is born healthy. This can make them feel cheated or disappointed when this one requirement is not met. They may experience a loss of self-esteem: They have given birth to an imperfect child and so they see themselves as imperfect. A woman sometimes responds with a grief reaction, as if her child had died because the image of the “perfect” child she thought she was carrying *has* died.

Parents should be shown their child moments after birth so if a condition or problem exists, the newborn’s condition, prognosis, and usual plans for care can be immediately explained to them. Although hearing such an explanation is a shock to couples, it allows them to face the problem as early as possible and while they are surrounded by professional support people. The primary care provider usually makes it her or his responsibility to tell the parents about the infant’s concern. Be prepared to reinforce this information or review the explanation during the postpartum period because people who are under stress are not good listeners and may need repeated explanations before they completely understand the problem.

Encourage the parents to care for the child during the postpartal period, so they can touch, relate to, and “claim” the infant in as nearly normal a manner as possible. Many women wait until their support person is present to visit an intensive care nursery so that visiting with their ill newborn is a family activity.

Open lines of communication between the parents and the hospital staff, which allow for free discussion of feelings and fears, will do much to strengthen parent–child relationships and prepare for future hospitalizations or care of the child.

### **The Woman Whose Newborn Has Died**

A woman whose newborn dies at birth always has questions about what happened. She is likely to feel bewildered, perhaps bitter, and perhaps resentful that despite emergency interventions, the hospital staff was not able to save her child. She asks, “Why me? Of all the women here, why was my baby the one who died?” She and her family need concerned support from healthcare personnel to help them cope with such a devastating loss (Ellis, Chebsey, Storey, et al., 2016).

Most women are interested in seeing the baby. This is generally therapeutic because it helps them begin grieving. Clean the baby, wrap the baby in an infant blanket, and bring him or her to the parents. Remain with them but give them time to handle and inspect the child as they wish. Parents may want to take a photograph or a lock of hair for a memory book. Be familiar with the forms the mother or father have to sign when a baby dies or is born dead. Know whether your state requires stillborn infants to be given a name and a burial.

Other women on the unit tend to stay away from a woman whose child has died, as if what happened to her baby is contagious. Friends and relatives may be equally unable

to talk about the situation. Most women, therefore, are anxious to have a nurse approach them and say, “Do you want to talk about what’s happened?” Be careful not to use trite sympathy phrases such as “one door closes, another one opens” or “God must have another purpose for you” because although these may be your beliefs, they may not be the woman’s beliefs.

Provide a private room for the family to allow them an opportunity to grieve and visit freely as they begin to work through this potentially devastating event in their life. The process of grieving and the support a woman requires at this time is further discussed in [Chapter 56](#).

#### *What If . . . 25.4*

**The nurse is particularly interested in exploring one of the 2020 National Health Goals with respect to complications of the puerperium (see [Box 25.1](#)). What would be a possible research topic to explore pertinent to this goal that would be applicable to Bailey’s family and that would also advance evidence-based practice?**

### **KEY POINTS FOR REVIEW**

- Hemorrhage (defined as a loss of blood greater than 500 ml within a 24-hour period) is a major potential danger in the immediate postpartal period. The most frequent causes of postpartal hemorrhage are uterine atony or a retained placental fragment. Continuous limited blood loss can be as important as sudden, intense bleeding. Administration of oxytocin or uterotonics may be necessary to initiate uterine tone and halt the bleeding.
- Other causes of hemorrhage include lacerations (vaginal, cervical, or perineal) and DIC. Lacerations are most apt to occur with an instrument birth or with the birth of a large infant.
- Puerperal infection (a temperature greater than 100.4°F [38.0°C]) after the first 24 hours is a potential complication after any birth until the denuded placental surface has healed. Retained placental fragments and the use of internal fetal monitoring leads are potential sources of infection.
- Thrombophlebitis, an inflammation of the lining of a blood vessel, occurs most often as an extension of an endometrial infection. Therapy includes bed rest with moist heat applications and anticoagulant therapy. *Never massage the leg of a woman with thrombophlebitis.* Doing so can cause the clot to move and become a pulmonary embolus, which is a possibly fatal complication.
- Mastitis is an infection of the breast. The symptoms include pain, swelling, and redness. Antibiotic therapy is necessary to promote healing.
- Postpartal “blues” are a normal accompaniment to birth. Postpartal depression (a feeling of extreme sadness) and postpartal psychosis (an actual separation from

reality) are not normal and need accurate assessment so a woman can receive adequate therapy for these conditions.

- A woman whose child dies at birth or is born with a physical or cognitive challenge needs special consideration after birth. This obviously creates a time of stress, and a woman needs supportive nursing care.
- Establishing a firm family–newborn relationship may be difficult when a woman has a postpartal complication. Planning nursing care that allows a woman to care for her baby and begin her new family role not only meets QSEN competencies but also best meets a family’s total needs.

### CRITICAL THINKING CARE STUDY

Jonella is a 37-year-old gravida 5, para 5 who gave birth to a boy (8 lb 6 oz) last night. You enter her postpartum room because you’ve noticed her newborn has been crying for some time. You find Jonella lying in bed reading from an electronic reader, seemingly unaware that her baby, swaddled in a bassinette at the foot of the bed, is crying. When you ask her if she would like some help with her newborn, she sighs as if exhausted, slowly puts down her reader, and says, “I’m waiting for someone to bring him a bottle.” Jonella’s chart shows she’s not going to breastfeed because she has four other children (10, 8, 5, and 2 years of age) at home. Her husband’s occupation is listed as a maintenance man on a Gulf of Mexico oil rig. Because her labor only lasted 6 hours, he wasn’t able to get home in time to be with her in labor. Her mother also couldn’t come because she is watching Jonella’s other children.

1. Jonella seems less than pleased to have had a new baby. Is her attitude typical for a mother having her fifth child or would you want to investigate mother–newborn bonding further?
2. Jonella had an episiotomy for birth and so has painful perineal stitches. She’s had urinary retention since birth and has a Foley catheter inserted. When her husband arrives, you notice he is enthusiastic about having a boy because now he has a “basketball team of boys.” He confides to you the only reason his wife consented to have another child was because she was certain this one would be the girl she always wanted. He tells you, “Guess she’s pretty depressed.” Could Jonella’s lack of interest in her baby be the beginning of postpartal depression? What risk factors does she have for developing this?
3. Jonella will be discharged tomorrow. Her husband will be back at work in 3 days, and her mother has arthritis and so is “little help.” In addition to developing postpartal depression, for what other postpartal complications is Jonella high risk?

## Nursing Care of a Family With a High-Risk Newborn

*Mr. and Mrs. Atkins are the parents of a 30-week-gestation, 2-lb baby boy born last night after a short, 4-hour labor. Their baby took a few gasping respirations at birth but then stopped breathing. He was resuscitated by the neonatal nurse practitioner and respiratory therapist and then transported to the intensive care nursery. Mr. Atkins was not present for the birth because he was out of town on business. You notice Mrs. Atkins has not visited the intensive care nursery to see her son. She has also refused to fill in the birth certificate because she tells you, “I don’t want to give him our favorite name because he might die.” Mr. Atkins called early this morning and acted more upset that the baby was born than relieved the baby was receiving intensive care. You hear him ask his wife, “Did you do something to cause this?”*

*Previous chapters described the birth and care of well newborns. This chapter adds information on the care of newborns who are ill or who are born with a significant variation in gestational age or weight. Learning to recognize these infants at birth and organizing care for them can be instrumental in helping protect both their present and future health.*

**What type of help does the Atkins family need to better accept what has happened to them?**

### KEY TERMS

acute bilirubin encephalopathy (ABE)  
 apnea  
 apparent life-threatening event (ALTE)  
 appropriate for gestational age (AGA)  
 brown fat  
 developmental care  
 dysmature  
 extremely-low-birth-weight (ELBW) infant  
 extracorporeal membrane oxygenation (ECMO)  
 fetal alcohol spectrum disorder

**gestational age**  
**hemorrhagic disease of the newborn**  
**hydrops fetalis**  
**hyperbilirubinemia**  
**intrauterine growth restriction (IUGR)**  
**large for gestational age (LGA)**  
**low-birth-weight (LBW) infant**  
**macrosomia**  
**ophthalmia neonatorum**  
**periodic respirations**  
**periventricular leukomalacia (PVL)**  
**postterm infants**  
**preterm infants**  
**retinopathy of prematurity (ROP)**  
**shoulder dystocia**  
**small for gestational age (SGA)**  
**term infants**  
**very-low-birth-weight (VLBW) infant**

## **OBJECTIVES**

**After mastering the contents of this chapter, you should be able to:**

1. Define the common classifications of high-risk infants and describe common illnesses that occur in these classifications of newborns.
2. Identify 2020 National Health Goals related to high-risk newborns that nurses can help the nation achieve.
3. Assess a high-risk newborn to determine whether safe transition to extrauterine life has occurred.
4. Formulate nursing diagnoses related to a high-risk newborn and family.
5. Identify expected outcomes for a high-risk newborn and family to help parents manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care for a high-risk newborn, such as monitoring body temperature.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of the needs of a high-risk newborn with the interplay of nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

During pregnancy, screening women for risk factors such as younger or older than average maternal age, having concurrent disease conditions such as diabetes or HIV infection, experiencing pregnancy complications such as placenta previa, or an unhealthy maternal lifestyle such as drug abuse—all of which could lead to illness in a newborn—is essential to identify infants who may need greater than usual care at birth (Eken, Tuten, Ozkaya, et al., 2016; Hoppe, 2013).

Unfortunately, not all instances of high risk can be predicted during pregnancy or birth because even a newborn from a “perfect” pregnancy may require specialized care or may develop a problem over the first few days of life, necessitating special interventions. Any infant, especially one who is born **dysmature** (a newborn whose birth weight is inappropriately low for gestational age), whether preterm, term, or postterm, is at risk for complications at birth or in the first few days of life. Parents need a thorough explanation of their baby’s health because these problems may require rehospitalization or additional follow-up at home. Because preterm birth, in particular, has the potential for leading to high-risk newborns, several 2020 National Health Goals directly concern preterm births (Box 26.1).

#### BOX 26.1

#### Nursing Care Planning Based on 2020 National Health Goals

A preterm birth has the potential for leading to so many complications in newborns that several 2020 National Health Goals were written specifically concerning preterm birth:

- Reduce low birth weight (LBW) to an incidence of no more than 7.8% of live births and very low birth weight (VLBW) to an incidence of no more than 1.4% of live births from baselines of 8.2% and 1.5%, respectively.
- Increase the proportion of VLBW infants born at level III hospitals or subspecialty perinatal centers from a baseline of 76.1% to a target level of 83.7%.
- Reduce the rate of fetal and infant deaths during the perinatal period (28 weeks of gestation to 7 days or more after birth) to 5.9 per 1,000 live births from a baseline of 6.6 per 1,000 live births.
- Reduce the rate of deaths from sudden infant death syndrome (SIDS) to 0.5 per 1,000 live births from a baseline of 0.55 per 1,000 live births (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by teaching women the symptoms of preterm labor so that, ideally, birth can be delayed until infants reach term. Nurses also need to be prepared for resuscitation at birth for high-risk infants and to plan developmental care that can help prevent conditions such as apnea, intraventricular hemorrhage, and periventricular leukomalacia.

Being able to predict if an infant is at high risk allows for advanced preparation so that specialized, skilled healthcare personnel can be present at the child's birth to perform necessary interventions, such as resuscitating a newborn who has difficulty establishing respirations. Immediate, skilled handling of any problems that occur may help to save the newborn's life and also prevent future problems, such as neurologic disorders (Wyckoff, Aziz, Escobedo, et al., 2015).

### *Nursing Process Overview*

#### **ASSESSMENT**

All infants need to be assessed at birth for obvious congenital anomalies and **gestational age** (number of weeks the newborn remained in utero). Both determinations can be done by the nurse who first examines an infant. Be certain such a first assessment is done under a prewarmed radiant heat warmer to guard against heat loss.

Continuing assessment of high-risk infants involves the use of technology and equipment such as cardiac, apnea, oxygen saturation, and blood pressure monitoring. Regardless of how many monitors are used, they do not replace the role of frequent, close, common sense observations by a nurse who knows an infant well from having cared for the baby consistently over time because such a nurse often senses changes before a monitor or other equipment begins to put a quantitative measurement on the change. Carefully evaluate comments from fellow nurses such as an infant "isn't himself" or "breathes irregularly." These comments, although not evidence based, are the same observations that parents who know their baby well report at healthcare visits.

#### **NURSING DIAGNOSIS**

To establish nursing diagnoses for high-risk infants, it is important to be aware of the usual parameters of newborns. Examples of nursing diagnoses that center on the priority areas of care for all newborns include:

- Ineffective airway clearance related to the presence of mucus or amniotic fluid in the airway
- Ineffective tissue oxygenation related to breathing difficulty
- Ineffective thermoregulation related to immature status
- Risk for deficient fluid volume related to insensible water loss
- Risk for imbalanced nutrition, less than body requirements, related to the lack of strength for effective sucking
- Risk for infection related to lowered immune response due to prematurity
- Risk for impaired parenting related to illness in newborn at birth
- Deficient diversional activity (lack of stimulation) related to illness at birth
- Readiness for developmental care to decrease overstimulation easily caused by necessary lifesaving procedures

## **OUTCOME IDENTIFICATION AND PLANNING**

Be certain when establishing expected outcomes that they are consistent with a newborn's potential. A goal that implies complete recovery from a major illness, for example, may be unrealistic for one newborn but completely appropriate for another. Be certain plans for care are individualized considering a newborn's developmental level as well as physiologic strengths, weaknesses, and needs. Many families of a high-risk newborn will need support to care for their infant at home and therefore may need a referral to a home health care or other agency. Direct patients to helpful websites and other resources when appropriate (see [Chapter 20](#)).

## **IMPLEMENTATION**

Interventions for any high-risk newborn are best carried out by a consistent caregiver and should focus on conserving the baby's energy and providing a thermoneutral environment to prevent exhaustion and hypothermia. Painful procedures should be kept to a minimum to help the infant achieve a sense of comfort and balance. Assisting parents to participate in care such as bathing or feeding their infant can help make the child real to them for the first time and can set the stage for effective bonding.

## **OUTCOME EVALUATION**

High-risk newborns need long-term follow-up so any consequences of their birth status, such as minimal neurologic injury, can be identified, and arrangements for special schooling or counseling can be made. Examples of expected outcomes include:

- Infant maintains a patent airway.
- Infant demonstrates an ability to suck effectively.
- Infant tolerates procedures without accompanying apnea, bradycardia, or oxygen desaturation.
- Infant demonstrates growth and development appropriate for gestational age, birth weight, and condition.
- Infant maintains a body temperature of 98.6°F (37.0°C) in an open crib with one added blanket.
- Parents visit at least once and make three telephone calls to the neonatal nursery weekly.
- Parents demonstrate positive coping skills and behaviors in response to the newborn's condition and ability to care for their newborn.

## **Newborn Priorities in the First Days of Life**

All newborns have a number of needs in the first few days of life that take priority. They include:

1. Initiation and maintenance of respirations
2. Establishment of extrauterine circulation

3. Maintenance of fluid and electrolyte balance
4. Control of body temperature
5. Intake of adequate nourishment
6. Establishment of waste elimination
7. Prevention of infection
8. Establishment of an infant–parent/caregiver relationship
9. Institution of developmental care or care that balances physiologic needs and stimulation for best development

These same needs are also the primary needs of high-risk newborns. Because of small size or immaturity or illness, however, fulfilling these needs may require special equipment or care measures. Not all newborns will be able to achieve full wellness because of extreme insults to their health during pregnancy or at birth or difficulty adjusting to extrauterine life. Indications a newborn is having difficulty making the immediate transition from intrauterine to extrauterine life may be first apparent by a low Apgar score rating (see [Chapter 18](#)).

## INITIATING AND MAINTAINING RESPIRATIONS

Ultimately, the prognosis of a high-risk newborn depends primarily on how the first moments of life are managed because most deaths occurring during the first 48 hours after birth result from the newborn's inability to establish or maintain adequate respirations ([National Vital Statistics Service \[NVSS\], 2011](#)). An infant who has difficulty accomplishing effective breathing may experience residual neurologic morbidities as a result of cerebral hypoxia. Therefore, prompt, thorough, and immediate care is necessary for the best outcome.

Most infants are born with some degree of respiratory acidosis. However, this initial acidosis is rapidly corrected by the spontaneous onset of respirations. If respiratory activity does not begin immediately, respiratory acidosis not only doesn't improve but also increases in amount so much that the blood pH and bicarbonate buffer system can fail. Newborn defense mechanisms then become inadequate to reverse the process. This means the effort to establish respirations must be started immediately after birth because, by 2 minutes, the development of severe acidosis is already well under way ([Dani, Bresci, Berti, et al., 2013](#)).

Any infant who sustains any degree of asphyxia in utero, such as could occur from cord compression, maternal anesthesia, placenta previa, intrauterine growth restriction, or premature separation of the placenta, may already be experiencing acidosis at birth and may have difficulty before the first 2 minutes of life.

An additional concern that ineffective respirations creates is the failure of fetal circulatory shunts, particularly the ductus arteriosus, to close. Because left-side heart pressure is stronger than right-side pressure, blood then circulates through the patent ductus arteriosus from the left to right or from the aorta to the pulmonary artery, thus creating ineffective pump action in the heart. Struggling to breathe and circulate blood, the infant is forced to use available serum glucose quickly and so may become

hypoglycemic, compounding the initial problem even further.

For all these reasons, resuscitation is important for both infants who fail to take a first breath and for those who have difficulty maintaining adequate respirations on their own (Wyckoff et al., 2015). Common factors that predispose infants to respiratory difficulty and so may require resuscitation are shown in [Box 26.2](#).

## BOX 26.2

### Factors Predisposing Infants to Respiratory Difficulty in the First Few Days of Life

- Low birth weight
- Intrauterine growth restriction
- Maternal history of diabetes
- Premature rupture of membranes
- Maternal use of barbiturates or narcotics close to birth
- Meconium staining
- Irregularities detected by fetal heart monitor during labor
- Cord prolapse
- Lowered Apgar score (<7) at 1 or 5 minutes
- Postmaturity (postterm)
- Small for gestational age
- Breech birth
- Multiple birth
- Chest, heart, or respiratory tract anomalies

## Resuscitation

Approximately 10% of newborns require some assistance to begin breathing at birth. In order to assure newborn resuscitation can be consistent from infant to infant and one facility to the next, the American Academy of Pediatrics (AAP) has instituted a Neonatal Resuscitation Program updated at intervals that lists steps and rationales for newborn resuscitation (Sawyer, Umoren, & Gray, 2017).

Based on these recommendations, resuscitation should follow an organized process: (a) Establish an airway, (b) expand the lungs, and (c) initiate and maintain effective ventilation. If respiratory depression becomes so severe that a newborn's heart begins to fail (heart rate is less than 60 beats/min) despite effective positive pressure ventilation, resuscitation should then also include chest compressions (Wyckoff et al., 2015).

## Airway

For a well, term newborn, usually warming, drying, and stimulating the baby by rubbing the back is enough to initiate respirations. A rubber bulb syringe is a standard piece of equipment in most birthing rooms and was often used in the past to suction infants'

noses and mouths, but because bradycardia can be associated with bulb suctioning, routine suctioning of the nose and mouth is no longer recommended unless there is concern that the airway is obstructed (Wyckoff et al., 2015).

If a newborn does not initiate spontaneous breathing following gentle stimulation, place the infant under a radiant heat warmer in a “sniffing” position (head slightly tipped back) and rub and dry his or her back and hair again to see if this additional stimulation initiates respirations. Assess a precordial pulse over the heart and attach a pulse oximeter to monitor oxygen saturation. It is reasonable to consider the application of a 3-lead cardiac monitor during resuscitation to obtain an accurate heart rate quickly (Wyckoff et al., 2015).

A newborn whose amniotic fluid was meconium stained at birth but is breathing does not need suctioning to clear the airway. If the newborn whose amniotic fluid was meconium stained at birth presents with poor muscle tone and inadequate breathing, it is important to begin the initial steps of resuscitation under the warmer. Positive pressure ventilation should be initiated immediately if the newborn is not breathing or the heart rate is less than 100 beats/min (Wyckoff et al., 2015). In most newborns, this degree of resuscitation will initiate responsive respirations and a strong heartbeat (over 100 beats/min). Color, muscle tone, and reflexes will all improve. Mechanical suctioning should occur only if there is an obstruction such as a mucus plug that is interfering with effective breathing; otherwise, it may cause bradycardia (Fig. 26.1).

**Figure 26.1** Suctioning a newborn with mechanical suction controlled by a finger valve. The suction is applied as the catheter is withdrawn. If the catheter is rotated as it is withdrawn, the risk of traumatizing the membrane is reduced.

An infant who still makes no effort at spontaneous respirations after these initial steps may require insertion of an endotracheal tube to be certain the airway is not

obstructed so air can be effectively administered. If the heart rate or oxygen saturation levels remain low with air, oxygen may be administered to achieve a preductal oxygen saturation close to the interquartile range measured in healthy term infants after vaginal delivery (Wyckoff et al., 2015).

In the first few seconds of life, a newborn this severely depressed may take several weak gasps of air and then almost immediately stop breathing; the heart rate begins to fall. This period of halted respirations is termed *primary apnea*. After 1 or 2 minutes of **apnea** (defined as a pause in respirations longer than 20 seconds with accompanying bradycardia), an infant again tries to initiate respirations with a few strong gasps. Most newborns, however, cannot maintain this effort longer than 4 or 5 minutes. After this, the respiratory effort will become weaker again and the heart rate will fall further until the newborn stops the gasping effort altogether. The infant then enters a period of *secondary apnea*. Although usually a phenomenon that occurs after birth, both types of apnea may occur in utero.

During the period of first gasps, resuscitation attempts are generally successful. Once a newborn is allowed to enter a secondary apnea period, however, resuscitation becomes difficult and may be ineffective. Because it is impossible to distinguish between the two periods simply by observation, resuscitation must always be started as if secondary apnea is the phase occurring.

A healthcare provider skilled in laryngoscope and endotracheal tube insertion should be present at the birth of all infants identified as high risk so a laryngoscope can be quickly inserted into the airway as necessary (Wyckoff et al., 2015). Laryngoscope insertion is easy in theory; in practice, the wide variation in the size of infants' posterior pharynxes and tracheas and the emergency conditions present under which it is attempted, make it an often difficult procedure (Fig. 26.2).

**Figure 26.2** Intubation. Place the head in a neutral position with a towel under the shoulders. The blade of the laryngoscope is inserted to reveal the vocal cords. An endotracheal tube for ventilation is then

passed into the trachea, past the laryngoscope.

Laryngoscopes are equipped with different-size blades; a size 0 or 1 should be available for newborns. Following insertion of the laryngoscope, an endotracheal tube is slid through the laryngoscope down into the trachea. Infants under 1,000 g need a 2.5-mm endotracheal tube (think of a thin coffee straw); those over 3,000 g need a 4.0-mm tube. Because preterm infants are prone to hemorrhage because of capillary fragility, gentle care during insertion is crucial.

## Lung Expansion

Once an airway has been established, a newborn's lungs need to be expanded. Well newborns inflate their lungs adequately independently with a first breath. The sound of the baby crying loudly is proof that lung expansion is good because the vocal sounds are produced by a free flow of air over the vocal cords.

If an infant needs air or oxygen by bag and mask to aid lung expansion, be certain the mask covers both the mouth and the nose. However, it is important to make sure it doesn't cover the eyes because eye injury could occur from either pressure of the mask on the eyes or from drying of the cornea from air or oxygen administration. Air (or oxygen if needed) should be administered at a rate of 40 to 60 ventilations per minute. To prevent unnecessary cooling or drying, the oxygen that is administered should be both warmed (between 89.6° and 93.2°F [32° and 34°C]) and humidified (60% to 80%).

The pressure needed to open lung alveoli for the first time can be as high as 40 cm H<sub>2</sub>O. After that, pressures of 15 to 20 cm H<sub>2</sub>O are generally adequate to continue inflating alveoli (Wyckoff et al., 2015). The pressure from anesthesia bags is controlled solely by the pressure a healthcare provider uses when the hand squeezes against the bag. Other types of bags such as the self-inflating (Ambu) bag can be set with a blow-off valve that limits the pressure in the apparatus to be certain only gentle pressure is applied (Fig. 26.3).

**Figure 26.3** Types of ventilation bags used in neonatal resuscitation. **(A)** The flow-inflating (anesthesia) bag requires a compressed gas source for inflation but is able to deliver 100% oxygen. **(B)** The self-inflating (Ambu) bag remains inflated at all times and is not

dependent on a compressed gas source. It is limited to delivering oxygen concentration to about 40%.

It is important not to let oxygen levels in a newborn fluctuate greatly because fluctuation can cause bleeding from immature cranial vessels. In addition, applying pressure above what is necessary could rupture lung alveoli. If adequate ventilation is not achieved, however, a newborn stands little chance of survival. To be certain air is reaching the lungs with resuscitation, monitor the newborn's oxygen saturation with pulse oximetry in addition to auscultating the chest for the sounds of air movement (Wyckoff et al., 2015).

Be certain to listen to both lungs to verify both lungs are being aerated. If air can be heard on only one side or sounds are not symmetric, the endotracheal tube is probably at or below the bifurcation of the trachea (where the trachea splits into the left and right main-stem bronchi) and the tube is likely blocking the air from entering one of the main-stem bronchi. Pulling the tube back half a centimeter will usually allow oxygen to flow to both lungs. Correct placement of the endotracheal tube in the trachea and not the esophagus can be confirmed by a CO<sub>2</sub> monitor (no CO<sub>2</sub> will return if the tube is in the esophagus) immediately after insertion. An X-ray will confirm proper placement and depth in the trachea.

When air is given under pressure to a newborn this way, the stomach also quickly fills with air. If the resuscitation has continued for over 2 minutes, insert an orogastric tube (through the mouth to the stomach instead of through the nose to the stomach because babies are obligate nose breathers). Leaving the distal end open helps deflate the stomach, which allows for better ventilation of the lungs and decreases the possibility that vomiting and aspiration of stomach contents from overdistention will occur.

## Drug Therapy

Few medications are necessary for newborn resuscitation. Even if an infant's respiratory depression appears to be related to the administration of a narcotic such as morphine or meperidine (Demerol) to the mother during labor, naloxone (Narcan), a drug to reverse the action of narcotics, should not be routinely administered because it has little effect and may cause seizures in a newborn (Leone, Finer, & Rich, 2012). Instead, resuscitation efforts should focus on effective ventilation and airway support for the persistently apneic newborn (Wyckoff et al., 2015). If heart rate continues to be inadequate (less than 60 beats/min), epinephrine 1:10,000 may be administered intravenously (IV) to stimulate heart action. Preterm infants may receive surfactant to replace the natural surfactant that has not yet formed in their lungs.

## Ventilation Maintenance

To allow a newborn to adjust to and maintain the cardiovascular changes that occur at

birth, effective ventilation (continued respirations) must be maintained. Healthy newborns accomplish this task on their own. Those who have difficulty establishing respirations at birth need to be carefully observed in the first few hours after birth to be certain respirations are maintained. Use of pulse oximetry is crucial to be certain oxygen saturation remains adequate; infants this young do not have dramatic skin color changes as do older infants and can be mildly hypoxic (low in oxygen) without becoming cyanotic.

A steadily increasing respiratory rate, grunting, and nasal flaring are often the first signs of obstruction or respiratory compromise in newborns. If these are present, undress the baby's chest and look for intercostal retractions (inward sucking of the anterior chest wall on inspiration). Pulling in the chest muscle this way reflects the degree of difficulty the newborn is having in breathing in air (tugging so hard to inflate the lungs that the anterior chest muscles are pulled inward).

Place a newborn who is having difficulty with maintaining respirations under an infant radiant warmer to help prevent cooling and acidosis; under a warmer, the clothing (except diaper) should be removed to promote better respiration and observation while keeping the newborn warm. Positioning an infant on the back with the head of the mattress elevated approximately 15 degrees can also help because it allows the abdominal contents to fall away from the diaphragm, thus increasing breathing space.

If secretions accumulating in the respiratory tract appear to be creating ineffective breaths, an infant may need additional suctioning. "Bagging" the infant with a mask and positive-pressure ventilation bag for a minute before suctioning will usually improve the infant's oxygen level and prevent it from desaturating to dangerous levels during suctioning. As a final step, the cause of the respiratory distress must be determined and appropriate interventions must be undertaken to correct the difficulty (see [Chapter 40](#)).

## **ESTABLISHING EXTRAUTERINE CIRCULATION**

Although establishing respirations is the first priority at a high-risk infant's birth, lack of cardiac function may be present concurrently or may develop if respiratory function cannot be quickly initiated and maintained. If an infant has no audible heartbeat, or if the cardiac rate is below 60 beats/min, chest compressions should be started. Hold the infant with fingers encircling the chest and wrapped around the back and depress the sternum with both thumbs on the lower third of the sternum, approximately one third of its depth (1 or 2 cm) at a rate of at least 100 times per minute ([Wyckoff et al., 2015](#)). Lung ventilation at a rate of 30 times per minute should be coordinated with chest compressions at a rate of 90 compressions per minute at a ratio of three compressions to one ventilation. If a newborn's heart rate is greater than 60 but less than 100 beats/min, chest compressions can be stopped but ventilations should be continued. Ensuring adequate ventilation is the major priority and should continue until the heart rate is greater than 100 beats/min.

Continue to monitor pulse oximetry to evaluate respiratory function and cardiac efficiency. If the pressure and the rate of chest compressions used are adequate, it

should be possible, in addition, to palpate a femoral pulse. If the heartbeat is not above 60 beats/min after at least 30 seconds of coordinated positive-pressure ventilation and chest compressions, intravenous epinephrine to stimulate heart action may be prescribed (Wyckoff et al., 2015). Following cardiopulmonary resuscitation, newborns should be transferred to a transitional or high-risk nursery for continuous cardiorespiratory observation and care to be certain cardiac function is maintained.

## **MAINTAINING FLUID AND ELECTROLYTE BALANCE**

After an initial resuscitation attempt, hypoglycemia (decreased blood glucose) often results from the effort the newborn expended to begin breathing. Dehydration may also result from increased insensible water loss caused by rapid respirations. Infants with hypoglycemia are treated initially with intravenous 10% dextrose in water to restore their blood glucose level. Fluids such as a dilute mixture of saline and dextrose in water are commonly used to maintain glucose and fluid levels and electrolytes. Sodium, additional glucose, and potassium are added as needed according to electrolyte laboratory results.

Be certain to monitor the rate of fluid administration conscientiously in high-risk newborns because a high fluid intake can lead to fluid overload, resulting in a patent ductus arteriosus or heart failure. When using a radiant warmer, remember there is a tendency for water loss from either convection or radiation. A newborn on a warmer, therefore, may require more fluid than if he or she were placed in a double-walled incubator.

Monitor fluid status both by urine output and urine specific gravity values. An output less than 2 ml/kg/hr or a specific gravity greater than 1.015 to 1.020 suggests inadequate fluid intake.

If hypovolemia is present immediately after birth, the cause is usually fetal blood loss from a condition such as placenta previa (see [Chapter 21](#)) or twin-to-twin transfusion. With hypovolemia, typically tachypnea, pallor, tachycardia, decreased arterial blood pressure, decreased central venous pressure, and decreased tissue perfusion of peripheral tissue, with a progressively developing metabolic acidosis, will develop. The hematocrit may be normal for some time after acute blood loss, however, because blood cells present are in proportion to plasma. An isotonic solution (usually normal saline) may be administered to increase blood volume. A vasopressor such as dopamine may be given to increase blood pressure and improve cell perfusion.

## **REGULATING TEMPERATURE**

All high-risk infants may have difficulty maintaining temperature because, in addition to stress from an illness or immaturity, the infant's body is often exposed for long periods during procedures such as resuscitation.

It's important to keep newborns in a neutral-temperature environment, one that is neither too hot nor too cold because doing so places less demand on them to maintain a

minimal metabolic rate necessary for effective body functioning. If their environment becomes too hot, they are forced to decrease metabolism to cool their body. If it becomes too cold, they must increase their metabolism to warm body cells. Increased metabolism can be destructive because it calls for increased oxygen, and without this oxygen available because of respiratory difficulty, body cells become hypoxic. To spare oxygen for essential body functions, vasoconstriction of peripheral blood vessels occurs so blood can be pushed into the central torso. If this process continues for too long a time, pulmonary vessels constrict and pulmonary perfusion decreases. The infant's  $PO_2$  level will fall and  $P_{CO_2}$  will increase. As mentioned previously, a lowered  $PO_2$  level causes fetal shunts such as the ductus arteriosus to remain open. Surfactant production in the lungs can halt as well, further interfering with lung function. To supply glucose to maintain increased metabolism, an infant has to resort to anaerobic glycolysis, which pours acid into the bloodstream. As the infant becomes more and more acidotic, the risk of acute bilirubin encephalopathy or *kernicterus* (the accumulation of unconjugated bilirubin into brain cells) increases as more bilirubin-binding sites are lost and more bilirubin is free to pass out of the bloodstream in brain cells. In short, because of becoming chilled, heart action, breathing, electrolytic balance, and possibly brain function all become compromised.

In addition to covering the newborn with an infant cap, wiping the body and head dry with a towel or blanket, and using a radiant warmer or prewarmed incubator (Fig. 26.4), suggest skin-to-skin contact with one of the parents. Additional measures that can be used to ensure the infant's temperature stays between  $36.5^{\circ}C$  and  $37.5^{\circ}C$  ( $97.8^{\circ}F$  and  $99.5^{\circ}F$ ) axillary are plastic wrap, increasing the room temperature, and warmed mattresses (Wyckoff et al., 2015). To prevent heat loss, be certain during any procedure that the infant is not placed on a cool X-ray table or scale.

A

B

**Figure 26.4** A neutral thermal environment. **(A)** A neonate in an intensive care bed with overhead radiant warmer can be examined periodically with ease. **(B)** Use of an incubator allows maintenance of a neutral thermal environment for neonates not requiring minute-to-minute interventions.

## Radiant Heat Sources

Radiant heat warmers are open beds that have an attached overhead source of radiant heat and provide both warmth and visibility for observation. Such units have small probes, covered by a small shield, often silver metallic, which when placed on the baby's skin, register the baby's temperature. Abdominal skin temperature, when measured this way, should be 95.9° to 97.7°F (35.5° to 36.5°C). If an infant's temperature falls below this level, an alarm on the unit can be set to sound. Be certain, with the infant laying on his or her back, you tape the probe or disk onto the infant's abdomen between the umbilicus and the xiphoid process. Do not tape it on the underside of an infant or it will register a falsely high reading. Be certain as well it is not over the liver because the heat generated by the liver can lead to false high readings or over the rib cage where the thin subcutaneous tissue and ribs are also apt to yield an inaccurate reading. When performing care or leaning over the infant, be careful your head does not block the heat from the overhead source so it no longer reaches the baby. An additional warming pad placed under an infant may be necessary for very preterm infants or for lengthy procedures to maintain body heat.

## Incubators

Newborns needing both warmth and visual observation may also be cared for in incubators. By placing the baby in such a steady, warm environment, the need for clothing can be eliminated, so the observation for any respiratory difficulty, possible color changes, or unusual movements (such as seizures) can be readily observed. The temperature of incubators varies with the amount of time portholes remain open and the temperature of the area in which the incubator is placed. Placing one in direct sunlight or near a warm radiator, for example, can increase the internal temperature markedly. Placing it near a cold window can decrease the temperature. For these reasons, a newborn's temperature must be assessed at frequent intervals when in an incubator to be certain the temperature level designated is being maintained. Use of an additional acrylic shield inside the incubator helps prevent radiation and convection heat loss when portholes are opened and may be necessary for very immature infants.

Similar to radiant warmers, some incubators have servo control mechanism units that monitor the infant's temperature once the probe is placed on their abdomen and automatically changes the temperature of the incubator as needed. Portholes must remain closed to keep the servo control operating efficiently.

As infants become both medically stable and old enough to maintain a steady body

temperature, they can be weaned from an incubator. Dress the infant as if he or she were going to be in a bassinet and then set the incubator about 2°F (1.2°C) below the infant's temperature. After a half hour, assess whether the infant is able to maintain body temperature. If so, lower the incubator temperature another 2°F and continue until room temperature is reached. If an infant cannot maintain adequate temperature as the incubator temperature level is lowered, it suggests the infant is not yet ready for room-temperature air, and the weaning process should be slowed or stopped until the baby is more mature or better able to self-regulate temperature.

### Skin-to-Skin Care

Originally referred to as *kangaroo care*, skin-to-skin care is the use of skin-to-skin contact with a parent to maintain body heat. Provide a quiet setting with lights dimmed. Undress the infant except for a diaper and a cap. Assist the parent to sit comfortably in a chair and hold the infant snugly against his or her unclothed chest, skin to skin. Place a blanket over the infant for added warmth. This method of care not only supplies heat but also encourages parent–child bonding (Moore, Anderson, Bergman, et al., 2012).

#### QSEN Checkpoint Question 26.1

##### Evidence-Based Practice

A review of the literature was completed to examine interventions that prevent hypothermia in the premature newborn in the delivery room and that maintain core body temperature. In addition to the use of the standard thermoregulation interventions such as knit hats, the literature showed using respiratory gases during ventilation, the use of gel thermal mattresses, and the use of polyethylene wraps or bags (Fawcett, 2014). Based on the previous study, which response by Mrs. Atkins, whose infant was born prematurely, would alert the nurse she may need further teaching?

- “Holding my baby directly on my chest will help with warmth and temperature stability.”
- “I like singing to him and notice that helps his temperature stay even.”
- “I’ll use this adorable little hat I was given to help him stay warm.”
- “I’m afraid he’ll suffocate if he sleeps on a warmed mattress.”

Look in [Appendix A](#) for the best answer and rationale.

### ESTABLISHING ADEQUATE NUTRITIONAL INTAKE

Infants who experienced severe asphyxia at birth usually receive intravenous fluids so they do not become exhausted from sucking or until necrotizing enterocolitis has been ruled out, which can result when there is a temporary reduction of oxygen to the bowel (see [Chapter 45](#) for a discussion of necrotizing enterocolitis). If an infant's respiratory rate remains so rapid that the infant cannot suck effectively, gavage feedings may be

introduced (Fig. 26.5). Others with a long-term nutrition concern may have gastrostomy tubes placed. Preterm infants should be fed breast milk if at all possible because of the immune protection this offers (Lee, Martin-Anderson, Lyndon, et al., 2013; Martin, Ling, & Blackburn, 2016). If breastfeeding is not possible because the infant is too immature to suck effectively, a mother can manually express breast milk or use a breast pump to initiate and continue her milk supply until the time the infant is mature enough or otherwise ready to breast feed. Her expressed breast milk can then be used in the infant's gavage feeding (Martin et al., 2016). Be certain when bottled breast milk is supplied by the mother that it is well marked with the infant's name, date and time it was pumped, and medical record number or breast milk errors can occur the same as medication errors (Centers for Disease Control and Prevention [CDC], 2016). It should be stored in polycarbonate- (bisphenol A) free plastic bags or bottles, which can leech into stored milk and possibly lead to endocrine disruptions (Trasande, 2014).

**Figure 26.5** Infants who are ill at birth often need supplemental feedings by nasogastric or gastrostomy tube.

Preterm infants reveal hunger by the same signs as term infants, such as rooting, crying, and sucking motions. All babies who are gavage or gastrostomy fed need oral stimulation from nonnutritive sucking and so seem to enjoy a pacifier at feeding times. In immature infants, this may actually help them develop an effective sucking reflex. In mature infants, pacifier use has also been shown to be a deterrent to sudden infant death syndrome (Alm, Wennergren, Möllborg, et al., 2016). Exceptions to pacifier use are for infants too immature to have a sucking reflex; infants who must not swallow air, such as those with a tracheoesophageal fistula awaiting surgery; or infants mature enough to breastfeed. The techniques of gavage feeding and gastrostomy feeding are both discussed in Chapter 37.

## **ESTABLISHING WASTE ELIMINATION**

Although most immature infants void within 24 hours of birth, they may void later than term newborns because, as a result of all the procedures for resuscitation, their blood

pressure may not be adequate to optimally supply their kidneys. Carefully document any voidings that occur during resuscitation because this is proof that hypotension is improving and the kidneys are being perfused. Immature infants also may pass stool later than the term infant because meconium has not yet reached the end of the intestine at birth.

## PREVENTING INFECTIONS

Infections in high-risk newborns may occur from prenatal, perinatal, or postnatal causes. In some instances, such as preterm premature rupture of the membranes, the risk of adverse neurodevelopmental outcomes from the infection is what places the infant in a high-risk category ([Committee on Practice Bulletins-Obstetrics, 2016](#)). Contracting an infection has the potential to drastically complicate a high-risk newborn's ability to adjust to extrauterine life, another reason breastfeeding is good for such infants because, beginning with colostrum, it supplies important immune protection ([Verardo, Gómez-Caravaca, Arráez-Román, et al., 2017](#)). Infection, like chilling, has the detrimental effect of increasing metabolic oxygen demands as well as stressing an immature immune system, thus lowering defense mechanism protection.

Common viruses that affect infants during intrauterine life are cytomegalovirus and toxoplasmosis virus. An infant born after contracting either of these infections may be born with congenital anomalies from the virus invasion (see [Chapter 12](#)). The most prevalent perinatal infections are those contracted from the vaginal canal during birth such as herpes simplex 2 and hepatitis B. Early-onset sepsis is most commonly caused by group B streptococcus, *Escherichia coli*, *Klebsiella* (a gram-negative rod that causes pneumonia), and *Listeria monocytogenes* (a gram-positive bacteria associated with nausea, vomiting, and possibly meningitis). Late-onset, or hospital-acquired, infections are more commonly caused by *Staphylococcus aureus*, *Enterobacter*, and *Candida*. Late-onset infections are probably most commonly spread to newborns from healthcare personnel, which is the reason all persons coming in contact with or caring for infants must observe good hand washing techniques and standard precautions to reduce the risk of infection transmission. Healthcare personnel with infections have a professional and moral obligation to refrain from caring for newborns or wear protective measures such as a face mask to avoid spreading infections.

## ESTABLISHING PARENT-INFANT BONDING

It is helpful if all women who are diagnosed as having a high-risk pregnancy are offered a tour of a neonatal intensive care unit (NICU) during pregnancy, so if their infant should be admitted to a NICU, they will be more comfortable in the high-tech environment.

Be certain the parents of a high-risk newborn are kept informed of what is happening during resuscitation at birth. They should be able to visit the special nursing unit where the infant is admitted as soon as possible and as often as they choose, and,

after washing their hands and in some situations wearing a gown, hold and touch their infant, both of which are actions that help make the infant's birth more real to them. Should an infant not survive an initial illness, these interactions can also help make the death more real and can help parents work through their feelings to accept this event.

Most parents handle newborn babies tentatively until they have "claimed" them or have become firmly acquainted. If an infant was ill at birth, it may take days or weeks before the parents are able to handle their baby comfortably and confidently because of the number of tubes involved in care and their fear of doing something that could hurt the infant. Urge parents to spend as much time with their infant in the intensive care nursery as possible, especially as the infant is improving and is able to begin interacting with them. Be certain parents have continuing access to healthcare personnel after discharge so they can care confidently for the infant at home.

If an infant dies despite newborn resuscitation attempts, parents need to see the infant when no longer attached to equipment. Viewing the baby can help reassure them the baby was a perfect newborn in every other way except lung function or whatever was the infant's specific fatal disorder. Believing this is one way they may be able to develop confidence to plan for other children or simply to continue their lives after such a devastating experience.

## **ANTICIPATING DEVELOPMENTAL NEEDS**

High-risk newborns need special care to ensure the amount of pain they experience during procedures is limited to the least amount possible and that they also receive adequate stimulation for growth. Most high-risk infants experience "catch-up" growth once they stabilize from the trauma of birth or whatever caused them to be considered high risk. They quickly move to playing with age-appropriate toys and interacting with parents. Some parents may need support before and after their infant is discharged home so they can begin to view their child as well and capable of doing all the things the infant is now capable of doing. Discussing usual growth and development of infants can help prepare them and look forward to the next developmental step.

### **Follow-Up of the High-Risk Infant at Home**

Each time parents visit a special/intensive care nursery, assess their level of knowledge about their child's condition and development. For parents whose child has a complex concern, additional education and referral to a home care agency may be necessary to help them continue with the level of care required when the infant is discharged home (see [Chapter 4](#)). Before discharge, the safety of their home for the care of an infant that has healthcare needs (physical or developmental) should be evaluated. Transporting a preterm infant in a car, for example, will require special measures, including a commercial head support because a very small infant does not fit securely into a standard infant car seat.

Although not well documented regarding when or why it occurs, some preterm

infants experience episodes of oxygen desaturation, apnea, or bradycardia when seated in standard car safety seats (Davis, 2015). To detect if this will occur, the AAP recommends all preterm infants be assessed for cardiorespiratory stability in their car seat prior to discharge from the healthcare facility—the “car seat challenge” (AAP, 2012).

## High-Risk Infants and Child Maltreatment

When a child is born ill or preterm, the expected reaction of parents would be to protect the infant even more than the healthy infant so no further harm could occur. In actuality, particularly in reference to the preterm infant, the opposite may occur. Probably related to the feeling they are “different” or because they were separated from the parents for a long time following birth, the preterm infant may be at an increased risk for maltreatment (see Chapter 55) (Nandyal, Owora, Risch, et al., 2013).

### *What If . . . 26.1*

**The nurse hears Mr. Atkins repeat the question he first asked his wife when he heard his baby had been born prematurely, “What did you do to cause this?” Would the nurse try to intervene or allow the Atkins to work out their feelings as a couple?**

## The Newborn at Risk Because of Altered Gestational Age or Birth Weight

Infants need to be evaluated as soon as possible after birth to determine their weight, height, head circumference, and gestational age to determine their immediate healthcare needs and to help anticipate possible future problems. Birth weight is normally plotted on a growth chart such as the Colorado (Lubchenco) Intrauterine Growth Chart, a special chart for newborns (available at <http://thePoint.lww.com/Flagg8e>).

**Term infants** are those born after the beginning of week 38 and before week 42 of pregnancy (calculated from the first day of the last menstrual period). Approximately 90% of all live births fall into this category. Infants born before term (before the beginning of the 38th week of pregnancy) are classified as **preterm infants** regardless of their birth weight (Quinn, Munoz, Gonik, et al., 2016). Infants born after the end of week 41 of pregnancy are classified as postterm infants or postmature (Blencowe, Cousens, Oestergaard, et al., 2012).

Normally, birth weight increases for each additional gestational week of age. Infants who fall between the 10th and 90th percentiles of weight for their gestational age, whether they are preterm, term, or postterm, are considered **appropriate for gestational age (AGA)**. Infants who fall below the 10th percentile of weight for their age are considered **small for gestational age (SGA)**. Those who fall above the 90th

percentile in weight are considered **large for gestational age (LGA)**. Other terms used include:

- **Low-birth-weight (LBW) infant:** one weighing less than 2,500 g at birth
- **Very-low-birth-weight (VLBW) infant:** one weighing less than 1500 g at birth
- **Extremely-low-birth-weight (ELBW) infant:** one weighing less than 1,000 g at birth

Infants in all of these classifications have immediate needs that are different from or that are more pronounced than the needs of AGA term newborns. Each of these categories also carries its own set of potential risks.

## THE PRETERM INFANT

A preterm infant is traditionally defined as a live-born infant born before the end of week 37 of gestation. In terms of the degree of care needed, they are further divided into *late preterm* (born between 34 and 37 weeks) and *early preterm* (born between 24 and 34 weeks). Neonatal assessments such as inspection for sole creases, skull firmness, ear cartilage, and neurologic development plus the mother’s report of the date of her last menstrual period along with a sonographic estimation of age all can be helpful to determine gestational age. Preterm birth occurs in approximately 11% of live births worldwide, with the United States having one of the highest rates of preterm births (Blencowe et al., 2012).

Most preterm infants need intensive care from the moment of birth to give them their best chance of survival without neurologic aftereffects because they are more prone than others to hypoglycemia and intracranial hemorrhage. Lack of lung surfactant, because this does not form until about the 34th week of pregnancy, makes them extremely vulnerable to respiratory distress syndrome (Landry & Menzies, 2011).

No matter what their weight, the initial assessment needs to differentiate healthy preterm babies from SGA babies (who also may have a low birth weight but have more possibility of being unhealthy and so require more help to adjust to extrauterine life). In contrast to an SGA infant, a preterm infant appears immature and has a low birth weight but is well proportioned for age because the baby appears to have been doing well in utero. For an unexplained reason, however, the trigger that initiates labor was activated too early and birth resulted even though the baby was not yet mature. Characteristics of SGA and preterm infants are compared in Table 26.1.

**TABLE 26.1** Contrasts Between Small-For-Gestational-Age and Preterm Infants

Characteristic	Small-for-Gestational-Age Infant	Preterm Infant
Gestational age	24–44 wk	<37 wk
Birth weight	<10th percentile	Normal for age
Congenital malformations	Strong possibility	Possibility

Pulmonary problems most apt to occur	Meconium aspiration, pulmonary hemorrhage, pneumothorax	Respiratory distress syndrome
Hyperbilirubinemia	Possibility	Very strong possibility
Hypoglycemia	Very strong possibility	Possibility
Intracranial hemorrhage	Strong possibility	Possibility
Apnea episodes	Possibility	Very strong possibility
Feeding problems	Most likely because of accompanying problem such as hypoglycemia	Small stomach capacity; immature sucking reflex
Weight gain in nursery	Rapid	Slow
Future restricted growth	Possibly always be <10th percentile because of poor organ development	Not likely to be restricted in growth because “catch-up” growth occurs

## Etiology

At least 50% of neonatal deaths are preterm (Blencowe, Cousens, Chou, et al., 2013). Infant mortality could be reduced dramatically if the causes of preterm birth could be discovered and corrected and all pregnancies could be brought to term. However, even with the examples of possible causes listed in the following, the exact cause of premature labor and early birth is rarely exactly known.

Box 26.3 summarizes factors associated with preterm birth. Important among these is a high correlation between low socioeconomic level and early birth. In women from middle and upper socioeconomic groups, for example, only 4% to 8% of pregnancies are not carried to term. In women from low socioeconomic levels, as many as 10% to 20% end before term (Joseph, Fahey, Shankardass, et al., 2014). Risk factors associated with preterm birth include inadequate nutrition and smoking or alcohol use. The increasing use of assisted fertility methods that result in multiple births, such as in vitro fertilization, is another reason preterm births can occur because more multiple pregnancies result in preterm birth than term pregnancies (Blencowe et al., 2013). Iatrogenic (health-care-caused) issues, such as elective cesarean birth or inducing labor before 39 weeks of pregnancy (which is not recommended but sometimes necessary because of maternal illness or fetal reasons), also result in early births.

### BOX 26.3

#### Common Factors Associated With Preterm Birth

- Low socioeconomic level

- Poor nutritional status
- Lack of prenatal care
- Multiple pregnancy
- Previous early birth
- Race (non-Whites have a higher incidence of prematurity than Whites)
- Cigarette smoking
- Age of the mother (highest incidence is in mothers younger than age 20 years)
- Order of birth (early birth is highest in first pregnancies and in those beyond the fourth pregnancy)
- Closely spaced pregnancies
- Abnormalities of the mother's reproductive system, such as intrauterine septum
- Infections (especially urinary tract infections)
- Pregnancy complications, such as premature rupture of membranes or premature separation of the placenta
- Early induction of labor
- Elective cesarean birth

## Assessment

Although a detailed pregnancy history may sometimes reveal the reason for a preterm birth, the pregnancy history is often normal up to the beginning of labor. When interviewing parents of a preterm infant, be careful not to convey disapproval of reported pregnancy behaviors such as cigarette smoking that may have contributed to preterm birth. Once an infant is born, a new mother needs a high level of self-esteem and all of her inner resources to sustain her through this crisis and not be burdened by guilt over what should or could have been. An accurate but comforting answer to a direct inquiry about why preterm birth occurs is, "No one really knows what causes prematurity."

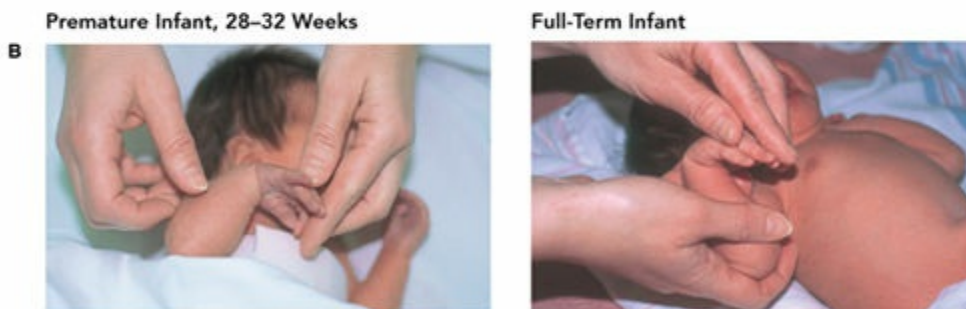

Observing a number of physical findings and reflex testing is used to differentiate between term and preterm newborns at birth (Figs. 26.6 and 26.7). On gross inspection, a preterm infant's head appears disproportionately large ( $\geq 3$  cm greater than chest size). The skin is generally unusually ruddy because there is so little subcutaneous fat beneath it, making veins easily noticeable; a high degree of acrocyanosis may be present. Newborns delivered at greater than 28 weeks of gestation are typically covered with vernix caseosa. In very preterm newborns, however (less than 28 weeks of gestation), the vernix will be lacking. Lanugo is usually scant the same way in very low gestation infants but will be extensive, covering the back, forearms, forehead, and sides of the face in late preterm babies. Both anterior and posterior fontanelles will be small. There are few or no creases on the soles of the feet (Visscher & Narendran, 2014).

**Figure 26.6** An immature newborn at birth. (Photodisc/PunchStock.)

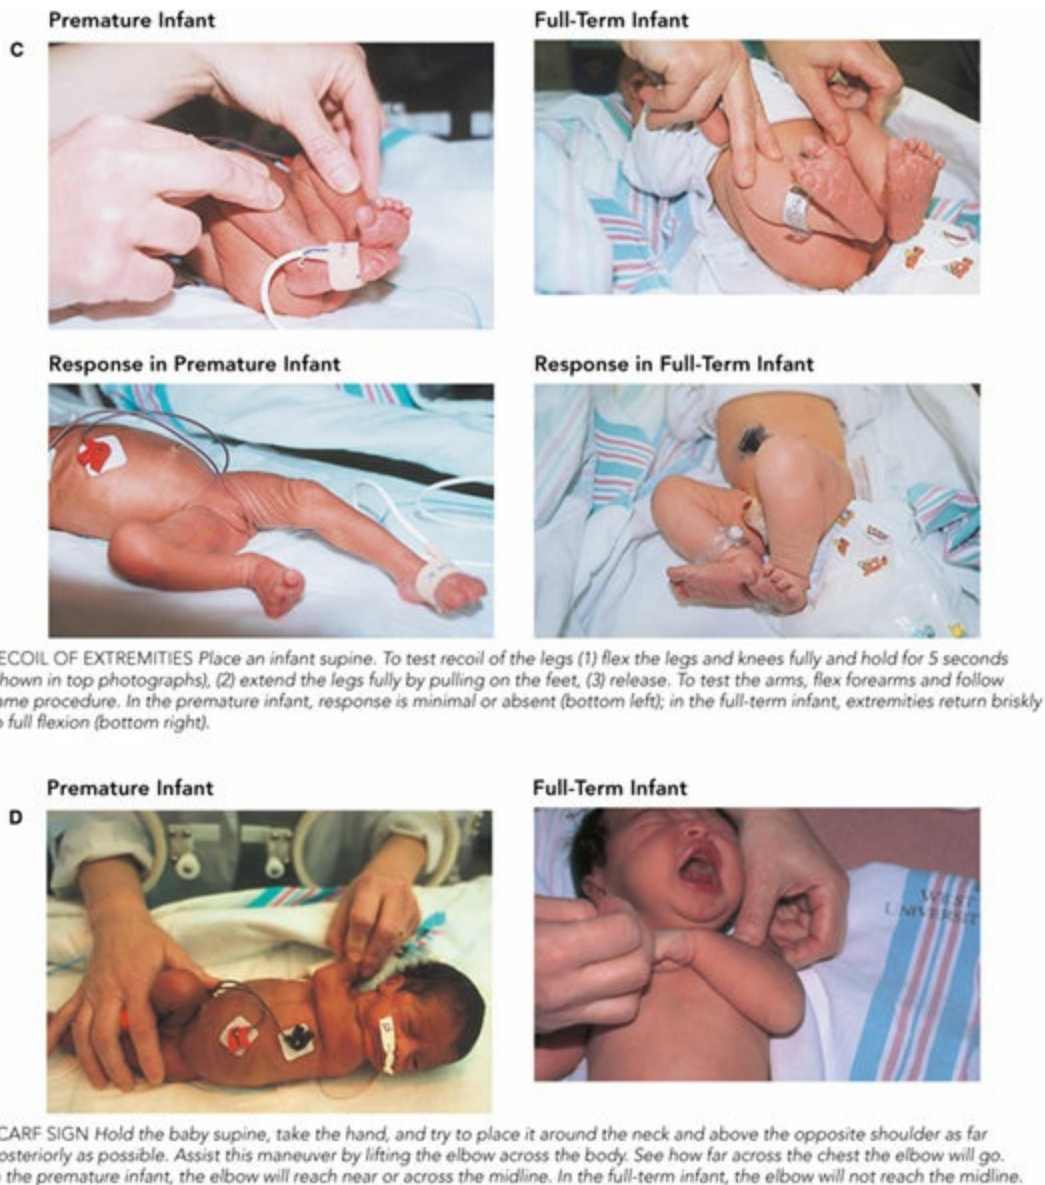

**RESTING POSTURE** The premature infant is characterized by very little, if any, flexion in the upper extremities and only partial flexion of the lower extremities. The full-term infant exhibits flexion in all four extremities.

**WRIST FLEXION** The wrist is flexed, applying enough pressure to get the hand as close to the forearm as possible. The angle between the hypothenar eminence and the ventral aspect of the forearm is measured. (Care must be taken not to rotate an infant's wrist.) The premature infant at 28–32 weeks gestation will exhibit a 90-degree angle. With the full-term infant, it is possible to flex the hand onto the arm.

**Figure 26.7** Examples of physical examination findings and reflex tests used to judge gestational age. (A) A resting posture. (B) Wrist flexion. (C) Recoil of extremities (legs). (D) The scarf sign. (E) Heel to ear. (F) Plantar creases. (G) Breast tissue. (H) Ears. (I) Male genitalia. (J) Female genitalia. (© Caroline Brown, RNC, MS, DEd.)

The eyes of most preterm infants appear small in relation to term infants. Although difficult to elicit, a pupillary reaction is present. An ophthalmoscopic examination is extremely difficult and often uninformative because the vitreous humor may be hazy. A preterm infant has varying degrees of myopia (nearsightedness) because of a lack of eye globe depth.

The ears appear large in relation to the head. The cartilage of the ear is immature and allows the pinna to fall forward. The level of the ears should be carefully inspected to rule out chromosomal abnormalities (see [Chapter 8](#)).

Neurologic function in the preterm infant is often difficult to evaluate because the

neurologic system is still immature. Observing the infant make spontaneous or provoked muscle movements can be as important as formal reflex testing. If they are tested, reflexes such as sucking with coordinated swallowing and breathing will be absent if an infant's age is below 33 weeks; deep tendon reflexes such as the Achilles tendon reflex will also be markedly diminished. During an examination, a preterm infant is much less active than a mature infant and rarely cries. If the infant does cry, the cry is weak and high pitched.

Laboratory values for a preterm infant are compared with those of the term infant at <http://thePoint.lww.com/Flagg8e>.

## Potential Complications

Because of immaturity, preterm infants are prone to several specific conditions.

### Anemia of Prematurity

Many preterm infants develop a normochromic, normocytic anemia (normal cells, just few in number), which can make infants appear pale, lethargic, and anorectic. Anemia occurs from a combination of immaturity of the hematopoietic system (the effective production of red cells with an elevated reticulocyte count may not begin until 32 weeks of pregnancy) combined with the destruction of red blood cells because of low levels of vitamin E, a substance that normally protects red blood cells against oxidation.

Excessive blood drawing for electrolytes, complete blood counts, or blood gas analysis after birth can potentiate the problem. For this reason, it's important to see that blood draws in preterm infants are coordinated to the fewest possible and a record of the blood loss for these tallied. Delaying cord clamping at birth to allow a little more blood from the placenta to enter the infant may also help reduce the development of anemia (Frank, Mueller-Burke, Bullard, et al., 2015).

### Acute Bilirubin Encephalopathy

**Acute bilirubin encephalopathy (ABE)** is the destruction of brain cells by invasion of indirect or unconjugated bilirubin (Mesić, Milas, Medimurec, et al., 2014). This invasion results from the high concentration of indirect bilirubin that forms in the bloodstream from an excessive breakdown of red blood cells at birth. Preterm infants are more prone to this condition than term infants because, with the acidosis that occurs from poor respiratory exchange, brain cells appear to be more susceptible to the effect of indirect bilirubin than usual. Preterm infants also have less serum albumin available to bind indirect bilirubin and inactivate its effect. Because of this, ABE may occur at lower levels in these infants than in term newborns (Thilo & Rosenberg, 2012). At the point that indirect bilirubin levels rise and jaundice occurs, phototherapy or exchange transfusion can be initiated to prevent excessively high indirect bilirubin levels.

### Persistent Patent Ductus Arteriosus

Because preterm infants may lack surfactant, their lungs are noncompliant, so it is more difficult for them to move blood from the pulmonary artery into the lungs. This condition leads to pulmonary artery hypertension, which then interferes with closure of the ductus arteriosus. Always administer intravenous therapy cautiously to preterm infants, therefore, because increasing blood pressure could further compound this problem. In term infants, indomethacin or ibuprofen may be used to cause closure of a patent ductus arteriosus, making ventilation more efficient; however, indomethacin is given cautiously to preterm infants because it has been associated with adverse effects such as decreased renal function, decreased platelet count, and gastric irritation (Mitra, Florez, Tamayo, et al., 2014). Carefully monitor urine output and observe for bleeding, especially at injection sites, if this is prescribed.

### Periventricular/Intraventricular Hemorrhage

Preterm infants are prone to periventricular hemorrhage (bleeding into the tissue surrounding the ventricles) or intraventricular hemorrhage (bleeding into the ventricles) because of fragile capillaries and immature cerebral vascular development. When there is a rapid change in cerebral blood pressure, such as could occur with hypoxia, intravenous infusion, ventilation, or pneumothorax (lung collapse), capillary rupture could occur; brain anoxia then occurs distal to the rupture.

Intraventricular hemorrhage occurs most often in VLBW infants and is classified as:

- Grade 1, bleeding in the periventricular germinal matrix regions or germinal matrix, occurring in one ventricle
- Grade 2, bleeding within the lateral ventricle without dilation of the ventricle
- Grade 3, bleeding causing enlargement of the ventricles
- Grade 4, bleeding in the ventricles and intraparenchymal hemorrhage

A long-term effect of hemorrhage may be the development of hydrocephalus if there was bleeding into the narrow aqueduct of Sylvius (Robinson, 2012). Preterm infants usually have a cranial ultrasound performed after the first few days of life and again at different intervals based on the gestational age of the infant to detect if a hemorrhage has occurred. Infants with grade 1 or 2 bleeds have a good long-term prognosis; the prognosis of those with more intense bleeds is guarded until further complications are ruled out (Shah & Wusthoff, 2016).

### Other Potential Complications

Preterm infants are also particularly susceptible to several illnesses in the early postnatal period, which can also occur in term infants, including respiratory distress syndrome, apnea, and retinopathy of prematurity (all discussed later in this chapter), as well as necrotizing enterocolitis (discussed in Chapter 45).

## Nursing Diagnoses and Related Interventions

Because a preterm infant has few body resources, both physiologic and psychological stress must be reduced as much as possible and interventions should be initiated gently to prevent the depletion of available resources. Close observation and an analysis of findings are essential so concerns can be managed quickly.

**Nursing Diagnosis Risk:** Impaired gas exchange related to immature pulmonary functioning

**Outcome Evaluation:** Newborn initiates breathing at birth after resuscitation; maintains normal newborn respirations of 30 to 60 breaths/min free of assisted ventilation; exhibits oxygen saturation levels of at least 95% as evidenced by pulse oximetry.

Preterm infants have great difficulty initiating respirations at birth because pulmonary capillaries are still so immature, and lung surfactant, which does not form in adequate amounts until about the 34th to 35th week of pregnancy, may not be present. Inadequate lung surfactant leads to alveolar collapse with each expiration. This collapse forces the infant to use maximum strength to inflate lung alveoli each time. Because this is so tiring, it becomes very difficult for infants to maintain effective ventilations under these stressful conditions.

Cesarean birth, although it has the advantage of reducing pressure on the immature head, may be elected with a preterm birth but also may lead to additional respiratory complications because infants born by cesarean birth retain more lung fluid than those born by vaginal birth. Giving the mother oxygen by mask during the birth can help provide a preterm infant with optimal oxygen saturation at birth (85% to 90%). Keeping maternal analgesia and anesthesia to a minimum also offers a preterm infant the best chance of initiating effective respirations.

Even term infants experience temporary respiratory acidosis until they take a first breath. Once respirations are established, however, this condition quickly clears. Because preterm infants cannot initiate effective respirations as quickly as mature infants, they are susceptible to irreversible acidosis. Birthing room teams need to be prepared with preterm-size laryngoscopes, endotracheal tubes, suction catheters, and synthetic surfactant to be administered by the endotracheal tube so resuscitation can be accomplished immediately. Be certain infants are kept warm during resuscitation so they do not have to expend extra energy to increase metabolic rate to maintain body temperature. Be certain as well that all procedures are carried out gently; a preterm infant's tissues are extremely sensitive to trauma and can be damaged or bruised easily by an oxygen mask. When blood from bruising is reabsorbed, this could yet lead to **hyperbilirubinemia** (an excess amount of bilirubin in the blood).

Many preterm babies, particularly those under 32 weeks of age, continue to have an irregular respiratory pattern (a few quick breaths, a period of 5 to 10 seconds without respiratory effort, a few quick breaths again, etc.). There is no bradycardia with this irregular pattern (sometimes termed **periodic respirations**). Although the pattern is seen in term infants as well, it seems to be intensified by immaturity. If true

apnea, which needs immediate attention, is occurring, the pause in respirations is more than 20 seconds and usually results in bradycardia.

The soft rib cartilage of a preterm infant is yet another source of respiratory problems because it causes ribs to collapse on expiration. The accessory muscles of respiration may be underdeveloped as well, leaving preterm infants with no backup muscles to use when they become fatigued. Because of this, preterm infants may need continued oxygen administration after resuscitation to allow them to effectively maintain respirations.

Giving a high level of oxygen to preterm infants during resuscitation or to maintain respirations presents two additional dangers: pulmonary edema and ROP. The development of both of these conditions depends on saturation of the blood with oxygen ( $P_{O_2}$ ) of more than 100 mmHg, which usually occurs when oxygen is administered at a concentration over 70% (Abdel Ghany, Alsharany, Ali, et al., 2016).

**Nursing Diagnosis:** Risk for deficient fluid volume related to insensible water loss at birth and small stomach capacity

**Outcome Evaluation:** Plasma glucose is between 40 and 60 mg per 100 ml; specific gravity of urine is maintained at 1.003 to 1.020; urine output is maintained at a minimum of 1 ml/kg/hr; electrolyte levels are within normal limits.

A preterm newborn experiences a high insensible water loss because of a large body surface relative to total body weight. Preterm infants also cannot concentrate urine well because of immature kidney function. Because of this, a high proportion of body fluid is excreted. All these factors may make a preterm baby need a higher percentage of fluid daily than a term infant (Mohan & Jain, 2012).

Intravenous fluid should be given via a continuous infusion pump to ensure a constant infusion rate and to prevent accidental overload. Assess intravenous sites conscientiously because, if infiltration should occur, the lack of subcutaneous tissue places a preterm newborn at risk for damaged tissue. Specially designed small gauge needles are available for use on small veins. However, many preterm infants lack adequately sized peripheral veins for even this small of a needle. Therefore, they need to receive intravenous fluid by an umbilical or central venous catheter.

Monitor the baby's weight, urine output and specific gravity, and serum electrolytes to ensure adequate fluid intake because too little fluid and calories can lead to weight loss, dehydration and starvation, and increased acidosis. Overhydration may lead to nonnutritional weight gain, pulmonary edema, and heart failure.

Most preterm infants void and pass meconium within 24 hours after birth, although this is delayed in very small infants. Measure urine output by weighing diapers rather than using urine collection bags because disposable collection bags can lead to skin irritation and breakdown from frequent changing and leaking.

The amount of urine output for the first few days of life in preterm babies is high in comparison with that of the term baby because of poor urine concentration: 40 to

100 ml/kg per 24 hours, compared with 10 to 20 ml/kg per 24 hours, respectively. The specific gravity is low, rarely more than 1.012 (normal term babies may concentrate urine up to 1.030). Test urine as well for glucose and ketones because these can reveal hyperglycemia caused by the glucose infusion, which then can lead to diuresis and extreme fluid loss. If too little glucose is being supplied and body cells are using protein for metabolism, ketone bodies will appear in the urine.

Blood glucose determinations should range between 40 and 60 mg/dl. Check for blood in stools to evaluate possible bleeding from the intestinal tract because this can help determine a cause of hypovolemia if this occurs.

**Nursing Diagnosis:** Risk for imbalanced nutrition, less than body requirements, related to additional nutrients needed for maintenance of rapid growth, possible sucking difficulty, and small stomach

**Outcome Evaluation:** Infant's weight follows percentile growth curve, skin turgor is good, specific gravity of urine is maintained between 1.003 and 1.020; the infant has no more than 15% weight loss in the first 3 days of life and continues to gain weight after this point.

Nutrition problems can arise with a preterm infant because the infant's body is attempting to continue to maintain the rapid rate of intrauterine growth appropriate for the gestational age. Because of this, a preterm newborn requires a relatively larger amount of nutrients than the mature infant, 115 to 140 calories per kilogram of body weight per day compared with 100 to 110 calories per kilogram of body weight per day needed by a term infant. Protein requirements are 3 to 3.5 g per kilogram of body weight, compared with 2.0 to 2.5 g per kilogram for a term newborn. Because preterm infants have a smaller stomach capacity than term neonates, as a rule, they must be fed more frequently with smaller amounts than term infants, perhaps as small as 1 or 2 ml every 2 to 3 hours.

If these nutrients are not supplied, an infant can develop hypocalcemia (decreased serum calcium) or azotemia (low protein level in the blood). Delayed feeding and a resultant decrease in intestinal motility may also add to hyperbilirubinemia, a problem infants already are at high risk of developing when fetal red blood cells begin to be destroyed.

Digestion and absorption of nutrients in a preterm infant's stomach and intestine may be immature, making the digestion of milk difficult. Nutrition problems are further compounded by a preterm infant's immature reflexes, which make swallowing and sucking difficult. Increased activity that occurs from ineffective sucking may increase the metabolic rate and oxygen requirements; if this happens, it increases the caloric requirements even more. In addition, the preterm infant's stomach capacity is so small that feedings quickly fill the stomach. If a small stomach is distended from a full feeding, this puts pressure on the diaphragm and can lead to respiratory distress. An immature cardiac sphincter (between the stomach and esophagus) allows regurgitation to occur readily. The lack of a cough reflex may lead

an infant to aspirate regurgitated formula.

**Feeding Schedule.** With the early administration of intravenous fluid to prevent hypoglycemia and supply fluid, feedings may be safely delayed until an infant has stabilized his or her respiratory effort from birth. Very preterm infants may be fed by total parenteral nutrition until they are stable enough for enteral feedings. Breast, gavage, or bottle feedings are then begun as soon as the infant is able to tolerate them to prevent the deterioration of the intestinal villi. Preterm infants may have a chest X-ray taken before a first feeding. The presence of air in the stomach shows that the route to the stomach is clear or that no anomaly such as a tracheoesophageal fistula exists.

**Gavage Feeding.** Although a sucking reflex is present earlier, the ability to coordinate sucking and swallowing is inconsistent until approximately 34 weeks of gestation. A gag reflex is not intact until 32 weeks of gestation. For this reason, for infants who are ill or experiencing respiratory distress may be started on gavage feedings; bottle feeding or breastfeeding will then be gradually introduced as the infant matures and begins to demonstrate feeding behaviors such as being awake, moving, or fussing as if hungry (Fig. 26.8). To avoid tiring, preterm nipples with a slightly larger hole than regular nipples and that are softer are used for bottle feedings.

**Figure 26.8** Feeding a preterm infant. Notice the small bottle used. (Fuse/PunchStock.)

Observe preterm infants closely after oral or gavage feeding to be certain their filled stomach is not causing respiratory distress. Offering a pacifier during gavage feeding can help strengthen the sucking reflex, better prepare an infant for bottle feeding or breastfeeding, and provide oral satisfaction.

Gavage feedings may be given intermittently every few hours or continuously via tubes passed into the stomach or intestine through the mouth or nose. This can be helpful for infants on ventilators or those who cannot tolerate intermittent feedings

because of the volume. If feedings are given intermittently, stomach contents may be aspirated, measured, and replaced before each feeding. An infant who has a large amount of milk left in the stomach (volume depends on the amount of milk the infant is receiving) is not digesting the milk. Feedings should not be increased and possibly even cut back to ensure better digestion and to decrease the possibility of regurgitation and aspiration. An inability to digest in this way is also a sign that necrotizing enterocolitis, a destructive intestinal disorder that often occurs in preterm babies, may be developing (Su, Lin, Huang, et al., 2015) (see Chapter 45).

*Breast Milk.* There is increasing evidence that although preterm infants grow well on commercial formulas, the best milk for them, the same as with term infants, is breast milk (Briere, McGrath, Cong, et al., 2016). The immunologic properties of breast milk may play a major role in preventing neonatal necrotizing enterocolitis as well as an increase in immune defenses.

Mothers can express breast milk manually or with a breast pump for their infant's gavage feedings. If a woman cannot bring this in daily, she can freeze it for safe transport and storage. The sodium content of breast milk in a mother whose infant was born preterm is higher than that of milk in a mother whose infant has been born at term. Therefore, it is better for infants to receive their own mother's breast milk rather than banked milk if possible. This high level of sodium seems to be necessary for fluid retention in the preterm infant. Breast milk is 20 calories per ounce, so parents may be advised to add a human milk fortifier to supplemental bottles of breast milk to supply additional calories, protein, vitamins, and minerals (Brooks, Vickers, & Aryal, 2013). Urge mothers to continue to breastfeed their preterm infants after hospital discharge.

*Formula.* The caloric concentration of formulas used for preterm infants is usually 22 calories per ounce compared to 20 calories per ounce for a term baby (Mohan & Jain, 2012). Supplementing additional minerals such as iron, calcium, and phosphorus and electrolytes such as sodium, potassium, and chloride may be necessary, depending on the newborn's blood studies. Vitamin A is important in improving healing and possibly reducing the incidence of lung disease. Vitamin E seems to be important in preventing hemolytic anemia in preterm infants (Londhe, Nolen, Das, et al., 2013).

**Nursing Diagnosis:** Ineffective thermoregulation related to immaturity

**Outcome Evaluation:** Infant's temperature is maintained at 97.6°F (36.5°C) axillary.

Preterm newborns have a great deal of difficulty maintaining body temperature because they have a relatively large surface area per kilogram of body weight. In addition, because they do not flex their body well but remain in an extended position, rapid cooling from evaporation is more likely to occur.

A preterm infant has little subcutaneous fat for insulation and poor muscular development and so cannot move as actively as an older infant to produce body heat. A preterm infant also has a limited amount of **brown fat**, the special tissue present in

newborns that helps maintain body temperature. Preterm infants also cannot shiver, a useful mechanism to increase body temperature, nor can they sweat and thereby reduce body temperature because of their immature central nervous system and hypothalamic control. This makes preterm infants dependent on the environmental temperature provided to keep warm. In a birthing room, typically kept at 62° to 68°F (16.6° to 20°C), a 1,500-g infant exposed to this low temperature loses 1°C of body heat every 3 minutes if left unprotected. Keeping preterm infants under radiant heat warmers, in incubators, or warmed by skin-to-skin contact helps to counteract this natural cooling. It is recommended that the birthing room temperature be increased to 76°F. Be certain a radiant heat warmer is prewarmed before the infant is born. Unless there are obvious abnormalities noted, a physical assessment of a preterm infant, even weighing, can be delayed until the infant can be placed in the warmth of an incubator or under a radiant warmer with a servo control. Some radiant warmers are equipped with built-in scales to weigh the newborn.

If an infant is going to be transported to a department within the hospital, such as the X-ray department, or to a regional center for specialized care, keeping the newborn warm during transport is crucial. Remember that infants lose heat by radiation as well as conduction. If a warmed incubator is placed in a cold transport ambulance, for example, the infant will lose heat to the distant source. An additional heat shield or plastic wrap may need to be placed over an infant, or a portable warming mattress can be placed under the infant to help conserve heat during transport.

**Nursing Diagnosis:** Risk for infection related to immature immune defenses in the preterm infant

**Outcome Evaluation:** Temperature is maintained at 97.6°F (36.5°C) axillary; further signs and symptoms of infection such as poor growth or a reduced temperature are absent.

The skin of a preterm infant is easily traumatized and therefore offers less resistance to infection than the skin and mucous membrane of a mature infant. In addition, preterm infants have a lowered resistance to infection because they have difficulty producing phagocytes to localize infection as well as a deficiency of immune globulin M (IgM) antibodies because of insufficient production. To help prevent infection, linen and equipment used with preterm infants must not be shared with other infants. Staff members must be free of infection, and hand washing and gowning (if indicated) regulations should be strictly enforced.

**Nursing Diagnosis:** Risk for impaired parenting related to interference with parent–infant attachment resulting from hospitalization of infant at birth

**Outcome Evaluation:** Parents visit frequently and hold the infant; parents speak of their child in positive terms.

In a preterm infant, the first and second periods of reactivity normally observed in

newborns at 1 hour and 4 hours of life (see [Chapter 18](#)) may be delayed. In some infants, no period of increased activity or tachycardia may appear until 12 to 18 hours of age. If the purpose of a period of reactivity is to stimulate respiratory function, this places a preterm infant at an even greater threat of respiratory failure because respiratory efforts may not be stimulated. A second consequence of a delayed period of reactivity is the loss of an opportunity for interaction between parents and the newborn in the early postpartum period.

Although it is extremely important to conserve a preterm infant's strength by reducing sensory stimulation as much as possible and handling an infant gently, preterm infants appear to need as much attention and affection as term newborns. Rocking, singing and talking to them, and gentle holding them are measures to help preterm infants develop a sense of trust in people, which will enable them to relate satisfactorily to people in the future. Encourage parents to begin interacting with their infant as soon as possible ([Box 26.4](#)). Holding an infant with skin-to-skin contact is an effective way to begin this interaction.

#### BOX 26.4

### Nursing Care Planning to Empower a Family

#### Guidelines for Parents of a Newborn in Intensive Care

**Q.** Mrs. Atkins tells you, “I’m always afraid I’ll touch the wrong thing when I visit our son in the neonatal intensive care unit. What can I do to feel more comfortable there?”

**A.** Here are some guidelines that should be helpful:

- Learn the name of your child's primary healthcare provider and primary nurse or care manager. Make a point of talking to them when you visit so the information you receive is consistent and so these important people can get to know you.
- Discuss with your child's primary nurse the time you will usually visit so she or he can schedule your baby's procedures and rest times other than when you visit so there is time for you to hold your child and interact with him uninterrupted.
- Ask for explanations of any equipment or medications being used with your child so you understand the plan of care. Insist on being included in care decisions. The nurses are always nearby and will be happy to explain what can be touched and moved and what should be left alone for now.
- Any day you are unable to visit, call the nursery and ask to talk to your child's primary care nurse. Such telephone calls are not viewed as a bother but are welcomed as the mark of a concerned parent.
- Ask if you can supply expressed breast milk for your infant as soon as feedings are started so you can feel you're having a greater part in your baby's care.
- You might supply a tape recording of your voice so your baby can learn to recognize it, as well as supply a small toy for your baby's bed. These actions not

only supply auditory and visual stimulation for your infant but also help to give you a more “normal” feeling toward infant care.

- Use your baby’s name when you talk about him (not “the baby”) to help you gain a firm feeling that this is your baby, not the nursery’s.
- If your child is hospitalized a distance from home, ask if transfer to a local hospital in a less technical environment will be possible as soon as he’s not so ill.

Before effective bonding can be established, parents may need time to come to terms with their feelings of disappointment that the infant is so small or guilt that they were not able to prevent the preterm birth. Helping them air these feelings and develop a more positive attitude toward their preterm infant is an important nursing responsibility.

Because parents may not be psychologically ready for birth when a preterm infant is born, it may be more difficult for them to believe they have a child and to begin interacting than if the infant had been born at term. Even if an infant cannot be removed from an incubator or a radiant heat warmer, parents can still handle and stroke the infant in the incubator or warmer for interaction. Encourage the mother to come to the nursery and hold the infant before and after gavage feedings and to breastfeed or bottle feed as soon as the baby is ready for this. By feeding her infant or expressing milk for feedings, the mother is directly participating in care and learning the first steps of her new role.

If the baby is going to be transferred to a regional center, make sure the parents have an opportunity to see the infant before the transfer. A photograph of the infant for them to keep is helpful in making the birth more real. Encourage them to visit the distant site as often as possible. Sending them photos snapped with a cell phone or pasting notes as if they’re messages from the baby taped to the incubator or warmer (“Hi, Mom & Dad. I’m doing well”) for them to see when they visit can not only keep parents involved but also help with bonding.

On days they cannot visit, parents can still stay in touch by telephone, video, or nursery e-mail. By these means, by the time the baby is ready for discharge, the parents should be able to feel they are taking home “their” baby, one whom they know and have already begun to love.

Parents visiting a high-risk nursery often need a great deal of support from nursing personnel. Remember that, although radiant warmers, incubators, ventilators, and monitors are familiar equipment to nurses, they are unusual and frightening to parents (Box 26.5). In such a high-tech setting, a parent may want very much to touch his or her infant but is so afraid touching might set off an alarm that he or she stands with arms folded (Fig. 26.9).

#### BOX 26.5

#### Nursing Care Planning Tip for Effective Communication

Mrs. Atkins gave birth 2 days ago to a 2-lb boy at 30 weeks of pregnancy who has been classified as a small-for-gestational-age preterm infant. Although you have told Mrs. Atkins twice she is welcome to visit the neonatal intensive care unit (NICU) as much as she'd like, you notice her electronic record indicates she has done so only once.

*Tip:* Ask enough questions to determine what the patient wants without making assumptions. In this scenario, the nurse could have assumed waiting for the husband to come to the hospital was what was important, but the patient most desired another person to accompany her to the nursery—a need the nurse could meet. Visiting a NICU can be intimidating for parents, not only because of the high-tech equipment that surrounds their baby but also because their baby often appears much smaller or sicker than they imagined.

**Nurse:** Mrs. Atkins, I've noticed you haven't been to the nursery to see your son yet.

**Mrs. Atkins:** I'm waiting for my husband to get here.

**Nurse:** Will that be today?

**Mrs. Atkins:** Tomorrow. He's still out of town on business.

**Nurse:** Have you called the nursery and asked about your son?

**Mrs. Atkins:** I'm waiting for my husband. We'll do it together.

**Nurse:** I know it seems important for you to go as a family, but I hate to see you miss these first few days with your son. What if I go with you?

**Mrs. Atkins:** Could you? I absolutely can't go up there alone.

**Figure 26.9** Encourage families to visit with immature infants to establish bonding. (Phanie/Alamy Stock Photo)

Because preterm infants can be hospitalized for long periods, parents can feel baffled by receiving information from a parade of different healthcare providers or a different person every time they visit. Primary nursing or case management with one nurse as the consistent caregiver helps to reduce the number of people who contact

the parents and who communicate the parents' needs to the rest of the staff.

Try to make a baby's siblings as welcome in a high-risk nursery as the baby's parents in order to build family unity. Check to be certain siblings do not have an upper respiratory infection or fever. Also, their immunizations should be up to date and they should not have been recently exposed to a communicable disease, such as chickenpox, before they visit.

**Nursing Diagnosis:** Deficient diversional activity (lack of stimulation) related to preterm infant's rest needs

**Outcome Evaluation:** Infant demonstrates interaction with caregivers by attuning to faces or voices. Preterm infants need rest to conserve energy for growth and respiratory function, to combat hypoglycemia and infection, to stabilize temperature, and to develop inner balance and attentiveness. To allow for this, try to organize procedures to maximize the amount of rest available to an infant. If not a coordinated effort, an infant may be awakened constantly for procedures. Preterm infants may have more difficulty blocking out stimuli than term infants do because their nervous systems are so immature. They may demonstrate they are overstimulated by such behaviors as gagging, crying, splaying fingers and toes, or going limp when exposed to bright lights, noise, pain, or overly strenuous handling. Because these infants have little strength to move away from an unwanted stimulus, it is a caregiver's responsibility to be sensitive to these cues and move the object or noise away from the infant (Silberstein & Litmanovitz, 2016). Until ready to take in stimuli, the infant may need to be shielded from noise and light and pain may need to be limited as much as possible.

Just as a preterm infant needs rest, he or she also needs planned periods of pleasing sensory stimulation. Like all newborns, preterm infants respond best to stimulation that appeals to their senses of sight, sound, and touch. A passive face, picture, or decal may be appealing for only a short period of time.

The acrylic dome of an incubator can distort an infant's view. Also, most people view an infant in an incubator with themselves standing up and the infant lying horizontally. This means that an infant's face is rarely in the same line of vision as the adult's (an *en face* position). It is important to look directly at an infant in the straightforward position as much as possible so the infant is provided with the stimulation of a human face. As infants mature, they should have mobiles (perhaps black and white) or bright objects placed in view. As an infant's position is changed from the left side to the right side, move the object to be in line with the child's vision.

Infants in closed incubators may be able to hear nothing but the sound of the incubator motor. They may see people looking or nodding at them and may see their mouths moving, but they cannot benefit from the sound of their voices because this is obscured by the continuous hum of the motor. To help them hear better, provide some "talk time"—words spoken softly but clearly into an infant's ear during each

nursing shift, perhaps while the infant is being fed out of the incubator, to offer usual sensory stimulation.

Even an infant who cannot be removed from an incubator should not suffer from lack of touch. Gently stroking an infant's back or smoothing the back of the head should not be tiring. Pulse oximetry can be used to help you recognize when an infant is comforted by handling (e.g., oxygen saturation remains steady or increases) and when the infant is growing tired (e.g., oxygen saturation falls). Be certain during every nursing shift that close interaction is provided, particularly if clinical interventions with an infant include uncomfortable procedures such as suctioning or blood drawing. As soon as infants can be out of incubators or removed from warmers, they need special time just to be rocked and held.

**Nursing Diagnosis:** Risk for disorganized infant behavior related to prematurity and environmental overstimulation

**Outcome Evaluation:** Newborn's vital signs remain within normal limits; infant demonstrates increasing ability to adapt to stimuli; demonstrates decreasing levels of irritability, crying, respiratory pauses, tachypnea, and color changes.

The amount of rest and stimulation required by preterm infants for healthy development is best individualized. **Developmental care** (care designed to meet the specific needs of each infant) can lead to increased weight gain and decreased crying and apnea spells in preterm infants ([Samra, McGrath, Wehbe, et al., 2012](#)) ([Box 26.6](#)).

## BOX 26.6

### Developmental Care

Developmental care is care individually designed based on a preterm infant's behavioral cues to meet the special needs of a preterm or newborn infant. Common measures include:

#### PARENT WELCOMING PROCEDURES

- Make parents feel welcome in a neonatal intensive care environment by both words and actions.
- Provide room around incubators or warmers for rocking chairs so parents can hold their baby comfortably.
- Encourage parent participation in feeding or supplying nonnutritive sucking experiences.
- Demonstrate the infant's capabilities and how, although immature, these are correct for the infant's age or weight.
- Keep parents informed of their baby's progress and the rationale for therapies.
- Ask parents for input into their baby's rhythm of care that will best suit them and the infant after they return home.

## INFANT DEVELOPMENTAL PROCEDURES

- Provide a consistent routine to help the infant develop sleep/wake cycles.
- Time infant care and feeding based on the sleep/wake cycle of the infant.
- Cluster aspects of care so the infant enjoys the longest possible sleep intervals to conserve energy.
- Provide a “nest” with blankets to offer a sense of boundaries or security.
- Position infants so they can self-soothe—curled on side, or hands near face, knees tucked near body, or whatever way each baby seems to prefer.
- Provide quiet or rest times by covering an incubator and limiting sound.
- Provide tactile stimulation by back stroking or massage.
- Provide audio and visual stimulation by the use of mobiles and music or a parent’s voice.
- Halt procedures as soon as the infant evidences stress.

Because preterm infants have an immature central nervous system, their reactions or adjustments to stimuli may be different from those of term infants. The environment of an intensive care unit is also totally different from what infants would have experienced if they had remained in utero until term. Based on these two premises, nursing care should be geared toward making the environment of infants as atraumatic as possible while helping them adjust to new experiences within their limited ability.

The usual sound level of nurseries, for example, has been documented to be about 40 to 50 dB; a radio playing raises this to 60 to 65 dB. The closing of portholes or tapping on the sides of incubators raises the sound level inside them to 80 dB or more, or a sound level that can be painful. Other abnormal stimuli are bright lights for 24 hours a day, frequent handling, and painful procedures.

Activities such as dimming the lights or covering an incubator, turning an infant to the side and containing the body with rolled towels (nesting), offering nonnutritive sucking, and maintaining a “quiet hour” to reduce sound are all ways to reduce stimuli or construct an environment conducive to healthy development (Laubach, Wilhelm, & Carter, 2014).

**Nursing Diagnosis:** Parental health-seeking behaviors related to preterm infant’s needs for health maintenance

**Outcome Evaluation:** Parents describe schedule for basic immunizations and health assessments and state who will provide ongoing health care.

Discharge from a NICU is a major transition for parents as well as their infant. Before discharge, the parents of a preterm infant need to learn and practice any special methods of care necessary for their infant and interventions to help maximize their child’s development. Some parents tend to overprotect preterm infants, such as not allowing visitors or not taking an infant outside. Let parents know their concern is

normal, but overprotection is not necessary.

Ongoing health maintenance of a preterm infant follows the usual pattern of well-child care. Basic immunizations are given according to the chronologic age of an infant. In many communities, NICUs maintain their own well-child settings for infants who were hospitalized there. This allows for long-term follow-up studies on the effect of oxygen or drug therapy and continuity of care. Many parents prefer bringing their infant back to such a facility rather than establishing a new network of health care because they have already established trust and confidence in that healthcare team. This often also increases their self-esteem because they hear the staff's delight in the progress made by their child. However, preterm infants can be followed by any healthcare provider for well-child care.

When plotting the height and weight of preterm infants at well-child visits, remember to account for early birth on the growth chart by double charting—that is, plotting the child's weight and height according to the chronologic age (a pattern that, in the early months, probably places the child below the 10th percentile). Then, in another color, plot the height and weight according to an infant's adjusted age, or plot the weight of a baby born 2 months early 2 months earlier on the graph. A preterm baby typically gains “catch-up” weight in the first 6 months of life, so by 1 year of age, a baby plots over the 10th percentile on a growth chart without accounting for a setback age.

Evaluate growth and developmental milestones of a preterm infant in the same manner. A preterm infant can be expected to meet first-year milestones not at the chronologic age but at the setback age. To evaluate the parents' transition to having so small an infant at home, ask at health promotion visits if the parents are:

- Beginning to feel more comfortable with their infant
- Able to allow the child to stay with a babysitter or another family member
- Beginning to incorporate their infant into their family life
- Making plans for the infant beyond the immediate newborn period

### *QSEN Checkpoint Question 26.2*

#### **Teamwork & Collaboration**

Baby Atkin's father plays in a garage band for a hobby, and his mother enjoys knitting. The nurse's care team has agreed to design a developmental care environment for Baby Atkins that will both make him feel secure and help his parents interact more with him. The care team determines which action is best?

- a. Turning up the lights in his part of the nursery so he can see his parents better
- b. Asking the father to bring in a recording of his band to play for the baby
- c. Arranging a blanket Mrs. Atkins has knit into a circle or “nest” for the baby
- d. Reminding the parents that he must stay awake for extended periods for his eyes to fully develop

## THE SMALL-FOR-GESTATIONAL-AGE INFANT

An infant is SGA (also called microsomia) if the birth weight is below the 10th percentile on an intrauterine growth curve for that age. Such infants may be born:

- Preterm: before week 38 of gestation
- Term: between weeks 38 and 42
- Postterm: past 42 weeks

SGA infants are small for their age because they have experienced **intrauterine growth restriction (IUGR)** or failed to grow at the expected rate in utero (Rahimian, 2013). This characteristic makes them distinctly different from infants who are born with a less weight than usual but their low weight is consistent for their gestational age.

### Etiology

A woman's nutrition during pregnancy plays a major role in fetal growth, so a lack of adequate nutrition may be a major contributor to IUGR (Ota, Tobe-Gai, Mori, et al., 2012).

Adolescents are prone to having a high incidence of SGA infants because if they eat only enough to meet their own nutritional and growth needs, the needs of a growing fetus can be compromised. In still other instances, the placental supply of nutrients is adequate but an infant cannot use them because of a chromosomal abnormality or an intrauterine infection such as rubella or toxoplasmosis.

Even in light of these nutritional influences, the most common cause of IUGR is a placental issue: either the placenta did not obtain sufficient nutrients from the uterine arteries or it was inefficient at transporting nutrients to the fetus. Placental underdevelopment or damage, such as partial placental separation with bleeding is an example of a situation that would limit placental function because the area of placenta that separated infarcted and fibrosed, reducing the placental surface available for nutrient exchange. Women with systemic diseases that decrease blood flow to the placenta, such as severe diabetes mellitus or gestational hypertension (diseases in which blood vessel lumens are narrowed), are at higher risk for birthing SGA babies than others. Women who smoke heavily or use opiates also tend to have SGA infants (Ortigosa, Friguls, Joya, et al., 2012).

### Assessment

The SGA infant may be detected in utero when fundal height during pregnancy becomes progressively less than expected. However, if a woman is unsure of the date of her last menstrual period, this discrepancy can be hard to substantiate; a sonogram can then demonstrate the decreased size. A biophysical profile including a nonstress test, placental grading, amniotic fluid amount, and an ultrasound examination documents additional information on placental function and fetal growth. If poor placental function

is apparent from such determinations, it can be predicted that the infant will do poorly during labor during the periods of relative hypoxia, which occur during contractions. Cesarean birth, therefore, is the birth method of choice in such circumstances.

## Appearance

Generally, an infant who suffers nutritional deprivation early in pregnancy, when fetal growth consists primarily of an increase in the number of body cells, is below average in weight, length, and head circumference. An infant who suffers deprivation late in pregnancy, when growth consists primarily of an increase in cell size, may have only a reduction in weight. Regardless of when deprivation occurs, the infant tends to have an overall wasted appearance. The infant may have poor skin turgor and generally appears to have a large head because the rest of the body is so small. Skull sutures may be widely separated. Hair may be dull and lusterless. The infant may have a small liver, which can cause difficulty regulating glucose, protein, and bilirubin levels after birth. The abdomen may be sunken. The umbilical cord often appears dry and may be stained yellow.

In contrast, because an infant's age is more advanced than the weight implies, an infant may have better developed neurologic responses, sole creases, and ear cartilage than expected for a baby of that weight. The infant may also seem unusually alert and active. As a first assessment, the SGA infant needs to be examined carefully for possible congenital anomalies that occurred because of the poor nutritional intrauterine environment.

## Laboratory Findings

Blood studies at birth usually show a high hematocrit level (less than normal amounts of plasma in proportion to red blood cells are present because of a lack of fluid) and an increase in the total number of red blood cells (polycythemia). The increase in red blood cells occurs because anoxia during intrauterine life stimulated excess development of them. An immediate effect of polycythemia is to cause increased blood viscosity, a condition that puts extra work on the infant's heart because it is more difficult to effectively circulate thick blood. As a consequence, acrocyanosis (blueness of the hands and feet) may be prolonged and persistently more marked than usual. If the polycythemia is extreme, vessels may actually become blocked and thrombus formation can result. If the hematocrit level is more than 65% to 70%, an exchange transfusion to dilute the blood may be necessary.

A second problem of polycythemia is hyperbilirubinemia because so many extra red blood cells break down and release bilirubin.

Because SGA infants have decreased glycogen stores, still another common problem that develops is hypoglycemia (decreased blood glucose, or a level below 45 mg/dl). Such infants may need intravenous glucose to sustain blood sugar until they are able to suck vigorously enough to take sufficient oral feedings.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Ineffective breathing pattern related to underdeveloped body systems at birth

**Outcome Evaluation:** Newborn maintains respirations at a rate of 30 to 60 breaths/min after resuscitation at birth.

Birth asphyxia is a common problem for SGA infants, both because they have underdeveloped chest muscles and because they are at risk for developing meconium aspiration syndrome (MAS) as a result of meconium release, which occurs when fetal anoxia develops during labor to cause reflex relaxation of the anal sphincter. When gasping for breath in utero, the fetus draws meconium discharged from the intestine into the amniotic fluid down into the trachea and bronchi. Acting as a foreign substance, this blocks airflow into the alveoli and causes the SGA infant to need resuscitation at birth. Closely observe both respiratory rate and character in the first few hours of life as underdeveloped chest muscles not only make taking the first breath difficult but can make SGA infants unable to sustain an adequate newborn respiratory rate.

**Nursing Diagnosis:** Risk for ineffective thermoregulation related to lack of subcutaneous fat

**Outcome Evaluation:** Infant's temperature is maintained at 36.5°C (97.8°F) axillary.

SGA infants are less able to control body temperature than other newborns because they lack subcutaneous fat. A carefully controlled environment is essential to keep the infant's body temperature in a neutral zone (see [Chapter 18](#)).

**Nursing Diagnosis:** Risk for impaired parenting related to child's high-risk status and possible cognitive or neurologic impairment from lack of nutrients in utero

**Outcome Evaluation:** Parents express interest in infant and ask questions about what the child's care needs will be at home; parents hold infant warmly.

Although SGA infants may gain weight and appear to thrive in the first few days of life, their cognitive development may have been impaired because of lack of oxygen and nourishment in utero. Babies who were growing normally in utero but whose gestation was interrupted (true preterm, AGA babies) usually gain weight and height so rapidly that by the end of the first year of life they are near the 50th percentile on growth charts. SGA infants, in contrast, may always be below the usual height on standard growth charts. This inability to reach normal levels of growth and development can interfere with bonding if a child does not meet the parents' expectations. Eventually, it can interfere with the child's self-esteem if the child is never able to meet parental expectations or reach full height.

Yet, another need of an SGA infant is adequate stimulation during the infant period in order to reach normal growth and developmental milestones. Encourage parents to provide toys suitable for their child's chronologic age, not physical size. Because an infant tires easily in the first few weeks of life, urge them to space play periods with rest periods or hypoglycemia or apnea can occur. All infants with IUGR need continued follow-up after hospital discharge because they may have neurologic deficits that will interfere with learning at preschool age (Murray, Fernandes, Fazel, et al., 2015).

## THE LARGE-FOR-GESTATIONAL-AGE INFANT

An infant is LGA (also termed **macrosomia**) if the birth weight is above the 90th percentile on an intrauterine growth chart for that gestational age. Such a baby appears deceptively healthy at birth because of the weight, but a gestational age examination often reveals immature development. It is important that LGA infants be identified immediately so they can be given care appropriate to their gestational age rather than being treated as term newborns (Sjaarda, Albert, Mumford, et al., 2014).

### Etiology

Infants who are LGA have been subjected to an overproduction of nutrients and growth hormone in utero. This happens most often to infants of women who are obese or who have diabetes mellitus (Sjaarda et al., 2014). Multiparous women may also have large babies because with each succeeding pregnancy, babies tend to grow larger. Beckwith-Wiedemann syndrome, a rare condition characterized by general body overgrowth and congenital anomalies such as omphalocele, may also be a cause.

### Assessment

A fetus is suspected of being LGA when a woman's uterus appears to be unusually large for the date of pregnancy. Abdominal size can be deceptive, however. Because a fetus lies in a flexed fetal position, he or she does not occupy significantly more space at 10 lb than at 7 lb. If a fetus does seem to be growing at an abnormally rapid rate, a sonogram can confirm the suspicion. A nonstress test to assess the placenta's ability to sustain a large fetus during labor may be prescribed. Lung maturity may be assessed by amniocentesis.

If an infant's large size was not detected during pregnancy, it may be first recognized during labor when the baby appears too large to descend through the pelvic rim. If this happens, a cesarean birth may be necessary because **shoulder dystocia** (the wide fetal shoulders cannot pass; or needs significant manipulation to pass through the outlet of the pelvis) would halt vaginal birth at that point.

### Appearance

At birth, LGA infants may show immature reflexes and low scores on gestational age examinations in relation to their size. They may have extensive bruising or a birth injury such as a broken clavicle or Erb–Duchenne paralysis from trauma to the cervical nerves if they were stressed in order for the wide shoulders to be born vaginally (see [Chapter 51](#)). Because the head is large, it may have been exposed to more than the usual amount of pressure during birth, causing a prominent caput succedaneum, cephalohematoma, or molding.

Because LGA newborn are large but often immature, they require the same cautious care necessary for a preterm infant. Specific criteria for initial or continuing assessments are shown in [Table 26.2](#).

**TABLE 26.2 Important Assessment Criteria for a Large-For-Gestational-Age Infant**

Assessment	Rationale
Assess skin color for ecchymosis, jaundice, and erythema	Bruising occurs with vaginal birth because of the large size; polycythemia causes ruddiness of skin. Ecchymosis is important to document because jaundice may occur from breakdown of ecchymotic collections of blood.
Assess motion of upper extremities is spontaneous and also occurs in response to a Moro reflex to detect if clavicle fracture (crepitus or swelling may then be palpated at the fracture site) or Erb’s palsy caused by edema of the cervical nerve plexus are present.	Clavicle or cervical nerve injuries may occur because of problem at birth of wider than usual shoulders.
Assess asymmetry of the anterior chest or unilateral lack of movement to detect diaphragmatic paralysis from edema of the phrenic nerve.	The cervical nerve may be stretched by birth of wide shoulders.
Assess eyes for evidence of unresponsive or dilated pupils; assess for vomiting, bulging fontanelles, or a high-pitched cry suggestive of increased intracranial pressure.	The larger than usual head can be more compressed than usual resulting in increased intracranial pressure. Compression of the third, fourth, and sixth cranial nerves limits eye response; other signs are additional signs of increased intracranial pressure.
Assess for activities such as jitteriness, lethargy, and uncoordinated eye	Seizures are yet another indication of increased intracranial pressure;

movements that suggest seizure activity.

hypoglycemia seizures in newborns from the result of a low glucose level often produce the more vague symptoms.

## Cardiovascular Dysfunction

Polycythemia may occur in an LGA fetus as the fetus attempts to fully oxygenate more than the average amount of body tissue. Following birth, observe LGA infants closely for signs of hyperbilirubinemia that may result from absorption of blood from bruising and breakdown of the extra red blood cells created by polycythemia. Assess the infant's heart rate also. If cyanosis is present, it may be a sign of poor heart function, but it could also be from transposition of the great vessels, a serious heart anomaly associated with macrosomia (see [Chapter 41](#)).

## Hypoglycemia

LGA infants also need to be carefully assessed for hypoglycemia in the early hours of life because large infants require large amounts of nutritional stores to sustain their weight. If the mother had diabetes that was poorly controlled (the cause of the large size), the infant would have had an increased blood glucose level in utero to match the mother's glucose level; this caused the infant to produce elevated levels of insulin. After birth, these increased insulin levels will continue for up to 24 hours of life, possibly causing rebound hypoglycemia.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Ineffective breathing pattern related to possible birth trauma in the LGA newborn

**Outcome Evaluation:** Newborn initiates independent breathing at birth; maintains usual newborn respiratory rate of 30 to 60 breaths/min.

Some LGA infants have difficulty establishing respirations at birth because of birth trauma. Increased intracranial pressure from birth of the larger than usual head, for example, could have led to pressure on the respiratory center causing a decrease in respiratory function. If the infant was born vaginally, a diaphragmatic paralysis or broken clavicle, both of which can prevent effective lung function, may have occurred in order for the wide shoulders to be born. If the infant was born by cesarean birth, transient fluid can remain in the lungs and can interfere with effective gas exchange. Careful observation is needed, therefore, to detect all these conditions. Care of an infant with transient lung fluid is discussed later in this chapter.

**Nursing Diagnosis:** Risk for imbalanced nutrition, less than body requirements, related to additional nutrients needed to maintain weight and prevent hypoglycemia

**Outcome Evaluation:** Infant's weight follows percentile growth curve, skin turgor is good, specific gravity of urine is 1.003 to 1.020; serum glucose is above 45 mg/dl.

As a rule, an LGA infant needs to be fed immediately after birth (preferably by breastfeeding) to prevent hypoglycemia. Evaluate carefully the intake of LGA infants at this feeding so you don't overestimate their ability to suck effectively. Such infants may seem as if they should be able to suck well because they are already the size of a 2-month-old. However, despite their size, these infants are inexperienced newborns, and sucking may not be effective enough to obtain the larger than usual amount of milk needed.

These infants may need supplemental formula feedings after breastfeeding to supply enough fluid and glucose for the larger than normal size for the first 24 hours. Newborns who are offered bottles often have more difficulty than do others learning to breastfeed, however, so in light of this, although it seems extreme, additional glucose may be offered intravenously.

**Nursing Diagnosis:** Risk for impaired parenting related to high-risk status of LGA infant

**Outcome Evaluation:** Parents hold infant warmly; speak of the child in positive terms; state accurately why their infant needs to be closely observed in postnatal period.

Parents may also underestimate this infant's needs because of the child's large size. He or she seems so big and healthy, so it can be confusing to be told the infant needs careful observation. If they are worried the infant must be sick in some way and they are not being told about, it can interfere with bonding happening as instinctively as it might. If a woman sustained a cervical or perineal tear or required a cesarean birth, she may need some time to air any negative feelings she may be experiencing toward the infant for causing her extra pain. Otherwise, her perception that her infant is the cause of her additional distress is another factor that could interfere with her ability to bond with the child.

Note whether parents treat their baby as a newborn who needs warm nurturing care, not as a tough, big infant who has grown past that stage because the baby may miss out on usual parental comforting measures. You may need to remind parents an infant's birth weight does not correlate with the child's projected adult size. Otherwise, parents may fear their infant may grow to be a larger than usual adult.

### *What If . . . 26.2*

**Mrs. Atkins tells the nurse she wishes her baby was 11 lb like the baby in the**

**incubator next to hers so he wouldn't have any problems. What patient education would the nurse provide?**

## THE POSTTERM INFANT

A **postterm infant** is one born after the 41st week of a pregnancy (Rahimian, 2013). Infants who stay in utero past week 41 are at special risk because a placenta appears to function effectively for only 40 weeks. After that time, it seems to lose its ability to carry nutrients effectively to the fetus, and the fetus begins to lose weight (postterm syndrome). Infants with this syndrome demonstrate many of the characteristics of the SGA infant: dry, cracked, almost leatherlike skin from lack of fluid, and an absence of vernix. They may be SGA, and the amount of amniotic fluid surrounding them may be less at birth than usual and it may be meconium stained. Fingernails will have grown well beyond the end of the fingertips. Because they are older than a term infant, they may demonstrate an alertness much more like a 2-week-old baby than a newborn.

When a pregnancy becomes postterm, a sonogram is usually obtained to measure the biparietal diameter of the fetus. A nonstress test or complete biophysical profile (see Chapter 9) may be done to establish whether the placenta is still functioning adequately. A cesarean birth may be indicated if a nonstress test reveals that compromised placental functioning is apt to occur during labor.

At birth, the postterm baby is likely to have difficulty establishing respirations, especially if meconium aspiration occurred. Polycythemia may have developed from decreased oxygenation in the final weeks. The hematocrit may be elevated because polycythemia and dehydration have lowered the circulating plasma level. In the first hours of life, hypoglycemia may develop because the fetus had to use stores of glycogen for nourishment in the last weeks of intrauterine life. Subcutaneous fat levels may also be low, having been used in utero. This loss of fat can make temperature regulation difficult, making it important to prevent a postterm infant from becoming chilled at birth or during transport.

Any woman is anxious when she does not have her baby on her due date. She is apt to become extremely anxious and perhaps angry when it is determined her baby is postterm. It seems that, if her baby stayed so long in utero under her protection, the baby should be extra healthy and strong. Why, then, she asks, is her baby being transferred for special care? The mother may also feel guilty for not providing well for her infant in the last few weeks of the pregnancy.

Make certain a woman spends enough time with her newborn to assure herself that although birth did not occur at the predicted time, the baby should do well with appropriate interventions to control possible hypoglycemia or meconium aspiration. All postterm infants need follow-up care until at least school age to track their developmental abilities because the lack of nutrients and oxygen in utero may have left them with neurologic symptoms that will not become apparent until they attempt fine-motor tasks.

## Illnesses That Occur in Newborns

A number of illnesses occur specifically in newborns that automatically cause the infant to be classified as high risk.

### RESPIRATORY DISTRESS SYNDROME

Respiratory distress syndrome (RDS) of the newborn, formerly termed *hyaline membrane disease*, is most often seen in newborns born prematurely. Other causes of RDS include newborns with meconium aspiration syndrome, sepsis, a newborn who is slow to transition to extrauterine life, and pneumonia (Hermansen & Mahajan, 2015).

The pathologic feature of RDS is a hyalinelike (fibrous) membrane formed from an exudate of an infant's blood that begins to line the terminal bronchioles, alveolar ducts, and alveoli. This membrane prevents the exchange of oxygen and carbon dioxide at the alveolar–capillary membrane, interfering with effective oxygenation. The cause of RDS is a low level or absence of surfactant, the phospholipid that normally lines the alveoli and reduces surface tension to keep the alveoli from collapsing on expiration. Because surfactant does not form until the 34th week of gestation, as many as 30% of LBW infants and as many as 50% of VLBW premature infants are susceptible to this complication.

### Pathophysiology

High pressure is required to fill the lungs with air for the first time and overcome the pressure of lung fluid. For example, it takes a pressure between 40 and 70 cm H<sub>2</sub>O to inspire a first breath but only 15 to 20 cm H<sub>2</sub>O to maintain quiet, continued breathing. If alveoli collapse with each expiration, as happens when surfactant is deficient, forceful inspirations requiring optimum pressure are still required to inflate them.

Even very immature infants release a bolus of surfactant at birth into their lungs from the stress of birth. However, with deficient surfactant, areas of hypoinflation begin to occur and pulmonary resistance increases. Blood then shunts through the foramen ovale and the ductus arteriosus as it did during fetal life. The lungs become poorly perfused. As a result, the production of surfactant decreases even further.

The poor oxygen exchange that results leads to tissue hypoxia, which causes the release of lactic acid. This, combined with the increasing carbon dioxide level resulting from the formation of the hyaline membrane on the alveolar surface, leads to severe acidosis. Acidosis causes vasoconstriction and decreased pulmonary perfusion from vasoconstriction, which further limits surfactant production. With surfactant production almost lost, the ability to stop alveoli from collapsing with each expiration becomes more and more difficult. This vicious cycle continues until the oxygen–carbon dioxide exchange in the alveoli is no longer adequate to sustain life without ventilator support.

### Assessment

Most infants who develop RDS have difficulty initiating respirations at birth. After resuscitation, they appear to have a period of hours or a day when they are free of symptoms because of an initial release of surfactant. During this time, however, subtle signs may appear, such as:

- Low body temperature
- Nasal flaring
- Sternal and subcostal retractions
- Tachypnea (more than 60 breaths/min)
- Cyanotic mucous membranes

Within several hours, expiratory grunting occurs caused by closure of the glottis as it tries to increase the pressure in alveoli on expiration in order to help to keep them from collapsing. Even with this attempt at better oxygen exchange, however, as the disease progresses, infants become cyanotic and their  $P_{O_2}$  and oxygen saturation levels fall in room air. On auscultation, there may be fine rales and diminished breath sounds because of poor air entry. As distress increases, an infant may exhibit:

- Seesaw respirations (on inspiration, the anterior chest wall retracts and the abdomen protrudes; on expiration, the sternum rises)
- Heart failure, evidenced by decreased urine output and edema of the extremities
- Pale gray skin
- Periods of apnea
- Bradycardia
- Pneumothorax

The diagnosis of RDS is made on the clinical signs of grunting, central cyanosis in room air, tachypnea, nasal flaring, and retractions. A chest X-ray will reveal a diffuse pattern of radiopaque areas that look like ground glass (haziness) in the lungs. Blood gas studies will reveal respiratory acidosis. A  $\beta$ -hemolytic, group B streptococcal infection may mimic RDS because this infection is so severe in newborns that it stops surfactant production. Cultures of blood, cerebrospinal fluid, and skin may be obtained, therefore, to rule out this condition. An antibiotic (penicillin or ampicillin) and an aminoglycoside (gentamicin or kanamycin) may be started while culture reports are pending.

## Therapeutic Management

### Surfactant Replacement

RDS can be largely prevented by the administration of surfactant at birth for an infant at risk because of low gestational age (Box 26.7). Immediately after birth, synthetic surfactant is administered into an endotracheal tube by a syringe or catheter (lung lavage) (Wyckoff et al., 2015).

#### BOX 26.7

### **SURFACTANT (SURVANTA)**

(<http://survanta.com/dosage.cfm>)

**Action:** Surfactant restores naturally occurring lung surfactant to improve lung compliance.

**Pregnancy Risk Category:** X

**Dosage:** 4 ml/kg intratracheally; four doses in first 48 hours of life

**Possible Adverse Effects:** Transient bradycardia, rales

#### **Nursing Implications**

- Suction infant before administration.
- Assess infant's respiratory rate, rhythm, oxygen saturation, and color before administration.
- Ensure proper endotracheal tube placement before dosing.
- Change infant's position during administration to encourage the drug to flow to both lungs.
- Assess infant's respiratory rate, color, and pulse oximetry or arterial blood gases after administration.
- Do not suction endotracheal tube for 1 hour after administration to avoid removing the drug (Karch, 2013).

It's important the infant is tipped to an upright position following administration and the infant's airway is not suctioned for as long as safely possible after administration of surfactant to help it reach lower lung areas and to avoid suctioning the drug away. Although there are almost no unfavorable reactions to surfactant administration, some, such as mucus plugging from the solution, do occur. An infant who is receiving surfactant and then is placed on a ventilator needs close observation because lung expansion can improve so rapidly, the ventilator pressure becomes too high. Anticipate the need to adjust ventilator settings to accommodate the vastly improved lung function.

#### **Oxygen Administration**

The administration of oxygen is often necessary to maintain correct  $PO_2$  and pH levels following surfactant administration, and it may be administered in a variety of ways from a simple cannula or mask, continuous positive airway pressure (CPAP), or assisted ventilation with positive end-expiratory pressure (PEEP). The advantage of CPAP or PEEP is that this exerts pressure on the alveoli at the end of expiration and helps keep alveoli from collapsing in addition to supplying oxygen (Wyckoff et al., 2015). High-frequency, oscillatory, and jet ventilation are still other methods of introducing oxygen to infants with noncompliant lungs. These systems maintain airway pressure and then intermittently "jet" or oscillate an additional amount of air at a rapid rate (400 to 600

times per minute) to inflate alveoli.

A possible complication of oxygen therapy in the very immature or very ill infant is ROP (see discussion later in chapter) or bronchopulmonary dysplasia (BPD) which is also known as chronic lung disease (see [Chapter 40](#)).

## Ventilation

Normally, on a ventilator, inspiration is shorter than expiration, or there is an inspiratory/expiratory (I/E) ratio of 1:2. It is difficult to deliver enough oxygen to stiff, noncompliant lungs in this usual ratio, however, without forcing the air into the lungs at such a high pressure and rapid rate that a pneumothorax becomes a constant concern ([Kitsommart, Martins, Bottino, et al., 2012](#)). Infant ventilators are therefore available with a reversed I/E ratio (2:1). These are pressure cycled to control the force with which air is delivered.

Complications of any type of ventilation are possible, such as pneumothorax and impaired cardiac output because of decreased blood flow through the pulmonary artery from increased lung pressure. There is also a possible risk of increased intracranial and arterial pressure and hemorrhage from fluctuating blood pressures. Being certain infants are not overhydrated is important to help prevent increased blood pressure and increased pulmonary artery pressure, which may delay the closure of the ductus arteriosus and interfere with both heart and lung function.

## Additional Therapy: Nitric Oxide

An additional therapy that can help to oxygenate a newborn's lungs is the administration of nitric oxide, a potent vascular dilator. It causes pulmonary vasodilation without decreasing systemic vascular tone. It combines with hemoglobin in the intravascular space to form methemoglobin. This causes systemic vasodilation. The nitric oxide enters the alveoli on ventilation and redirects the pulmonary blood by dilating the pulmonary arterioles ([Nair & Lakshminrusimha, 2014](#)).

## Extracorporeal Membrane Oxygenation

**Extracorporeal membrane oxygenation (ECMO)** was first developed as a means of oxygenating blood during cardiac surgery. Its current use has expanded to include the management of severe hypoxemia in newborns with illnesses such as meconium aspiration, RDS, pneumonia, and diaphragmatic hernia. Formerly used as a mainstay of therapy for RDS, it is now rarely needed because surfactant lavage is so effective.

### *What If . . . 26.3*

**While the nurse was caring for Baby Atkins, who is ventilator dependent and receiving the paralyzing agent pancuronium, a power failure occurred. What would be the nurse's first actions?**

## Supportive Care

An infant with RDS must be kept warm because cooling increases acidosis in newborns, and for the newborn with RDS, acidosis may increase to lethal levels. Keeping an infant warm also reduces the infant's metabolic oxygen demand. Provide hydration and nutrition with intravenous fluids and glucose or gavage feedings because the respiratory effort makes an infant too exhausted to suck. [Box 26.8](#) shows an interprofessional care map illustrating both nursing and team planning for a newborn with RDS.

### BOX 26.8

#### Nursing Care Planning

##### AN INTERPROFESSIONAL CARE MAP FOR A NEWBORN WITH RESPIRATORY DISTRESS SYNDROME

Mr. and Mrs. Atkins are the parents of a 30-week-old, 2-lb baby boy, born last night after a short 4-hour labor.

**Family Assessment:** Family consists of two parents: Mr. Atkins works as a consulting engineer; Mrs. Atkins worked before pregnancy as a home decorator. Mr. Atkins was out of town on business so was not present for the infant's birth. Mrs. Atkins has not visited the intensive care nursery. She refused to sign the birth certificate because she could not decide on a name. She said, "I don't want to give him our favorite name because he might die." Mr. Atkins telephoned early this morning and acted more upset the baby was born than relieved that the baby was receiving intensive care. He asked his wife, "What did you do to cause this?"

**Patient Assessment:** A 2-lb newborn, 5 hours old, born vaginally. Had difficulty establishing respirations at birth. Resuscitated by the neonatal nurse practitioner and respiratory therapist and then transported to the intensive care nursery. Temperature: 97.2°F (36.2°C). Bradycardic and tachypneic with grunting respirations. Sternal and subcostal retractions present. Skin pale and somewhat cyanotic. Chest X-ray shows "ground-glass" appearance. Arterial blood gases (ABGs) reveal respiratory acidosis. Endotracheal (ET) intubation, mechanical ventilation, supplemental oxygen, and intravenous fluid therapy initiated.

**Nursing Diagnosis:** Impaired gas exchange related to immaturity of newborn's lungs and lack of surfactant

**Outcome Criteria:** Vital signs within acceptable parameters. Temperature maintained at 97.7°F (36.5°C). Absence of cyanosis, diminished retractions, ABG values within acceptable parameters, and no sound of grunting with respirations.

Refer parents to helpful websites for preterm information and suggest they join local Parents of Premies organization.	Parents may need continued support after they return home with a small infant.	Parents, example how the making plans for infant's discharge care.

## Prevention

RDS rarely occurs in mature infants. Dating a pregnancy by sonogram and by documenting if the level of lecithin in surfactant obtained from amniotic fluid exceeds that of sphingomyelin by a 2:1 ratio are both important ways to be certain an infant born by cesarean birth or for whom labor is induced is mature enough that RDS is not likely to occur.

Using a tocolytic agent such as magnesium sulfate can help prevent preterm birth for a few days. During this time, if a woman receives two injections of a glucocorticosteroid, such as betamethasone, it may be possible to prevent RDS in the newborn because steroids appear to quicken the formation of lecithin. The administration is most effective when given between weeks 24 and 34 of pregnancy. Unfortunately, there is often no warning that preterm birth is imminent until hours before birth. Because the steroid does not take effect before 24 to 48 hours, some labors and births will progress too rapidly for this preventive measure to be effective.

### *QSEN Checkpoint Question 26.3*

#### **INFORMATICS**

Baby Atkins has surfactant administered at birth. When Mrs. Atkins asks why her baby had to receive surfactant, the nurse determines which response is best?

- “Surfactant helps him raise his lung secretions by relaxing his airway.”

- b. “Surfactant keeps his tiny lung sacs open and this improves his breathing.”
- c. “Surfactant relaxes his respiratory muscles to synchronize his breathing pattern.”
- d. “Surfactant reduces the amount of lung secretions that he produces.”

*Look in [Appendix A](#) for the best answer and rationale.*

## **TRANSIENT TACHYPNEA OF THE NEWBORN**

At birth, a newborn may have a rapid rate of respirations, up to 80 breaths/min when crying, caused by retained lung fluid ([Wyckoff et al., 2015](#)).

Within 1 hour, however, this rapid rate slows to between 30 and 60 breaths/min. In about 5 or 6 out of 1,000 live births, the respiratory rate doesn't slow as a result of a delayed absorption of alveolar fluid in the lungs. The infant does not appear to be in a great deal of distress aside from the tiring effort of breathing. Mild retractions and some nasal flaring may be noticed, enough to make feeding difficult because the infant cannot suck and breathe this rapidly at the same time. A chest X-ray will reveal some fluid in the lung along with hyperexpansion. Blood gases may show some respiratory acidosis, hypercapnia, and hypoxemia ([Hermansen & Mahajan, 2015](#)).

Although transient tachypnea of the newborn (TTN) may reflect a slight decrease in the production of phosphatidylglycerol or mature surfactant, it is a direct result of retained lung fluid, which then limits the amount of alveolar surface that is available for oxygen exchange. This limitation requires an infant to increase respiratory rate and depth of respirations to better use the limited surface available. TTN occurs more often in infants who are born by cesarean birth, in infants whose mothers received extensive fluid administration during labor, and in preterm infants. Infants born by cesarean birth are probably more prone to develop this form of respiratory distress because the thoracic cavity is not compressed as it is in a vaginal birth, and so less lung fluid is expelled.

Close observation of such a newborn is a priority. Watch carefully to be certain the increased effort is not tiring and other signs of respiratory distress such as nasal flaring or retractions are not occurring because a rapid respiratory rate is often the first sign of respiratory obstruction. Other signs that suggest illness are grunting and difficulty feeding. Oxygen administration may be necessary for some infants. Some infants will be prescribed a mild glucocorticoid to reduce respiratory tract inflammation. TTN usually has an onset at about two hours of life and can last approximately 36 hours. The higher the respiratory rate at onset, the longer TTN lasts. Treatment is supportive and typically by 72 hours of life it resolves ([Hermansen & Mahajan, 2015](#)).

## **MECONIUM ASPIRATION SYNDROME**

Meconium is present in the fetal bowel as early as 10 weeks of gestation. If hypoxia occurs, a vagus reflex is stimulated, resulting in relaxation of the rectal sphincter. This releases meconium into the amniotic fluid. Babies born breech may expel meconium

into the amniotic fluid from pressure on the buttocks. In both instances, the appearance of the fluid at birth is green to greenish black from the staining. Meconium staining occurs in approximately 10% to 20% of all births; in 2% to 4% of these births, infants will aspirate enough meconium to cause meconium aspiration syndrome (MAS) (Wyckoff et al., 2015). Meconium aspiration does not tend to occur in ELBW infants because the substance has not passed far enough in the bowel for it to be at the rectum in these infants.

An infant may aspirate meconium either in utero or with the first breath at birth. Meconium can cause severe respiratory distress (tachypnea, retractions, and grunting). The infant may also require increased oxygen to maintain saturations in the mid to upper 90s. This oxygen requirement usually starts in the first couple hours after birth without any congenital anomalies that may cause the low oxygen saturations (Lindenskov, Castellheim, Saugstad, et al., 2015).

### Assessment

Infants with meconium-stained amniotic fluid can have difficulty establishing respirations at birth (those who were not born breech have had a hypoxic episode in utero to cause the meconium to be in the amniotic fluid). The Apgar score is apt to be low. Almost immediately, tachypnea, retractions, and cyanosis begin. The infant should be placed on the warmer, and resuscitation should begin including the initiation of positive pressure ventilation as necessary (Wyckoff et al., 2015).

After the initiation of respirations, an infant's respiratory rate may remain rapid (tachypnea) and coarse bronchial sounds may be heard on auscultation. The infant may continue to have retractions because the inflammation of bronchi tends to trap air in the alveoli, limiting the entrance of oxygen. This air trapping may also cause enlargement of the anteroposterior diameter of the chest (barrel chest). Pulse oximetry or blood gases will reveal poor gas exchange evidenced by a decreased  $PO_2$  and an increased  $PCO_2$ . A chest X-ray will show bilateral coarse infiltrates in the lungs, with spaces of hyperaeration (a peculiar honeycomb effect). The diaphragm will be pushed downward by the overexpanded lungs.

### Therapeutic Management

Amnioinfusion can be used to dilute the amount of meconium in the amniotic fluid and has shown to improve the outcomes for the newborn with meconium in situations where perinatal observation is limited. The benefits may be related to dilution of the meconium or having an effect on the oligohydramnios (Hofmeyr, Xu, & Eke, 2014). If deeply stained amniotic fluid is identified during labor, the infant may be scheduled for a cesarean birth. After birth, infants may need to be treated with oxygen administration and assisted ventilation. Antibiotic therapy may be prescribed to forestall the development of pneumonia as a secondary problem. If lung compliance is poor, surfactant may be administered (Wyckoff et al., 2015). If lung noncompliance

continues, this may necessitate high inspiratory pressure. Unfortunately, this can cause a pneumothorax or pneumomediastinum (air in the chest cavity). Observe the infant closely, therefore, for signs of trapping air in the alveoli because the alveoli can expand only so far and then will rupture, sending air into the pleural space (pneumothorax).

Yet, a further complication that can occur because of increased pulmonary resistance is the ductus arteriosus remaining open, causing blood to shunt from the pulmonary artery into the aorta and compromising cardiac efficiency and increasing hypoxia. To detect this, observe an infant closely for signs of heart failure such as increased heart rate or respiratory distress. Maintain a temperature-neutral environment to prevent the infant from having to increase metabolic oxygen demands. A chest physiotherapy with percussion and vibration may be helpful to encourage the removal of remnants of meconium from the lungs (see [Chapter 40](#)). Some infants may need to be administered nitric oxide or maintained on ECMO to ensure adequate oxygenation ([Chettri, Bhat, & Adhisivam, 2016](#)).

## APNEA

Apnea is a cessation in respirations lasting longer than 20 seconds, sometimes accompanied by bradycardia and/or cyanosis. Many preterm infants have periods of apnea as a result of fatigue or the immaturity of their respiratory mechanisms. Babies with secondary stresses, such as infection, hyperbilirubinemia, hypoglycemia, or hypothermia, tend to have a high incidence of apnea also ([Thilo & Rosenberg, 2012](#)).

Gently stimulating an infant or flicking the sole of the foot often causes the baby to breathe again, almost as if the infant needed to be reminded to maintain this function. If an infant does not respond to these simple measures, positive-pressure ventilation and resuscitative interventions may be necessary.

Closely observe all newborns, especially preterm ones, to detect these apneic episodes. Apnea monitors that record respiratory movements are invaluable tools to detect apnea and sound a warning when an infant needs attention. Infants with frequent or difficult-to-correct episodes may be placed on respiratory support (CPAP or ventilator) until they are more mature.

To help prevent episodes of apnea, maintain a neutral thermal environment and use gentle handling to avoid excessive fatigue. Always suction gently and only when needed to minimize nasopharyngeal irritation, which can cause bradycardia because of vagal stimulation. Using indwelling nasogastric tubes rather than intermittent ones can also reduce the amount of vagal stimulation. After feeding, observe an infant carefully because a full stomach can put pressure on the diaphragm and can potentially compromise respirations. Careful burping also helps to reduce this effect. Never take rectal temperatures in infants prone to apnea because the resulting vagal stimulation can reduce the heart rate (bradycardia). Caffeine, a methylxanthine, may be prescribed for apnea of prematurity to stimulate breathing ([Kreutzer & Bassler, 2014](#)). The mechanism by which this medication reduces the incidence of apneic episodes is unclear, but they appear to increase the infant's sensitivity to carbon dioxide, which stimulates respiratory

function. Infants who have had an apneic episode severe enough to require resuscitation are at a high risk for sudden infant death syndrome. Such infants may be discharged home with a monitoring device to be used for the first several months of life.

## **SUDDEN INFANT DEATH SYNDROME**

Sudden infant death syndrome (SIDS) is a sudden unexplained death in infancy. It tends to occur at a higher than usual rate in infants of adolescent mothers, infants of closely spaced pregnancies, and underweight and preterm infants. Also prone to SIDS are infants with BPD, twins, Native American infants, Alaskan Native infants, economically disadvantaged Black infants, and infants of narcotic-dependent mothers. The peak age of incidence is 2 to 4 months of age ([AAP, 2011b](#)).

Although the cause of SIDS is unknown, in addition to prolonged but unexplained apnea, other possible contributing factors include:

- Sleeping prone rather than supine
- Viral respiratory or botulism infection
- Exposure to secondary smoke
- Pulmonary edema
- Brainstem abnormalities
- Neurotransmitter deficiencies
- Heart rate abnormalities
- Distorted familial breathing patterns
- Decreased arousal responses
- Possible lack of surfactant in alveoli
- Sleeping in a room without moving air currents (the infant rebreathes expired carbon dioxide)

Typically, affected infants are well nourished. Parents may report an infant had a slight head cold. After being put to bed at night or for a nap, the infant is then found dead a few hours later. Infants who die this way do not appear to make any sound as they die, which indicates they die with laryngospasm. Although many infants are found with blood-flecked sputum or vomitus in their mouths or on the bedclothes, this seems to occur as the result of death, not as its cause. An autopsy often reveals petechiae in the lungs and mild inflammation and congestion in the respiratory tract. However, these symptoms are not severe enough to cause sudden death. It is clear these infants do not suffocate from bedclothes or choke from overfeeding, underfeeding, or crying. Since the AAP made the recommendation to put newborns to sleep on their back, the incidence of SIDS has declined almost 50% to 60%. Other recommendations include the use of a firm sleep surface; breastfeeding; room sharing without bed sharing; routine immunizations; consideration of using a pacifier; and avoidance of soft bedding, overheating, and exposure to tobacco smoke, alcohol, and illicit drugs ([Byars & Simon, 2017](#)). Although it was once thought having infants sleep with a fan in their room to keep air moving might decrease the incidence of SIDS, the AAP has noted that, currently, there is insufficient evidence to recommend the use of a fan as a SIDS risk-

reduction strategy (AAP, 2011b).

Parents have a difficult time accepting the death of any child. This can be especially difficult when it happens so suddenly and to an infant. In discussing the child, they often use both the past and present tense as if they are not yet aware of the death. Many parents experience a period of somatic symptoms that occur with acute grief, such as nausea, stomach pain, or vertigo. Parents should be counseled by someone who is trained in counseling at the time of the infant's death; it helps if they can talk to this same person periodically for however long it takes to resolve their grief. The American Sudden Infant Death Syndrome Institute, listed at the beginning of the chapter, offers suggestions for counseling.

Autopsy reports should be given to parents as soon as they are available (if toxicology tests are included in the autopsy, results will not be available for weeks). Reading that their child's death was unexplained can help to reassure parents the death was not their fault. They need this assurance if they are to plan for other children. If there are older children in the family, they also need assurance SIDS is a disease of infants and the strange phenomenon that invaded their home and killed a younger brother or sister will not also kill them. If they wished the infant dead, as some children wish siblings were dead occasionally, they need reassurance their wishes did not cause the baby's death.

When another child is born, parents can be expected to become extremely frightened at any sign of illness in their child. They need support to see them through the first few months of the second child's life, particularly until past the point at which the first child died. Some parents may need support to view a second child as an individual child and not as a replacement for the first child.

A new baby born to a family in which a SIDS infant died can be screened using a sleep assessment as a precaution within the first 2 weeks of life or, if the parents' level of anxiety is acute, before hospital discharge. The baby may then be placed on continuous apnea monitoring pending the results of the sleep assessment.

## APPARENT LIFE-THREATENING EVENT

Some infants have been discovered cyanotic and limp in their beds but have survived after mouth-to-mouth resuscitation by parents. This event, also referred to as an **apparent life-threatening event (ALTE)** is characterized by a noticeable color change, some degree of apnea, and decreased tone (Sahewalla, Gupta, & Kamat, 2016). For these infants, as well as for preterm infants with a tendency toward apnea, or new babies born to a family whose child died from SIDS, apnea monitoring may be prescribed. With apnea monitoring in place, an alarm sounds when the infant experiences a period of apnea of 20 seconds or longer or a decreased heart rate below 80 beats/min (or as determined by the medical provider) (Fig. 26.10). If parents are going to use an apnea monitor at home, make certain they will be able to hear it in all parts of the house or apartment. Usually, for example, the alarm is not loud enough to be heard in the basement from an upstairs bedroom. Caution parents about household noises such as a

loud television, radio, vacuum cleaner, or hair dryer that may interfere with hearing the alarm. Be certain they know how to apply and reposition the apnea leads and that they are comfortable enough with the monitor to see past it to the infant. In addition, parents should be taught infant cardiopulmonary resuscitation before their infant is discharged from the hospital; reviewing the technique of this at healthcare visits is helpful (Fig. 26.11).

**Figure 26.10** A home apnea monitor is used for this high-risk infant during sleep to alert the parents of any apnea episodes. (From Hatfield, N. T. [2014]. *Introductory maternity & pediatric nursing* [3rd ed.]. Philadelphia, PA: Wolters Kluwer.)

**Figure 26.11** Parents of infants with respiratory disorders need to learn cardiac massage before their infant is discharged from the hospital. Here, parents learn the technique using specialized dolls. (Ian Miles, Flashpoint Pictures/Alamy.)

Caring for a child at home on an apnea monitor may be extremely stressful because parents are often reluctant to leave the baby in someone else's care for even a short time or they have difficulty finding a competent babysitter. These parents can benefit from a community or home care referral so they have a second opinion regarding how well they are managing as well as a listening ear to discuss the strain of having to be constantly alert for a sound that means their infant has stopped breathing. Having someone periodically review with them what steps to take should the alarm sound (e.g., gently stimulate the baby, begin mouth-to-mouth resuscitation, call emergency response personnel) can be very comforting.

### ***QSEN Checkpoint Question 26.4***

#### **SAFETY**

Baby Atkins is at risk for having apnea and bradycardia. What initial nursing intervention should the nurse initiate during these events to maintain his vital signs in a safe range?

- a. Administer 2 drops (gtt) of oral theophylline by a small syringe into his mouth.
- b. Gently flick the sole of his foot to stimulate the baby to breathe again.
- c. Monitor rectal temperatures to prevent him from becoming cold or hot.
- d. Vigorously suction him every 2 hours to keep airway clear of secretions.

*Look in [Appendix A](#) for the best answer and rationale.*

## **PERIVENTRICULAR LEUKOMALACIA**

**Periventricular leukomalacia (PVL)** is the result of ischemia of the white matter of the brain ([Gupta, Sodhi, Saxena, et al., 2016](#)). It is caused by an anoxic episode that interferes with circulation to a portion of the brain. Phagocytes and macrophages invade the area to clear away necrotic tissue. What is left is an abnormality in the white matter of the brain, which is revealed on a sonogram as a hollow space. PVL occurs most frequently in preterm infants who experience cerebral ischemia. Once the condition has occurred, there is no therapy. Infants may die of the original insult; they may be left with long-term effects such as learning disabilities or cerebral palsy. Any action to reduce environmental stimuli or sudden shifts in cerebral blood flow, such as avoiding rapid fluid infusions or reducing pain, is important for preventing PVL and limiting this long-term effect of prematurity ([Alderliesten, Lemmers, Smarius, et al., 2013](#)).

## **HEMOLYTIC DISEASE OF THE NEWBORN (HYPERBILIRUBINEMIA)**

The term “hemolytic” is Latin for “destruction” (lysis) of red blood cells. A certain degree of lysis of red blood cells in the newborn results from the destruction of red blood cells by a normal physiologic process as the newborn breaks down excess red

blood cells formed in utero (see [Chapter 18](#)). Hemolytic disease is present when there is excessive destruction of red blood cells, which leads to elevated bilirubin levels (hyperbilirubinemia). In the past, hemolytic disease of the newborn was most often caused by an Rh blood type incompatibility. Because the prevention of Rh antibody formation has been available for almost 50 years, the disorder is now most often caused by an ABO incompatibility. In both instances, because the fetus has a different blood type than the mother, the mother builds antibodies against the fetal red blood cells, leading to hemolysis of the cells, severe anemia, and hyperbilirubinemia.

### **Rh Incompatibility**

In every pregnancy, a few red blood cells enter the maternal circulation. If the mother's blood type is Rh negative and the fetal blood type is Rh positive, this introduction of fetal blood causes sensitization to occur and the woman to begin to form antibodies against the specific antigen (most commonly the D antigen). Few antibodies actually form this way during pregnancy, however. Most form in the woman's bloodstream in the first 72 hours after birth because there is an active exchange of fetal–maternal blood as placental villi loosen and the placenta is delivered. Because of this surge in antibody formation after a pregnancy, in a second pregnancy, there will be a high level of antibody already circulating in the woman's bloodstream. This will then act to destroy the fetal red blood cells beginning early in the next pregnancy if the new fetus is Rh positive, leading to the fetus being severely compromised by the end of that pregnancy.

Rh incompatibility is not commonly seen today because if Rh-negative women receive Rho immune globulin (RHIG or RhoGAM) (passive Rh antibodies) within 72 hours after birth of an Rh-positive newborn, the process of antibody formation will be halted and sensitization will not occur. The possibility Rh incompatibility could exist, however, must be assessed for during pregnancy and again at birth because some women (especially those who received prenatal care in another country) may not have received RHIG following the birth or miscarriage of a former Rh-positive fetus.

### **ABO Incompatibility**

In most instances of ABO incompatibility, the maternal blood type is O and the fetal blood type is either A or B type blood.

Hemolysis can become a problem with a first pregnancy in which there is an ABO incompatibility because the antibodies to A and B cell types are naturally occurring antibodies or are present from birth in anyone whose red cells lack these antigens. Fortunately, unlike the antibodies formed against the Rh D factor, these antibodies are of the large (IgM) class and so do not cross the placenta. An infant of an ABO incompatibility, therefore, is not born anemic, as the Rh-sensitized child could be. Hemolysis of the blood begins with birth, when blood and antibodies are exchanged during the mixing of maternal and fetal blood as the placenta is loosened; destruction may continue for as long as 2 weeks. Interestingly, preterm infants do not seem to be

affected by ABO incompatibility. This may be because the receptor sites for anti-A or anti-B antibodies do not appear on red cells until late in fetal life. Even in the mature newborn, a direct Coombs test may be only weakly positive because of the few anti-A or anti-B sites present. The reticulocyte count (immature or newly formed red blood cells) is usually elevated as the infant attempts to replace destroyed cells.

## Assessment

Rh incompatibility of the newborn can be predicted by finding a rising anti-Rh titer or a rising level of antibodies (indirect Coombs test) in a woman during pregnancy. It can be confirmed by detecting antibodies on the fetal erythrocytes in cord blood (positive direct Coombs test) by percutaneous umbilical blood sampling (see [Chapter 9](#)) or at birth. The mother in this situation will always have Rh-negative blood, and the baby will be Rh positive.

With Rh incompatibility, an infant may not appear pale at birth despite the red cell destruction that occurred in utero because the accelerated production of red cells during the last few months in utero compensates to some degree for the destruction. The liver and spleen may be enlarged from attempts to destroy damaged blood cells. If the number of red cells has significantly decreased, the blood in the vascular circulation may be hypotonic to interstitial fluid, causing fluid to shift from the lower to higher isotonic pressure by osmosis, resulting in extreme edema. Finally, the severe anemia can result in heart failure as the heart has to beat at a faster rate than normal to push the diluted blood forward. **Hydrops fetalis** is a Greek term that refers to a pathologic accumulation of at least two or more cavities with a collection of fluid in the fetus.

Most infants do not appear jaundiced at birth because the maternal circulation has evacuated the rising indirect bilirubin level. With birth, progressive jaundice, usually occurring within the first 24 hours of life, will begin, indicating in both Rh and ABO incompatibility that a hemolytic process is occurring. The jaundice occurs because, as red blood cells are destroyed, indirect bilirubin is released. Indirect bilirubin is fat-soluble and cannot be excreted from the body. Under usual circumstances, the liver enzyme glucuronyl transferase converts indirect bilirubin to direct bilirubin. Direct bilirubin is water-soluble and combines with bile for excretion from the body through feces. In preterm infants or those with extreme hemolysis, the liver cannot convert all of the indirect bilirubin produced into direct bilirubin fast enough, so jaundice occurs.

Normally, cord blood has a total serum bilirubin (TsB) level of 0 to 3 mg/100 ml. An increasing bilirubin level becomes dangerous if the level rises above 20 mg/dl in a term infant and perhaps as low as 12 mg/dl in a preterm infant because brain damage from bilirubin-induced neurologic dysfunction (BIND), a wide spectrum of disorders caused by increasingly severe hyperbilirubinemia ranging from mild dysfunction to acute bilirubin encephalopathy (ABE) (invasion of bilirubin into brain cells), can occur. A second concern that arises from excessive red blood cell destruction is that an infant is forced to use glucose stores to maintain metabolism in the presence of anemia. This can cause a progressive hypoglycemia, compounding the initial problem. A decrease in

hemoglobin during the first week of life to a level less than that of the cord blood is a later indication of blood loss or hemolysis.

## Therapeutic Management

Bilirubin levels in blood may be measured by either a blood draw (TsB) or by holding a transcutaneous meter against the infant's skin (transcutaneous bilirubin [TcB]). The initiation of early feeding (urge mothers to breastfeed 8 to 10 times a day for the first 2 days), use of phototherapy, and exchange transfusion all may be measures necessary to reduce the TsB level in an infant affected by a blood incompatibility. In infants with severe hemolytic disease, the hemoglobin concentration can continue to drop during the first 6 months of life, or their bone marrow may fail to increase production of erythrocytes in response to continuing hemolysis so they need an additional blood transfusion to correct this late anemia. Therapy with erythropoietin to stimulate red blood cell production is also possible ([Wüest, Manser, Küster, et al., 2016](#))

### The Initiation of Early Feeding

Bilirubin is removed from the body by being excreted through the feces. Therefore, the sooner bowel elimination begins, the sooner bilirubin removal begins. Early feeding (either breast milk or formula), therefore, stimulates bowel peristalsis and helps to accomplish this.

### Phototherapy

A fetus's liver processes little bilirubin in utero because the mother's circulation does this for the fetus. With birth, exposure to light is believed to trigger the liver to assume this function. Additional light supplied by phototherapy appears to speed the conversion of unconjugated (fat-soluble) into conjugated (water-soluble) bilirubin. Phototherapy exposes the infant to continuous specialized light such as quartz halogen, cool white daylight, or special blue fluorescent light. The lights are placed 12 to 30 in. above the newborn's bassinet or incubator.

Term newborns are generally scheduled for phototherapy when the TsB level rises to 10 to 12 mg/dl at 24 hours of age; preterm infants may have treatment begun at levels lower than this ([Bhardwaj, Locke, Biringer, et al., 2017](#)). Although the results of the therapy are mixed, the administration of intravenous immunoglobulin (IVIG) has been used in neonates with hemolytic disease in combination with phototherapy, especially in ABO incompatibility to try and extenuate the effect of phototherapy ([Keir, Dunn, & Callum, 2013](#)).

Continuous exposure to bright lights by phototherapy may be harmful to a newborn's retina, so the infant's eyes must always be covered while under bilirubin lights. Commercial phototherapy masks or eye coverings must be used at all times when the infant is under phototherapy (with the use of bilirubin blankets, eye protection is not usually necessary if it is a full-term newborn). Check the eye covering/mask frequently

to be certain it has not slipped. Infants are most apt to dislodge the eye covering when they cry as they wake for a feeding. Urge parents to respond quickly, therefore, if the infant is in their postpartum room to avoid eye damage and possible suffocation by the infant pushing the eye covering down over the nose (Fig. 26.12).

**Figure 26.12** A newborn receiving phototherapy is undressed except for a diaper so he receives maximum exposure to the lights. His eyes are covered snugly to protect them from the ultraviolet light.

The stools of an infant under bilirubin lights are often bright green because of the excessive bilirubin being excreted as the result of the therapy. They are also frequently loose and may be irritating to the skin. Urine may be dark colored from urobilinogen formation. Monitor the infant's axillary temperature to prevent him or her from overheating under the bright lights. Assess skin turgor and intake and output to ensure dehydration is not occurring from the warm environment.

Infants receiving phototherapy should be removed from under the lights for feeding so they continue to have interaction with their mother. Remove the eye patches while the infant is out from under the lights for a period of visual stimulation. To prevent a lengthy hospital stay, infants may be discharged and continue therapy at home. Specialized fiber optic light systems incorporated into a fiber optic blanket also have been developed and are ideal for home care. The light generated by the blanket has the

same effect on bilirubin levels as banks of overhead lights. The infant is undressed except for a diaper to protect the ovaries or testes and so as much skin surface as possible is exposed to the light. Two big advantages are that an infant can be held for long periods without interrupting the phototherapy, and eye patches are unnecessary.

Parents need an explanation of the rationale for phototherapy and why their infant needs it. Although phototherapy has not been used long enough that long-term effects can be studied, there appears to be minimal risk to an infant from the procedure, provided the infant's eyes remain covered and dehydration from increased insensible water loss does not occur. Even though there is no evidence so far that infants who received phototherapy are at greater risk for developing skin cancer, all infants who receive phototherapy should (as should all infants) have sunscreen applied when they are in the sun and follow-up assessments in coming years to detect skin cancer that possibly could occur from the therapy (Oláh, Tóth-Molnár, Kemény, et al., 2013).

### Exchange Transfusion

The use of intensive phototherapy in conjunction with hydration and close monitoring of serum bilirubin levels has greatly reduced the need for exchange transfusions. If this is done, small amounts (2 to 10 ml) of the infant's blood are drawn from the infant's umbilical vein and then replaced with equal amounts of donor blood. The therapy may be used for any condition that leads to hyperbilirubinemia or polycythemia. When used as therapy for blood incompatibility, it removes approximately 85% of sensitized red cells. It reduces the serum concentration of indirect bilirubin and can prevent heart failure in infants with severe anemia or polycythemia.

A transfusion should be done under a radiant heat warmer to keep the infant warm during what can be a lengthy procedure to prevent energy expenditure from having to maintain body temperature. Donor blood must be maintained at room temperature, or hypothermia from the cold insult could result. Use only commercial blood warmers to warm blood, not hot towels or a radiant heat warmer, to avoid destroying red cells.

The type of blood used for transfusion is O Rh-negative blood, even if an infant's blood type is positive; if Rh-positive or type A or B blood were given, the maternal antibodies that entered the infant's circulation would destroy this blood also, and the transfusion would be ineffective. If the baby will be transported to a regional center for the exchange transfusion, a sample of the mother's blood should accompany the infant, so cross-matching on the mother's serum can be done there.

After a transfusion, closely observe the infant to be certain vital signs are stable and there is no umbilical vessel bleeding or inflammation of the cord if this was the transfusion site, which would suggest infection. Report any changes in vital signs. Monitor bilirubin levels for 2 or 3 days after the transfusion to ensure the level of indirect bilirubin is not rising again and that no further phototherapy or transfusion is necessary.

### TWIN-TO-TWIN TRANSFUSION

Twin-to-twin transfusion is a phenomenon that can occur if twins are monozygotic (identical; share the same placenta) and abnormal arteriovenous shunts occur that direct more blood to one twin than the other (Swiatkowska-Freund, Pankrac, & Preis, 2012). The process occurs in as many as one third of all identical twin pregnancies, although enough blood is exchanged to be clinically important in only about 15% of such pregnancies. The result of this shift of blood leads to anemia in the donor twin and polycythemia in the receiving twin. The anemic twin may also be pale and SGA because of the lack of nutrients or oxygen for growth as well as hypoglycemic from lack of glucose stores. The polycythemic twin is prone to hyperbilirubinemia as the excessive red blood cell level is broken down.

Twin-to-twin transfusion can be identified in utero by a sonogram because one twin is noticeably larger than the other. All identical twins should have hemoglobin determinations done at birth and the results should be compared. A hemoglobin difference of more than 5.0 g/100 ml is enough to suggest a transfusion between the twins has occurred. Each twin needs therapy as indicated by the extent of the blood distribution. The donor twin may need a transfusion to establish a functioning blood cell level, and the recipient twin may need an exchange transfusion to reduce the polycythemia and viscosity of the blood.

### ***QSEN Checkpoint Question 26.5***

#### **QUALITY IMPROVEMENT**

The nurse is concerned that Baby Atkins will develop hyperbilirubinemia because of his immaturity. Because the prevention of jaundice is one of the NICU's quality indicators, what priority nursing intervention would the nurse initiate to best prevent hyperbilirubinemia in Baby Atkins?

- a. Administering phenobarbital to all infants to help prevent jaundice
- b. Urging all mothers to breastfeed early to promote infants' bowel motility
- c. Placing all preterm and SGA infants in warm, dark, comforting environments
- d. Immediately placing all infants under phototherapy following birth

*Look in Appendix A for the best answer and rationale.*

### **NECROTIZING ENTEROCOLITIS**

Necrotizing enterocolitis (NEC) is a gastrointestinal disease. Premature newborns are at the greatest risk for developing the disease, with approximately 5% of all infants developing it in intensive care nurseries (Pun, Jones, Wolfe, et al., 2016). The bowel develops necrotic patches, interfering with digestion and possibly leading to a paralytic ileus, perforation, and peritonitis. It occurs because of anoxia to the bowel and so may result as a complication of exchange transfusion or an episode of breathing difficulty. Because it shares common features with other gastrointestinal disorders, it is discussed in Chapter 45.

## RETINOPATHY OF PREMATURITY

**Retinopathy of prematurity (ROP)**, an acquired ocular disease that leads to partial or total blindness in children, is caused by vasoconstriction of immature retinal blood vessels. It was first recognized as an eye disorder in 1942, but only later was a high concentration of oxygen established as the causative agent (Fleck & Stenson, 2013). Immature retinal blood vessels constrict when exposed to high oxygen concentrations; endothelial cells in the periphery of the retina then proliferate, causing retinal detachment and possible blindness. Infants who are most immature and most ill (and consequently receive the most oxygen) are at the highest risk for developing ROP.

When blood  $P_{O_2}$  levels rise to higher than 100 mmHg, the risk of the disease increases greatly. Based on this, all preterm infants who receive oxygen must have blood oxygen levels monitored by pulse oximeter or blood gas monitoring so the blood  $P_{O_2}$  level can be regulated within normal limits.

In the past, once ROP occurred, there was no reversing it. Today, cryosurgery or laser therapy may be effective at preserving sight. A person experienced in recognizing ROP should examine the eyes of all babies who have received oxygen (especially LBW newborns) before discharge from a hospital nursery and again at 4 to 6 weeks of age to detect any occurrence of the syndrome. Nurses can be instrumental in limiting the occurrence of ROP by securing oxygen saturation levels and by the conscientious management of oxygen (Martínez-Castellanos, Schwartz, Hernández-Rojas, et al., 2013).

## The Newborn at Risk Because of a Maternal Infection

Newborns are susceptible to infections during pregnancy and at birth because their ability to produce antibodies is immature. A number of infections in newborns, such as toxoplasmosis, rubella, syphilis, and cytomegalovirus infections, spread to the fetus across the placenta in utero and are discussed in Chapter 12 with other complications of pregnancy. Other infections, such as those discussed in the following sections, are not contracted in utero but are contracted from exposure to vaginal secretions at birth.

### $\beta$ -HEMOLYTIC, GROUP B STREPTOCOCCAL INFECTION

A serious cause of infection in newborns is the gram-positive  $\beta$ -hemolytic, group B streptococcal (GBS) organism, a natural inhabitant of the female genital tract. Between 50 and 300 infants out of every 1,000 live births display a positive culture for the organism (AAP, 2011a). It also may be spread from baby to baby if good hand washing technique is not used in caring for newborns. If a woman is found to be positive for GBS during late pregnancy (see Chapter 21), ampicillin administered IV during pregnancy and again during labor helps to reduce the possibility of newborn exposure.

### Assessment

Universal screening is recommended for pregnant women at 35 to 37 weeks of gestation to see if they have GBS organisms in their vaginal secretions (Albright, MacGregor, Sutton, et al., 2017). Typically, a newborn at risk, such as one born after prolonged rupture of membranes or if the woman's vaginal culture is positive for GBS, will be screened at birth for infection by a specialized GBS blood culture.

Colonization by GBS can result in either an early-onset or a late-onset illness. With the early-onset form, signs of pneumonia such as tachypnea, apnea, extreme paleness, hypotension, or hypotonia become apparent within the first day of life. Decreased urine output can occur from the hypotension. A chest X-ray may not be diagnostic because the changes seen are almost indistinguishable from those of RDS (a ground-glass appearance). Without therapy, the disease progresses so rapidly, as many as 20% of infants who contract the infection die within 24 hours of birth.

A late-onset type occurs at 2 to 4 weeks of age. With this, instead of pneumonia being the infection focus, meningitis tends to occur. Typical signs include lethargy, fever, loss of appetite, and bulging fontanelles from increased intracranial pressure. Mortality from the late-onset type is not as high as that from the early-onset form (15% vs. 20%), but neurologic consequences can occur in up to 50% of infants who survive.

### Therapeutic Management

If a newborn displays signs of infection or a blood screening test is positive, antibiotics such as penicillin, cefazolin, clindamycin, or vancomycin are all effective against the GBS organism.

Parents may have difficulty understanding how their infant could suddenly have become this ill, and they may need a great deal of support to care for their infant. This is even more important if the newborn survives the infection but is left neurologically challenged. In the future, immunization of all women of childbearing age against streptococcal B organisms could decrease the incidence of newborns infected at birth.

### OPHTHALMIA NEONATORUM

**Ophthalmia neonatorum** is an eye infection that occurs at birth or during the first month of life (Matejcek & Goldman, 2013). The most common causative organisms are *Neisseria gonorrhoeae* and *Chlamydia trachomatis*, which are contracted from vaginal secretions. An *N. gonorrhoeae* infection is an extremely serious form of infection because, if left untreated, the infection progresses to corneal ulceration and destruction, resulting in opacity of the cornea and severe vision impairment.

### Assessment

Ophthalmia neonatorum is generally bilateral. The conjunctivae become fiery red and covered with thick pus. The eyelids appear edematous. Although this usually occurs on day 1 to day 4 of life, it should be considered as a possibility when conjunctivitis occurs in any infant younger than 30 days of age.

## Prevention

The prophylactic instillation of erythromycin ointment into the eyes of newborns prevents both gonococcal and chlamydial conjunctivitis. In the past, eye prophylaxis was given immediately after birth so it was never forgotten. Now it is more customary to delay the administration of the ointment until after the first reactivity period so the newborn can clearly see the parents during this important attachment period. This makes it easy for administration to be forgotten, so use some type of a checklist as a reminder of this important prophylaxis. Infants born outside the hospital also need prophylaxis to prevent ophthalmia neonatorum, the same as for infants born in a birthing room.

## Therapeutic Management

If conjunctivitis occurs, therapy is individualized depending on the organism cultured from the exudate. If gonococci are identified, intravenous ceftriaxone (Rocephin) and penicillin are effective drugs. If *Chlamydia* is identified, an ophthalmic solution of erythromycin is commonly used.

Use standard and contact infection precautions when caring for this newborn. In addition to systemic antibiotic therapy, sterile saline solution lavage to clear the copious discharge from the eyes may be prescribed. When irrigating eyes, use a sterile medicine dropper or bulb syringe and use barrier protection, including goggles to avoid splashing any solution into your own eye. The solution should be at room temperature. Direct the stream of the irrigation fluid laterally so it does not enter and contaminate the other eye.

The mother of the infected infant needs treatment for gonorrhea or chlamydia before fallopian tube sterility or pelvic inflammatory disease can result. Sexual contacts of the mother should be treated also so the spread of the disease can be halted. With either infection, parents can be assured with early diagnosis and treatment that the prognosis for normal eyesight in their child is good.

## HEPATITIS B VIRUS INFECTION

Hepatitis B virus (HBV) can be transmitted to the newborn through contact with infected vaginal blood at birth when the mother is positive for the virus (positive for the surface antigen of the hepatitis B virus [HBsAg+]). Hepatitis B is a destructive illness with greater than 90% of infected infants becoming chronic carriers of the virus as well as the risk of developing liver cancer later in life (Ni, 2011). To reduce the possibility of HBsAg being spread to newborns in the future, parents are asked if they would like their infant vaccinated against hepatitis B at birth (Kurosky, Davis, & Krishnarajah, 2016).

If the mother is identified as HBsAg+, her infant should be bathed as soon as possible after birth to remove HBV-infected blood and secretions. Gentle suctioning is necessary to avoid trauma to the mucous membrane, which could allow HBV invasion. To further protect against infection, the infant is administered serum hepatitis B immune globulin (HBIG) in addition to the HBV vaccination. Although the virus is transmitted

in breast milk, once immune globulin has been administered, women may breastfeed without risk to an infant. Hepatitis B is further discussed in [Chapter 45](#) because it shares common symptoms with other liver disorders and also occurs in older children.

## GENERALIZED HERPESVIRUS INFECTION

A herpes simplex virus type 2 (HSV-2) infection, which is most prevalent among women with multiple sexual partners, can be contracted by a fetus across the placenta if the mother has a primary infection during pregnancy. More often, however, the virus is contracted from the vaginal secretions of a mother who has active herpetic vulvovaginitis at the time of birth. Between 15% and 30% of women of childbearing age demonstrate antibodies to this virus or have the potential to have active lesions during labor ([Looker, Magaret, May, et al., 2017](#)).

### Assessment

If the infection was acquired during pregnancy, an infant may be born with vesicles covering the skin. The long-term prognosis of the child is guarded because severe neurologic damage may have occurred simultaneously with the development of the lesions. If infants don't acquire the infection until birth, by day 4 to day 7 of life, they show a loss of appetite, perhaps a low-grade fever, and lethargy. Stomatitis (ulcers of the mouth) or a few vesicles on the skin appear. Herpes vesicles always cluster, are pinpoint in size, and are surrounded by a reddened base. After the vesicles appear, infants become extremely ill. They develop dyspnea, jaundice, purpura, convulsions, and hypotension. Death may occur within hours or days. Between 25% and 70% of newborns who survive generalized herpesvirus infections have permanent central nervous system sequelae ([Pinninti & Kimberlin, 2014](#)).

To confirm the diagnosis, cultures are obtained from representative vesicles as well as from the nose, throat, anus, and umbilical cord. Blood serum is analyzed for IgM antibodies.

### Therapeutic Management

An antiviral drug such as acyclovir (Zovirax), a drug that inhibits viral DNA synthesis, is effective in combating this overwhelming infection. Prevention, however, is the newborn's best protection. Antenatal antiviral prophylaxis reduces viral shedding and recurrences at birth and reduces the need for cesarean birth ([Pinninti & Kimberlin, 2014](#)). Women with active herpetic vulvar lesions are advised to have cesarean birth rather than vaginal birth to minimize the newborn's exposure. Infants with an infection should be separated from other infants in a nursery. Although transmission from this source is rare, women with herpes lesions on their face (herpes simplex I, or cold sores) need to be assessed before they hold their newborns to be sure lesions are crusted and, therefore, are no longer contagious. Healthcare personnel who have herpes simplex infections should not care for newborns until the lesions are crusted. Although facial

herpes simplex lesions are probably caused by herpesvirus type 1, limiting contact does not seem excessive in light of the severity of HSV-2 disease. Urge a woman who is separated from her newborn at birth to view her infant from the nursery window and participate in planning care to aid bonding.

## **HIV INFECTION**

HIV infection and AIDS can be caused by placental transfer or direct contact with maternal blood during birth. Because older children can also be exposed to this disease, the care of children with this infection is discussed in [Chapter 42](#).

## **The Newborn at Risk Because of a Maternal Illnesses**

### **AN INFANT OF A WOMAN WHO HAS DIABETES MELLITUS**

Infants of women who have diabetes mellitus whose illness was poorly controlled during pregnancy are typically longer and weigh more than other babies (macrosomia). The baby also has a greater chance of having a congenital anomaly such as a cardiac anomaly because hyperglycemia is teratogenic to a rapidly growing fetus.

Most such babies have a cushingoid (i.e., fat and puffy) appearance. They tend to be lethargic or limp in the first days of life as a result of hyperglycemia. The macrosomia results from overstimulation of pituitary growth hormone and extra fat deposits created by high levels of insulin during pregnancy. This infant's large size is deceptive, however, because, like all LGA babies, they are often immature. RDS occurs at a higher rate than usual in these infants because they may be born preterm or, if born at term, lecithin pathways may not be mature. High fetal insulin secretion during pregnancy to counteract the hyperglycemia can interfere with cortisol release. This could block the formation of lecithin and further prevent lung maturity ([Murphy, Janzen, Strehlow, et al., 2013](#)). A term frequently used for these infants is "fragile giant."

An infant of a woman with diabetes loses a greater proportion of weight in the first few days of life than does the average newborn because of the loss of extra fluid accumulated. Observe such an infant closely to be certain this weight loss actually represents a loss of extra fluid and that dehydration is not occurring.

### **Complications**

A macrosomic infant has a greater chance of birth injury, especially shoulder and neck injury. A cesarean birth may be necessary to avoid cephalopelvic disproportion. Immediately after birth, the infant tends to be hyperglycemic because the mother was at least slightly hyperglycemic during pregnancy and excess glucose transfused across the placenta. During pregnancy, the fetal pancreas responded to this high glucose level with islet cell hypertrophy, resulting in matching high insulin levels. After birth, as an infant's glucose level begins to fall because the mother's circulation is no longer supplying glucose, the overproduction of insulin will cause the development of severe

hypoglycemia. Hyperbilirubinemia also may occur in these infants because, if immature, they cannot effectively clear bilirubin from their system. Hypocalcemia also frequently develops because parathyroid hormone levels are lower in these infants due to hypomagnesemia from excessive renal losses of magnesium.

Although infants of women with diabetes are usually LGA, an infant born to a woman with extensive blood vessel involvement may be SGA because of poor placental perfusion. The problems of hypoglycemia, hypocalcemia, and hyperbilirubinemia remain the same.

## Therapeutic Management

In a newborn, hypoglycemia is defined as a serum glucose level of less than 45 mg/dl. To avoid a serum glucose level from falling this low, infants of women with diabetes need to be fed early; if they are unable to suck, a continuous infusion of glucose can be prescribed. It is important the infant not be given only a bolus of glucose; otherwise, rebound hypoglycemia (accentuating the problem) can occur. Some infants of women with diabetes have a smaller than usual left colon, apparently another effect of intrauterine hyperglycemia, which can limit the amount of oral feedings they can take in their first days of life. Signs of an inadequate colon include vomiting or abdominal distention after the first few feedings. Careful monitoring for any vomiting and normal bowel movements can help identify this condition.

### QSEN Checkpoint Question 26.6

#### PATIENT-CENTERED CARE

Mrs. Atkins asks the nurse why the baby in the incubator next to her baby whose mother has diabetes mellitus was fed so soon after birth. Why is it important for infants of women with diabetes to be fed early?

- Their stomach is larger than usual due to overgrowth.
- This helps prevent rebound hypoglycemia from occurring.
- The mother probably didn't eat much during her labor.
- This helps clear thick mucus from the lower intestinal tract.

Look in [Appendix A](#) for the best answer and rationale.

## AN INFANT OF A DRUG-DEPENDENT MOTHER

Infants of drug-dependent women tend to be SGA. If the woman took a drug close to birth, her infant may show withdrawal symptoms (neonatal abstinence syndrome) shortly after birth ([Box 26.9](#)). These include such signs as:

- Irritability
- Disturbed sleep pattern
- Constant movement, possibly leading to abrasions on the elbows, knees, or nose
- Tremors

- Frequent sneezing
- Shrill, high-pitched cry
- Possible hyperreflexia and clonus (neuromuscular irritability)
- Convulsions
- Tachypnea (rapid respirations), possibly so severe that it leads to hyperventilation and alkalosis
- Vomiting and diarrhea, leading to large fluid losses and secondary dehydration

## BOX 26.9

### Nursing Care Planning Using Assessment

#### ASSESSING THE NEWBORN OF A DRUG-DEPENDENT MOTHER

Specific neonatal abstinence scoring tools can be used to quantify and assess an infant's status. When symptoms begin to appear and when they fade varies with the drug involved, but, on average, symptoms occur in 24 to 48 hours and last about 2 weeks. The infants of women who were on methadone maintenance during pregnancy will show the same beginning and length of symptoms. The abstinence sequence for the cocaine-addicted neonate is usually milder, but factors such as maladaptive coping behaviors may be present in such newborns into preschool ([Buckingham-Howes, Berger, Scaletti, et al., 2013](#)).

Narcotic metabolites or quinine (heroin is often mixed with quinine) may be obtained from an infant's urine or meconium in the first hour after birth to establish that the drug was transferred into the infant before birth. These products are quickly cleared from the body, however, so by the time symptoms become severe, detection of narcotic substances may no longer be possible. Cocaine, in contrast, may be detected in infants' hair samples for an extended time.

Infants of drug-dependent women usually seem most comfortable when firmly swaddled. Keep them in an environment free from excessive stimuli (a small isolation nursery or the mother's room, not a large, open nursery). Some quiet best if the room is darkened. Some may suck vigorously and continuously and seem to find comfort and quiet if given a pacifier. In contrast, infants of methadone- and cocaine-addicted women may have extremely poor sucking ability and may have difficulty achieving sufficient fluid intake unless gavage fed. Unless a woman intends to remain drug free, she is usually advised not to breastfeed to avoid passing narcotics in breast milk to the infant.

Specific therapy for an infant has to be individualized according to the nature and severity of the signs. If an infant has vomiting or diarrhea, intravenous administration of fluid may be indicated. The most common medications to counteract abstinence symptoms are morphine and methadone (Bagley, Wachman, Holland, et al., 2014). Other drugs that may be used include methadone, chlorpromazine (Thorazine), and diazepam (Valium). These are typically used if the neonatal abstinence scoring system average score is elevated on three successive occasions and other nursing interventions do not reduce the score.

Once an infant has been identified as having been exposed to drugs in utero, the mother needs treatment for withdrawal symptoms and follow-up care as much as the infant. In addition, an evaluation is necessary to determine before discharge from the healthcare facility whether an environment that allowed for drug abuse will be safe for an infant at home (Bagley et al., 2014). Infants also need long-term follow-up because long-term neurologic problems may develop.

## AN INFANT WITH FETAL ALCOHOL EXPOSURE

Alcohol crosses the placenta in the same concentration as is present in the maternal bloodstream so may result in fetal alcohol exposure, or **fetal alcohol spectrum disorder** (Tsai, Manchester, & Elias, 2012). The disorder appears in about 2 out of 1,000 newborns and is often more difficult to document than recreational drug exposure because alcohol abuse may be more difficult to document. Because alcohol has serious deteriorating effects on the placenta and it is unknown if there is a safe threshold of alcohol ingestion during pregnancy, all pregnant women are advised to avoid alcohol intake to prevent any teratogenic effects on their newborn (Dunney, Muldoon, & Murphy, 2015).

A newborn with fetal alcohol spectrum disorder has several possible problems at birth. Characteristics that mark the syndrome include prenatal and postnatal growth restriction; central nervous system involvement such as cognitive challenge,

microcephaly, and cerebral palsy; and a distinctive facial feature of a short palpebral fissure and thin upper lip. During the neonatal period, an infant may appear tremulous, fidgety, and irritable and may demonstrate a weak sucking reflex. Sleep disturbances are common, with the baby tending to be either always awake or always asleep depending on the mother's alcohol level close to birth.

The most serious long-term effect is cognitive challenge. Behavior problems such as hyperactivity may occur in school-age children. Growth deficiencies may remain throughout life. An infant needs conscientious follow-up so any future problems can be discovered. The mother needs a follow-up to see if she can reduce her alcohol intake for better overall health (Cook, Green, Lilley, et al., 2016)

#### *What If . . . 26.4*

**The nurse is interested in exploring one of the 2020 National Health Goals with respect to high-risk newborns (see Box 26.1). Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Atkins family and that would also advance evidence-based practice?**

### **KEY POINTS FOR REVIEW**

- Priorities for infants born with special needs, such as preterm or postterm infants, are the same as for term infants: initiation and maintenance of respirations, establishment of extrauterine circulation, control of body temperature, intake of adequate nourishment, establishment of waste elimination, establishment of an infant–parent relationship, prevention of infection, and provision of developmental care for mental and social development.
- Many high-risk infants need resuscitation at birth. Prompt action with such measures as warmth, oxygen, intubation, and suctioning are needed.
- An SGA infant is one whose birth weight is below the 10th percentile on an intrauterine growth curve for that gestational age infant. An infant could be born preterm, term, or postterm. They typically have difficulty maintaining body warmth because of low fat stores and may develop hypoglycemia from low glucose stores.
- An LGA infant is one whose birth weight is above the 90th percentile on an intrauterine growth chart for that gestational age. The infant could be born preterm, term, or postterm. They tend to be infants of women with diabetes, and they are particularly prone to hypoglycemia or birth trauma.
- An early preterm infant is one born between 24 and 34 weeks of gestation; a late preterm infant is one born between 34 and 37 weeks of gestation. Preterm infants have particular problems with respiratory function, anemia, jaundice, persistent patent ductus arteriosus, and intracranial hemorrhage.

- Infants who are born weighing less than 2,500 g at birth are termed low–birth-weight infants, those born weighing less than 1,500 g are termed very-low-birth-weight infants, and those born weighing less than 1,000 g are extremely low–birth-weight infants. Most of these infants need intensive care from the moment of birth to give them their best chance of survival.
- A postterm infant is one who has remained in utero past week 42 of pregnancy. Postterm infants have particular problems with establishing respirations, meconium aspiration, hypoglycemia, temperature regulation, and polycythemia.
- RDS commonly occurs in preterm infants from a deficiency or lack of surfactant in the alveoli. Without surfactant, the alveoli collapse on expiration and require extreme force for reinflation. Primary therapy is synthetic surfactant replacement at birth, followed by oxygen and ventilatory support.
- TTN is a temporary condition caused by the slow absorption of lung fluid at birth. It is seen most often in infants born by cesarean birth. Close observation of the infant is necessary until the fluid is absorbed and respirations slow to a usual rate.
- MAS occurs when an infant aspirates meconium-stained amniotic fluid before or during birth. Meconium is irritating to the airway and so leads to both airway spasm and pneumonia. Infants need oxygen, ventilatory support, and possibly an antibiotic until the effects of the insult to the airway subside.
- Apnea is a pause in respirations longer than 20 seconds and may be accompanied by bradycardia. It tends to occur in preterm infants who have secondary stresses such as an infection, hyperbilirubinemia, hypoglycemia, or hypothermia. Apnea monitors are used to detect this, and infants who are at high risk for apnea may be discharged with a home monitoring program.
- SIDS is the sudden, unexplained death of an infant. It is associated with infants sleeping on their stomachs (prone) and infants born preterm. An important preventive measure is advising parents to position their infant on the back and possibly use a pacifier for sleeping.
- Hyperbilirubinemia results from the destruction of red blood cells, owing either to a usual physiologic response or an abnormal destruction of red blood cells. Hemolytic disease of the newborn occurs from destruction of red blood cells from Rh or ABO incompatibility. The administration of RHIG (Rh antibodies) to Rh-negative mothers during pregnancy and after the birth of an Rh-positive infant to an Rh-negative mother has greatly reduced the incidence of the condition. Affected infants appear jaundiced from the release of bilirubin from injured red blood cells. Phototherapy and an exchange transfusion are used to prevent ABE (the deposition of bilirubin in brain cells, causing destruction of the cells).
- **Hemorrhagic disease of the newborn** is a lack of clotting ability resulting from a deficiency of vitamin K at birth. This disorder is prevented by administering vitamin K to a newborn within the first hour following birth.
- ROP is destruction of the retina caused by exposure of immature retinal capillaries to high levels of oxygen. Monitoring oxygen saturation by pulse oximetry or ABGs are

important preventive measures and help in planning nursing care that not only meets QSEN competencies but that also best meets a family's total needs.

- Severe infections acquired by infants at birth include streptococcal group B pneumonia, hepatitis B infection, ophthalmia neonatorum (gonococcal and chlamydial conjunctivitis), and herpesvirus infections. Assessing newborns for symptoms of these infections is an important nursing responsibility.
- Infants of women with diabetes and those of drug-abusing women are at high risk at birth for further complications. Both need a careful assessment for respiratory distress and hypoglycemia.

### CRITICAL THINKING CARE STUDY

Priscilla Angelini is an unmarried 17-year-old who has just given birth via cesarean birth to her first baby, a girl, at 37 weeks of gestation because of a breech presentation. Priscilla did not receive any prenatal care. At birth, she tests positive for group B streptococcal infection. When assessing her newborn, you conclude she is SGA. At 6 hours of age, Priscilla calls you and explains her baby seems to be struggling to breathe. She wants to know if this is normal. When you assess the newborn, you find a respiratory rate of 70 breaths/min and mild subcostal retractions.

1. What possible risk factors should you look for in Baby Angelini?
2. What is the most likely explanation for Baby Angelini's respiratory rate and the subcostal retractions? What priority nursing intervention should you initiate? What should you tell Priscilla about the situation?
3. Does Priscilla's infection put Baby Angelini at risk? What nursing interventions should be in the newborn's care plan to prevent infection and what signs and symptoms of infection should you look for in the newborn?

# Nursing Care of the Child Born With a Physical or Developmental Challenge

*Maia Sparrow, 22 years old, is a new mother whose newborn has been admitted to the neonatal intensive care unit for care of a neural tube disorder and developmental dysplasia of the hip. Ms. Sparrow is obviously upset over the diagnosis. She has not named the baby, and her parents have not visited. She says to you, "I'm a good person. The only thing I did wrong during pregnancy was to take some cough medicine. How could this have happened to me?"*

*Previous chapters described the importance of assessing all newborns at birth. This chapter includes information about common congenital anomalies or structural disorders that may occur in newborns. This information serves as a basis for a newborn assessment and for health teaching for parents.*

**How would you answer this mother? What type of advice and support does she need?**

## KEY TERMS

**achondroplasia**  
**ankyloglossia**  
**atresia**  
**cleft lip**  
**cleft palate**  
**craniosynostosis**  
**developmental dysplasia of the hip (DDH)**  
**fistula**  
**frenulum**  
**gastroschisis**  
**glossoptosis**  
**hydrocephalus**  
**meconium plug**  
**omphalocele**  
**pectus excavatum**

**polydactyly**  
**spina bifida**  
**stenosis**  
**syndactyly**  
**talipes**  
**torticollis**  
**transillumination**  
**volvulus**

## **OBJECTIVES**

**After mastering the contents of this chapter, you should be able to:**

1. Describe common physical and developmental disorders that occur in newborns, infants, and children.
2. Assess newborns who are born physically or developmentally challenged.
3. Formulate nursing diagnoses for newborns born with a physical or developmental challenge.
4. Establish expected outcomes to meet the needs of the child with a physical or developmental challenge and assist parents to manage transitions across differing healthcare settings.
5. Implement nursing interventions for care of a newborn born with a physical or developmental challenge, such as preventing infection in a child with a neural tube disorder.
6. Evaluate expected outcomes to determine achievement and effectiveness of care.
7. Integrate knowledge of congenital physical or developmental challenges with the interplay of nursing process; the six competencies of Quality & Safety Education for Nurses (QSEN), including Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics; and Family Nursing to promote quality maternal and child health nursing care.
8. Assist with achieving 2020 National Health Goals related to newborns born physically or developmentally challenged.

Few things can change the usually joyous tone of a birthing room faster than the birth of a baby with a physical or developmental challenge. Primary care providers who are used to saying mentioning the “perfect” boy or girl find themselves without words. The usual congratulatory remarks hang unsaid in the air.

When a newborn is born with an apparent physical or developmental challenge, nurses play a major role in supporting and educating the parents to promote bonding. With some newborns, their congenital disorder may be corrected with surgery, and they

will have no long-term sequela. With other newborns, the congenital disorders may require long-term care even with surgical correction. This chapter covers physical disorders of the skeletal, gastrointestinal, and neurologic systems that are apparent at birth or recognized soon after. Congenital disorders of the cardiovascular system are addressed in [Chapter 41](#).

Birth defects remain a major public health burden. The Centers for Disease Control and Prevention (CDC) estimates that 3% of all newborns born in the United States are affected by a birth defect and 20% of all infant deaths are attributed to birth defects (CDC, 2016). [Box 27.1](#) shows 2020 National Health Goals related to decreasing the number of newborns born with congenital anomalies.

### BOX 27.1

#### Nursing Care Planning Based on 2020 National Health Goals

Many congenital anomalies, such as a cleft lip, an omphalocele, and neural tube disorders, can be detected by sonogram during intrauterine life. The following 2020 National Health Goals address the importance of prevention and therapy postbirth:

- Increase the proportion of women delivering a live birth who took multivitamins/folic acid prior to pregnancy from a baseline of 30.1% to 33.1%.
- Reduce the occurrence of spina bifida from 34.2 per 100,000 live births to 30.8 per 100,000 live births per year.
- Reduce the occurrence of anencephaly from 24.6 per 100,000 live births to 22.1 per 100,000 live births per year.
- Increase the proportion of children with special healthcare needs who have access to a medical home from 47.1% to 51.8%.
- Increase the proportion of children aged 0 to 11 years with special healthcare needs who receive their care in family-centered, comprehensive, and coordinated systems from a baseline of 20.4% to 22.4%; and in children aged 12 to 17 years from 13.7% to 15.1% (U.S. Department of Health and Human Services, 2010; see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by urging women to enter pregnancy with an adequate folic acid level, ensuring women obtain prenatal care, and receive comprehensive advice and support after diagnosis of a fetal or newborn disorder.

### *Nursing Process Overview*

#### FOR CARE OF A NEWBORN WHO IS PHYSICALLY OR DEVELOPMENTALLY CHALLENGED

##### **ASSESSMENT**

The nursing assessment of a newborn who is physically or developmentally challenged focuses on determining the infant's immediate physiologic needs required

to sustain life and the parents' immediate emotional needs to promote bonding. These are not different than those of all newborns. The following eight primary needs of newborns should be assessed for signs that they are being established considering the newborn's physical and developmental challenges:

- Adequate respiration
- Extrauterine circulation
- Body temperature stabilization
- Blood sugar stabilization
- Prevention of infection
- An infant–parent bond
- Adequate stimulation
- Ability to take in adequate nutrients
- Ability to achieve waste elimination

Anomalies that affect a newborn's appearance may have the most immediate effect on the parents' ability to establish a positive bond with their child. It is important, however, not to jump to conclusions about what will be the parents' response. An assessment of the family's verbal and nonverbal responses may reveal that parents are prepared and agreeable to meet this infant's special needs. The parent's adjustment may be affected by their prior knowledge of their child's physical or developmental challenge.

### **NURSING DIAGNOSIS**

Many nursing diagnoses established for children who are physically or developmentally challenged address the effect of the disorder on body function, including the child's primary needs and the family's coping ability (Farrell & Krahn, 2014).

Examples of possible diagnoses include:

- Imbalanced nutrition, less than body requirements, related to inability to take in adequate nutrition secondary to a physical challenge
- Impaired physical mobility related to congenital anomaly
- Risk for impaired parenting related to the birth of child with a congenital anomaly
- Anticipatory grieving (parental) related to loss of the idea of the "perfect" child

### **OUTCOME IDENTIFICATION AND PLANNING**

Nurses play an important role in providing immediate care to high-risk newborns at birth as well as stabilizing them until the pediatric team arrives to assume care or transport the newborn to a high-risk nursery. Consideration of the family's resources, both emotional and financial, is an important aspect of planning care and establishing expected outcomes (Nes, Røysamb, Hauge, et al., 2014). It's important to consider both the short- and long-term needs of the newborn and how these needs may affect the family. Supportive family members can be a critical asset to parental adjustment (Carmichael, Ma, Tinker, et al., 2014). Providing nursing support as part of an

interdisciplinary team, including social workers, therapists, nutritionists, medical specialists, and other community resources can also help with parental adjustment. Refer parents to helpful websites and other resources when appropriate (see [Chapter 20](#)).

### IMPLEMENTATION

Nursing interventions for a newborn who is physically challenged include immediate life-sustaining measures such as providing oxygen or adequate intake of nutrients when a disorder prevents the infant from establishing respirations or sucking. Encouraging skin-to-skin contact and interacting with the newborn promotes infant–parent bonding. Educating the parents about procedures the infant may undergo lessens the parental anxiety and enhances self-esteem.

Parents experience the same stages of grief: denial, anger, bargaining, depression, and adjustment as those whose child has died at birth (see [Chapter 56](#)). It is important for the nurse to provide positive role modeling when caring for the emotional and physical needs of the newborn; it helps the parents to adjust to parenting a child born with a physical or developmental challenge.

### OUTCOME EVALUATION

Outcome evaluation should focus on establishing expected outcomes for the child’s physical and developmental health needs as well as the family’s coping ability for current and future health of the child. This includes addressing the family concerns and providing resources to support the family during and after discharge.

Examples of expected outcomes may include:

- Parent describes positive features of child by 2 weeks.
- Parents state they are comfortable with enteral feeding by 1 month.
- Child is ambulatory with walker or wheelchair by 2 years of age.

## Care at Birth of the Newborn Who Is Physically or Developmentally Challenged

The pediatric provider or neonatologist typically provides the parents with medical information regarding the health status of their newborn. This information should be provided to the parents as quickly and accurately as possible. The nurse can provide support to the family by keeping them informed of their newborn’s health status and facilitating their interaction with the healthcare team. It is distressing for parents, who expect to hold their newborn immediately after birth, to watch their newborn undergo a medical evaluation and medical intervention while physically separated from their newborn ([Box 27.2](#)).

BOX 27.2

Nursing Care Planning to Respect Cultural Diversity

The causes of most congenital anomalies are unknown, although they probably arise from a combination of environmental and genetic factors. New parents need an explanation of their child's disorder and a chance to talk about why they believe their child's disorder occurred. Despite the evidence, many cultural myths persist around congenital anomalies. Many people persist in believing infants with congenital anomalies are born to people less deserving than others. Common beliefs include myths such as being looked on by an evil eye (*mal de ojo* in Spanish) can cause a deformity. Parents may also blame themselves for their child's condition thinking something they did or didn't do may have caused it. Common beliefs also include the idea that eating raisins causes brown birth marks and eating strawberries causes red hemangiomas. Educating parents relieves any guilt that they were the cause of the anomaly, helping them regain sufficient self-esteem to raise a child with a congenital disorder.

When the parents are with their newborn, the nurse can begin by describing the newborn's physical condition, related to the diagnosis, to the parents. Medical equipment and its purpose should also be explained. Parents should be given the opportunity to ask questions and interact with their newborn. Comments by the nurse related to normal newborn observations can assist the parents in relating their newborn. A typical explanation for Maia, for example, might be, "When your doctor placed your baby on your abdomen, you might have noticed that your baby's spinal cord isn't completely formed, something called a meningocele. Although that could be more extensive, at first inspection, it seems to be a problem that can be repaired. Her hips may also need some treatment. I'll bring the baby's Isolette over so you can see her. Notice how bright-eyed and alert she is for just being born." Referring to the newborn by their name is helpful to personalize the interaction.

### *What If... 27.1*

**The nurse notices Maia remains obviously upset at her child's appearance. She doesn't want to feed him and tells the nurse she'd like to place him for adoption. In contrast, the child's father, also a teenager, handles the baby warmly and asks questions about surgery. No grandparents visit. What interventions would the nurse want to begin with this family?**

## Physical and Developmental Disorders of the Skeletal System

Either genetic or environmental factors can compromise fetal physical growth to such an extent that they result in skeletal disorders in the newborn.

## ABSENT OR MALFORMED EXTREMITIES

Congenital skeletal disorders can result from reasons such as maternal drug ingestion or virus invasion or amniotic band formation in utero. In most instances, however, the cause of the anomaly is unknown. Children born without an extremity or with a malformed extremity can be fitted with a prosthesis as early in life as about 6 months so the infant can learn to stand at the normal time or handle and explore objects readily. However, it may be adventitious to allow the child to grow and learn to use their altered body or limb without a prosthesis. Introducing a prosthesis early in life may prevent a child from adjusting to a missing extremity, for example, such as learning to write with their feet or sliding across the floor rather than walking. Often, parents and therapists will teach children in therapy to function both with and without a prosthesis. Children are resilient and can become so proficient at these adjustments in their born deformity that later in life they may not see any advantage to using a prosthesis. Those affected by a skeletal anomaly can choose to use a prosthesis as an adult or not.

Depending on the condition, in many children, there is a potential for better function if the malformed portion of an extremity is amputated before a prosthesis is fitted. This creates a difficult decision for parents because it is one they cannot undo later. They need assurance that hands with malformed fingers, for example, will not later grow to become normal and that a well-fitted prosthesis will allow their child a more usual childhood and adult life than if the original disorder was left unchanged (Fig. 27.1).

**Figure 27.1** A young child learns to use a hand prosthesis during play.  
(M. Grecco/Stock Boston.)

Learning to use a hand prosthesis takes weeks to months, and it also involves therapy. It helps if parents can think of interesting activities when introducing the prosthesis so the child can immediately see how useful it will be to use. Gait training for the use of lower extremity prostheses begins with the use of parallel bars and proceeds to independent walking and mastery of steps. Again, suggesting activities the child needs to walk to do offers motivation for trying to use the prosthesis.

Children who are born with an absent extremity may need help not only in mastering the use of a prosthesis but also in forming a positive body image of themselves as whole. If possible, in the newborn period, introduce parents to the rehabilitation team who will be following their child. Further steps will then be outlined to help them move past the helplessness they may be feeling to more positive actions. Visiting with a child who uses a prosthesis well can be a great help in convincing parents that their child can lead a normal life. Young children with a congenital extremity may not grieve over the lost extremity as do adults or older children.

## FINGER AND TOE CONDITIONS

Finger or hand deformities occur in about 3% of all births. **Polydactyly** is the presence of one or more additional fingers or toes. When an entire extra finger or toe forms, the supernumerary digit is usually amputated in infancy or early childhood. These extra fingers are often just cartilage or skin tags, and removal is simple and cosmetically sound. In **syndactyly** (two fingers or toes are fused), the fusion is usually caused by a simple webbing (Fig. 27.2); separation of the digits into two sound and cosmetically appealing ones is usually successful. In other instances, the bones of the fingers or toes are also fused, and cosmetic appearance and function cannot be fully reconstructed (Sullivan & Adkinson, 2016).

**Figure 27.2** Syndactyly. (JPD/Custom Medical Stock Photograph.)

These digit anomalies are always upsetting to parents (one of the first things new parents do is count the fingers and toes of newborns) and may cause them to view their infant as defective rather than being an infant with a simple anomaly. Encourage them to air their feelings and concerns as they deliver the news to family and friends. Because hands are so important for writing, self-care, or computing, they may need reassurance at health maintenance visits for the first few years of their child's life that the child is perfect in other ways so they can accept and help the child develop self-esteem. Children may need this same type of assurance as they grow older so they can think of themselves as well people. Often, identifying a skill or talent that the child excels in can provide another avenue for developing self-esteem. There are many examples of children with one limb or a deformity playing sports, such as swimming, excelling in the arts, or playing musical instruments. If a child expresses a desire to learn these activities, allowing the child to participate (if medically safe and sound) typically leads

to profound beneficial outcomes for all.

## CHEST DEVIATIONS

**Pectus excavatum**, or “funnel chest,” is an indentation of the lower portion of the sternum. It is the most common congenital deformity of the anterior chest, occurs in about 1 out of 500 live births, and affects boys 4 times more often than girls. The concern may not be present at birth but becomes more obvious as the child grows to school age or adolescence. As a result of the deformity, lung volume is apt to be decreased and the heart is displaced to the left. The condition can be repaired, for either cosmetic reasons or physiologic reasons, such as to expand lung volume (Abdullah & Harris, 2016). With *pectus carinatum*, the sternum is displaced anteriorly, increasing the anteroposterior diameter of the chest. This anomaly can be surgically corrected (Tikka, Kalkat, Bishay, et al., 2016).

## TORTICOLLIS (WRY NECK)

**Torticollis** is a term derived from the terms *tortus* (“twisted”) and *collum* (“neck”). Torticollis (wry neck) occurs as a congenital anomaly when the sternocleidomastoid muscle is injured and bleeds during birth (Ryu, Kim, Kim, et al., 2016). This tends to occur in newborns with wide shoulders when pressure is exerted on the head to deliver the shoulder either with a vaginal or cesarean birth. The infant holds the head tilted to the same side as the muscle that is involved; the chin rotates to the opposite side. The injury may not be noticeable in the newborn and may become evident only as the original hemorrhage recedes and fibrous contraction occurs at 1 to 2 months of age. A thick mass over the muscle can usually be palpated at that time.

To relieve torticollis, parents need to begin a program of passive stretching exercises and therapy, laying the infant on a flat surface and rotating the head through a full range of motion. Often, pediatric physical therapists are involved in the home therapy treatment for infants with torticollis. In addition, parents should always encourage the infant to look in the direction of the affected muscle. They can encourage this by holding the child to feed in such a position that the child must look in the desired direction. Placing a mobile on the child’s crib can encourage the child to look toward the affected side. Speaking to and handing the child objects from the affected side is another helpful exercise.

If manual stretching is begun early and performed consistently by parents, further treatment usually is not necessary. If extreme injury to the muscle occurred, torticollis can lead to the continued elevation of one shoulder. Although a rare complication, this has the potential to lead to scoliosis later in life. Therefore, help parents to understand that their actions are important therapy, not just games. Otherwise, the exercises seem so simple parents may not take them seriously. In the few instances in which simple exercises are not effective and the condition still exists at 1 year of age, surgical correction followed by a neck immobilizer may be necessary.

### **PATIENT-CENTERED CARE**

Suppose Maia's baby develops a torticollis, and she is distraught by her baby's appearance. What care measure would best relieve the infant's physical anomaly and Maia's distress?

- a. Teach Maia how to perform her baby's neck stretching exercises.
- b. Wrap the infant's neck in a warm towel for 15 minutes twice daily.
- c. Assure Maia that the anomaly will resolve spontaneously.
- d. Administer 80 mg of aspirin with each of his bottle feedings.

*Look in [Appendix A](#) for the best answer and rationale.*

### **CRANIOSYNOSTOSIS**

**Craniosynostosis** is the premature closure of the sutures of the skull. This may occur in utero or early in infancy because of rickets or irregularities of calcium or phosphate metabolism; it also occurs as a dominantly inherited trait and occurs more often in boys than in girls ([Children's Craniofacial Association, n.d.](#)). Measuring the infant's head circumference during the first 18 months of life is advocated by the American Academy of Pediatrics (AAP; [Mulpuri, Song, Gross, et al., 2015](#)).

This condition needs to be detected early because premature closure of the suture line will close the fontanelles, seal the skull closed, and compromise brain growth. If the sagittal suture line is the one that closes prematurely, the child's head tends to grow anteriorly and posteriorly. If the coronal suture line fuses early, the orbits of the eyes become misshapen and the increased intracranial pressure may lead to eye disorders such as exophthalmos, nystagmus, papilledema, strabismus, and atrophy of the optic nerve with consequent loss of vision. Premature closure of the coronal suture line is associated with syndactyly. Therefore, make a point at well-child assessments to observe the head circumference for all infants, especially those with syndactyly. Cardiac anomalies, choanal atresias, or disorders of elbows and knee joints can also be associated.

Craniosynostosis is diagnosed by X-ray or ultrasound, which reveals the fused suture line. If the suture line involved is the sagittal, treatment may involve only careful observation; if the coronal suture line is involved, it will need to be surgically opened to prevent brain compression and an abnormally shaped head by 9 to 12 months ([Jubbal, Agrawal, & Hollier, 2017](#)).

### **ACHONDROPLASIA**

**Achondroplasia** (chondrodystrophia) is a failure of bone growth inherited as a dominant trait, which causes a disorder in cartilage production in utero. The epiphyseal plate of long bones cannot produce adequate cartilage for longitudinal bone growth; this results in both arms and legs becoming stunted ([Ornitz & Legeai-Mallet, 2017](#)).

Because the bones of the cranium are of membranous origin, the head continues to grow normally, causing children's heads to appear unusually large in contrast to their extremities. The forehead is particularly prominent and the bridge of the nose becomes flattened. Children's trunks are of near-normal size, but a thoracic kyphosis (outward curve) and lumbar lordosis (inward curve) of the spine may develop. Because this is a cartilage, not a brain growth concern, gross motor development may be slowed, but intelligence is not affected.

Achondroplasia can be diagnosed in utero by ultrasound or at birth by X-ray by comparing the length of extremities to the usual length (in the average child, the arms can be extended to the distance of the mid thigh). An X-ray will also reveal characteristic abnormally flaring epiphyseal lines. Children with achondroplasia rarely reach a height of more than 4 ft 6 in. (140 cm). Women with this condition may have difficulty with childbearing because of a small pelvis, generally necessitating a cesarean birth.

Children with achondroplasia become aware of their appearance as early as the preschool years. They are apt to become acutely aware of their appearance during school age, when they realize they look so different from other children. In order to help them grow, they may be prescribed growth hormone, or although controversial, leg lengthening may be possible (Ornitz & Legeai-Mallet, 2017). Ideally, such children have parents who have helped them adjust well to their short stature as well as help them develop good self-esteem so they can be happy in their body, no matter what is their final height.

Children need to be informed as they reach adolescence that, as with all dominantly inherited disorders, there is a high probability their children will inherit the disorder. This can make adolescence a particularly difficult time for these children as they realize both some occupational and reproductive options may be limited for them. Continued guidance or counseling can help them to emerge from this period with feelings of high self-esteem as adults.

## TALIPES DISORDERS

The word *talipes* is formed from the Latin *talus* ("ankle") and *pes* ("foot"). The **talipes** deformities, therefore, are ankle-foot disorders, popularly called clubfoot. The term "clubfoot" implies permanent crippling to many people, and because this is no longer true with effective surgery, avoid using the term when discussing talipes disorders with parents. Concerns that may remain after surgery include that the child's right and left shoe size may vary and the child may have asymmetry of leg length.

Approximately 1 child in every 1,000 is born with a talipes disorder, and it occurs more often in boys than in girls. It probably is inherited as a polygenic pattern, and it usually occurs as a unilateral problem (Sanzarello, Nanni, & Faldini, 2017).

Some newborns who appear to have a talipes disorder actually have only an unusual foot position (a pseudotalipes) that developed because of their cramped intrauterine position. In these infants, the foot can be brought into a straight position by manual

manipulation. In a true disorder, the foot cannot be properly aligned without further intervention. Be certain to demonstrate to parents that, if a pseudodisorder is present, the foot can easily be brought into line or is not deformed. Otherwise, the first time parents fit booties or shoes on the infant, they may notice this odd position and worry the foot is misshapen when it is not. Stretching the foot into line every day will solve the problem in a short time.

A true talipes disorder can be one of four separate types: plantar flexion (an equinus or “horse foot” position, with the forefoot lower than the heel); dorsiflexion (the heel is held lower than the forefoot or the anterior foot is flexed toward the anterior leg); varus deviation (the foot turns in); or valgus deviation (the foot turns out). Most children with talipes deformities have a combination of these conditions or have an equinovarus (Fig. 27.3A) or a calcaneovalgus disorder (a child walks on the heel with the foot everted).

**Figure 27.3** (A) Talipes equinovarus. (SPL/Photo Researchers, Inc.)  
(B) Casts for bilateral equinovarus.

### Assessment

The earlier a true disorder is recognized, the better will be the correction. Make a habit, therefore, of straightening all newborn feet to the midline as part of the initial assessment to detect this disorder. If there is a possible questionable deformity, refer to the pediatric physician and orthopedist specialist to begin the process of evaluating the infant properly.

### Therapeutic Management

Correction is achieved best if it is begun in the newborn period. For correction, a series of casts or braces are applied to gradually mold the foot into good alignment (a Ponseti method) (Sanzarelli et al., 2017). Although the disorder involves the ankle, the cast or brace extends above the knee to ensure a firm correction (see Fig. 27.3B). (Care of the child in a cast is discussed in Chapter 51.) Because talipes casts are high on the leg, change diapers frequently to prevent a wet diaper from touching the cast and causing it to become soaked with urine or meconium. Review with parents how to check the infant's toes for coldness or blueness and how to blanch a toenail bed and watch it turn

pink to assess for good circulation. Because a newborn cannot report pain except by generalized crying, they must evaluate crying episodes in the infant carefully. Such crying may be because of colic, hunger, or wet diapers, or it might also be because of the tingling feeling of circulatory compression (as when a foot is “asleep”) from too tight a cast.

Infants grow so rapidly in the neonatal period that casts or braces for talipes deformities must be changed or adjusted almost every 1 or 2 weeks. If a mother has a complication or is exhausted from childbirth, be certain she will be able to make arrangements for another family member or friend to bring the infant to the hospital for frequent cast changes or brace adjustments.

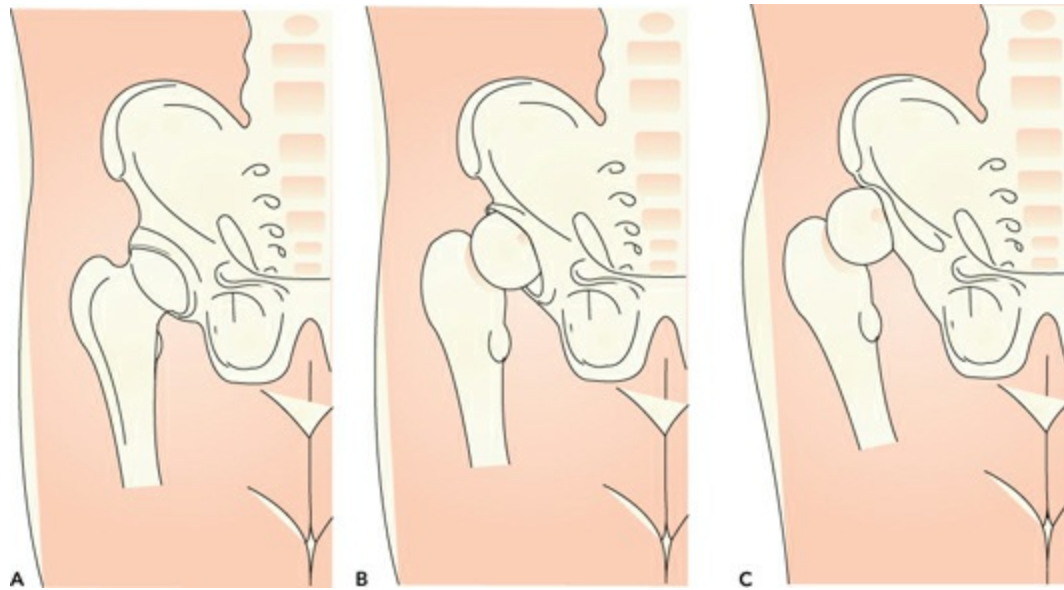

After approximately 6 weeks (the time varies depending on the extent of the problem), the final cast will be removed. Following this, the infant may have to sleep in Denis Browne splints (shoes attached to a metal bar to maintain position) or high-top shoes at night for a few more months to ensure an effective correction. Parents may need to perform passive foot exercises such as putting the infant’s foot and ankle through a full range of motion several times a day for several months. These seem to be simple maneuvers, so be certain to stress their importance to the parents; otherwise, they are easy exercises to omit when people’s lives are busy. Pediatric physical therapists are often part of the interprofessional therapy team to assist in rehabilitation at the hospital and at home.

Although a successful correction cannot be guaranteed, the prognosis for a full correction is good. For children who do not achieve correction by casting, additional surgery is yet another option to achieve a final correction.

## **DEVELOPMENTAL DYSPLASIA OF THE HIP**

**Developmental dysplasia of the hip (DDH)** (often referred to as congenital hip dysplasia) is improper formation and function of the hip socket and is considered a spectrum of abnormalities affecting the hip joint. DDH is a fairly common musculoskeletal condition found in newborns, with the prevalence estimated to range from 1.6 to 28.5 per 1,000 infants, averaging about 5% of newborns who have some radiographic abnormality of the hip ([Shaw & Segal, 2016](#)).

DDH is a leading cause of orthopedic disability in childhood and adult life because it can lead to premature arthritis requiring hip replacement (the disorder is responsible for up to 28% of hip replacements in people under 60 years of age) ([Shaw & Segal, 2016](#)). The disorder may be evident as either subluxation or dislocation of the head of the femur ([Fig. 27.4](#)).

**Figure 27.4** Hip dysplasia. (A) A normal femur head and acetabulum. (B) A subluxated hip. The femur head is “riding high” in the shallow acetabulum. (C) A dislocated hip. The femur head is not engaged in the shallow acetabulum.

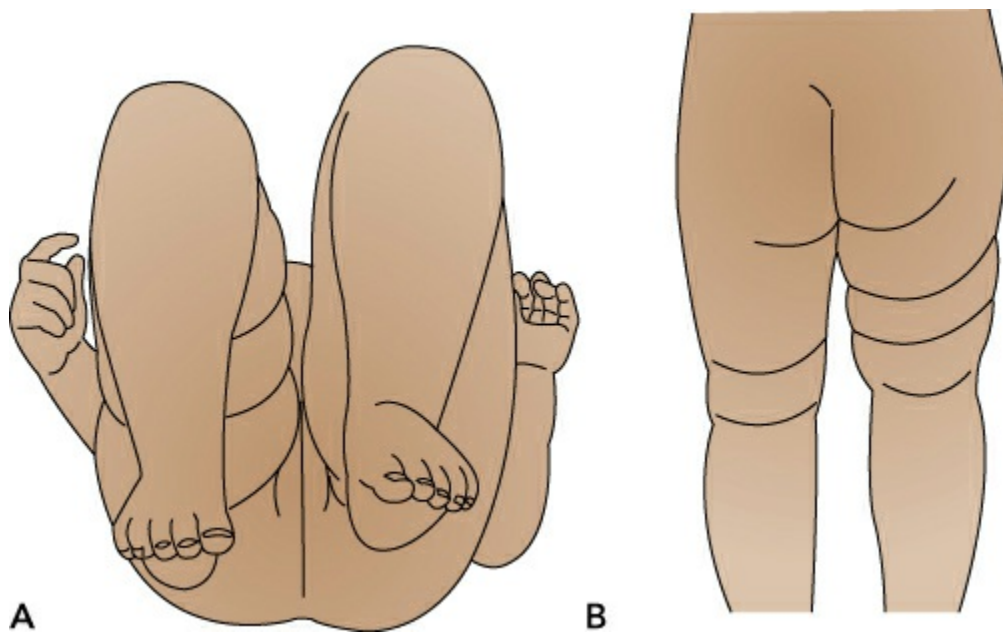

With the disorder, the acetabulum of the pelvis is unusually flattened or shallow. This prevents the head of the femur from remaining in the acetabulum and rotating adequately. In a subluxated hip, the femur “rides up” because of the flat acetabulum; in a dislocated hip, the femur rides so far up it actually leaves the acetabulum. Why the disorder occurs is unknown, but it may be from a polygenic inheritance pattern. It may also occur from a uterine position that causes less-than-usual pressure of the femur head on the acetabulum.

DDH is more likely to occur with breech birth, a female infant, and a mother’s first pregnancy (Jackson, Runge, & Nye, 2014). It is usually unilateral and found 6 times more frequently in girls than in boys, possibly because the hips are normally more flaring in females and possibly because the maternal hormone relaxin causes the pelvic ligaments to be more relaxed during pregnancy, which causes the femur to not press as effectively into the acetabulum during intrauterine life, thus deepening the space. Additional risk factors include family history of DDH, oligohydramnios, large birth weight for gestational age, metatarsus adductus, and torticollis (Shaw & Segal, 2016). Current literature suggests that the natural history to delineate the reason for the DDH appears to be dependent both on the type and severity of the hip abnormality and may be the combination of risk factors presented (Mulpuri et al., 2015).

### Assessment

All infants should be screened for DDH from birth and up until 3 months of age by performing the Ortolani & Barlow maneuver (Shaw & Segal, 2016). Detecting developmental dysplasia of the hip in the newborn is important because the longer the

condition goes undetected, the more difficult it is to correct. On inspection, the affected leg may appear slightly shorter than the other because the femur head rides so high in the socket. This is most noticeable when the child is lying supine and the thighs are flexed to a 90-degree angle toward the abdomen, causing one knee to be lower than the other (a Galeazzi sign; Fig. 27.5A). An unequal number of skin folds may also be present on the posterior thighs (see Fig. 27.5B). This finding is unreliable, however, because some infants with normal hips have an uneven number of posterior thigh skin folds. Subluxated or dislocated hips are best assessed by noting whether the hips abduct (Box 27.3).

**Figure 27.5** Signs of developmental dysplasia of the hip. **(A)** With the child in a supine position, the right knee on the side of the subluxation appears lower than the left because of malposition of the femur head. **(B)** Asymmetry of skin folds and prominence of the trochanter on the right side.

**BOX 27.3**

**Nursing Care Planning Using Procedures**

**ASSESSING ORTOLANI AND BARLOW SIGNS**

**Purpose:** To assist in detecting developmental dysplasia of the hip

Procedure	Principle
1. Lay the infant supine and flex the knees to 90 degrees at the hips.	1. Proper positioning helps ensure accurate results.
2. Place your middle fingers over the greater trochanter of the femur and your thumb on the internal side of the thigh	2. Placing your fingers in this way allows for abduction of the hips.

over the lesser trochanter (Fig. A).

3. Abduct the hips while applying upward pressure over the greater trochanter, and listen for a clicking sound.
4. Next, with your fingers in the same position and holding the hips and knees at 90-degree flexion, apply a backward pressure (down and laterally) and adduct the hips. Note any feeling of the femoral head slipping (Fig. B).

3. Normally, no sound is heard. A clicking or clunking sound is a positive Ortolani sign as it occurs when a displaced femoral head reenters the acetabulum.
4. Normally, the hip joint is stable. A feeling of the femur head slipping out of the socket posterolaterally is a positive Barlow sign, which is indicative of hip instability associated with the developmental dysplasia of the hip.

In some infants, the hip abducts properly at a newborn assessment, but at the time of a health maintenance visit at 4 to 6 weeks, a secondary shortening of the adductor muscles will have occurred, and the disorder will be first evident. Hip dysplasia may also be difficult to detect at birth in an infant who was born from a breech presentation because the knees tend to be stiff and not flex readily. Because tight adductor muscles occur in children with cerebral palsy, these children also need careful assessment. Current guidelines recommend physical exam screening of all infants up to 6 to 12 months of age at all primary care visits via hip assessment and continual screening of those with risk factors until walking age (Mulpuri et al., 2015). In regard to radiologic screening, current guidelines recommend performing an imaging study, such as a hip ultrasound, before 6 months of age only in infants with one or more of these risk factors: such as breech presentation, family history, or history of clinical hip instability (Mulpuri et al., 2015). Hip ultrasonography has a good negative predictive value (as high as 90%) for ruling out DDH (Shaw & Segal, 2016). Generally plain radiography (X-ray) is not as effective in children less than 6 months of age due to musculoskeletal immaturity and unreliability to accurately screen for DDH; in children older than 6 months, radiology may be a useful assessment evaluation tool of treatment progress.

### **Therapeutic Management**

Current recommendations from American Academy of Orthopaedic Surgeons and the AAP (2017) suggest close monitoring in mild DDH cases because 60% to 80% of clinically identified abnormalities and 90% of ultrasonographic abnormalities spontaneously resolve without treatment in early infancy (Mulpuri et al., 2015). In

contrast, severe DDH may adversely affect normal hip growth and development and may cause issues into adulthood, such as osteoarthritis of the hip (Shaw & Segal, 2016). Infants less than 6 months of age are usually treated by using flexion-abduction splinting devices. Correction of subluxated and dislocated hips involves positioning the hip into a flexed, abducted (externally rotated) position to press the femur head against the acetabulum and cause the acetabulum to deepen its contour from the pressure. Brace and splints, such as the von Rosen, Pavlik, Craig, or Frejka, may be utilized for treatment of an unstable hip, and patient–family preferences should have a substantial influence on which type is chosen (Mulpuri et al., 2015). The Pavlik harness is shown to have a high success rate in treating subluxation and reducible DDH. There will be a small number of children who do not achieve correction by noninvasive methods will have corrective and therapeutic hip surgery, which may involve having a pin inserted to stabilize the hip.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Deficient parental knowledge related to splint, halter, or cast correction for hip dysplasia

**Outcome Evaluation:** Parents verbalize correct technique for and correctly demonstrate application and removal of splint or halter device and care of device or cast.

*A Pavlik Harness.* A Pavlik harness is an adjustable chest halter that abducts the legs. It is the method of choice for therapy because it reduces the time interval for therapy to 3 to 4 weeks and simplifies care (Fig. 27.6A). Soft plastic stirrups (booties) with quick-fastening closures attach to leg extension straps and hold the hips flexed, abducted, and externally rotated. Instruct parents how to lay the infant supine, grasp the infant’s thighs, and abduct them to place the femoral head into the acetabulum and then apply the harness. The harness is then worn under clothing continually except for bathing. Advise parents to assess the skin under the straps daily for irritation or redness or potential skin breakdown from the harness rubbing. Caution them also that the harness achieves its effect by gentle continual pressure; it will be ineffective if parents remove it frequently or forget to put it in place.

**A**

**B**

**Figure 27.6** (A) A Pavlik harness (shown over clothing for illustrative purposes). (B) A hip abduction cast for correction of subluxation of the hip.

*A Spica Cast.* If a hip is fully dislocated or the subluxation is severe, an infant may be placed immediately in a frog-leg, A-line cast, or a spica cast to maintain an externally rotated hip position (see Fig. 27.6B). These casts are heavy and are so wide that dressing infants or sitting them in an infant car seat or using a bassinet can be difficult. Be certain parents have a car seat that can be modified to accommodate a large cast. Like babies with a talipes, these infants are unable to report a cast is causing circulatory constriction, so they need to be assessed hourly for circulation to

the extremities for the first 24 hours the cast is in place and daily thereafter. Teach parents how to do this type of neurovascular assessment (check temperature and circulation in toes) before they take an infant home from the hospital so they can prevent circulatory compression from a rapidly growing leg outgrowing the cast. Casts will be changed as growth and casting therapy require but maintained for 6 to 9 months. Casting is a second line of correction because the child is much harder to care for because of the weight of the cast. In some cases, the joint may become compressed due to the reduction maneuver or tension in the soft tissues around the hip, blocking the blood supply to the femoral head (avascular necrosis). In its severest form, this can lead to femoral head death and loss of future growth at the proximal growth plate, causing unequal leg lengths.

*General Care Guidelines.* Rarely, but sometimes surgery may still be necessary for a final correction. With severe hip involvement, some children will be 2 years old before the final cast is removed.

The child and parents will be visiting their orthopedist frequently during these early years. Assess that they also schedule general health maintenance visits for routine immunizations and overall growth and development assessment. Spend time during health maintenance visits talking with them about infant stimulation. Teach parents to hold their child for feeding and to rock and cuddle the infant, even though a large cast or a brace may be bulky and awkward. Discuss how to bring experiences to the infant because the child cannot crawl and walk toward interesting objects in the environment. A child's wagon can supply convenient and fun transportation. The child may also be able to lie prone and move about on a large skateboard. Many parents worry the child who is still in a large cast at the normal age for walking (12 months) will never learn to walk. They can be assured that this is not a problem; when the cast is removed, the child will quickly catch up with this developmental step. Children who are diagnosed with severe DDH will often have an adjunct therapy team, such as pediatric physical therapists who are assisting with gross-motor milestone development while the child is in a brace or recovering from surgery. Nurses must assess that the family is receiving any needed adjunct therapies, such as physical therapy, and assist with any referrals that are necessary.

### ***QSEN Checkpoint Question 27.2***

#### **INFORMATICS**

Because Maia's baby was born with developmental dysplasia of the hip, he has a Pavlik harness prescribed. What information would the nurse want Maia to know about his care?

- a. The harness may not be effective, but she should trial it before surgery.
- b. She should keep the harness on her baby for 12 hours a day.
- c. Her baby should wear the harness at all times except while bathing.

d. For more advice, she should look at mothers' blogs online.

*Look in Appendix A for the best answer and rationale.*

## Physical and Developmental Disorders of the Gastrointestinal System

Many of the most common congenital anomalies of the gastrointestinal system, such as cleft lip and cleft palate, occur because of midline closure failure extremely early in intrauterine life. Others occur because the tract first forms as a solid tube and then undergoes canalization (hollowing out). At any site where this hollowing out does not occur, a partial or complete blockage or obstruction will be present. All gastrointestinal disorders can interfere with an infant's ability to take in nourishment to some degree at birth.

### ANKYLOGLOSSIA (TONGUE-TIE)

**Ankyloglossia** is an abnormal restriction of the tongue occurring in a small number of newborns caused by an abnormally tight **frenulum**, the membrane attached to the lower anterior tip of the tongue (Yoon, Zaghi, Weitzman, et al., 2017). Tongue-tie (ankyloglossia) is a congenital anomaly in which a tight or shortened lingual frenulum causes restricted tongue mobility and impaired tongue function (Hazelbaker, 2010). Incidence rate is estimated to range from 4% to 10% within the newborn population (Yoon et al., 2017). Normally, the frenulum appears short and is positioned near the tip of the tongue. As the anterior portion of the infant's tongue grows, the frenulum becomes located farther back. In most instances, therefore, an infant suspected of being tongue-tied has a normal tongue at birth; it just seems short to parents who are unaware of a newborn's appearance. Tongue tie is often evaluated based on the mobility and how close to the tip of the tongue the leading edge of the frenulum is attached. Types 1 and 2 are the most common, accounting for 75% of tongue-ties and are often called "classic" and "anterior ties." Types 3 and 4 account for remaining 25 % and are often referred as "posterior ties."

The Hazelbaker Assessment tool can also be used to evaluate an infant's tongue-tie. The grading levels range from Class I (least severe) to Class IV (most severe) and are based on the tongue's appearance and function (Hazelbaker, 2010). With the increased emphasis on initiating and maintaining breastfeeding, a resurgence of feeding difficulties due to tongue-tie has been identified. In addition, decreased tongue mobility may cause short- and long-term consequences including feeding, speech, orthodontic problems, mandibular abnormalities, and difficulty with oral cleanliness (Academy of Breastfeeding Medicine [ABM], 2017).

This condition may cause difficulty with breastfeeding due to difficulty with tongue mobility and the ability to latch to create a strong suction at the breast. Mother's will often note that their infants (with a tongue-tie) tend to slip off the breast and cannot

maintain a long latch without falling asleep. In addition, this mismatch will often cause moderate to severe nipple pain in about 80% of breastfeeding mothers. If it does, then a frenotomy release can be performed in the newborn period, typically by a trained physician, pediatric dentist, or advanced practice registered nurse (APRN). Ankyloglossia or tongue-tie are associated with a 25% to 60% incidence of breastfeeding difficulty and contributes to 10% to 26% of early cessation of breastfeeding (Wong, Patel, Cohen, et al., 2017). Current literature supports frenotomy for treatment of clinically significant tongue-tie that is causing difficulty with breastfeeding. Early identification of tongue-tie allows for close evaluation of breastfeeding and possible difficulties that might arise and referral to a specialist for a frenotomy if indicated. The majority of infants with tongue-tie have the ability to breastfeed successfully but may require extra lactation support, guidance, and feeding assistance by additional specialists, such as a lactation consultant (ABM, 2017).

## THYROGLOSSAL CYSTS

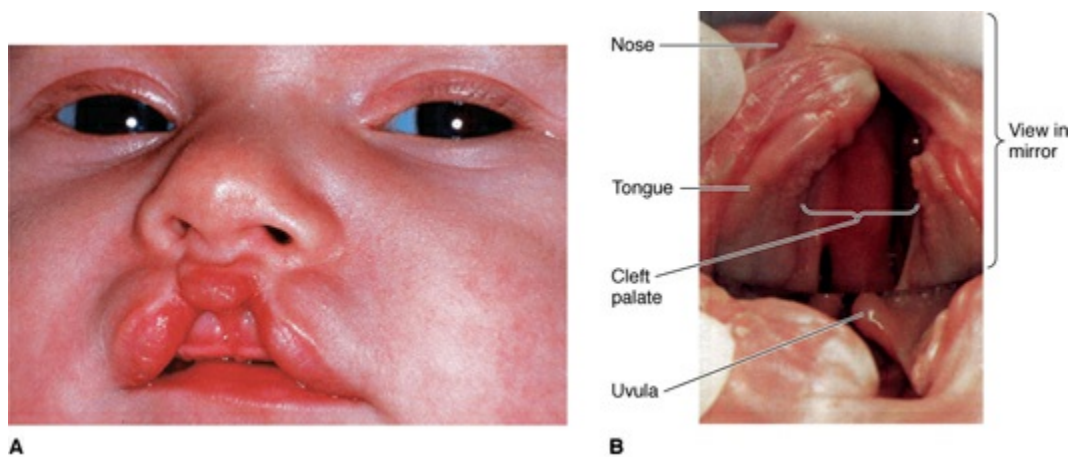

A thyroglossal cyst arises from an embryogenic fault that leaves a cyst formed at the base of the tongue, which then drains through a **fistula** (an abnormal or surgically made passage between a hollow or tubular organ and the body surface, or between two hollow or tubular organs) to the anterior surface of the neck (Gowda & Joseph, 2017).

Thyroglossal cysts are congenital defects located in or around the midline of the neck, extending to the base of the tongue. This condition may occur as an autosomal dominant trait. The cyst may involve the hyoid bone (the bone at the anterior surface of the neck at the root of the tongue) and may contain aberrant thyroid gland tissue. As the cyst fills with fluid, swelling and obstruction can lead to respiratory difficulty from pressure on the trachea. If infected, the cyst often appears swollen and reddened, with drainage of mucus or pus from the anterior neck and requires antibiotic therapy.

The cyst is surgically removed to avoid future infection of the space and, if thyroid tissue is present, the possibility of developing thyroid carcinoma later in life. Observe infants closely in the immediate postoperative period for respiratory distress because the operative area will develop at least minimum edema from surgical trauma. Position infants on their sides so secretions drain freely from their mouths. Intravenous (IV) fluid therapy is given after surgery until the edema at the incision recedes somewhat and swallowing is safe once more (approximately 24 hours). If the mother is breastfeeding, encourage her to express her milk via a hospital-grade pump or manual expression during this time to preserve her milk supply. Observe infants closely the first time they take fluid orally to be certain they do not aspirate. Be certain parents have a chance to feed their infant before the infant is discharged from the surgical unit so they can be assured the infant is swallowing safely, thus allowing them to feel confident at feeding the infant at home in a relaxed and comfortable way.

## OROFACIAL CLEFTS: CLEFT LIP AND CLEFT PALATE

The maxillary and median nasal processes normally fuse between weeks 5 and 8 of intrauterine life. In infants with **cleft lip**, the fusion fails to occur in varying degrees, causing this disorder to range from a small notch in the upper lip to total separation of the lip and facial structures up into the floor of the nose, with even the upper teeth and gingiva absent. The deviation may be unilateral or bilateral. The infant's nose generally appears flattened because the incomplete fusion of the upper lip has allowed it to expand in a horizontal dimension (Allori, Mulliken, Meara, et al., 2017) (Fig. 27.7A). Overall rates of cleft lip and/or palate in the United States average to 1 in 600 newborns (American Cleft Palate–Craniofacial Association, n.d.).

**Figure 27.7** Appearance of (A) a cleft lip and (B) a cleft palate. (From Moore, K. L., Agur, A. M. R., & Dalley, A. F. [2013]. *Clinically oriented anatomy* [7th ed.]. Philadelphia, PA: Wolters Kluwer.)

Cleft lip is the most common orofacial cleft. It is more prevalent among boys than girls and occurs at a rate of approximately 20 cases per day and 7,500 cases each year in the United States (Tolarova & Elluru, 2015). This incidence is highest in the Asian population at 1 out of every 500 people, moderate in the European-derived population at 1 out of 1,000 people, and significantly lower in the African-derived population at 1 out of 2,500 people. It appears to be caused by the transmission of multiple genes aided by teratogenic factors present during weeks 5 to 8 of intrauterine life, such as a viral infection, certain seizure medicines such as phenytoin, maternal smoking or binge drinking, hyperthermia, stress, and maternal obesity (Funato & Nakamura, 2017). Folic acid deficiency may also be associated with incomplete anterior midline closures (Funato & Nakamura, 2017).

Because of the genetic influence, parents of a child with a cleft lip should be referred for genetic counseling to ensure they understand they have a small increased chance of having another child with a cleft lip or palate and that any future children are at a greater risk than usual for this problem.

A **cleft palate** is an opening of the palate and occurs when the palatal process does not close as usual at approximately weeks 9 to 12 of intrauterine life. The incomplete closure is usually on the midline and may involve the anterior hard palate, the posterior

soft palate, or both (see [Fig. 27.7B](#)). It may occur as a separate anomaly or in conjunction with a cleft lip. As a single entity, in contrast to cleft lip, it tends to occur more frequently in girls than boys. Like cleft lip, it appears to be the result of polygenic inheritance or environmental influences. In connection with cleft lip, the incidence is approximately 1 out of every 1,000 births. As a single entity, it occurs in approximately 1 out of every 2,000 births. Almost 30% of children with both cleft lip and palate have associated birth defects, or the cleft palate occurs as only a portion of a larger syndrome ([Dixon, Marazita, Beaty, et al., 2011](#)).

### Assessment

Cleft lip may be detected by a sonogram while an infant is in utero. If not detected then, it is readily apparent on inspection of the mouth at birth. When assessing newborns, be sure you have good lighting so you can visualize the palate clearly. Because cleft palate is a component of many syndromes, assess the child for other congenital anomalies as well.

### Therapeutic Management

If a cleft lip is discovered while the infant is still in utero, fetal surgery can repair the condition, although this procedure is not usually attempted. If the disorder is discovered at birth, a cleft lip can be repaired surgically shortly thereafter, often at the time of the initial hospital stay or between 2 and 12 weeks of age. Because the deviation of the lip interferes with sucking, infants may be a better surgical risk as newborns than they are after a month or more of poor nourishment. Early repair also helps infants experience the pleasure of sucking as soon as possible. It is equally important from a psychological standpoint as a parent may need caring support to bond with an infant whose face is deformed in this way ([Nidey, Moreno Uribe, Marazita, et al., 2016](#)). Because facial contours change as a child grows, a revision of the original repair or a nasal rhinoplasty to straighten a deviated nasal septum may be necessary when the child reaches 4 to 6 years of age. Some infants may have a nasal mold apparatus applied before surgery to shape a better nostril ([Funato & Nakamura, 2017](#)).

The optimal time for repair of a cleft palate is controversial because early repair increases speech development but may result in a necessary second-stage repair as the child's palate arch expands with growth ([Taub & Piccolo, 2016](#)). Surgery may be recommended as a two-stage palate repair, with soft palate repair at 3 to 6 months of age and hard palate repair at 6 to 18 months of age, called the Malek protocol. This type of repair results in less need for future surgery and better facial results ([Taub & Piccolo, 2016](#)). Using infant orthodontic devices and delaying hard palate closure until later has not been shown to increase speech clarity or overall wellness ([Taub & Piccolo, 2016](#)).

Currently, the results of surgical repair of cleft lip and cleft palate are excellent ([Fig. 27.8](#)). It is helpful to show parents photographs of babies with good repairs to assure them their child's outcome can also be as successful.

**Figure 27.8** An infant showing surgical repair of cleft lip. Parents can be encouraged that the results of cleft lip repair are generally excellent. (Photo Researchers, Inc.)

One issue that may remain is that because palate repair narrows the upper dental arch, a child may be left with less space in the upper jaw for the eruption of teeth, creating poor teeth alignment. All children born with a cleft palate, therefore, need follow-up treatment by a pediatric dentist skilled in children's dental problems, so that as the child grows, extractions or realignment of teeth can be done as indicated. Children also need follow-up to detect if hearing or speech difficulty occurs; because the angle of the eustachian tube may be changed in surgery, a child may develop more ear infections than usual, possibly leading to some hearing impairment. After surgical repair, about 80% of children affected by cleft palate progress to develop normal speech, yet referral to speech therapy early in infancy should always occur to ensure successful speech development ([American Cleft Palate–Craniofacial Association, n.d.](#)).

Children with cleft problems tend to receive better, more frequent, and well-coordinated care when seen in an interprofessional team setting including pediatric

dentists, audiologists, speech pathologists, geneticists, and craniofacial surgeons, so referring parents to an appropriate interprofessional center before discharge is critical for these infants and their families (Taub & Piccolo, 2016).

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for imbalanced nutrition, less than body requirements, related to feeding problem caused by cleft lip or palate

**Outcome Evaluation:** Newborn ingests an adequate diet of 110 kcal/kg (50 kcal/lb) in 24 hours; weight is maintained within 10% of birth weight.

*Preoperative Period.* Before a cleft lip or palate is repaired, feeding the infant becomes a concern because the infant has difficulty maintaining suction with a bottle or breast; there is evidence of slower growth when compared to infants without a cleft disorder (Taub & Piccolo, 2016). In addition, it is important the child does not aspirate.

It may be possible for an infant with a cleft lip to breastfeed because the bulk of the mother's breast tends to form a seal against the incomplete upper lip. Although the baby needs the enjoyment of sucking, some surgeons do not want a baby to either breastfeed or suck on a nipple, however, before surgical correction of the disorder to avoid any local bruising of tissue. Therefore, the best feeding method for the child with cleft lip may be to support the baby in an upright position and feed the infant gently using a soft bottle and a commercial cleft lip nipple or a spoon. Breck or Haberman feeders are commercial apparatuses similar to a bulb syringe, which also can be used (Fig. 27.9). If the surgical repair for a cleft lip will be done immediately, the mother will be able to breastfeed as early as 7 to 10 days after surgery. Typically after the surgical repair and healing, the baby can latch to the breast. If there is difficulty with latching, a nipple shield can be suggested to help form a tighter seal at the breast. Review with the mother how to pump or manually express breast milk to maintain a milk supply prior to surgical correction and after, if needed. If surgery will be delayed for 1 month, the mother will need continuing support from the nursing staff to support her efforts on pumping and to remind her that her breast milk will be very beneficial to her infant and the healing process.

**Figure 27.9** (A) Specialty feeding devices used for infants with cleft lip and cleft palate. (B) An infant uses a Haberman Feeder.

If a cleft extends to the nares so the nose and mouth are joined, breathing causes the oral mucous membranes and lips to become dry. Offering small sips of fluid between feedings can help keep the mucous membranes moist and prevent cracks and fissures that could lead to infection. Following a feeding, be certain an infant with a cleft lip is burped well because the inability to grasp a nipple or syringe edge securely causes the infant to swallow more air than usual.

Infants with a cleft palate cannot suck effectively either because pressing their tongue or a nipple against the roof of their mouth forces milk up into their pharynx, possibly leading to aspiration. The most successful method for feeding this infant, like the child with a cleft lip, therefore, is to use a commercial cleft palate nipple that has an extra flange of rubber to close the roof of the mouth. If the nipple is used with a plastic bottle that can be squeezed gently to increase the flow of the feeding, this can compensate for poor sucking. A Breck feeder may also be used to feed infants with a cleft palate.

If surgery will be delayed beyond 6 months of age or the time when solid food would usually be introduced, teach parents to be certain any food they offer is soft because particles of coarse food could invade the nasopharynx and be a cause of aspiration.

*Postoperative Period.* After surgery for cleft lip or palate, an infant is kept nothing by mouth (NPO) for approximately 4 hours and then introduced to liquids such as plain water. Be certain to begin this process with only a small amount each time to prevent vomiting.

It's important that no tension is placed on a lip suture line because this helps keep the sutures from pulling apart and leaving a large scar. During this immediate postoperative period, therefore, the infant is usually fed using a specialized feeder because this causes less suture line tension than bottle feeding or breastfeeding.

After palate surgery, only liquids are generally given the first 3 or 4 days, and then a soft diet is followed until healing is complete. Ask parents before surgery what fluids the child prefers so they can be made available postsurgery.

When children begin to eat soft food, observe they don't use a spoon because

spoons can invariably be pushed against the roof of their mouth and possibly disrupt sutures. If being fed rather than allowing the infant to use a spoon evokes an intense reaction, it is probably better to leave a child on a liquid diet until the sutures are removed. Be certain milk is not included in the first fluids offered because milk curds tend to adhere to the suture line and so are difficult to remove. After a feeding, always offer the child a sip of clear water to rinse the suture line and keep it as clean as possible. Also, educate parents to be diligent about oral health care. In infants with clefts involving the maxillary alveolar ridge (upper gum), it is common for some teeth—typically the upper incisors and cuspids on the side of the cleft—to be misshapen or turned (Cleft Palate Foundation, 2010). Prudent twice-daily gum and teeth brushing with an age appropriate toothbrush and tooth paste is crucial, as are biyearly dental visits for monitoring.

**Nursing Diagnosis:** Risk for ineffective airway clearance related to oral surgery

**Outcome Evaluation:** Child's respiratory rate remains at baseline level for age without retractions or obvious distress.

Because of the local edema that occurs after cleft lip or palate surgery, it's important to observe children closely in the immediate postoperative period for respiratory distress. Remember that before surgery, the infant with a cleft lip may have breathed through the mouth. After surgery, the infant now has to learn to breathe through the nose, possibly adding to respiratory difficulty. Generally, however, this is not a problem because newborns normally are strict nose breathers.

Following either cleft lip or cleft palate surgery, infants may need their mouth suctioned to remove mucus, blood, and unswallowed saliva. When doing this, be exceedingly gentle so you don't touch the suture line with the catheter. Place infants on their side to allow mouth secretions to drain forward. And, following a cleft lip repair, be sure a child does not turn onto his or her abdomen because this could put pressure on the suture line, possibly tearing it. Placing the child in an infant bouncy chair is another possibility.

**Nursing Diagnosis:** Impaired tissue integrity at incision line related to cleft lip or cleft palate surgery

**Outcome Evaluation:** Incision line appears clean and intact and free of erythema or drainage during postoperative period.

After cleft lip surgery, the suture line may be held in close approximation by a Logan bar (a wire bow taped to both cheeks; Fig. 27.10) or an adhesive bandage such as a Band-Aid simulating a bar that brings together the incision line but does not cover the incision. Assess the simulated or Logan bar is secure and continues to protect the suture line from tension after each feeding or cleaning of the suture line. Furnish adequate pain relief also so the infant does not cry because this puts increased tension on the sutures. To help avoid crying, try to anticipate the infant's needs by having formula ready to feed. Help the parents use whatever measures, such as rocking,

carrying, or holding, that are necessary to make the infant feel secure and comfortable.

**Figure 27.10** A Logan bar is an apparatus that may be used to protect the surgical incision for a cleft lip repair.

Nothing hard or sharp must come in contact with a recent cleft suture line. Observe infants after palate repair carefully, therefore, to be certain they do not put toys with sharp edges into their mouths. It's also good practice to not allow them to use a straw to drink or hold a toothbrush to clean their teeth so they don't brush the suture line accidentally. Keep elbow restraints in place as necessary so they do not put their fingers in their mouth and poke or pull at the sutures. Sutures on the lip or palate feel extremely odd, so most children not only run their tongue over their sutures but also don't respond to advice not to do this. Because this often occurs when children have nothing to think about, help the parents provide diversional activities such as reading or singing to keep the child's attention off the suture line.

If parents will be continuing to give an analgesic such as acetaminophen (Tylenol) or ibuprofen (Advil) after they return home, be certain they are aware of the correct dosage and time schedule for administration of the liquid forms. They must also continue to keep the suture line protected until healing is complete.

**Nursing Diagnosis:** Risk for infection related to surgical incision

**Outcome Evaluation:** Infant's temperature is below 98.6°F (37°C) by tympanic membrane; incision site is clean, dry, and intact without erythema or foul drainage.

An infection and subsequent scarring may result if crusts from serous drainage are allowed to form on a cleft lip suture line. Most surgeons, therefore, prescribe cleaning the suture line with sterile water or sterile saline with sterile cotton-tipped applicators after every feeding or whenever the normal serum that forms on suture lines

accumulates. Do not rub the suture line; use a smooth, gentle, rolling motion to avoid loosening sutures. Gently dry the suture line with a dry sterile cotton-tipped applicator afterward. Remember that the infant has sutures on the inside of the lip that need the same meticulous care as those visible on the outside.

**Nursing Diagnosis:** Risk for impaired parenting related to birth of an infant who is physically challenged

**Outcome Evaluation:** Parents state they believe there will be a positive outcome for their child and demonstrate positive coping behaviors evidenced by holding and helping with infant care.

To promote effective bonding, parents need to hold and interact with their infant during both the preoperative and postoperative periods. Caution them the child's incision line will appear swollen in the immediate postoperative period, but its appearance will improve with time. As soon as the child's sutures have been removed, parents may breastfeed or feed with an ordinary bottle. Caution both the breastfeeding mother (who has been maintaining her milk supply through expression) and the formula-feeding mother that because the infant has never sucked before, time will be needed to learn how to suck, just like a newborn.

Observe whether parents look at their baby's face while feeding the baby. Help them to understand that any negative feelings they feel toward the child or themselves, such as sadness or anger, are normal. This assurance does not instantly make them feel better about what has happened, but the knowledge the feelings they are experiencing are normal can help them begin to deal with such emotions. Many communities have support groups for parents of children born with a cleft lip or palate. Referral to these groups can offer parents additional support. The National Cleft Palate Foundation provides parent education materials at [www.cleftline.org](http://www.cleftline.org).

**Nursing Diagnosis:** Risk for situational low self-esteem related to child's facial surgery

**Outcome Evaluation:** Child participates in normal childhood activities that involve contact with other people, states activities he or she enjoys at healthcare visits, and demonstrates age-appropriate developmental milestones.

If a scar remains after cleft lip surgery, children may need some help adjusting to their appearance until a second cosmetic repair can be completed later in life. Reinforce children's positive attributes, stressing that the scar is only one small aspect of who they are. As children reach adolescence, you may need to review a familial inheritance pattern of cleft lip so they are aware of the possible risk for transmission to their own children.

**Nursing Diagnosis:** Risk for infection (ear) related to the altered angle of the eustachian tube with cleft palate surgery

**Outcome Evaluation:** Outcome Evaluation: Parents state signs and symptoms of ear

infection and importance of early treatment; parents list signs of diminished hearing and appropriate agencies for support and guidance.

Changing the contour of the palate when it is repaired also changes the slope of the eustachian tube to the middle ear. This can lead to a high incidence of middle ear infection (otitis media) because organisms are able to reach this area from the oral cavity more readily than usual. Review the signs of infection such as fever, pain, pulling on an ear, or discharge from the ear with parents. Remind them of the importance of reporting pharyngeal infection to their primary care provider promptly so it can be treated before the infection spreads to the middle ear. Because the eustachian tube may remain partially closed in its changed position, serous otitis media (accumulation of fluid in the middle ear) also tends to occur more frequently in these children than in others. If this happens, myringotomy tubes may be inserted to drain middle ear fluid and to help protect hearing (see [Chapter 50](#)). Be certain parents understand the need for routine screening for hearing loss during childhood because this is a common early sign of serous otitis media.

**Nursing Diagnosis:** Risk for impaired verbal communication related to cleft palate

**Outcome Evaluation:** Family members voice satisfaction with child's speech; developmental milestone of clearly articulated two-word sentences by age 2 years is met.

Infants with a cleft palate will begin to make speech sounds at the normal time (age 2 months). This speech, however, is usually guttural and unclear as many alphabet sounds are made by touching the tongue against the roof of the mouth. Depending on the age of the cleft palate repair, some children will continue to have accompanying speech difficulty because the soft palate must function for the child to pronounce “p” and “b” sounds ([Prathanee, Pumnum, Seepuaham, et al., 2016](#)). If cleft palate surgery is going to be delayed past age 2 years (as might happen if the child has other congenital anomalies, such as heart disease), a plastic prosthesis to cover the incomplete palate may be prescribed because this allows the child to articulate more efficiency.

Altered speech patterns in children generally do not resolve spontaneously and require intervention by a speech pathologist prior to school age.

### *QSEN Checkpoint Question 27.3*

#### **EVIDENCE-BASED PRACTICE**

Maia is having difficulty caring for her new baby because he was born with a birth disorder. To investigate whether it is common for a woman whose child is born with a birth anomaly to act differently than other mothers, researchers studied maternal gaze between mothers and infants and found maternal gaze changes as infants become more social. A decrease in gaze to the mouth area was associated with

infant's with cleft lip and might affect maternal responsiveness (De Pascalis, Kkeli, Chakrabarti, et al., 2017). This decrease in maternal gaze could be the basis for interventions for mothers of infants born with oral abnormalities (De Pascalis et al., 2017).

Based on the study, what type of role modeling would the nurse demonstrate to a mother when caring for a newborn with a cleft lip?

- a. Omit picking up the infant to show the mother how uncaring her actions seem.
- b. Hold the infant warmly; smile and play and talk to him.
- c. Tactfully point out to the mother that her actions may be seen to be uncaring.
- d. Ask the mother what you could do to help her adjust better.

---

## THE PIERRE ROBIN SEQUENCE

The Pierre Robin sequence (also called Pierre Robin syndrome) is a rare triad of micrognathia (small mandible), cleft palate, and **glossoptosis** (a tongue malpositioned downward). This triad of conditions can result in severe upper airway obstruction, which then may cause secondary respiratory distress due to upper airway obstruction. Estimates of occurrence range from 1 in every 8,500 births to 1 in every 20,000 births; the primary event that leads to the syndrome tends to be unknown. More than half of the children born with Pierre Robin syndrome have associated disorders of congenital glaucoma; cataracts; cardiac disorders; or other genetic, chromosomal, or medical concerns. They need thorough physical and genetic assessments to be certain that none of these other associated disorders are present (Bütow, Zwahlen, Morkel, et al., 2016).

Monitor infants for possible airway obstruction (as a result of their small jaw, their tongue tends to drop backward and obstruct their airway). Suctioning to remove secretions may be necessary. A side-lying rather than a supine sleeping position is recommended for all newborns and infants (until they can roll over) to avoid obstruction. Occasionally, infants have such extensive airway obstruction that a suture is attached to the anterior aspect of the tongue and the mucous membrane of the lower lip to pull the tongue forward and prevent the rear of the tongue from blocking the upper airway. Maintaining positioning as the infant grows and gains mobility may be increasingly difficult, but sleep studies have shown these children have severe sleep apnea, with as many as 49 episodes of apnea leading to oxygen desaturation per hour if sleeping supine (Bütow, Naidoo, Zwahlen, et al., 2016). Nasopharyngeal airways (NPAs) have been shown to be effective in upper airway obstruction, and 86.5% of infants studied maintained adequate airways with positioning or temporary placement of an NPA for several months. The airways of older children can be well maintained using nasal continuous positive airway pressure (CPAP); with this, after several years of therapy, the episodes of obstructive sleep apnea decrease to about five per hour, possibly decreasing the need for more invasive surgery.

As the child grows older, the jaw will grow somewhat, although the mandible will

always be small. Parents need instructions on how to feed these infants until the cleft palate can be repaired. The child may have a gastrostomy tube or button inserted to relieve feeding difficulty (see [Chapter 37](#)).

Parents of the child with this syndrome take on a great deal of responsibility when they assume their infant's care; it's best if they are referred to an interprofessional team prior to discharge from the hospital. Be certain they have the name and number of a primary healthcare provider they can call when they have questions. Many of these parents grow exhausted during the first few weeks of their child's life, afraid they may sleep so soundly at night they miss their child having respiratory difficulty. Using a respiratory monitor at night can be helpful. As parents' confidence grows in their ability to provide care, this problem lessens, but it may be months or even years before a high level of confidence is achieved.

## **ESOPHAGEAL ATRESIAS AND TRACHEOESOPHAGEAL FISTULAS**

Between weeks 4 and 8 of intrauterine life, the laryngotracheal groove in the chest develops into the larynx, trachea, and beginning lung tissue; the esophageal lumen forms parallel to this. A number of anomalies can occur if the trachea and esophagus are affected by some teratogen that does not allow the two organs to fully form separately and possibly become connected.

Esophageal atresia is the incomplete formation of the esophageal lumen, resulting in the proximal (upper) esophagus forming a "blind pouch," which then does not connect to any other structure. *Tracheoesophageal fistula* occurs when an opening develops between the closed distal (lower) esophagus and the trachea. Five usual types of esophageal atresia that result are:

1. The esophagus ends in a blind pouch; there is a tracheoesophageal fistula between the distal part of the esophagus and the trachea ([Fig. 27.11A](#)).
2. The esophagus ends in a blind pouch; there is no connection to the trachea (see [Fig. 27.11B](#)).
3. A fistula is present between an otherwise normal esophagus and trachea (see [Fig. 27.11C](#)).
4. The esophagus ends in a blind pouch. A fistula connects the blind pouch of the proximal esophagus to the trachea (see [Fig. 27.11D](#)).
5. There is a blind end portion of the esophagus. Fistulas are present between both widely spaced segments of the esophagus and the trachea (see [Fig. 27.11E](#)).

**Figure 27.11** An esophageal atresia and a tracheoesophageal fistula.

**(A)** In the most common type of esophageal atresia, the esophagus ends in a blind pouch. The trachea communicates by a fistula with the lower esophagus and stomach (approximately 90% of infants with the defect have this type). **(B)** Both upper and lower segments end in blind pouches (5% to 8% of infants with the defect have this type). **(C)** Both upper and lower segments communicate with the trachea (2% to 3% of infants with the defect have this type). **(D)** Very rarely, the upper segment ends in a blind pouch and communicates by a fistula to the trachea, or **(E)** a fistula connects to both upper and lower segments of the esophagus.

All of these are potentially serious disorders because, during a feeding, milk can fill the blind pouch of the upper esophagus and then overflow into the trachea, or a fistula can allow milk to enter the trachea from the esophagus, resulting in aspiration. Even if not fed, the swallowed saliva of the baby will fill the esophagus and overflow into the airway, resulting in repeated aspiration. The incidence of the disorder ranges from 1 out of 2,500 to 4,500 live births ([Vergouwe, IJsselstijn, Wijnen, et al., 2015](#)).

### Assessment

Esophageal atresia must be ruled out in any infant born to a woman with hydramnios (excessive amniotic fluid). This is because hydramnios occurs because, normally, a fetus swallows amniotic fluid during intrauterine life. A fetus with esophageal atresia cannot effectively swallow, so the amount of amniotic fluid can grow abnormally large. Many infants with esophageal atresia are born preterm because of the accompanying hydramnios, compounding their original problem with immaturity. The infant needs to be examined carefully for other congenital anomalies that could have occurred from the teratogenic effect at the same week in gestation, such as vertebral, anal, cardiac, tracheoesophageal, renal, and limb anomalies (VACTERL syndrome) ([Vergouwe et al., 2015](#)).

If not diagnosed in utero, diagnosing a child who has an esophageal atresia/tracheoesophageal fistula before the infant is first fed is important. Otherwise, the infant will cough, become cyanotic, and have obvious difficulty breathing as fluid is aspirated. Newborns who have so much mucus in their mouths that they appear to be

blowing bubbles should be suspected of having either disorder. Esophageal atresia can be diagnosed with certainty if a catheter cannot be passed through the infant's esophagus to the stomach so stomach contents can be aspirated. If helping with this, supply a firm catheter because a soft one will curl in a blind-end esophagus and appear to have passed. An X-ray will reveal a radiopaque catheter coiled in the blind end of the esophagus. A flat-plate X-ray of the abdomen or an ultrasound also may reveal a stomach distended with the air that has passed from the trachea into the esophagus and stomach, demonstrating that a fistula is present. Either a barium swallow or a bronchial endoscopy examination can also reveal the blind-end esophagus and fistula.

### **Therapeutic Management**

Emergency actions are required for the infant with this group of esophageal disorders in order to prevent the development of pneumonia, one of the major complications that is apt to occur from leakage of oral or stomach secretions into the lungs. The best position for the infant is an upright, 60-degree angle so acid stomach fluids stay in the stomach through the use of gravity (sitting the baby in an infant chair does this). If a nasogastric tube is inserted into the distal end of the esophagus and connected to low intermittent suction, oral secretions will no longer collect in the blind pouch, decreasing aspiration risks. A gastrostomy may be inserted into the stomach (under local anesthesia) with the tube allowed to drain by gravity as another way of keeping the stomach empty of secretions and preventing reflux into the lungs. IV fluids and parenteral nutrition are begun to prevent dehydration and an electrolyte imbalance from lack of oral intake. IV medications that restrict the stomach's ability to produce acid may be prescribed, and an antibiotic may be prescribed to help prevent an infection.

When the infant has been stabilized by this sequence of measure, surgery consists of closing the fistula and anastomosing the esophageal segments. If the defect was only a simple fistula, surgery may be done by thoracoscopy to minimize the time required for surgery ([Vergouwe et al., 2015](#)). If the repair will be more complex, it may be necessary for the surgery to be completed in different stages and to use a portion of the intestine to complete the anastomosis if the esophageal segments are too far apart to join readily. After an anastomosis repair, observe infants closely at postoperative days 7 to 10 because this is the point when their internal sutures will dissolve, possibly allowing a leak from the anastomosis site to occur at this time. If such a leak occurs, fluid and air can leak out into the chest cavity, and pneumothorax (collapse of a lung) can occur.

In some infants, some stenosis or stricture at the anastomosis site remains. If this occurs, esophageal dilatation at periodic intervals to keep the repaired esophagus fully patent may be necessary. Gastroesophageal reflux may also occur after a repair, especially if the esophagus is left shorter than usual; this can lead to recurrent fistula formation and irritation from the presence of stomach acid in the esophagus ([Vergouwe et al., 2015](#)).

The ultimate prognosis for children with this disorder depends on the extent of the repair necessary, the condition of the child at the time of surgery, and the presence or

absence of other congenital anomalies. Even with larger disorders, if surgery can be performed before pneumonia develops, the repair of the esophagus and trachea will be effective. The mortality rate for the condition remains high, however, because of the presence of other congenital disorders and low birth weight that often accompanies the tracheal abnormality.

## Nursing Diagnoses and Related Interventions

Both nursing diagnosis and outcomes established for the child with either a tracheoesophageal fistula or esophageal atresia must be realistic in terms of the extent of the disorder, the timing of anticipated surgery, and the stage of grief or readiness for decision making and planning the parents have reached.

**Nursing Diagnosis:** Risk for imbalanced nutrition, less than body requirements, related to inability to take in oral feedings

**Outcome Evaluation:** Child maintains weight within 10% of birth weight and maintains weight in same percentile on growth curve.

Before surgery, because oral fluid cannot be given until the esophagus is repaired, IV therapy or total parenteral nutrition (TPN) can be used to supply fluid and calories. Following surgery, the infant may be fed orally, may be continued on TPN, or may be started on gastrostomy feedings, depending on whether the surgery could be completed in one stage or not.

Early introduction of oral fluid may help to ensure patency of the esophagus because it helps to decrease adhesion formation at the anastomosis site and also allows the infant the enjoyment and practice of sucking. If formula is given by gastrostomy feedings, be certain to introduce it into the tube slowly and allow it to run by gravity pressure only to prevent fluid from entering the esophagus and putting pressure on the new suture line. After the feeding, the end of the tube should be elevated, covered by sterile gauze, and kept in the elevated position, *not clamped*, so any air introduced during the feeding will be released from the tube and not enter the esophagus to put pressure on the suture line. This also helps to ensure that if the infant should vomit the feeding, the vomitus will be projected into the gastrostomy tube and again will not contaminate the fresh sutures. Most newborns enjoy sucking a pacifier during gastrostomy feedings for sucking pleasure. If a mother wishes to breastfeed, she can manually express breast milk for the gastrostomy feedings.

If the child is to return home to await a second-stage operation, the gastrostomy tube will be left in place. Be certain parents are comfortable doing gastrostomy feedings as well as usual infant care, such as holding or talking to the infant in the face of this different feeding method.

**Nursing Diagnosis:** Risk for infection related to aspiration or seepage of stomach secretions into lungs

**Outcome Evaluation:** Child's temperature remains below 98.6°F (37°C) axillary; there is absence of rales on auscultation.

*Preoperative Care.* In addition to measures such as keeping the child in a sitting position, if surgery will be significantly delayed, an infant may have a cervical esophagostomy (the distal end of the blind esophagus is brought to the surface just over the sternum) as a method to allow oral secretions to drain. Use absorbent gauze around the opening of the site to absorb moisture and apply a protective ointment liberally to the skin to help prevent excoriation of the skin. Consult as necessary with a wound, ostomy, and continence therapy nurse to prevent further skin irritation.

Keeping the infant under a radiant heat warmer with a high-humidity oxygen source helps to maintain body heat and liquefy bronchial secretions. Try to keep the infant from crying because, with crying, air enters the stomach from the trachea, distending the stomach and possibly causing vomiting with aspiration into the lungs. A pacifier may be helpful to relax the baby and also to satisfy a sucking need.

*Postoperative Care.* The baby will return from final surgery with multiple tubes (e.g., chest tubes, endotracheal tube, Foley catheter, multiple IV lines, probably an arterial line, possibly a gastrostomy tube if not previously inserted), as well as blood pressure, oxygen saturation, and electrocardiography monitoring equipment. The posterior chest tube drains collecting fluid, and the anterior tube allows air to leave the chest space so the lungs can reexpand (see [Chapter 41](#) for care of an infant with chest tubes in place).

Anticipatory teaching about how the infant will appear is important for the family at this stressful time to keep them from growing overwhelmed. Skilled nursing care of both the child and family is essential.

In the first few days after surgery, a major assessment is to observe the infant for respiratory distress. Continue to suction saliva from the mouth as prescribed because this tends to continue to accumulate in the pharynx. Suctioning must be done only shallowly, however, to prevent the suction catheter from touching the suture line in the esophagus. Turning the child frequently discourages fluid from accumulating in the lungs. Humidified oxygen helps to keep respiratory secretions moist and not become stagnant. Keep an infant laryngoscope and endotracheal tube readily available at the bedside in case extreme edema develops, which may increase the infant's risk for airway obstruction.

**Nursing Diagnosis:** Risk for impaired skin integrity related to gastrostomy tube insertion site

**Outcome Evaluation:** Skin surrounding gastrostomy tube remains clean, dry, and without erythema.

Gastric secretions, which are highly acidic, can leak onto the skin from the

gastrostomy site, leading to skin irritation. Protect the skin by using a cream or commercial skin protection system. If the problem is not easily resolved, consult with a wound, ostomy, and continence therapy nurse to reduce the possibility of skin irritation and infection.

## ABDOMINAL WALL DEFECTS

Abdominal wall defects, with the exception of umbilical hernia, are potentially serious disorders because they directly affect the gastrointestinal system and infant nutrition.

### Umbilical Hernias

An umbilical hernia is a protrusion of a portion of the intestine through the umbilical ring, muscle, and fascia surrounding the umbilical cord (Mirza & Ali, 2016). This creates a bulging protrusion under the skin at the umbilicus. It is rarely noticeable at birth while the cord is still present but becomes increasingly noticeable at healthcare visits during the first year.

Umbilical hernias occur most frequently in Black children (seen in 30% term infants), low-birth-weight infants, and more often in girls than in boys. The structure is generally 1 to 2 cm (0.5 to 1 in.) in diameter but may be as large as an orange when children cry or strain. The size of the protruding mass is not as important as the size of the fascial ring through which the intestine protrudes. If this fascial ring is less than 2 cm, closure will usually occur spontaneously after the child begins to walk to around 2 years of age, so surgical repair is often not necessary for mild (small) cases. If the fascial ring is larger than 2 cm, ambulatory surgery repair is generally indicated to prevent herniation and intestinal obstruction or bowel strangulation. This is usually done at 1 to 2 years of age. If the small umbilical hernia has not closed by preschool age, a repair will often be done when the child is 4 to 5 years old.

Some parents believe holding an umbilical hernia in place by using “belly bands” or taping a silver dollar over the area will help reduce the hernia. These actions can actually lead to bowel strangulation and so should be avoided.

The child returns from surgery with a dressing, which remains in place until the sutures are well healed. Remind parents to sponge bathe the child until they return for a postoperative visit when the dressing is removed. If the child is not yet toilet trained, caution parents to keep diapers folded well below the dressing to prevent contaminating the suture line with stool.

### Omphaloceles

An **omphalocele** is a protrusion (herniation) of abdominal contents through the abdominal wall at the point of the junction of the umbilical cord and abdomen (Fig. 27.12). The herniated organs involved are usually the intestines, but they may include the stomach and liver. Occurring about 1 out of 5,000 live births, the organs are usually

covered and contained by a thin transparent layer of amnion and chorion with the umbilical cord protruding from the exposed sac. This condition occurs because, at approximately weeks 6 to 8 of intrauterine life, the fetal abdominal contents, which grow faster than the fetal abdomen, are pushed out from the abdomen into the base of the umbilical cord. At 7 to 10 weeks, when the fetal abdomen has enlarged sufficiently, the intestine normally returns to the abdomen. An omphalocele occurs when abdominal contents fail to return in the usual way. In 67% of cases, the occurrence is associated with other congenital disorders such as cardiac, neurologic, genitourinary, skeletal, and chromosomal abnormalities (Tappero & Honeyfield, 2015).

**Figure 27.12** An omphalocele with a membrane sac covering the organs.

### Gastroschisis

**Gastroschisis**, a term derived from the Greek word for “stomach cleft” or “fissure,” is a condition similar to an omphalocele, except the abdominal wall disorder is a distance from the umbilicus, usually to the right, and abdominal organs are not contained by a membrane but rather spill freely from the abdominal wall (Jones, Isenburg, Salemi, et al., 2016). Also, a greater amount of intestinal contents tends to herniate, increasing the potential for volvulus and obstruction. The condition occurs because of failure of the abdominal wall to close, usually during the fourth week of development, and its incidence is about 4 to 5 per 10,000 live births. The disorder is similar to a neural tube defect (covered later in this chapter) because both are a failure to close at about the same gestational time. Children with gastroschisis often have decreased bowel motility and, even after surgical correction, may have difficulty with absorption of nutrients and

passage of stool. Long-term follow-up may be necessary to ensure that nutrition and elimination are adequate (Jones et al., 2016).

## Assessment

The incidence of omphalocele remains steady, whereas the incidence of gastroschisis is steadily rising, perhaps associated with maternal obesity (Jones et al., 2016). The wall defect with the herniated organs may be identified by sonogram during intrauterine life (Jones et al., 2016). These may also be revealed by an elevated maternal serum  $\alpha$ -fetoprotein (MAFP) examination during pregnancy, which is done at the 15th week of pregnancy; the level of MAFP will be abnormally increased if there is an open spinal or abdominal lesion. If the result is elevated, an amniocentesis is then done to assess the level of AFP in amniotic fluid. A prenatal sonogram is also helpful to determine the presence of both abdominal wall or spinal disorders (see Chapter 11 for further discussion of these prenatal assessments). If an omphalocele or gastroschisis is not identified during pregnancy, their presence is obvious on inspection at birth. When an omphalocele or gastroschisis is identified in utero, a cesarean birth may be performed to protect the exposed intestine. If this is the only disorder identified, however, a vaginal birth may be preferred. Be certain to document the general appearance of the defect and its size in centimeters at birth to serve as a baseline assessment. Both conditions can vary greatly in size, from small, where the exposed intestine is the size of a ping-pong ball, to extensive, where all of the abdominal contents are externalized.

## Therapeutic Management

With both omphalocele and gastroschisis, until surgery and the bowel is effectively returned to the abdomen, the infant will be fed by TPN to supply nutrients and keep the bowel from filling with air or stool. Most infants with gastroschisis will have surgery within 24 hours to replace the bowel before the blood supply becomes hampered, the intestinal membranes dry, bowel volvulus occurs, or the bowel becomes infected. It is often difficult to replace the entire bowel with immediate surgery because the infant's abdomen, which did not need to grow to accommodate the abdominal contents, is smaller at birth than usual. Replacing the total bowel into this small abdomen could result in respiratory distress from the pressure of the visceral bulk on the diaphragm and lungs. Also, the bowel might not have room for effective peristalsis. If a gastroschisis is small, a one-stage repair may be possible. If large, one surgical approach is the use of a prosthetic patch repair that bridges the unformed gap on the abdomen with a synthetic material; the skin is then drawn tight and closed over the patch. A second approach is to replace only a portion of the bowel at one time. The remainder is contained by a Silastic pouch termed a "silo" that is suspended over the infant's bed. Over the next 5 to 7 days, the bowel is gradually returned to the abdomen by multiple surgical procedures (O'Connell, Dotters-Katz, Kuller, et al., 2016).

For an omphalocele, if the sac is ruptured, the defect is treated like gastroschisis

because of the potential for infection. If unruptured, an external dressing producing mild pressure may be used over the intact membrane. This gradually compresses the abdominal contents, allows the skin to stretch between treatments, and does not appear to be a painful procedure.

## Nursing Diagnoses and Related Interventions

Both nursing diagnosis and outcomes established for the infant with gastroschisis or an omphalocele, like those with esophageal disorders, must be realistic in terms of the extent of the disorder, the timing of anticipated surgery, and the stage of grief or readiness for decision making and planning the parents have reached. Gastroschisis and omphalocele defects can be an extreme shock to parents because they are conditions that are obviously severe yet also generally unknown.

**Nursing Diagnosis:** Risk for infection related to exposed abdominal contents

**Outcome Evaluation:** Child's temperature remains below 98.6°F (37°C) axillary; skin surrounding omphalocele remains clean, dry, and intact, without erythema or foul drainage.

Before surgery, it is important that the lining of the peritoneum covering an omphalocele not be ruptured or allowed to dry and crack; if this happens, infection and malrotation of the uncontained intestine can then occur, thus complicating the surgical repair. Exposure of the intestine to air also causes a rapid loss of body heat. Therefore, be certain not to leave an infant with either gastroschisis or an omphalocele under a radiant heat source in the birthing room because this will quickly dry the exposed bowel. Place the baby in a warmed incubator instead. In both instances, also cover the herniated bowel with either sterile, warm, saline-soaked gauze or a sterile plastic bowel bag until surgery can be scheduled. Because of the large amount of exposed intestinal surface, be certain the saline is at body temperature to prevent lowering the baby's body temperature.

The prognosis for a final successful surgical repair with both these conditions is good (Emil, Canvasser, Chen, et al., 2012). Except for a large abdominal scar, following surgery, the child who had gastroschisis or an omphalocele will be the child originally envisioned by parents. If the size of the scar is a problem for the child in later life, cosmetic surgery can reduce its appearance.

**Nursing Diagnosis:** Risk for imbalanced nutrition, less than body requirements, related to exposed abdominal contents

**Outcome Evaluation:** Child's weight remains within 10% of birth weight; skin turgor is good; specific gravity of urine is 1.003 to 1.030.

Infants are maintained on TPN prior to surgery. A nasogastric tube for decompression

is inserted at birth to prevent intestinal distention, which would enlarge the bowel lumen and make it even more difficult to replace. Do not feed the infant orally or allow the infant to suck on a pacifier until the bowel repair is complete because doing so would distend the exposed bowel with food or air and would also make its return to the abdomen more difficult. Some infants have an accompanying **volvulus** (a twisting of the bowel causing obstruction), which is another reason to omit oral feedings. After surgery, the infant continues to be maintained on TPN until the final stage of bowel repair is complete, and breastfeedings or formula feedings can be gradually introduced. Assess infants carefully for signs of obstruction such as abdominal distention, constipation, diarrhea, or vomiting when they begin oral feedings to be certain a bowel obstruction or volvulus is not present.

Infants with extensive repairs can be hospitalized for as long as 1 or 2 months until second-stage or even a third-stage operation is complete (an average is about 30 days). Encourage parents to room-in or visit frequently because this is a critical adjustment period for both the infant and parents. Be sure the infant has age-appropriate toys available for stimulation.

Parents may voice frustration because their child's treatment is being done in such small stages. Offer support to help them accept this treatment method as the best way to manage this type of intestinal disorder and to protect the safety and long-term function of the bowel.

### **QSEN Checkpoint Question 27.4**

#### **Safety**

Maia tells the nurse her baby was born on an unlucky day because the baby born before hers had his bowel outside his body. What is the most important nursing consideration at birth in the care of a baby with gastroschisis?

- a. Position the infant on his or her stomach so the intestine is well contained.
- b. Wrap the intestines with chilled gauze to prevent intestinal swelling.
- c. Keep the infant seated upright under a radiant warmer for warmth.
- d. Contain the intestine in a warmed, sterile saline-lined bowel bag.

*Look in [Appendix A](#) for the best answer and rationale.*

### **Intestinal Obstructions**

If canalization of the intestine does not occur in utero at any point, an **atresia** (complete closure) or **stenosis** (narrowing) of the fetal bowel can develop, although the most common site is the duodenum.

Obstruction may also occur because the mesentery of the bowel twisted as the bowel reentered the abdomen after being contained in the base of the umbilical cord early in intrauterine life or from looseness of the intestine in the abdomen after it was returned (Juang & Snyder, 2012). This twisting pattern is termed a *volvulus* and continues to be a

potential problem for the first 6 months of life until the infant develops firmer intestinal supports. Yet another reason obstruction can occur is because of thicker-than-usual meconium formation, blocking the lumen (meconium plug or meconium ileus).

## Assessment

Intestinal obstruction may be anticipated if the mother had hydramnios during pregnancy (i.e., swallowed amniotic fluid could not be absorbed effectively by the fetus) or if more than 30 ml of stomach contents can be aspirated from the newborn stomach by catheter and syringe at birth (fluid is not passing freely through the tract). If the obstruction is not revealed by either of these findings, then symptoms of intestinal obstruction in the neonate are the same as at any other time in life: The infant passes no meconium or may pass one stool (meconium that formed below the obstruction) and then not pass any more; the abdomen becomes distended and tender. As the effect of the obstruction progresses, the infant will vomit. Remember, many neonates spit up feedings when burped. This rapid ejection of milk smells barely sour. True vomiting from intestinal obstruction is usually sour smelling (stomach acid has acted on it), includes bile, and occurs spontaneously without coughing or back patting. Vomitus may also be black from the color of meconium.

Bowel sounds will begin to increase in number as the bowel increases peristaltic action in an effort to push stool past the point of obstruction. Waves of peristalsis may be observable across the abdomen. The infant may reveal that abdominal pain is developing by crying—hard, forceful, indignant crying—and by pulling the legs up against the abdomen. Lastly, the child's respiratory rate will increase as the intestine fills, the diaphragm is pushed up harder and harder against the lungs, and lung capacity decreases. An abdominal X-ray, sonogram, MRI, or barium enema will reveal no air below the level of obstruction in the intestine or isolate the level of the obstruction.

## Therapeutic Management

As soon as a bowel obstruction is confirmed, an orogastric or nasogastric tube is inserted and then attached to low suction or left open to the air to prevent further gastrointestinal distention (see [Chapter 37](#)). Always use low intermittent suction with decompression tubes in neonates because pressure greater than this can irritate and ulcerate their sensitive stomach lining.

IV therapy is begun to restore fluid and electrolyte balance; immediate surgery is scheduled to relieve the obstruction before pressure on the bowel causes death of the involved intestinal lining ([Sundaram, Hoffenberg, Kramer, et al., 2012](#)).

Repair of the obstruction (with the exception of meconium plug syndrome) can usually be accomplished by laparoscopy, although full abdominal surgery may be necessary. The area of stenosis or atresia is removed, and the bowel is anastomosed. If the repair is anatomically difficult or the infant has other anomalies that interfere with overall health, a temporary colostomy may have to be constructed, and the infant

discharged to home care with follow-up surgery rescheduled at 3 to 6 months of age (see [Chapter 37](#) for care of a child with a colostomy). If a large portion of the bowel has to be removed, this can have an impact on nutrient absorption (called short bowel syndrome) as the child grows older.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for deficient fluid volume related to vomiting

**Outcome Evaluation:** Child's skin turgor is good; capillary refill is 1 to 2 seconds; pulse rate is at least 100 to 120 beats/min; no further vomiting occurs; urine output is at least 1 to 2 ml/kg/hour.

Once an obstruction is suspected, keep an infant NPO to prevent the bowel from filling and causing vomiting and aspiration. Vomiting is always serious in neonates not only because aspiration may occur but also because infants can become dehydrated rapidly. They also lose chloride (a component of the hydrochloric acid found in stomach contents), which then leads to metabolic alkalosis. As a way of compensating for the loss of chloride, the baby's kidneys excrete potassium, which can cause infants to become hypokalemic. Keeping an infant NPO, restoring fluid by IV therapy, and monitoring laboratory values for electrolyte balance until surgery, therefore, are crucial actions to prevent all these events. Following surgery, TPN or IV fluid will be continued until bowel sounds return; after a short postoperative course, assuming no other bowel condition such as short bowel syndrome is present, an infant should have no further problems.

### Meconium Plug Syndrome

A **meconium plug** is an extremely hard portion of meconium that has completely blocked the intestinal lumen, causing bowel obstruction. The cause is unknown but probably reflects normal variations of meconium consistency. Meconium plugs usually form in the lower end of the bowel because this meconium formed early in intrauterine life and has the best chance to become dry and obstructive. The condition is associated with Hirschsprung disease, cystic fibrosis, hypothyroidism, and magnesium sulfate administration to halt preterm labor ([Cuenca, Ali, Kays, et al., 2012](#)).

#### Assessment

Because the obstruction is low in the intestinal tract, signs of obstruction such as abdominal distention and vomiting may not occur for at least 24 hours. Typically, the infant will be identified first as an infant who has had no meconium passage in the first 24 hours postbirth. A gentle rectal examination may reveal the presence of hardened

stool, although the plug may be too high up in the bowel to be palpated. An X-ray or sonogram may reveal distended air-filled loops of bowel up to the point of obstruction. A barium enema not only reveals the level of obstruction but also may be therapeutic in loosening the plug.

### Therapeutic Management

A subset of patients experiences spontaneous resolution of the meconium plug without any treatment. Of the 70% of patients requiring treatment, contrast or saline barium enema was used, with 97% success (Cuenca et al., 2012). The administration of a small (about 5 ml) saline enema (never use tap water in newborns, infants, and young children because it can lead to water intoxication) may cause enough peristalsis to expel the plug. Instillation of acetylcysteine (Mucomyst) rectally may be prescribed to soften stool. Gastrografin, a highly osmotic radiographic substance, administered as an enema, is yet another solution. Because it is hyperosmotic, the substance pulls fluid into the bowel, allowing the stool to soften and the plug to pass. Assess that the infant is well hydrated before and after the procedure because an infant can become hypovolemic from the effect of such a strong-acting medium.

Once the thickened portion of meconium has been passed, the infant should have no further difficulty and, over the next several hours, may pass a great amount of stool. Postprocedure prognosis is very good. Observe the infant for further passage of meconium (which should occur at least once daily) over the next 3 days, however, to be certain additional plugs do not exist farther up in the bowel. If an infant is going to be discharged before this time, instruct parents on the importance of observing for meconium and also about phoning their primary care provider should the infant have no further bowel movements while at home.

Occasionally, a neonate passes a small plug of hardened meconium—hard enough it would have caused an obstruction except it is so small—in the first 1 or 2 days of life. Be certain to record and report such a finding because the infant will need close observation for continued defecation, the same as for the infant who actually had an obstruction, to be certain there is not a larger and truly obstructing plug higher in the bowel.

Assess the family history of a newborn who has a meconium plug for cystic fibrosis, a recessively inherited disorder (see Chapter 40), aganglionic megacolon (Hirschsprung disease), or a polygenic inherited disorder (see Chapter 45) because, if there is a family history, the infant will need observation for these disorders. Hypothyroidism can also present with constipation or hardened stool in newborns along with signs such as a large protruding tongue, lethargy, and subnormal body temperature. Both hypothyroidism and cystic fibrosis screening are done along with phenylketonuria screening in newborns. Be certain this blood test is obtained in any newborn with a meconium plug (Levy, 2010). Infants born at home, especially, may not have had this done.

### Meconium Ileus

Meconium ileus (obstruction of the intestinal lumen by hardened meconium) is a specific phenomenon that occurs almost exclusively in infants with cystic fibrosis, resulting from the abnormal pancreatic enzyme function seen with cystic fibrosis (see [Chapter 40](#)) and reflects extreme meconium plugging ([Tappero & Honeyfield, 2015](#)). The usual symptoms of bowel obstruction occur: no meconium passage, abdominal distention, and vomiting of bile-stained fluid. Meconium ileus is the only bowel obstruction that can present with abdominal distention at birth ([Tappero & Honeyfield, 2015](#)). Unlike simple meconium plugging, the obstruction point may be too high in the intestine for enemas to reduce it; instead, the bowel must be incised and the hardened meconium removed by laparotomy. Meconium ileus is so strongly associated with cystic fibrosis, the infant needs close follow-up by an interprofessional cystic fibrosis team in the following months.

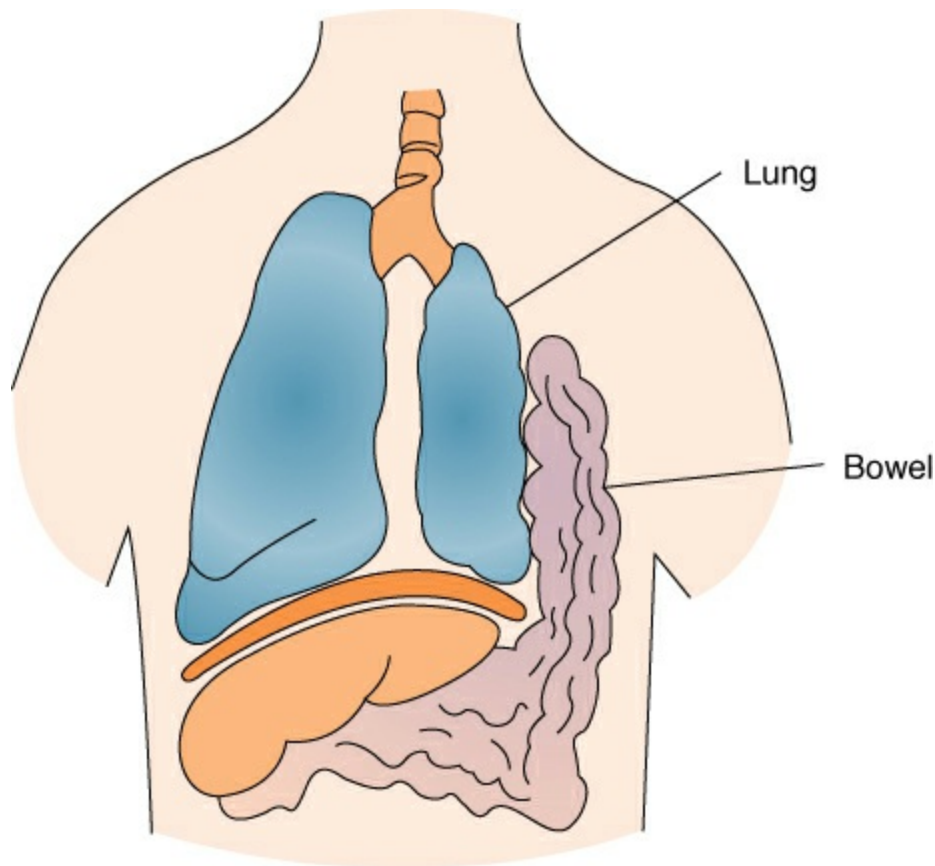

### *What If . . . 27.2*

**On the second day of life you notice Maia Sparrow's baby, who was born with meconium staining, is spitting up green mucus. Would it be safe to assume this is just more meconium-stained mucus? Should the nurse consider the baby might be vomiting bile-stained vomitus?**

## **Diaphragmatic Hernias**

A diaphragmatic hernia is a weakness in the musculature that permits a portion of the abdominal organs, such as the stomach or intestine, to protrude through the chest wall. This can cause a collapse of the left lung due to cardiac displacement on the right side of the chest. It occurs in 1 to 5 per 10,000 live births, with slight increased frequency in boys and a decreased frequency in Blacks ([Oluyomi-Obi, Kuret, Puligandla, et al., 2017](#)).

The defect is caused because, early in intrauterine life, the chest and abdominal cavity are one; at approximately week 8 of intrauterine growth, the diaphragm forms and divides them. If the diaphragm does not form completely, the intestines can herniate through the diaphragm opening into the chest cavity as a diaphragmatic hernia ([Fig. 27.13](#)).

**Figure 27.13** A diaphragmatic hernia. The bowel loop in the chest compresses the heart and lung on that side.

### Assessment

Diaphragmatic hernia is frequently detected in utero by routine sonogram ([Oluyomi-Obi et al., 2017](#)). If not, it is apparent at birth when the newborn has extreme difficulty establishing effective respirations. It can also be indicated by a scaphoid (sunken) abdomen caused by the displacement of abdominal contents into the chest ([Tappero & Honeyfield, 2015](#)). Surgeons have tried fetal surgery to correct or lessen the lung compromise from this diagnosis, but multiple randomized trials comparing prenatal surgical intervention to postnatal intervention show no benefit to prenatal intervention ([Hedrick, 2013](#)).

At birth, breath sounds are usually absent on the affected side of the chest cavity because at least one of the lobes of the lungs on that side cannot expand completely (and may not have fully formed). The infant may be cyanotic with intercostal or subcostal retractions. The abdomen generally appears sunken because it is not as filled with intestine as usual. These infants have a potential for developing persistent pulmonary hypertension because blood cannot perfuse readily through the unexpanded lung. This can lead to right-to-left shunting through the foramen ovale in the heart and also causes the ductus arteriosus to remain patent. One condition, then, has led to another until heart involvement complicates an already serious lung picture. The mechanics of right-to-left heart shunts are further discussed in [Chapter 41](#).

## Therapeutic Management

Although surgical repair may be done as an imminent surgical procedure, it is usually delayed until cardiorespiratory status has been stabilized as much as possible and the baby can be transported to a high-acuity nursery for care. Surgery includes repair of the diaphragm and replacement of the herniated intestine and organs back into the abdomen, possibly requiring both thoracic and abdominal incisions. If the disorder of the diaphragm is large, an insoluble polymer (Teflon) patch may be used to reconstruct a better diaphragm shape.

The repair can be complicated if there is not enough room in the abdomen for the intestine to be returned. In these infants, the abdominal incision may not be closed. The intestine is covered by silicone elastomer (Silastic) and left to be closed at a later date after the abdomen has grown, the same as gastroschisis surgery.

If the lung that was compressed in utero is truly hypoplastic and so cannot function, it will be removed at the time of surgery. If it is developed but just deflated, over the next week after surgery, the lung will gradually expand and begin to function. Chest tubes may not be used to avoid increased respiratory work and overdistention of the compromised lung. The mortality rate of children with diaphragmatic hernia is about 40%, with death often occurring because of associated anomalies of the heart, lung, and intestine and because of premature birth (Kadir & Lilja, 2017).

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Risk for ineffective gas exchange related to displaced bowel

**Outcome Evaluation:** The baby appears stabilized with  $PO_2$  over 40 mmHg,  $PCO_2$  under 60 mmHg, and pulmonary artery pressure at baseline level; lungs are clear to auscultation.

At birth, the infant is immediately endotracheally intubated and then gently ventilated with low-pressure, high-frequency, low-intensity oxygen to aid breathing. A nasogastric tube or a gastrostomy tube will be inserted to prevent the distention of the herniated intestine and to avoid further respiratory difficulty. Keep the infant NPO to prevent the bowel from filling and becoming distended. Be certain the suction is attached to only low intermittent suction to avoid injuring the lining of the newborn's stomach.

While they wait for surgery, infants breathe better if they are turned on their side with the compressed lung down and their head elevated because this allows the herniated intestine to fall back as far as possible into the abdomen and allows the unaffected lung to expand more completely.

Following surgery, maintain the infant in a head elevated position to keep the pressure of the replaced intestine off the repaired diaphragm. Suction the airway as

necessary and keep the infant in a warmed, humidified environment to encourage lung fluid drainage from the now uncompromised lungs. Chest physiotherapy may be prescribed to ensure lung secretions do not pool and cause pneumonia. Positive-pressure ventilation may be ordered to increase lung expansion, although this pressure is kept to a minimum to prevent tearing the undeveloped or previously unopened lung tissue. Maintaining arterial oxygen ( $PO_2$ ) at a lower level of 60 mmHg and permitting  $PCO_2$  to rise to a higher level of up to 60 mmHg may help prevent damage to the immature lung, thereby improving lung function (O'Rourke-Potocki, Ali, Murthy, et al., 2016). In addition, inhaled nitric oxide, or extracorporeal membrane oxygenation (ECMO) may be used as other ways to aid respirations and increase oxygenation.

**Nursing Diagnosis:** Risk for imbalanced nutrition, less than body requirements, related to NPO status

**Outcome Evaluation:** Child's skin turgor remains good; weight is maintained within 10% of birth weight or between a percentile curve on growth chart.

After surgery, to prevent pressure on the suture line in the diaphragm by a full stomach and bowel, nutrition will be supplied with TPN. When oral feedings are started, be certain to burp the infant frequently during and after feedings to reduce the amount of swallowed air and limit bowel pressure against the diaphragm.

### **QSEN Checkpoint Question 27.5**

#### **QUALITY IMPROVEMENT**

The nurse positions Mia's baby on his side to keep pressure off his back. She asks why the nurse isn't positioning a baby with diaphragmatic hernia in the same way. Before surgery, what would be the best position for a newborn with left-sided diaphragmatic hernia?

- a. On his left side to support his left lung
- b. On his stomach with his head turned sideways
- c. On his left side elevated in an infant chair
- d. On his right side so his left lung can expand

*Look in Appendix A for the best answer and rationale.*

### **An Imperforate Anus**

An imperforate anus (Fig. 27.14) is a stricture or the absence of the anus (Gourlay, 2013). In week 7 of intrauterine life, the upper bowel elongates to pouch and combine with a pouch invaginating from the perineum. These two sections of bowel meet, the membranes between them are absorbed, and the bowel is then patent to the outside. If this motion toward each other does not occur or if the membrane between the two

surfaces does not dissolve, an imperforate anus occurs. The disorder can be relatively minor, requiring just surgical incision of the persistent membrane, or much more severe, involving sections of the bowel that are many inches apart with no anus. There may be an accompanying fistula to the bladder in boys and to the vagina in girls (retrovaginal fistula), further complicating a surgical repair. The problem occurs in approximately 1 in 5,000 live births, more commonly in boys than in girls. It may occur as an additional complication of spinal cord disorders because both the external anal canal and the spinal cord arise from the same germ tissue layer.

**Figure 27.14** An imperforate anus. The lower bowel ends in a blind pouch.

### Assessment

The condition may be detected by a prenatal sonogram. It is discovered at birth when inspection of a newborn's anal region reveals no anus, a membrane filled with black meconium protrudes from the anus, or if it is impossible to insert a rubber catheter into the rectum. A "wink" reflex (touching the skin near the rectum should make the anus contract) cannot be elicited if sensory nerve endings in the rectum are not intact. Even with all these methods, some instances of the stricture will not be detected at birth because the anus appears as usual, and the stricture exists so far inside that it can't be seen. By 24 hours, no stool will be passed, and abdominal distention will become evident. An X-ray or sonogram will reveal the disorder if the infant is held in a slightly

head-down position to allow swallowed air to rise to the end of the blind pouch of the bowel. This method is also helpful to estimate the distance the intestine is separated from the perineum or the extent of the correction that will be necessary.

Because newborns are discharged at 2 or 3 days or even a few hours after birth, it's important that follow-up care by parents includes an assessment of whether the infant is defecating. If not, they may be asked to collect a urine specimen so it can be examined for the presence of meconium to help determine whether the infant has a rectal–bladder fistula. Placing a urine collector bag over the vagina in girls may reveal a meconium-stained discharge or that a rectovaginal fistula is present.

### Therapeutic Management

The degree of difficulty in repairing an imperforate anus depends on the extent of the problem. If the rectum ends close to the perineum (at or below the level of the levator ani muscle) and the anal sphincter is formed, repair involves simple laparoscopy with anastomosis of the separated bowel segments (Nam, Kim, & Kim, 2016). A repair becomes complicated if the end of the rectum is at a distance from the perineum (above the levator ani muscle), the anal sphincter exists only in an underdeveloped form, or a fistula to the bladder or vagina is present. If the repair is estimated to be extensive, the child may be given a temporary colostomy, and the final repair performed when the infant is somewhat older (6 to 12 months).

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Imbalanced nutrition, less than body requirements, related to bowel obstruction and inability to take in oral fluid

**Outcome Evaluation:** Child's weight remains within 10% of birth weight or is maintained on a percentile curve on a growth chart; skin turgor is good; urine output is 1 to 2 ml/kg/hour.

**Preoperative Care.** Before surgery, keep the infant NPO to avoid further bowel distention. A nasogastric tube attached to low intermittent suction for decompression will be inserted to relieve vomiting and prevent pressure on other abdominal organs or the diaphragm from the distended intestine. IV therapy or TPN will be started to maintain fluid and electrolyte balance.

**Postoperative Care.** The newborn will return from surgery with the nasogastric tube still in place. When bowel sounds can be heard so the nasogastric tube can be removed, small oral feedings of glucose water, formula, or breast milk can be started.

Infants who are scheduled for repair in a second-stage operation and who have a temporary colostomy are not permitted high-residue foods to lessen the bulk of stools. Although this is rarely a problem with infants because their diet naturally is a

low-residue one, do not assume parents know what low residue means. Examples include rice cereal and strained fruits and vegetables. They should avoid unrefined rice and grains, vegetables with fibers, or fruits with peels.

**Nursing Diagnosis:** Impaired tissue integrity at rectum related to surgical incision

**Outcome Evaluation:** Incision line remains free of erythema or drainage until it heals by about day 7 after surgery.

If a rectal repair was completed, remember there is a fresh suture line at the rectum. Take axillary or tympanic temperatures rather than rectal temperatures to avoid loosening a suture. The infant also should have no enemas, suppositories, or any other intrusive rectal procedures (it might be helpful to hang a sign above the infant's crib cautioning against these). Infants may be prescribed a stool softener daily to keep stool from becoming hard and tearing the healing suture line. Placing a diaper under, not on, the infant may be helpful so bowel movements can be cleansed away as soon as they occur. Clean the suture line well after each bowel movement by irrigating it with normal saline or other prescribed solution to help guard against infections. Do not place the infant on the abdomen because, in this position, newborns tend to pull their knees under them, causing tension in the perineal area and the suture line. A side-lying or supine position is best.

Some infants may need rectal dilatation done once or twice a day for a few months after surgery to ensure proper patency of the rectal sphincter. Review this technique (gently inserting a lubricated cot-covered finger into the rectum) with the parents and document they are able to perform this procedure before the child is discharged from the hospital. Be certain they also understand the importance of the procedure (the best surgical repair could end in failure if constriction occurs because parents do not follow up with this procedure). If infants are to be discharged with a prescription for a daily stool softener, be certain parents understand how important it is to give this and have a plan for remembering the correct times and dosage.

**Nursing Diagnosis:** Risk for impaired parenting related to difficulty in bonding with infant ill from birth

**Outcome Evaluation:** Parents hold and comfort infant; and describe positive characteristics of infant.

An imperforate anus may be a difficult anomaly for a parent to accept because it deals with a body area that they may not feel comfortable discussing. If it involves a temporary (or permanent) colostomy, learning to care for their infant can be difficult. For these reasons, parents need a great deal of support following the diagnosis. If a final surgical repair can be completed, they can be assured their child will have relatively normal bowel function thereafter. If a final repair could not be surgically achieved, they have the task of caring for a child with a permanent ostomy. You can assure them children who always have ostomies accept these well as they grow older because they have never known any other method of defecation (see [Chapter 37](#) for a

discussion of care priorities for the child with an ostomy).

## Physical and Developmental Disorders of the Nervous System

The most common developmental disorders of the nervous system at birth include abnormal accumulation of cerebrospinal fluid (CSF) (hydrocephalus), which has several causes, and abnormalities associated with neural tube closure (meningocele or meningomyelocele).

### HYDROCEPHALUS

CSF is formed in the first and second ventricles of the brain and then passes through the aqueduct of Sylvius and the fourth ventricle to empty into the subarachnoid space of the spinal cord, where it is absorbed. **Hydrocephalus** is the accumulation of an excess amount of CSF in the ventricles or the subarachnoid space (Tappero & Honeyfield, 2015). Hydrocephalus is thought to result from aqueductal stenosis and blockage of the CSF outflow from the fourth ventricle (Tappero & Honeyfield, 2015). Because cranial sutures are not firmly knitted in infants, the pressure of this excess fluid causes enlargement of their skull. If fluid is able to reach the spinal cord, the disorder is called a communicating or extraventricular hydrocephalus. If there is a block to CSF so it cannot circulate into the subarachnoid space, the disorder is termed obstructive or intraventricular hydrocephalus.

Hydrocephalus can occur at birth (congenital) or from an incident later in life (acquired). Although the increased fluid may occur in isolation, 90% of babies with congenital hydrocephalus have a diagnosis of meningomyelocele (discussed in the following paragraphs) (Sinha, Dhua, Mathur, et al., 2012). A preterm infant, less than 24 weeks gestation, may have acquired hydrocephalus from an intraventricular hemorrhage. The degree of blockage is directly related to the quantity of intraventricular blood, which blocks the passage of CSF (Oliveira, Teixeira, Norremose, et al., 2015).

Three main reasons explain why CSF accumulates:

- Overproduction of fluid by the choroid plexus in the first or second ventricle as could occur from a growing tumor (rare).
- Obstruction of the passage of fluid in the narrow aqueduct of Sylvius (the most common cause) or the foramina of Magendie and Luschka, the openings that allow fluid to leave the fourth ventricle. Hemorrhage from trauma, a growing tumor, or infections such as toxoplasmosis, meningitis, or encephalitis may leave adhesions behind that block fluid flow at these points. Arnold–Chiari disorder (elongation of the lower brain stem and displacement of the fourth ventricle into the upper cervical canal) or a Dandy–Walker cyst (a fluid-filled sack by one of the ventricles in the brain) are still other causes (Tappero & Honeyfield, 2015).

- Interference with the absorption of CSF from the subarachnoid space if a portion of the subarachnoid membrane has been removed, as occurs with surgery for a meningocele or after extensive subarachnoid hemorrhage, when portions of the membrane absorption surface become obscured.

## Assessment

With an obstruction present, excessive fluid accumulates and dilates the system forward of the point of obstruction. If the atresia is in the aqueduct of Sylvius, the first, second, and third ventricles will dilate. If it is at the exit from the fourth ventricle, all ventricles will dilate. Symptoms may develop rapidly or slowly depending on the extent of the atresia.

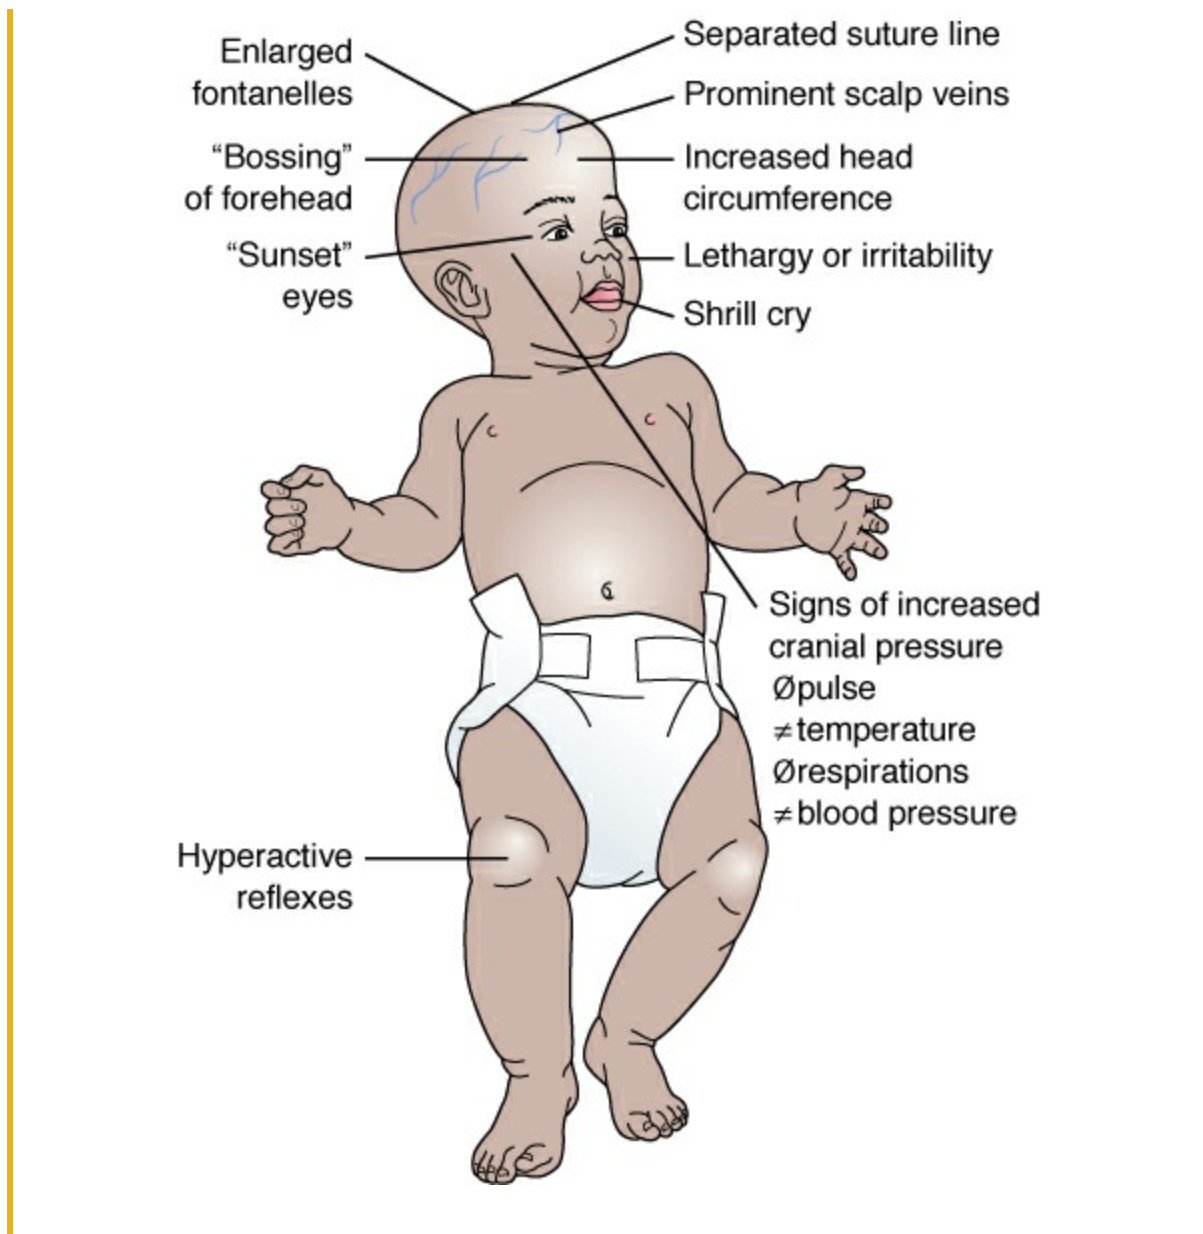

Hydrocephalus detected in utero through a prenatal sonogram may be shunted prior to birth, particularly if it is associated with a meningomyelocele (Moldenhauer, 2014). Although the condition occurs in approximately 3 to 4 out of 1,000 live births, it is only overtly evident during pregnancy or at birth in 15% of newborns with the disorder because intrauterine pressure prohibits skull expansion (Sinha et al., 2012). During the first few weeks of life, the infant's fontanelles widen and appear tense, the suture lines on the skull separate, and the head diameter enlarges. As the fluid accumulation continues, the scalp becomes shiny and scalp veins become prominent. The brow bulges forward (bossing), and the eyes become "sunset eyes" (the sclera shows above the iris because of upper lid retraction). Infants begin to show symptoms of increased intracranial pressure, such as decreased pulse and respirations, increased temperature and blood pressure, hyperactive reflexes, strabismus, and optic atrophy. They may become either irritable or lethargic with a typical shrill, high-pitched cry (Box 27.4). When a patient is suspected to have hydrocephalus, neurologic, neurosurgical, urologic, and orthopedic consultations should be considered to rule out any comorbid conditions (Tappero & Honeyfield, 2015).

### BOX 27.4

#### Nursing Care Planning Using Assessment

##### ASSESSING AN INFANT WITH HYDROCEPHALUS

Treatment is most effective when the disorder is recognized early because once intracranial pressure becomes so acute that brain tissue is damaged and motor or mental deterioration results, even the best shunting procedure cannot replace and repair this damage to brain cells. To best detect hydrocephalus, measure the head circumference of all newborns within an hour of birth and again before discharge from the healthcare facility to establish a baseline. All children younger than 2 years of age should then have their head circumference recorded and plotted on an appropriate growth chart at all healthcare visits so the child whose head is growing abnormally can be detected (Scheffler, Greil, & Hermanussen, 2017).

Because it is possible for infants to develop hydrocephalus following head trauma, all infants who have suffered head trauma severe enough to be seen in a medical facility should have their head circumference noted at the time of the accident so, if other symptoms of increased intracranial pressure appear, this head circumference

measurement can be a meaningful part of the store of information available concerning the child's condition (Scheffler et al., 2017).

In addition to the general enlargement of the head, note any asymmetry that is occurring because this may suggest the point of obstruction. A skull that is enlarging anteriorly with a shallow posterior fossa, for example, suggests the obstruction is in the aqueduct or third ventricle.

As the head continues to enlarge, the infant's motor function becomes impaired because of both neurologic impairment and atrophy caused by the inability to move such a heavy head. However, as long as a child has more than 1 cm of cerebral tissue present, motor function often is not impaired. Even with an extremely enlarged head, therefore, children's intelligence may also remain normal, although fine motor development may be affected.

Hydrocephalus can be demonstrated by ultrasound, computed tomography (CT), or MRI. A skull X-ray film will reveal the separating sutures and thinning of the skull. **Transillumination** (holding a bright light such as a flashlight or a specialized light [a Chun gun] against the skull with the child in a darkened room) will reveal that the skull is filled with fluid rather than solid brain tissue (Fig. 27.15). Assessing ventricular pressure will document the increased tension and presence of additional fluid.

**Figure 27.15** An infant with a hydrocephalus. Transillumination reveals a fluid-filled skull. (© Southern Illinois University/Photo Researchers, Inc.)

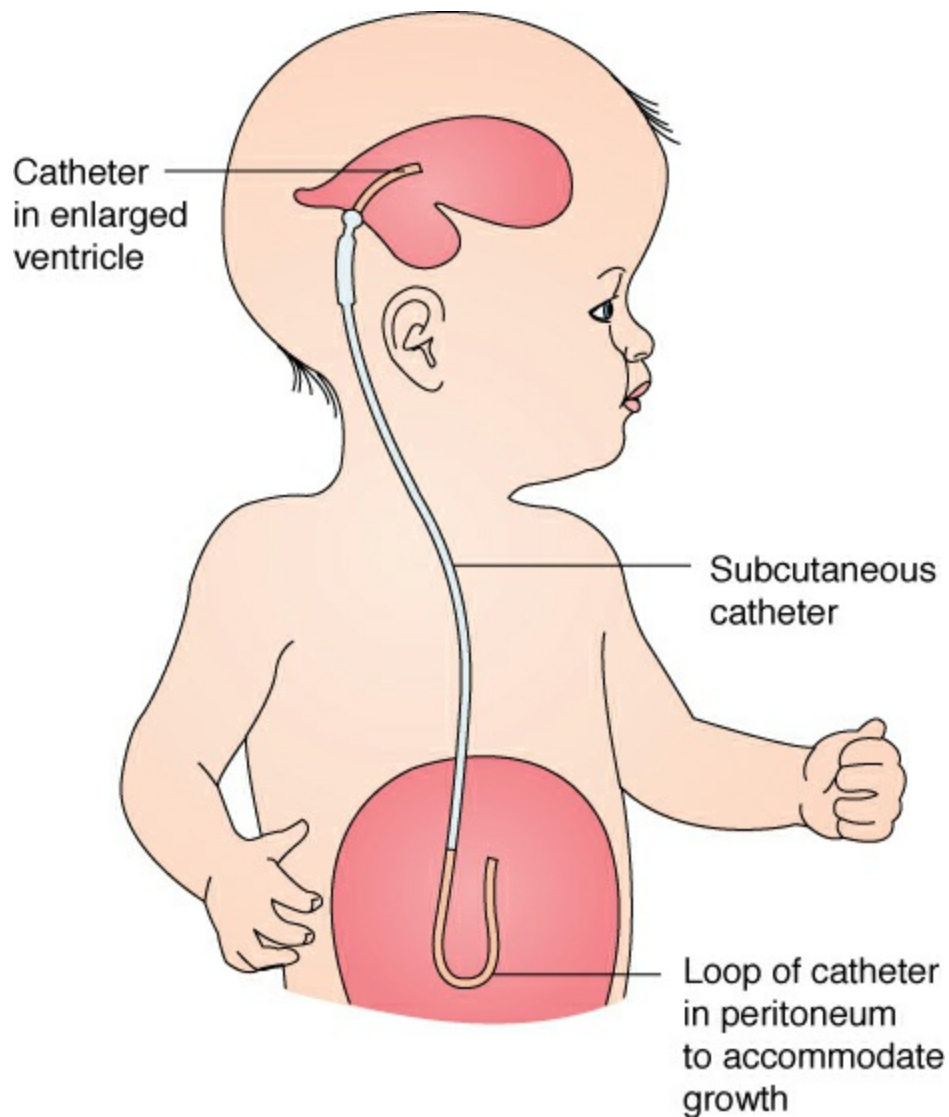

### Therapeutic Management

The treatment for hydrocephalus depends on its cause and extent. If it is caused by overproduction of fluid, acetazolamide (Diamox), a diuretic, may be prescribed to

promote the excretion of this excess fluid. Destruction of a portion of the choroid plexus may be attempted by ventricular endoscopy; if a tumor in that area is responsible for the overproduction of fluid, removal of the tumor should provide a solution. Hydrocephalus is usually caused by obstruction, however, so the treatment for children that do not have other neural tube involvement (such as a meningomyelocele) usually involves laser surgery to reopen the route of flow or bypassing the point of obstruction by shunting the fluid to another point of absorption. As more and more obstructions in the third or fourth ventricles are relieved by endoscopy, the next generation of children with isolated hydrocephalus may not need artificial shunting. Children today with hydrocephalus occurring with a meningomyelocele may still undergo a shunting procedure, however, and you may care for many older children or adults who have shunts in place.

A shunting procedure involves threading a thin polyethylene catheter under the skin from the ventricles to the peritoneum (a ventriculoperitoneal shunt) (Fig. 27.16). Fluid drains by this route into the peritoneum, where it is absorbed across the peritoneal membrane into the body circulation. The shunt usually has to be replaced as the child grows or it will become too short. As another complication, it could become enclosed in a fold of peritoneum and become obstructed or it could become infected.

**Figure 27.16** A ventriculoperitoneal shunt removes excessive cerebrospinal fluid from the ventricles and shunts it to the peritoneum. A one-way valve is present in the tubing behind the ear.

The ultimate prognosis for a child with hydrocephalus depends on whether brain damage occurred before shunting, whether the child develops a cerebral infection, and whether the parents can accept and recognize when a shunt needs to be replaced to prevent increased intracranial pressure (Box 27.5). Referral early in infancy for intervention services and screening is warranted to assess the infant's speech, fine, and gross motor milestones and detect any delays.

#### BOX 27.5

#### Nursing Care Planning Tips for Effective Communication

Maia's baby is scheduled to have a ventriculoperitoneal shunt inserted this afternoon. You talk to Maia before surgery.

*Tip:* Offer quick reassurance alleviates a parent’s concern. Better listening can also help reveal the true problem. Because surgical procedures are so safe today and the results of surgery for newborns are so successful, it is easy to begin to think of surgery as more inconvenient than serious. To a parent, however, the difference between a child born with one of these conditions and the “perfect” child the parent envisioned can be significant.

**Nurse:** Is there anything I can explain to you about your son’s surgery, Ms. Sparrow?

**Ms. Sparrow:** No. I just want to see him back here with a smaller head.

**Nurse:** The shunt won’t actually make his head smaller. Its purpose is to keep his head from growing any larger.

**Ms. Sparrow:** What is the chance he’ll die in surgery?

**Nurse:** All surgery has a risk, certainly, but he should do well.

**Ms. Sparrow:** But there is a chance he’ll die in surgery?

**Nurse:** You sound more worried than I’d expect. Is there something specific you’re worried about?

**Ms. Sparrow:** I wouldn’t feel bad if he died in surgery. I mean, how am I going to take care of a child with a tube in his head?

**Nurse:** Let’s sit down and talk about this some more.

## Nursing Diagnoses and Related Interventions

Nutrition and parent–child bonding are two major concerns for the infant with hydrocephalus. [Box 27.6](#) shows an interprofessional care map illustrating both nursing and team planning for an infant with the concern.

### BOX 27.6

#### Nursing Care Planning

### AN INTERPROFESSIONAL CARE MAP FOR A CHILD WITH HYDROCEPHALUS

At 1 month of age, Maia’s baby, still not named, has a ventriculoperitoneal shunt inserted for developing hydrocephalus.

**Family Assessment:** Child lives with 16-year-old mother, her parents, and four of mother’s siblings. Child’s father works as motorcycle mechanic; visits infant frequently. Mother no longer attending school because of child care. Mother asking many questions about the surgery. “This’ll fix everything, right? I want a healthy baby.”

**Patient Assessment:** One-month-old infant whose head circumference has continued to increase since meningomyelocele surgery at birth. Head circumference at birth was at 40th percentile, now is at 60th percentile. Mother noted infant has had increasing irritability and difficulty swallowing formula over the last few weeks.

Anterior fontanelle 4 × 4 cm; posterior fontanelle 3 × 1 cm. Sagittal suture line separated 0.25 in. Scalp veins prominent. No upward gaze. Parents report two episodes of forceful vomiting yesterday. Also, “His cry is so high pitched it hurts your ears.” Cerebral perfusion pressure, 55 mmHg. Blood pressure, 100/40 mmHg; pulse, 100 beats/min; respirations, 16 breaths/min. Afebrile.

**Nursing Diagnosis:** Risk for ineffective cerebral tissue perfusion related to increased intracranial pressure from hydrocephalus

**Outcome Criteria:** Infant’s vital signs are within age-appropriate parameters; head circumference is maintained at current level; infant responds to auditory stimuli; cerebral perfusion pressure remains above 50 mmHg.

Team Member Responsible	Assessment	Intervention	Rationale	Expected Outcome
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess if infant is able to turn freely because of increased head size.	Provide an environment for child that is stimulating yet not tiring (e.g., mobile, soft toys). Urge parent to interact with child.	Lack of mobility can lead to pressure ulcers on head as well as insufficient 1-month development.	Child’s parent plays with and feeds infant. Infant appears interested in age-appropriate toys. No irritated areas present on head.
<i>Teamwork and Collaboration</i>				
Nurse/primary healthcare provider	Assess if neurosurgeon is available to answer mother’s questions.	Arrange for consultation for mother with neurosurgeon to discuss surgery and child’s prognosis.	Viewing a child as totally disabled can cause a parent to not appreciate the child’s capabilities.	Neurosurgeon meets with mother to discuss that child’s IQ appears normal and that shunting will halt head growth.
<i>Procedures/Medications for Quality Improvement</i>				
Nurse	Assess infant’s	Position infant	Elevating head	Child’s cerebral

	neurologic status with head of bed postoperatively, including response to sound, pupillary response, increasing irritability, or lethargy.	slightly elevated; prevent flexion, hyperextension, or rotation of the head. Record cerebral perfusion pressure as prescribed.	of bed aids shunt perfusion, functioning, helping to reduce intracranial pressure. Cerebral perfusion pressure reveals the extent of intracranial pressure.	perfusion pressure remains greater than established parameter. Infant responds to sound; with no increasing irritability or lethargy.
Nurse	Assess head circumference and anterior fontanelle for tenseness every 4 hours as prescribed.	Document head circumference and appearance of anterior fontanelle.	A tense, bulging fontanelle or increasing head circumference indicates accumulating cerebrospinal fluid (CSF).	Child's head circumference does not increase in size; fontanelles no longer feel tense.
<i>Nutrition</i>				
Nurse/nutritionist	Observe mother feeding the infant.	Assist mother with positioning as necessary and avoid flexion or hyperextension of head during feeding.	Proper positioning is important to avoid pressure on the shunt, which could increase intracranial pressure.	Mother states she is comfortable feeding infant following surgery.
Nurse	Monitor intake and output closely.	Administer osmotic diuretic and corticosteroids as prescribed.	Adequate hydration is necessary to ensure renal function. Osmotic diuretics decrease intracranial pressure. Corticosteroids	Child's output remains over set parameter. Diuretic and corticosteroids are administered as necessary.

reduce inflammation.

*Patient-Centered Care*

Nurse/nurse practitioner	Assess the parents' understanding of a hydrocephalus and treatment measures.	Review the structure and function of the brain and explain how a hydrocephalus develops. Clarify any misconceptions.	Reviewing and clarifying aid in learning and strengthen understanding.	Mother states she understands the purpose of the shunt to relieve excess CSF.
--------------------------	--	--	--	---

*Psychosocial/Spiritual/Emotional Needs*

Nurse/nurse practitioner	Assess mother's acceptance of child in light of congenital disorders and no name for baby as yet.	Observe mother's interaction with infant and remind her that congenital disorders occur in a proportion of all births for unknown reasons.	Young mother may have had little experience with life crises; needs support from healthcare providers to master this crisis.	Mother states she understands child's condition is neither hers nor the child's fault and states she will be able to work through the present crisis.
--------------------------	---	--	--	---

*Informatics for Seamless Healthcare Planning*

Nurse	Assess if child's parents have adequate psychological support from family members or questions about care child will need for shunt care. Explore why child has not been named as yet.	Review care of child and assure parents healthcare providers can be contacted any time if they have questions. Establish a convenient follow-up care appointment.	In crisis situations, parents may need additional support to continue care of child and form a strong parent–infant bond. Positive reinforcement enhances self-esteem and aids in coping.	Mother states the grandmother is supportive. Together, they understand future care necessary and will contact primary care provider for any questions. Mother keeps postsurgery appointment and states she has
-------	--	---	---	--

				plans to name the child.
Nurse	Assess if parent would like home care follow-up.	Make referral for home care if needed. Also, refer parents to support group of other parents of children with hydrocephalus.	Support groups can decrease feelings of isolation and provide opportunities for further learning. Follow-up home care provides continuing support, guidance, and education.	Mother and grandmother state they will attend a support group at least once to evaluate benefit for them. Agree to at least one home visit for follow-up care.

**Nursing Diagnosis:** Risk for ineffective cerebral tissue perfusion related to increased intracranial pressure

**Outcome Evaluation:** Child shows no increased temperature or blood pressure, decreased pulse or respiratory rate or level of consciousness; PERLA (*pupils equal and reactive to light and accommodation*) is present; muscle strength is equal and strong bilaterally; head circumference is maintained at age-appropriate level.

Following the surgery for the initial shunt insertion, infants may have three incisions: one just behind the ear, one in the neck (done to help thread the catheter), and one in the abdomen where the end of the shunt is embedded. Their bed should be left flat or raised only about 10 degrees so their head remains level with the body so CSF does not flow too rapidly, possibly leading to tearing of cerebral arteries or signs of too rapid decompression.

A one-way valve, which is inserted into the shunt and can be palpated just behind the ear, opens when CSF has accumulated to the extent cerebral pressure has increased. It closes when enough fluid has drained to reduce the pressure. The surgeon who performed the shunting procedure prescribes how often the infant is to be turned and to what side after surgery. Often, infants are not turned to lie on the side with the shunt to prevent putting pressure on the valve, which might cause it to open and rapidly decompress CSF.

Formerly, shunts had fixed valves that allowed a set amount of CSF to be drained daily. Today, they are fitted with adjustable pressure valves. Because the valve contains a magnet, it can be readjusted to regulate the amount of CSF flow by manipulation of an external magnet, thus avoiding the problem of repeat surgery for readjustment (because shunts contain a magnet, remind parents to ask their primary

care provider if it would be safe for their child to have an MRI, and also to keep toys containing magnets or electronic devices such as tablet computers away from the child) (Strahle, Selzer, Muraszko, et al., 2012).

Continue to assess for signs of increased intracranial pressure after surgery such as tense fontanelles, increasing head circumference, irritability or lethargy, decreased level of consciousness, poor sucking ability, vomiting, an increase in blood pressure (difficult to measure accurately in infants unless arterial or umbilical lines are used with Doppler instrumentation), increasing temperature, and a decrease in pulse and respiratory rates (see Chapter 49 for tips on a complete neurologic assessment). Also, assess for symptoms of infection such as increased temperature, increased pulse rate, general malaise, and signs of meningitis such as a stiff neck and marked irritability (Box 27.7). Be certain a child receives adequate pain management not only for comfort but also because crying elevates CSF pressure.

### BOX 27.7

#### Nursing Care Planning Based on Family Teaching

#### CARING FOR A CHILD WITH A VENTRICULOPERITONEAL SHUNT

**Q.** Following her child's ventriculoperitoneal shunt surgery, Maia asks you, "What do I need to do to care for him as he grows older?"

**A.** Here are some helpful things to remember:

- Be aware of the signs of increased intracranial pressure, such as drowsiness, vomiting, headache, irritability, and lack of appetite.
- Observe the site of the pump daily for any sign of swelling or redness.
- Don't allow your baby to fall asleep with his head hanging over the side of a couch or bed or in a position that could bend the shunt at the neck.
- Offer sufficient fruit, vegetables, cereal, and a generous amount of fluid so he doesn't become constipated; hard stool might press against the shunt in the abdomen and obstruct the flow of fluid. In addition, straining to pass a hard stool can increase intracranial pressure.
- Do not call attention to the pump behind your child's ear; teach him not to touch the pump when he's nervous or as an attention-getting action.
- Be certain your child wears a helmet for tricycle and bicycle riding (as all children should) to avoid injury to the shunt. Monitor his participation in roughhousing or school sports to avoid head trauma.
- If your child develops signs of infection such as an increased temperature, phone your primary care provider. This could be a simple respiratory infection but could also indicate an infected shunt that needs immediate treatment.
- Be certain to keep your regularly scheduled health assessment visits. As your child grows taller, the shunt will eventually need to be replaced for proper functioning.

**Nursing Diagnosis:** Risk for imbalanced nutrition, less than body requirements, related to increased intracranial pressure

**Outcome Evaluation:** Child's weight remains within 5th to 95th percentile on height and weight chart; no vomiting occurs.

Because an abdominal incision is involved to thread the catheter into the peritoneum, an infant may be prescribed to be kept NPO until bowel sounds return. Introduce fluid gradually in small quantities because vomiting that results from the introduction of fluid too soon after any surgery causes increased intracranial pressure.

Like all infants, those with hydrocephalus should be held when being fed if possible. Be certain to support their heads well when moving them to avoid strain on their neck if their head appears enlarged. Help breastfeeding mothers to find a comfortable way to support the infant's head as needed. Use of a breastfeeding pillow will help to provide firm head support along with correct positioning at the breast.

Document whether the child sucks well because increasing intracranial pressure may be noted first because of poor or ineffective sucking. Vomiting after feeding without nausea (difficult to detect in a small infant) is also a common first sign of increased intracranial pressure.

Also, observe whether constipation exists because straining while passing stool is another cause of increased intracranial pressure. This is not usually a problem with young infants who are totally breastfed or formula fed. It can be a problem when children return for shunt replacement at an older age. Urge parents to offer adequate fluid and roughage in their child's diet as a preventive measure as the child grows.

**Nursing Diagnosis:** Risk for impaired skin integrity related to extra weight and immobility of the head

**Outcome Evaluation:** Child's skin remains clean, dry, and intact and without signs of erythema or ulceration.

If the infant's head has enlarged, it may be difficult for the infant to move it freely because of the extra weight. As the skin of the head stretches thin, skin breakdown can occur at the pressure point. Wash the child's head daily and change the position of the head approximately every 2 hours so no portion of the head rests against the mattress for a long period. A synthetic sheepskin or silicon pad or an air, water, or alternating air mattress may help to reduce pressure points. If a Kling or stockinette bandage is used to hold a surgical head dressing in place, place a piece of gauze or cotton behind the child's ear before the bandage is applied to prevent skin surfaces from touching and becoming excoriated. Make certain the bandage does not become wet from backward-draining oral secretions or drainage from the shunt insertion site. The infant is also at risk for developing a flattened surface on the side or back of the head (nonsynostotic plagiocephaly) because of the inability to freely move the head, so awareness of position also becomes important from a cosmetic craniofacial aspect (De Bock, Braum, Renz-Polster, 2017).

**Nursing Diagnosis:** Deficient knowledge related to home care needs of child with hydrocephalus

**Outcome Evaluation:** Parents state fears regarding ability to provide care but voice they are able to manage this; state signs of increased intracranial pressure for which they should watch; demonstrate competence in shunt care.

Caring for a child with a shunt in place is an ongoing responsibility for parents because most children will have a shunt in place for the rest of their life. If parents do not seem to be asking many questions about the child's care after surgery, do not assume this is because they are taking the child's care in stride. They may be too frightened or do not understand neuroanatomy enough to know what questions to ask. An opening question such as "Most parents are a little nervous when they think about taking a child home with a shunt in place; do you feel that way?" gives them an opportunity to discuss how they feel and, hopefully, bring their anxiety down to a manageable level. It also offers assurance that healthcare providers are interested in helping and supporting them.

As their child grows older, remind parents to stress to their child that the strange object that can be felt behind the ear should not be continually touched. A child nervously fidgeting with a pressure pump can inadvertently evacuate CSF from the ventricles at a dangerously rapid rate.

Before an infant with a shunt in place is discharged from the hospital after surgery, be certain the parents have ample opportunity to feed and provide care so they can feel comfortable and confident they "know" their infant. Because irritability, lethargy, vomiting, and a change in the baby's cry are signs of increased intracranial pressure, be certain parents have the telephone number of their primary healthcare provider so they can report these findings immediately. A referral for home care follow-up may be appropriate to offer further support.

Parents need an appointment for the child's first checkup or who to call to make an appointment. Be certain they understand an infection of the shunt is not just a possibility but a severe complication because it can lead to meningitis; this means they need to report ear or pharyngeal infections at the first sign of illness. If meningitis should develop, in addition to being rehospitalized and receiving the usual treatment for meningitis (see [Chapter 49](#)), the child may have an extraventricular shunt placed to promote drainage and allow antibiotics to be administered directly into the CSF to prevent infected CSF from draining into the peritoneal cavity, where it could cause peritonitis.

**Nursing Diagnosis:** Risk for delayed growth and development related to potential neurologic challenge

**Outcome Evaluation:** Child demonstrates regular observable growth and achieves age-appropriate developmental milestones.

Like all children, children with hydrocephalus need intellectual and emotional

stimulation such as being talked to, smiled at, and played with. Always role-model talking and singing to the child to help parents include these actions in their care. As necessary, reposition mobiles or pictures over a crib so the child can receive adequate visual stimulation without turning a heavier than usual head.

As the child reaches preschool and school age, parents need to confer with their primary healthcare provider to what sports will be safe. Usually, contact sports are contraindicated, although it may be allowed with helmet head protection. Carrying a heavy backpack or purse on the side of the shunt is also not advised to avoid breaking the shunt. Helmet use should be enforced with tricycle or bicycle riding or any other activities, such as skiing or snowboarding, where a head injury may be a concern.

### *QSEN Checkpoint Question 27.6*

#### **TEAMWORK & COLLABORATION**

The primary healthcare provider for Maia's baby asks the nurse to observe him for signs that he is developing increased intracranial pressure while he waits for surgery. What vital sign changes should most prompt the nurse to report the findings to the primary care provider?

- a. Decreased temperature and increased blood pressure
- b. Increased respirations and decreased pulse rate
- c. Increased temperature and decreased pulse rate
- d. Decreased blood pressure and increased temperature

*Look in Appendix A for the best answer and rationale.*

## **NEURAL TUBE DISORDERS**

The term “neural tube defect” (NTD) is used to describe many distinctly different malformations of the neural tube (Wallingford, Niswander, Shaw, et al., 2013). Because the neural tube forms in utero first as a flat plate and then molds to form the brain and spinal cord, it is susceptible to malformation. The term **spina bifida** (Latin for “divided spine”) is most often used as a collective term for all spinal cord disorders, but there are well-defined degrees of spina bifida involvement, and not all neural tube disorders even involve the spinal cord. All of these disorders, however, occur because of a lack of fusion of the posterior surface of the embryo in early intrauterine life. They can be compared with cleft palate or cleft lip, which are also midline closure disorders.

The worldwide incidence of NTDs ranges from 1 to 10 per 1,000 births. The incidence of neural tube disorders has fallen dramatically in the United States since the inclusion of 600 µg of folic acid in prenatal vitamins and the mandatory inclusion of folic acid in all cereal and grain products, reducing the rate to 2 in 10,000 live births. In addition to folic acid deficiency, other risks identified are maternal age under 20 years or over 40 years, maternal education below 12th grade level, and low socioeconomic status (Zaganjor, Sekkarie, Tsang, et al., 2016). However, 30% to 50% of NTDs are not

prevented by folate, indicating other possible environmental factors such as maternal diabetes, maternal obesity, and possibly certain drugs such as valproic acid (Wallingford et al., 2013). All women, especially those who have given birth to a first child with a spinal cord disorder, are advised to have maternal serum assay MAFP levels during a second pregnancy to determine if such a disorder could be present.

## Types of Neural Disorders

### Anencephaly

Anencephaly is the absence of the cerebral hemispheres. It occurs when the upper end of the neural tube fails to close in early intrauterine life. It is revealed by an elevated level of MAFP, amniocentesis, or a prenatal sonogram.

Labor with an infant with anencephaly may be prolonged because the infant may present in a breech position or the underdeveloped head may not engage the cervix well. On visual inspection at birth, the disorder is obvious (Fig. 27.17). Because the respiratory and cardiac centers are located in the intact medulla, infants may survive for several days after birth but cannot survive further because they have little or no cerebral function.

**Figure 27.17** An infant with anencephaly. (© Joseph R. Siebert, PhD/Custom Medical Stock Photograph.)

When the condition is discovered prenatally, parents are offered the option of pregnancy termination. If they elect to carry the pregnancy to term, they will need concerned support in the first few days of life as they realize the baby is as ill and incomplete as predicted. Providing culturally and spiritually sensitive care is a priority. Accommodate the needs of the family as best as possible, especially if the mother chooses to birth her baby. Allowing the parents to hold their newborn and to take photos can help with the grieving process. Many families opt to name their child and hold a funeral after the infant passes. This again can be helpful in their grieving process.

### Microcephaly

Microcephaly is a disorder in which the fetal brain grows so slowly that it falls more than three standard deviations below normal on a growth chart at birth. The cause might be a disorder in brain development associated with an intrauterine infection such as rubella, cytomegalovirus, or toxoplasmosis (Russo & Beltrão-Braga, 2017). Recently, the Zika virus, which is transmitted via an infected *Aedes* species mosquito, has been linked to infantile microcephaly (CDC, 2016). A pregnant woman infected with Zika can pass the virus to her fetus, causing a range of certain birth defects, including microcephaly (CDC, 2016). More information is being learned about Zika transmission and preventative measures along with the hopes for development of a vaccine. The CDC has published guidelines, specifically for women and men of childbearing age. For more information, refer to the CDC website. Microcephaly may also result from severe malnutrition or anoxia following birth or in early infancy.

The prognosis for a normal life is guarded in children with microcephaly and depends on the extent of restriction of brain growth and on the cause. Generally, the infant is cognitively challenged because of the lack of functioning brain tissue. True microcephaly must be differentiated from *craniosynostosis* (normal brain growth but premature fusion of the cranial sutures), which also causes decreased head circumference but is curable.

### Spina Bifida Occulta

Spina bifida occulta, the mildest form of all NTDs, occurs when the posterior laminae of the vertebrae fail to fuse. Spina bifida occulta is a malformation caused by nonclosure or incomplete closure of the posterior portion of the vertebrae (Tappero & Honeyfield, 2015). This occurs most commonly at the fifth lumbar or first sacral level but may occur at any point along the spinal canal. The appearance of a normal spinal cord is shown in Figure 27.18A. Spina bifida occulta may be first noticed as a dimpling at the point of poor fusion; abnormal tufts of hair or discolored skin may also be present (Ross, Mason, & Finnell, 2017). Simple spina bifida occulta is a benign disorder, and it can occur as frequently as in one out of every four children (see Fig. 27.18B).

**Figure 27.18** Degrees of spinal cord anomalies. **(A)** A normal spinal cord. **(B)** Spina bifida occulta. **(C)** A meningocele. **(D)** A meningomyelocele.

Because the term “spina bifida” is commonly used to denote all spinal cord anomalies, parents, when told their child has a spina bifida occulta, may interpret this as meaning their child has an extremely serious disorder. Help clarify the degree of this defect for them: It simply means a surface of bone is missing, and the spinal cord is intact.

### Meningocele

The spinal cord is protected by three layers of meninges or membranes: the pia mater, the arachnoid, and the dura mater. If these membranes herniate through an unformed vertebrae, they protrude as a circular mass, about the size of an orange, at the center of the back and termed a *meningocele* (see Fig. 27.18C). The protrusion generally occurs in the lower lumbar and lumbosacral region, although it might be present anywhere along the spinal canal. The protrusion is either covered by a layer of skin or, more frequently, only the clear dura mater. No sensory or motor deficits accompany the disorder unless the membrane sac should rupture, but damage to the cord could occur or infection could enter the now unprotected CSF.

### Meningomyelocele

This is the defect that most people think of when they say “spina bifida” because it is the most common birth defect affecting the central nervous system and is frequently viewed as the most complicated birth defect compatible with survival (Zaganjor et al., 2016). Lesions associated with spina bifida are called meningoceles. In a meningomyelocele, not just the meninges protrude through the vertebrae, but the spinal cord usually ends at the point of protrusion (Tappero & Honeyfield, 2015). Motor and sensory function will be decreased or absent beyond this point (see Fig. 27.18D).

Generally, the higher the defect is along the spine, the greater the degree of paralysis.

The child will have partial or complete paralysis, partial or complete lack of sensation of the lower extremities, as well as loss of bowel and bladder control. The

infant's legs may appear lax because the infant cannot move them; urine and stools continually dribble because of a lack of sphincter control. Children may have an accompanying talipes (clubfoot) disorder and developmental dysplasia of the hip. A hydrocephalus develops in as many as 90% of these infants because of the lack of an adequate subarachnoid membrane for CSF absorption and obstruction of CSF circulation from the spinal deformity; the higher the meningomyelocele occurs on the cord, the more likely it is that a hydrocephalus will accompany it. Simultaneous shunting during a primary meningomyelocele repair during the first 72 hours of life has been shown to decrease hospital stay length, decrease loss of and infection rates of CSF, and lessen damage from progressive ventricular dilation (Zaganjor et al., 2016).

## Encephalocele

An encephalocele is a cranial meningocele. These occur most often in the occipital area of the skull but may occur as a nasal or nasopharyngeal disorder. Encephaloceles generally are covered fully by skin, although they may be open or covered only by the dura. It is difficult to tell from the size of the encephalocele if only CSF is trapped in the protruding meninges or whether brain tissue could also be involved. Transillumination of the sac will reveal whether brain tissue is in the sac. A CT, MRI, or ultrasound will reveal the size of the skull disorder and help predict the extent of surgery, which will be needed.

### *Assessment*

Neural tube disorders may be discovered during intrauterine life by prenatal ultrasound, fetoscopy, amniocentesis (discovery of increased AFP in amniotic fluid), or analysis of MAFP. If the condition is discovered in utero, it may be possible to close the lesion by fetoscopic surgery. An infant may be born by cesarean birth to avoid pressure and injury to the spinal cord. It is generally difficult to tell from visual appearance whether the disorder is a meningomyelocele (Fig. 27.19) or the simpler meningocele. Observe and record whether an infant born with a neural tube disorder has spontaneous movement of the lower extremities to assess if the child has lower motor function. Also, assess the nature and pattern of voiding and defecation. The usual newborn appears to be “always wet” from voiding but actually voids in amounts of approximately 30 ml and then is dry for 2 or 3 hours before voiding again. An infant without motor or sphincter control voids continually. This pattern is the same for defecation. Observing these features aids in differentiating between a meningocele and a meningomyelocele. Differentiation will be further established by CT, ultrasound, or MRI.

**Figure 27.19** A meningocele. The infant also has hydrocephalus and a subluxated hip. (NMSB/Custom Medical Stock Photograph.)

### *Therapeutic Management*

Children with spina bifida occulta need no surgical correction because there is no tissue extruding from the vertebrae. The parents should be made aware of the defect, however, so they are not surprised if it is revealed on a spinal X-ray taken for some reason later in life. They should also receive adequate patient education so that they can recognize more serious symptoms as the child grows such as numbness, weakness, or pain, which might indicate a need for reevaluation. Some children may eventually need surgery to prevent vertebral deterioration because of the unbalanced spinal column.

Treatment for a meningocele or encephalocele involves immediate surgery to replace the meninges and to close the gap in the skin to prevent infection. This is done as soon after birth as possible (usually within 24 to 48 hours) so an infection through the exposed meninges does not occur. The surgery is not without risk, and if a brain disorder accompanies an encephalocele, the child's cognitive potential may be impaired. If a large portion of meninges have to be removed by surgery, this can limit the rate of absorption of CSF, which can lead to a buildup of CSF and hydrocephalus.

Children with a meningocele have the same surgery to return the meninges to the spinal cord and close the gap in the skin surface. The child will continue to have partial or complete paralysis of the lower extremities and loss of bowel and bladder function because, although the lesion on the back can be repaired, the absent lower cord cannot be replaced. There also is the same risk of hydrocephalus. [Table 27.1](#) provides a classification of motor function ability, which can be anticipated according to the location of a spinal cord disruption.

**TABLE 27.1** Motor Function Ability in Children With Meningocele

## Spinal Resultant Effects Cord

### *Lesion*

T6– T12	Complete flaccid paralysis of the lower extremities; weakened abdominal and trunk musculature in higher lesions; kyphosis and scoliosis common; ambulation with maximal support
L1– L2	Hip flexion present; paraplegia; ambulation with maximal support
L3– L4	Hip flexion, adduction, and knee extension present; hip dislocation common; some control of hip and knee movement possible; ambulation with moderate support
L5	Hip flexion, adduction, and varying degrees of abduction; knee extension and weak knee flexion; paralysis of the lower legs and feet; ambulation with moderate support
S1–S2	As previous, with preservation of some foot and ankle movement; ambulation with minimal support
S3	Mild loss of intrinsic foot muscular function possible; ambulation without support

## Nursing Diagnoses and Related Interventions

Although parents of an infant with a meningocele were told before surgery that their child's spinal disorder is a type that means motor and sensory function are absent in the child's lower extremities, they do not necessarily "hear" this information. It is only after surgery that they begin to comprehend the extent of physical challenges their child will face. Before the child is discharged from the hospital, be certain the parents are linked with an interprofessional care team specializing in neural tube disorders to prevent them from feeling deserted when they most need support—the time when they first begin to appreciate what this problem will mean to them in the coming years, and what it will mean to their child throughout life.

**Nursing Diagnosis:** Risk for infection related to rupture or bacterial invasion of the meningeal sac

**Outcome Evaluation:** Neural tube sac remains intact; axillary temperature remains below 98.6°F (37°C).

If the exposed meningeal sac is allowed to dry, it can crack, allowing CSF to drain and microorganisms to enter. Pressure on the protruding mass is a prime reason why

the sac ruptures. When this happens, it can lead to an infection such as meningitis as well as quick decompression of the CSF. Sudden compression can lead to herniation of the brain stem into the spinal cord and interference with respiratory and cardiac centers. Such pressure may also force CSF from the sac into the spinal column, thus increasing intracranial pressure. It is crucial, therefore, to prevent the drying of and pressure on the exposed membrane.

*Preoperative Positioning.* Before surgery, use sterile gloves and sterile linens when caring for an infant with either a meningocele or meningomyelocele. Use a sterile, wet, warm compress of saline, antiseptic, or antibiotic gauze over the lesion to keep the sac moist. Rather than remove this to wet it again and risk rupturing the sac, merely add additional warm fluid as needed.

Position infants carefully to prevent pressure on the exposed meninges, either in a prone position or supported on their side. When they are on their side, use a rolled blanket or diaper placed behind their upper back (above the disorder) and a separate one behind their lower back (below the disorder) so no pressure will be exerted on the lesion, and the infant will be protected from rolling backward onto it. Placing a folded diaper between the legs prevents skin surfaces from touching and rubbing in this position as well as helps to keep the hips from internally rotating. Positioning infants on their abdomen has the added advantage of keeping the flow of feces and urine away from the spinal defect as well as keeping the protruding meninges free from pressure (infants at home should sleep on their back but in an acute care setting with monitoring available, you can assure parents infants can be safely positioned on their abdomen). Placing a piece of plastic or sturdy plastic wrap below the protruding membranes on the child's back and taping it in place as an apron is another method of preventing feces from touching the open lesion.

A folded towel under the abdomen helps to flex the infant's hips in a prone position, reduce pressure on the sac, and ensure good leg position. Always notice if the position of the infant's legs appears comfortable because, if the infant lacks motor control, he or she cannot move them to a more comfortable position independently.

Although no pressure should be exerted on the open lesion by a top sheet or swaddling blanket, make certain the child is adequately warm. The presence of the sac adds to the amount of body surface area exposed, so heat loss will be greater than usual. Don't place the infant under a radiant heat source for warmth because the radiant heat can dry the lesion and cause cracking. An incubator both supplies a better heat source and also allows you to constantly assess and monitor the lesion. Any seepage of clear fluid from the defect should be reported promptly because this is probably escaping CSF. If you are in doubt whether the fluid is urine or CSF, check it against a glucose test strip: CSF will test positive for glucose, whereas urine or mucus will not.

*Postoperative Care.* After surgery, a baby is again placed on a cardiorespiratory monitor and positioned on the abdomen until the skin incision has healed (about 7

days). The same careful precautions against allowing urine or feces to touch the incision area continue.

**Nursing Diagnosis:** Risk for imbalanced nutrition, less than body requirements, related to difficulty assuming normal feeding position

**Outcome Evaluation:** Child's skin turgor is good; weight is maintained within 10% of birth weight; specific gravity of urine remains between 1.003 and 1.015.

If the defect repair was large and the risk of picking up the infant is too great, the infant may be fed while lying on the side in an incubator or prone on a specialized bed frame. Raise the infant's head slightly by slipping a folded diaper under it. Make certain your supporting arm does not press against the lesion. Remember (and remind parents) that, when burping the infant, not to pat the infant's back over the defect. Stroke the head, arms, or upper back while the infant sucks to try to give the child the same comfort and assurance at feeding time as a baby would receive if being held. Infants may enjoy a pacifier after feeding because they do not experience the same enjoyment of sucking while feeding that would be experienced if they could be held and cuddled. If a mother plans to breastfeed, urge her to pump and to provide expressed breast milk for the infant; as soon as the infant can be held, she can breastfeed (which will be as early as 3 to 4 days).

**Nursing Diagnosis:** Risk for ineffective cerebral tissue perfusion related to increased intracranial pressure

**Outcome Evaluation:** Child's head circumference remains within present percentile on growth chart; signs and symptoms of increased intracranial pressure are absent.

*Preoperative Care.* Increasing head size from poor absorption of CSF (hydrocephalus) is a common complication of both meningocele and meningomyelocele surgical repairs. To detect increased head size, measure head circumference as prescribed in the preoperative period to set a baseline. Head circumference measurements done by various caregivers are accurate only if the tape measure is placed on the same points of the child's head each time. Placing an indelible pen mark on the scalp above and below the tape measure over both ears and on the back of the scalp allows different people to measure the head at the same point while not leaving such a large mark that it interferes with facial features.

*Postoperative Care.* Head circumference measurement needs to be continued after surgery because this is the time when an increase in size most often occurs. Continue to observe the child as well for signs of increased intracranial pressure such as bulging fontanelles, vital change variations, neurologic signs such as pupillary changes, or behavioral changes such as irritability or lethargy to help detect if this is happening.

**Nursing Diagnosis:** Risk for impaired skin integrity related to required prone positioning

**Outcome Evaluation:** Infant's skin on knees remains intact, without erythema or ulceration.

Preserving skin integrity is a major problem before surgery because the constant prone position puts pressure on the infant's knees and elbows. If a hydrocephalus has developed, pressure areas at the temples can occur if the head is not repositioned about every 2 hours. After surgery, use paper tape or a stockinette for dressing changes or place a protective dressing such as Stomahesive on the skin under the area where the tape will touch. Change diapers frequently to prevent excessive contact of acidic urine with skin.

## Nursing Diagnoses and Related Interventions

**Nursing Diagnosis:** Impaired physical mobility related to neural tube disorder

**Outcome Evaluation:** Child ambulates with the least amount of accessory equipment possible.

Parents need to begin to plan stimulation activities that their infant can accomplish with limited mobility as soon as surgery is completed. Encourage them to take the infant to the places children normally accompany parents, such as relatives' homes, shopping, or the zoo, because encouraging children to be as independent as possible as they grow helps them lead as active a life as possible (Fig. 27.20) (Deroche, Holland, McDermott, et al., 2015).

**Figure 27.20** A child born with a neural tube disorder demonstrates her ability to walk using braces and a crutch. (Alexander Tsiara/Photo Researchers, Inc.)

Parents will need to perform passive exercises to prevent muscle atrophy and formation of contractures if a child has impaired lower extremity motor control. The child may need leg braces to help maintain good alignment and enable walking with crutches. Parents are generally anxious to do something for their child and follow routines of passive exercises well if they are given sufficient support for their accomplishments at healthcare visits. As the child grows older, tendon transplants or an osteotomy may be necessary to prevent contractures and poor bone alignment. Because children with meningocele have no sensation in their lower extremities, parents should make a routine of daily inspections of the child's lower extremities and buttocks for any area of irritation or possible infection. Teach children as they grow older to do this themselves. When children are using a wheelchair, be certain they press with their arms on the armrests to raise their buttocks off the wheelchair seat at least once every hour to help provide adequate

circulation to lower extremities. Often, children will have a team of rehabilitation therapists, such as occupational and physical therapists, who are involved with promoting the child's physical development, milestones, and strengths to their optimal abilities.

**Nursing Diagnosis:** Risk for impaired elimination related to a neural tube disorder

**Outcome Evaluation:** Child demonstrates ability to independently manage bowel and bladder elimination by school age.

To ensure bladder emptying, an intermittent clean urinary catheterization technique may be taught to parents (inserting a clean catheter through the urethra into the bladder every 4 hours to drain urine from the bladder; [Box 27.8](#)). An advantage of this is children who are begun on intermittent clean catheterization from birth require fewer bladder augmentation procedures as they grow older. As they reach early school age, they can learn this technique for themselves. In addition to self-catheterization, a drug such as oxybutynin chloride (Ditropan) may improve bladder capacity and allow a child to need less frequent catheterizations ([Box 27.9](#)) ([Karch, 2013](#)). In some children, it is possible to place artificial bladder sphincters to help establish continence. In other children, a continent urinary reservoir or a ureterosigmoidostomy (see [Chapter 46](#)) can be constructed to bypass the nonfunctioning bladder. The school nurse is a key facilitator to help enable the child to achieve their highest level of self-care and voiding during school hours.

## BOX 27.8

### Nursing Care Planning to Empower a Family

#### TECHNIQUE FOR CLEAN INTERMITTENT CATHETERIZATION

**Q.** Maia needs to learn clean intermittent catheterization for her son (now named Marcus Tyler). She asks you, “How do I do this?”

**A.** Here are some helpful guidelines to follow:

1. The purpose of intermittent catheterization is to keep the bladder empty by using a clean technique and frequent emptying so microorganisms do not have time to grow in urine or the bladder. Always use clean equipment and catheterize at least every 4 hours.
2. Always carry catheterization equipment with you when away from home (e.g., a plastic bag containing a new catheter and a water-soluble lubricant). If you will be using a public lavatory, you might want to include a presoaped washcloth rather than have to use rough paper towels.
3. To begin catheterization, wash your hands well in warm, soapy water. This reduces the chance you will introduce germs from your hands into your child's bladder.

4. Next, wash around your child's urinary meatus with a clean washcloth or paper towel and warm, soapy water. Rinse the washcloth and wash again with clear water. This reduces the chance that germs on the child's skin will be pushed into the bladder.
5. Coat the tip of the catheter with a water-soluble lubricant. This reduces friction and allows the catheter to slide into the bladder easily.
6. Quickly but gently insert the catheter into the urinary meatus approximately 3 in. Urine should begin to flow immediately through the catheter. Let this drain into a collecting bag.
7. When urine stops flowing, gently remove the catheter. Most health insurance plans furnish enough clean catheters that you don't ever have to reuse one. If you should need to do this, clean the catheter with soap and water, rinse with clear water, and replace in the plastic bag with the lubricant.
8. Be certain that on special days such as family celebrations or while on vacation, you do not forget the importance of catheterization.
9. As your child reaches school age, you can teach him how to do this himself. He will need to insert the catheter about 6 in. Be certain he will be able to have access to a school bathroom every 4 hours during the day so he can successfully do this.
10. Phone your healthcare provider if urine is ever blood tinged, smells foul, or is cloudy rather than clear or if your child appears to have pain in his abdomen or lower back or has an elevated temperature. These may be symptoms of a urinary tract infection, which will need treatment.

#### BOX 27.9

### Nursing Care Planning Based on Responsibility for Pharmacology

#### OXYBUTYNIN CHLORIDE (DITROPAN)

**Classification:** Oxybutynin is an anticholinergic, urinary antispasmodic.

**Action:** relaxes smooth muscle to relieve symptoms of bladder instability associated with neurogenic bladder (Karch, 2013)

**Pregnancy Risk Category:** C

**Dosage:** individually prescribed depending on weight of child

**Possible Adverse Effects:** drowsiness, dizziness, blurred vision, decreased sweating

#### Nursing Implications

- Advise parents to give or have the child take the medication exactly as prescribed.
- Alert parents about the need for frequent healthcare visits during treatment to document the drug's effect.
- Ask the child to report drowsiness or blurred vision. Caution the child to not attempt activities that require balance until they adjust to taking the drug.
- Caution the child and parents that the drug causes decreased sweating, which can

cause body temperature to rise. Encourage parents to keep the child's environment cool and to avoid extreme, high temperatures.

### *What If . . . 27.3*

**Maia repeats that she's too young to care for a child with so many problems so she wants to let him die rather than undergo palliative surgery to close the neural tube disorder. Whose rights should be honored, the parent's or the child's, and how should these rights be determined? What would be the nurse's role?**

## **ARNOLD–CHIARI (CHIARI II) MALFORMATION**

An Arnold–Chiari malformation is categorized as Chiari I, Chiari II, or Chiari III. Chiari Type I malformation involves the downward herniation of the caudal end of the cerebellar vermis through the foramen magnum. Chiari Type II occurs in 0.5 to 1 per 1,000 of children with spina bifida myelomeningocele. Children with Chiari I typically show symptoms in the second or third decade ([Wallingford et al., 2013](#)) of life, so it is referred to as an “adult type,” although current sonogram scan capabilities have allowed for earlier incidental diagnosis. Chiari II and the very rare Chiari III types are present at birth and so are considered primary neural tube abnormalities. The Chiari II disorder is caused by overgrowth of the neural tube in weeks 16 to 20 of fetal life. The cerebellum, medulla oblongata, and fourth ventricle project into the spinal canal at the cervical level, causing the upper cervical spinal cord to jackknife backward, obstructing CSF flow, and causing hydrocephalus. An accompanying lumbosacral meningocele is also present in about 50% of children with this anomaly ([Bernard, Knupp, Yang, et al., 2012](#)).

A diagnosis is made by MRI and is sometimes accidentally identified via an initial MRI because the older child is being evaluated for chronic headaches. The prognosis for the child with an Arnold–Chiari malformation depends on the extent of the disorder and the surgical repair procedure possible. Because of the upper motor neuron involvement, gagging and swallowing reflexes may be absent, increasing the risk for tracheal aspiration. Serious levels of sleep apnea may also occur ([Fuller, Sinha, Caruso, et al., 2016](#)), which require surgical intervention. Overall prognosis is encouraging. A lumbar puncture (LP) should never be performed on a child with Arnold–Chiari malformation for risk of a brainstem herniation; neurosurgery must always be consulted when necessary.

### *What If . . . 27.4*

**The nurse is interested in exploring one of the 2020 National Health Goals related to infants born with physical or developmental disorders (see [Box 27.1](#)).**

**Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore pertinent to these goals that would be applicable to the Sparrow family and that would also advance evidence-based practice?**

## **KEY POINTS FOR REVIEW**

- Learning about the way a child will be physically challenged immediately after birth helps parents adjust most easily. Advocate for parents by helping them obtain as much information as they need about their child's condition in order to help them manage transitions across different healthcare settings.
- Parent–infant bonding can be difficult to establish when a child is hospitalized at birth. Assess family relationships at health maintenance visits to see that bonding is occurring while incorporating cultural and spiritual respect and customs.
- Absent or malformed extremities may range from absence of a finger to absence of an entire limb. Children may need physical therapy and teaching on how to use a prosthesis to gain full mobility and function.
- Developmental hip dysplasia is the improper formation and function of the hip socket; talipes deformities are foot and ankle deformities. Children may need extensive bracing and casting to correct these disorders.
- Cleft lips and cleft palates result from the failure of the maxillary process to fuse in intrauterine life. Surgical repair is possible early in life, with a good prognosis for both of these conditions.
- Esophageal atresias and tracheoesophageal fistulas occur from failure of the trachea and esophagus to completely divide and fully form independently in intrauterine life. Surgical intervention begins immediately but often needs to be performed in several stages.
- Omphaloceles are protrusions of abdominal contents through the abdominal wall at birth, protected only by a peritoneal membrane. When the membrane is not present, this is called gastroschisis. Although several stages of repair are often necessary, surgical correction has a good outcome.
- Intestinal obstructions can result from atresia (complete closure) or stenosis (narrowing) of a part of the bowel. Correction is surgical removal of the narrowed bowel portion.
- Meconium plugs occur when an extremely hard portion of meconium blocks the lumen of the intestine. Infants with meconium plug syndrome need to be observed for continuing bowel function and assessed for cystic fibrosis because a meconium plug is often the first symptom of this illness.
- Diaphragmatic hernias occur when the abdominal organs protrude through a defect in the diaphragm into the chest cavity. This prevents the lungs from fully forming in utero or expanding at birth. These infants are critically ill at birth and need extensive surgical correction.

- An imperforate anus is the incomplete formation of the anus, resulting in an inability to pass stool. The infant may have a temporary colostomy created before a final surgical correction can be completed.
- Physical developmental disorders of the nervous system include hydrocephalus (excess CSF in the ventricles) and neural tube disorders (incomplete closure of the vertebrae). Infants with hydrocephalus need surgery to relieve a ventricular obstruction or have a shunt implanted from their ventricles to the peritoneal cavity to remove excess CSF. Children with meningomyeloceles, the most severe form of neural tube disorder, face a permanent full or partial loss of lower neuron function and require continued rehabilitation.
- Planning nursing care that includes assurance not only meets QSEN guidelines but also best meets the family’s total needs.

### CRITICAL THINKING CARE STUDY

Cecelia Dove is a 7-lb baby born by vaginal birth to a 25-year-old mother. At birth, she appeared healthy and cried lustfully. An hour after birth, however, the first time her mother tried to breastfeed her, she coughed and choked 5 minutes into the feeding. Her primary care provider suspects Cecelia may have esophageal atresia.

1. What steps should you immediately take because of this diagnosis while you wait for diagnostic tests to be scheduled?
2. After a barium swallow is completed, Cecelia’s mother is told her infant has an isolated esophageal atresia without a fistula. The mother exclaims, “I can’t take home a baby who isn’t normal. My mother will say it’s my fault because I never should have gotten pregnant. My boyfriend will be so embarrassed, he’ll leave me.” How could you help this mother gain a better insight into her child’s condition?
3. Cecelia returns from the operating room after successful surgery. She has a temporary gastrostomy tube in place for decompression and feedings of breast milk. When the mother asks you, “What now?” what would be your best answer?

UNIT 5

The Nursing Role in Health Promotion  
for Childrearing Family

## Principles of Growth and Development

*John Olson is a 6-year-old, mildly overweight boy brought into an emergency department because his leg is broken from a bicycle accident. At 4 months of age, John was placed in foster care because his mother was not caring for him adequately. He was then moved back and forth among 12 different foster homes until he was finally adopted at age 3.5 years. His adoptive parents now have 3-year-old twins of their own in addition to John. They tell you that, although John has lived with them for 3 years, they find him cold and unloving. They ask you what they can do to change this.*

*Nurses are directly responsible for assessing the growth and development of children in many healthcare settings. Previous chapters discussed childbearing and what an important time the first weeks after birth can be in a child's life. This chapter adds information about growth and development that are important for a child's continuing life.*

**How has John's background contributed to his behavior? What stage of psychosocial development does he not seem to have achieved? How could his adoptive parents help him at this point?**

### KEY TERMS

**abstract thought**  
**accommodation**  
**assimilation**  
**autonomy versus shame or doubt**  
**centering**  
**cognitive development**  
**conservation**  
**development**  
**developmental milestones**  
**developmental task**  
**growth**  
**identity versus role confusion**

**industry versus inferiority**  
**initiative versus guilt**  
**intimacy versus isolation**  
**maturation**  
**permanence**  
**reversibility**  
**role fantasy**  
**schemas**  
**sensorimotor stage**  
**temperament**  
**trust versus mistrust**

## OBJECTIVES

**After mastering the contents of this chapter, you should be able to:**

1. Describe principles of growth and development and developmental stages according to major theorists.
2. Identify 2020 National Health Goals related to growth and development that nurses can help the nation achieve.
3. Assess a child to determine if a stage of development has been achieved.
4. Formulate nursing diagnoses that address wellness as well as both a potential for and an actual delay in growth and development.
5. Identify expected outcomes for a growing child as well as how to manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care, such as suggesting age-appropriate play materials to support normal growth and development.
8. Evaluate outcome criteria for achievement and effectiveness of care.
9. Integrate knowledge of the principles of growth and development with the interplay of the nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

All children pass through predictable stages of growth and development as they mature. Parents often ask what to expect from their children regarding their developmental progress at healthcare visits. Such visits provide opportunities for you to assess growth and development and provide anticipatory guidance ([Butterworth & Kovas, 2013](#)).

For these reasons, including growth and development is essential to establish

complete and effective nursing care plans for children. This chapter addresses the most important factors to assess for each age group. Later chapters supply detailed descriptions of individual age groups. [Box 28.1](#) shows 2020 National Health Goals that speak directly to aspects of growth and development.

### BOX 28.1

#### Nursing Care Planning Based on 2020 National Health Goals

A number of 2020 National Health Goals speak to growth or development of children. They include:

- Increase the proportion of children with special healthcare needs who receive their care in family-centered, comprehensive, coordinated systems from 20.4% to a target level of 22.4%.
- Reduce the proportion of children diagnosed with a disorder through newborn blood spot screening who experience a developmental delay requiring special education services from 15.1% to a target level of 13.6%.
- Increase the proportion of young children who are screened for an autism spectrum disorder (ASD) and other developmental delays by 24 months of age from 19.5% to a target level of 21.5%.
- (Developmental) Increase the proportion of children with a developmental delay who have a first evaluation by 36 months of age.
- Reduce the proportion of children 2 to 5 years of age who are considered obese from 10.7% to a target level of 9.6%; for children 6 to 11 years, from 17.4% to 15.7%; and for adolescents, from 17.9% to 16.1% ([U.S. Department of Health and Human Services, 2010](#); see [www.healthypeople.gov](http://www.healthypeople.gov)).

Recognizing normal growth and development patterns of children helps to determine if children are following normal development and when referrals are needed. Nurses are the healthcare providers who interact with children as they weigh and measure them or help with interviewing or examinations and so are prime people to recognize developmental delays.

### *Nursing Process Overview*

#### FOR PROMOTION OF NORMAL GROWTH AND DEVELOPMENT

##### ASSESSMENT

To assess **growth** (defined as an increase in physical size, typically measured as height, weight and head circumference), measure and plot height and weight on a standard growth chart for children at all well-child care visits. Measurement of the head circumference is included for children age 2 years and younger. Growth charts are available through the Centers for Disease Control and Prevention (CDC; [www.cdc.gov/growthcharts/](http://www.cdc.gov/growthcharts/)) and the World Health Organization (WHO;

[www.who.int/childgrowth/standards](http://www.who.int/childgrowth/standards)). This will aid in determining if the child's growth is following the predicted pattern.

Obtain a developmental health history from both parents (if they are available) and the child (if age-appropriate). **Development** refers to the progression toward maturity in mental, physical, and social markers of normal development. Observe what specific activities the child can accomplish to establish whether **developmental milestones** (major markers of normal development) are achieved (Fig. 28.1).

Document a 24-hour recall history for nutritional intake, sleep, and a description of school and play behaviors (see Chapter 34). Periodic screening tests such as the Ages & Stages Questionnaires (<http://agesandstages.com/>) and routine screening, including hearing and vision, should be scheduled following the periodicity schedule of the American Academy of Pediatrics (AAP at <https://www.aap.org/en-us/professional-resources/practice-support/Pages/PeriodicitySchedule.aspx>).

**Figure 28.1** Growth and development are assessed by both observation and specific testing. Here, a 12-month-old demonstrates mastery of well-coordinated and intentional hand movements.

## **NURSING DIAGNOSIS**

When an assessment is completed, a nursing diagnosis can be identified to reflect the problem. Examples of nursing diagnoses applicable to growth and development include:

- Risk for delayed growth and development related to lack of age-appropriate toys and activities
- Delayed growth and development related to prolonged illness
- Readiness for enhanced family coping related to parents seeking information about a child's growth and development
- Health-seeking behaviors related to appropriate stimulation for infants
- Imbalanced nutrition, less than body requirements, related to parental knowledge deficit regarding a child's protein needs
- Deficient knowledge related to potential long-term effects of obesity in the school-age child

## **OUTCOME IDENTIFICATION AND PLANNING**

To provide holistic nursing care, consider all aspects of a child's health (physical, emotional, cultural, cognitive, spiritual, and social), remembering that each child's developmental progress is unique. Children achieve milestones at a predictable age range and identifying delays encourages prompt evaluation and treatment to promote the child's optimal potential.

Providing anticipatory guidance to caregivers provides them with realistic expectations for their child's achievements. Unrealistic parental expectations are factors that can lead to a child experiencing an unintentional injury (see [Chapter 52](#)). Planning should include a child's family because growth and development proceed within a family context. To develop psychosocially, children need emotional support from loved ones, just as they need nutritional support to grow physically.

Parents of a child with a developmental delay may use denial as a protective mechanism. Planning may have to initially focus on assisting parents with acceptance of the current situation. Plans for the child may have to be delayed until the parents are emotionally prepared to address the problem. It may be helpful to refer parents to online resources for further information.

## IMPLEMENTATION

Interventions to foster growth and development include encouraging age-appropriate self-care in a child and suggesting age-appropriate toys or activities to parents. Role modeling is an important ongoing intervention to help parents accept a child's delayed growth or appreciate a child who is scoring extremely high on standard scales and needs increased stimulation. Modeling, for example, can demonstrate that problem solving is a more effective approach to life's challenges than "acting out" behaviors.

## OUTCOME EVALUATION

An evaluation for specific growth and developmental milestones (see [Chapters 29 to 33](#)) must be conducted throughout childhood and repeated if there are any concerns regarding a delay. The evaluation must be comprehensive and include all physical growth parameters and all aspects of development. Developmental aspects include social, language, and fine motor and gross motor skills. Expected outcomes for abnormal findings include the following examples:

- Child, 5 years of age, expresses less negativism at next clinic visit.
- At the 9-month checkup, parents describe how they have made a safe space in their home for their infant to crawl so he is not confined to a playpen.
- Parents list household tasks they believe are appropriate for a 6-year-old child by the next office visit.
- Parents describe the pattern they are using to phase out high-carbohydrate, nonnutritive snacks for their preschooler.
- Parents express confidence that they will be able to guide their toddler past the stage of the "terrible twos."

## Growth and Development and the Role of the Nurse

Assessing for growth and development milestones is a nursing role in the care of both well and ill children.

### HEALTH PROMOTION AND ILLNESS PREVENTION

Determining a child's developmental stage is often the primary focus of a well-child health interview and examination. For instance, during her child's 24-month checkup, a mother might ask if it is normal that her child cannot yet pedal a tricycle, a question that cannot be answered without a full understanding of average ranges of motor coordination.

Parenting style and competence are major influences on the behavioral and mental health of children (Barton & Kirtley, 2012). In addition to reassuring parents that their child is doing well, parents also need periodic anticipatory guidance regarding their child's development. For example, it would be important to discuss additional home safety with a parent when a child is approaching the age for crawling. Parents should be cautioned to think about installing a gate in front of a stairway and removing products or installing a lock on accessible cabinets where hazardous materials are stored.

Parents of the 1-year-old child will appreciate being cautioned that their child's appetite may decrease during the coming year. This information helps prevent the misinterpretation of a child's rejection of food as the beginning of a feeding problem, and it helps the parents see it as a normal developmental stage instead. Likewise, the parent of a child approaching puberty generally welcomes discussion on how to prepare a child for this challenging growth phase.

Anticipatory guidance must be provided in a timely manner. Information given too early is forgotten by the time it is needed. Given too late, parents may have already addressed the issue and possibly not in the most growth-enhancing way for their child. Recognizing the predictable stages of growth and development, from newborn through late adolescence, will enable you to provide anticipatory guidance at the appropriate stage of the child's development (Halfon, Stevens, Larson, et al., 2011; The Nemours Foundation, 2016).

### HEALTH RESTORATION AND MAINTENANCE

It is equally essential to consider the developmental stage of a child when providing care during illness (both acute and chronic) and in preparation for a medical or surgical procedure. Preparing a 5-year-old child for surgery, for example, would be ineffective unless you know how much a 5-year-old child will understand (e.g., anesthesia, some body parts are necessary for life and some are not, or stitches will not stay in permanently). During the postsurgical period, you need growth and development knowledge to assess whether a child is old enough to swallow pills, whether a child will be able to accurately rate a degree of pain on a standard scale, and how to approach a child who says "no" to every suggestion.

Physical growth is another important factor to consider because disease affects children differently at various stages of growth. A 12-year-old child who has fractured a long bone, for example, has a potentially more serious fracture than an 8-year-old child who fractures the identical bone. This is because the 8-year-old must metabolize enough calcium to meet two major needs: healing the fracture site and maintaining healthy bone cells. The 12-year-old child, who is undergoing a period of rapid growth, must meet three needs: calcium for healing, maintaining existing healthy bone cells, and an additional amount for rapid bone growth. If a child does not take in adequate calcium during the healing period to supply the extra amount for growth, the affected limb could be left shorter than its mate. You can help protect against permanent disability by recommending ways the child can ingest extra calcium.

## Principles of Growth and Development

Growing up is a complex phenomenon because of the many interrelated facets involved. Children do not merely grow taller and heavier as they get older; maturing also involves growth in their ability to perform skills, to think, to relate to people, and to trust or have confidence in themselves.

The terms “growth” and “development” are sometimes used interchangeably, but they are actually different terms.

- Growth is used to denote an increase in physical size or a *quantitative* change. Growth in weight, for example, is measured in pounds or kilograms; growth in height is measured in inches or centimeters.
- Development indicates an increase in skill or the ability to function (a *qualitative* change). Development is measured by observing a child’s ability to perform specific tasks such as how well a child picks up small objects, by recording the parent’s description of a child’s progress, or by using standardized tests such as the Ages & Stages Questionnaires. **Maturation** is a synonym for development.

Psychosexual development is a specific type of development that refers to developing instincts or sensual pleasure (Freudian theory). Psychosocial development refers to Erikson’s stages of personality development. Kohlberg’s theory of moral development is the ability to know right from wrong and to apply these to real-life situations.

**Cognitive development** refers to the ability to learn or understand from experience, to acquire and retain knowledge, to respond to a new situation, and to solve problems (see the section that follows on Piaget’s theory of cognitive development). It is measured by intelligence tests and by observing children’s ability to function effectively in different environments.

## PATTERNS

Neither physical growth nor aspects of maturation occur haphazardly but in a predictable pattern governed by several principles (Box 28.2). As shown in Figure 28.2,

the pattern for general growth, such as respiratory, digestive, renal, musculoskeletal, and circulatory tissue, proceeds fairly smoothly during childhood. Certain body tissues, however, mature in spurts. Neurologic tissue (spinal cord and brain) grows so rapidly during the first 2 years that the brain reaches mature proportions by 2 to 5 years of age. Lymphoid tissue (spleen, thymus, lymph nodes, and tonsillar tissue) also grows rapidly during infancy and childhood to provide young children early protection against infection. In 5-year-olds, for example, tonsillar tissue has already reached its peak size (about twice that of an adult). On assessment, the back of the throat of young school-age children appears to be “all tonsils.” Although the spleen is not usually palpable in adults, the spleen is palpable 1 or 2 cm below the left ribs in preschool children as another example of this rapid immune tissue growth. In contrast, reproductive organs (genital tissue) show little growth until puberty (Levine, 2011).

## BOX 28.2

### Nursing Care Planning Based on Family Teaching

**Q.** John’s mother asks you, “Are there principles of growth and development I should know to be a better mother?”

**A.** Aspects of growth and development are well studied. General principles include:

- ***Growth and development are continuous processes from conception until death.*** Although there are highs and lows in terms of the rate at which growth and development proceed, a child is growing new cells and learning new skills at all times. An example of how the rate of growth changes is a comparison between that of the first year and later in life. An infant triples in birth weight and increases height by 50% during the first year of life. If this tremendous growth rate were to continue, a 5-year-old child, ready to begin school, would weigh 1,600 lb and be 12.5 ft tall.
- ***Growth and development proceed in an orderly sequence.*** Growth in height occurs in only one sequence—from smaller to larger. Development also proceeds in a predictable order. For example, the majority of children sit before they crawl, crawl before they stand, stand before they walk, and walk before they run. Occasionally, a child will skip a stage (or pass through it so quickly the parents do not observe the stage). Occasionally, a child will progress in a different order, but most children follow a predictable sequence of growth and development.
- ***Children pass through the predictable stages at different rates.*** All stages of development have a range of time rather than a certain point at which they are usually accomplished. Two children may pass through the motor sequence at such different rates, for example, that one begins walking at 9 months, whereas another starts at 14 months. They are both following the predictable sequence and are developing normally; they are merely developing at different rates.
- ***All body systems do not develop at the same rate.*** Certain body tissues mature more rapidly than others. For example, neurologic tissue experiences its peak

growth during the first year of life, whereas genital tissue grows little until puberty.

- **Development is cephalocaudal.** *Cephalo* is a Greek word meaning “head”; *caudal* means “tail.” Development proceeds from head to tail. Newborns can lift only their head off the bed when they lie in a prone position. By age 2 months, infants can lift both the head and chest off the bed; by 4 months, the head, chest, and part of the abdomen; by 5 months, infants have enough control to turn over; by 9 months, they can control legs enough to crawl; and by 1 year, children can stand upright and perhaps walk. Motor development has proceeded in a cephalocaudal order—from the head to the lower extremities.
- **Development proceeds from proximal to distal body parts.** This principle is closely related to cephalocaudal development. It can best be illustrated by tracing the progress of upper extremity development. A newborn makes little use of the arms or hands. Any movement, except to put a thumb in the mouth, is a flailing motion. By age 3 or 4 months, the infant has enough arm control to support the upper body weight on the forearms, and can coordinate the hand to scoop up objects. By 10 months, the infant can coordinate the arm and thumb and index fingers sufficiently to use a pincerlike grasp or to be able to pick up an object as fine as a piece of breakfast cereal on a high chair tray.
- **Development proceeds from gross to refined skills.** This principle parallels the preceding one. Once children are able to control distal body parts such as fingers, they are able to perform fine motor skills (e.g., a 3-year-old colors best with a large crayon; a 12-year-old can write with a fine pen).
- **There is an optimum time for initiation of experiences or learning.** Children cannot learn tasks until their nervous system is mature enough to allow that particular learning. A child cannot learn to sit, for example, no matter how much the child’s parents have him or her practice, until the nervous system has matured enough to allow for back control. Children who are not given the opportunity to learn developmental tasks at the appropriate or “target” times for a task may have more difficulty than the usual child learning the task later on. A child who is confined to a body cast at 12 months, the time the child would normally learn to walk, may take a long time to learn this skill once free of the cast at, say, age 2 years. The child has passed the time of optimal learning for that particular skill.
- **Neonatal reflexes must be lost before development can proceed.** An infant cannot grasp an item with skill until the grasp reflex has faded nor can the infant stand steadily until the walking reflex has faded. Neonatal reflexes are replaced by purposeful movements.
- **A great deal of skill and behavior is learned by practice.** Infants practice over and over taking a first step before they accomplish this securely. If children fall behind in growth and development because of an illness, they are capable of “catch-up” growth to bring them equal again with their age group.

**Figure 28.2** The main types of postnatal growth of various body tissue types. (Redrawn from Scammon, R. E. [1930]. The measurement of the body in childhood. In J. A. Harris, C. M. Jackson, D. G. Paterson, et al. [Eds.], *The measurement of man* [pp. 214–226]. Minneapolis, MN: University of Minnesota Press, with permission.)

**QSEN Checkpoint Question 28.1**

**INFORMATICS**

John is 6 years old. The nurse should teach his parents that which of his body systems should be reaching its peak point of development at this time?

- a. His neurologic system
- b. His lymphatic system
- c. His respiratory system
- d. His musculoskeletal system

*Look in Appendix A for the best answer and rationale.*

## Factors Influencing Growth and Development

Genetic and environmental influences are primary factors in determining if a child will be able to reach his or her genetic potential.

**Temperament**—the typical way a child reacts to situations—is an example of

genetic influence. Whether a fetus enjoyed a healthy uterine existence or whether the child was born into a family with sufficient funds to supply adequate health care are examples of environmental influences (Pike, Jane Pillow, & Lucas, 2012). Whether a child receives good nutrition, beginning with being breastfed, is yet another (Johnston, Landers, Noble, et al., 2012). It is the intertwining of these or a combination of these factors that determines how each child grows and matures.

## GENETICS

From the moment of conception when a sperm and ovum fuse, the basic genetic makeup of an individual is cast. In addition to physical characteristics such as eye color and height potential, inheritance determines characteristics such as learning style. A child may also inherit a genetic abnormality, which could result in disability or illness at birth or later in life and so prevent optimal growth.

## GENDER

On average, girls are born lighter (by an ounce or two) and shorter (by an inch or two) than boys. Boys tend to keep this height and weight advantage until prepuberty, at which time girls surge ahead as they begin their puberty growth spurt 6 months to 1 year earlier than boys. By the end of puberty (age 14 to 16 years), boys again tend to be taller and heavier than girls. This difference in growth patterns is why different growth charts are used for boys than for girls (available at <http://thePoint.lww.com/Flagg8e>) (Pastor & Reuben, 2011).

## HEALTH

A child who inherits a genetically transmitted disease may not grow as rapidly or develop as fully as a healthy child depending on the type of illness and the therapy or care available for the disease. Before insulin was discovered in 1922, for example, many children with type 1 diabetes mellitus died in early childhood; those who lived were left physically challenged. Currently, with good health supervision and insulin therapy, the effects of type 1 diabetes can be minimized so that children with diabetes both grow and thrive. Diabetes is still a major factor in the health of children, however. As more and more children become obese because of fast-food diets and lack of an exercise program, type 2 diabetes now has begun to occur in children as young as school age (Dea, 2011; Morgan, 2012)

## INTELLIGENCE

Children with high intelligence do not generally grow faster physically than other children, but they do tend to advance faster in skills. Occasionally, children of high intelligence actually fall behind in physical skills because they spend their time with books or mental games rather than with games that develop motor skills. Intelligence begins to make major differences as children become adolescents and begin to plan

future careers (Viner, Ozer, Denny, et al., 2012).

## TEMPERAMENT

Temperament is the usual reaction pattern of an individual or an individual's characteristic manner of thinking, behaving, or reacting to stimuli in the environment. Unlike cognitive or moral development, temperament is not developed in stages but is an inborn characteristic set at birth. Understanding that children are not all alike (e.g., some adapt quickly to new situations, others adapt slowly, some react intensely, some react passively based on an inborn disposition) helps parents better understand why their children are different from one another and help them plan individualized care for each child.

### Reaction Patterns

Chess and Thomas (1985) are the researchers who identified nine separate characteristics that define temperament, or how children react to common situations. Each child's pattern is made up of a combination of these individual elements.

#### Activity Level

The level of activity among children differs widely right from birth. Some babies seem to be constantly on the go and rarely are quiet. They wiggle and squirm in their crib as early as 2 weeks of age. Parents put such children to sleep in one end of a crib and find them in the other end an hour later; such children will not stay seated in bathtubs and refuse to be confined in playpens. Other babies, by contrast, move little, stay where they are placed, and appear to take in their environment in a quieter, more docile way. Both patterns are normal; they merely reflect the extremes of *activity level*, one characteristic of temperament.

#### Rhythmicity

A child who has *rhythmicity* manifests a regular rhythm in physiologic functions. Even as infants, such children tend to wake up at the same time each morning, are hungry at regular 4-hour periods, nap the same time every day, and have a bowel movement at the same time every day. They are predictable and easy to care for because their parents learn early on what to expect from them. On the other end of the scale are infants who rarely awaken at the same time 2 days in a row. They may go a long time without eating 1 day and the next day appear hungry almost immediately after a feeding. Such children are typically more difficult to care for because it is difficult to anticipate a schedule for them. Parents must constantly adapt their own routine to the child's routine.

#### Approach

*Approach* refers to a child's response on initial contact to a new stimulus. When

introduced to a new situation, some children approach the challenge in an unruffled manner. They smile and “talk” to strangers and accept a first feeding or a new food without spitting up or fussing. They explore new toys without apprehension. Other children demonstrate withdrawal rather than approach. They cry at the sight of strangers, new toys, and new foods; they fuss the first time they are placed in a bathtub. They are difficult to take on vacation or to meet a new childcare provider because they react so fearfully to new situations.

### Adaptability

*Adaptability* is the ability to change one’s reaction to stimuli over time. Infants who are adaptable can change their first reaction to a situation without exhibiting extreme distress. The first time such children are placed in a bathtub, they might protest loudly, for example, but by the third time, they sit splashing happily. This is in contrast to infants who cry for months whenever they are put into a bathtub or who cannot seem to accustom themselves to a new bed, new car seat, or new caregiver.

### Intensity of Reaction

A child who has an *intensity of reaction* meets new situations with their whole being. They cry loudly, thrash their arms, and begin temper tantrums when their diapers are wet, when they are hungry, and when their parents leave them. Other children, probably equally frustrated or angry, rarely demonstrate such overt symptoms or have a mild- or low-intensity reaction to stress.

### Distractibility

Children who are easily distracted or who can easily shift their attention to a new situation (*distractibility*) are easy to care for. If they are crying over the loss of a toy, they can be appeased by the offer of a different one. If children cannot be distracted this way, their parents may describe them as stubborn, willful, or unwilling to compromise because they persistently return to an activity or refuse to adapt or change.

### Attention Span and Persistence

*Attention span* is the ability to remain interested in a project or activity for an average length of time. Like other aspects of temperament, this can vary a great deal among children. Some play by themselves with one toy for an hour; others spend no more than 1 or 2 minutes with each toy. The degree of *persistence* also varies. Some infants keep trying to perform an activity even when they fail time after time; others stop trying after one unsuccessful attempt.

### Threshold of Response

The *threshold of response* is the intensity level of stimulation necessary to evoke a

reaction. Children with a low threshold need to meet little frustration before they react; those with a high threshold need intense frustration before they become upset over a situation or with a person.

## Mood Quality

A child who is always happy and laughing is said to have a positive *mood quality*. Obviously, this can make a major difference in the parents' enjoyment of a child; parents tend to spend more time with a child with a positive mood quality than with a child who seems always unhappy and whining or has a negative mood quality.

## Nursing Implications and Temperament

Four categories or levels of temperament are shown in [Box 28.3](#). Children who have a usual activity level and regular rhythmicity; who approach and adapt to new situations easily; and who have a long attention span, a high level of persistence, and a positive mood quality are “ideal” or “easy” children to care for from a parent's point of view. Highly active infants are much more difficult for parents to care for, especially if they demonstrate irregular physiologic rhythms, withdrawal rather than approach, and little ability to adapt. Such children require more planning and creative distraction measures.

### BOX 28.3

#### Nursing Care Planning to Empower a Family

#### CATEGORIES OF TEMPERAMENT

**Q.** Mrs. Olson asks the nurse why her children solve problems so differently.

**A.** Children's temperament can be a reason they approach problems differently.

#### **The Easy Child**

Children are rated as “easy to care for” if they have a predictable rhythmicity, approach and adapt to new situations readily, have a mild-to-moderate intensity of reaction, and have an overall positive mood quality. Most children are rated by their parents as being in this category.

#### **The Intermediate Child**

Some characteristics of both easy and difficult groups are present.

#### **The Difficult Child**

Children are “difficult” if they are irregular in habits, have a negative mood quality, and withdraw rather than approach new situations. Only about 10% of children fall into this category.

#### **The Slow-to-Warm-Up Child**

Children fall into this category if, overall, they are fairly inactive, respond only

mildly and adapt slowly to new situations, and have a general negative mood. About 15% of children display this pattern. When discussing this temperament with parents, try to use positive terms such as “ways to find a healthy fit for your child” rather than stressing ways the child is hard to manage.

Bringing characteristics of temperament to parents’ attention helps them better understand their child and lays the foundation for beginning to accept and respect the child as an individual, which is essential for successful childrearing (Hudson, Dodd, Lyneham, et al., 2011).

Noticing children’s temperament as they are admitted to a hospital can help you anticipate their probable reactions to procedures or pain. For example, a child with an intense reactivity pattern may voice even a minor discomfort loudly; a child with a less intense pattern may barely react. Both situations make it difficult to evaluate the true level of pain the children are experiencing unless temperament is considered.

### *What If . . . 28.1*

**John’s mother describes her 3-year-old twins as being “totally different” from each other. One is shy and quiet; the other is aggressive and persistent. The nurse recognizes that she probably views which child as easier to care for? What anticipatory guidance could the nurse give her to help her better understand these differences in temperament in her children?**

## **ENVIRONMENT**

Although children cannot grow taller than their genetically programmed height potential allows, their adult height can be considerably less than their genetic potential if their environment hinders their growth. For example, a child could receive inadequate nutrition because of a family’s low socioeconomic status, a parent could lack childcare skills or not give a child enough attention or stimulation, or a child could contract an infectious disease and be left with a long-term disability. Illness can lower children’s appetites, thus interfering with growth; others, such as certain endocrine disorders, directly alter growth rate. Having a parent who abuses alcohol or other substances can cause such inconsistency in care that it can affect mental health (Rossow & Moan, 2012).

Environmental influences, however, like genetic ones, are not always detrimental. For example, children with phenylketonuria, an inherited metabolic disease that leads to poor growth and cognitive challenge, can achieve normal growth and development in spite of their genetic makeup if their diet (a part of the environment) is properly regulated. The following environmental influences are those most likely to affect growth and development.

## Socioeconomic Level

Because health care and good nutrition both cost money, children born into families of low socioeconomic means may suffer from a lack of both of these. Poor health supervision can leave them without immunization against measles or other childhood illnesses and therefore vulnerable to permanent neurologic damage (Mulholland, Griffiths, & Biellik, 2012). Poor nutrition can also leave them vulnerable to disease because antibody formation depends on a good protein intake (Whitney & Rolfes, 2012).

## The Parent–Child Relationship

What a parent expects a child to become as an adult varies from culture to culture and family to family but plays a role in how much a child is guided to try to achieve in life. Cultural norms also play a role because some cultures have different perspectives on education and value different ways of contributing to society (Box 28.4).

BOX 28.4

### Nursing Care Planning to Respect Cultural Diversity

Not all nations foster the growth and development of children in the same manner, in part because of cultural variations. Childhood in the United States covers a relatively long period. In other countries, childhood is short because girls are asked to assume domestic responsibilities early in life and outside or farm work is required early for boys. In some countries, the predominant theory of childrearing is protective nurturing. Children are not rushed into new experiences like toilet training or beginning school. In others, it is customary to treat children in a harsh, strict manner, using shame or corporal punishment for discipline. Praising children for learning a new skill may be viewed as unnecessary or actually harmful because this could result in a child being subject to evil forces. In some Asian cultures, an infant's personality is thought to depend not so much on genetic or environmental influences but on the year and time of birth.

What foods children receive also varies with culture. Vegetables such as jicama and chayote, for example, may not even be recognized by children in the Northeast United States but may be popular with those in the Southwest.

Asking a parent questions such as “What do you do when your baby cries?” “What kind of things do you think a 2-year-old should be able to do?” and “What do you do when your 4-year-old misbehaves?” can help you to isolate and better understand cultural differences. Recognizing cultural variations this way helps to plan care individualized to a particular child and family.

Children who are loved and are paid attention to by their parents thrive better than those who are not (Feigelman, 2012). Luckily, for parents and children, either parent or

even a nonparent may form this primary parent–child love relationship. When assessing families, don’t just examine how much time parents spend with children; examine the quality of that time because it is the quality, not the quantity, that is most important (Box 28.5). Loss of love from a primary caregiver, as might occur with the death of a parent, or interruption of parental contact through hospitalization, imprisonment, or divorce can have such an effect on a child that it interferes with a desire to eat, improve, and advance. It is important to support parents’ active involvement in their child’s care so that a parent–child relationship is strengthened and is valued in all healthcare and childcare settings (Vicedo, 2011).

### BOX 28.5

#### Nursing Care Planning Tips for Effective Communication

You see John’s mother in clinic for a follow-up visit and ask about his socialization at meals.

*Tip:* Avoid asking multiple or compound questions because you might only receive incomplete answers. Ask individual questions with focused follow-up questions to obtain the information you need.

**Nurse:** How are you today, Mrs. Olson? How is John?

**Mrs. Olson:** I’m good.

**Nurse:** And John?

**Mrs. Olson:** He’s the same.

**Nurse:** Is your family eating more meals together?

**Mrs. Olson:** We eat together for sure three nights a week.

**Nurse:** Does John seem to enjoy that?

**Mrs. Olson:** He never talks at the table. It’s as if he isn’t there.

**Nurse:** Let’s talk about other ways you could bring John into the family.

### Ordinal Position in the Family

The position of a child in the family (e.g., first-born child, middle child, youngest child, only child) and the size of the family also have some bearing on a child’s growth and development. An only child or the oldest child in a family, for example, generally excels in language development because conversations are mainly with adults. Youngest children, in contrast, may develop language more slowly, especially if older children talk “baby talk” with them. Children learn by watching other children, however, so a youngest child who has many examples to watch may excel in other skills, such as toilet training or writing at an early age.

## Health

Diseases that come from environmental sources can have as strong an influence on growth and development as genetically inherited diseases. Infants cared for in neonatal intensive care units, for example, may develop some decrease in hearing because of the overstimulation of sound, an example of health being directly influenced by the environment (Matook, Sullivan, Salisbury, et al., 2010). Children who have residual heart impairment as a result of contracting rheumatic fever might be limited in their ability to play an active sport. The eventual degree of disability will depend, however, not only on the damage caused by the actual disease but also on the attitudes of the people around the child (i.e., how disabled they believe the child to be) (Russell, Sinclair, Poteat, et al., 2012). When parents treat children differently after they have been critically ill (i.e., don't react warmly to them), the children are referred to as "vulnerable children" (Green & Solnit, 1964). Fortunately, if an illness does not last long and leaves no permanent disability, most children achieve catch-up growth and score well on growth measures after an illness.

## Nutrition

In the past 20 years, nutrition has become a major focus of health promotion and disease prevention because the quality of a child's nutrition during the growing years (and prenatally) has such a major influence on health, weight, and stature (Whitney & Rolfes, 2012). Poor maternal nutrition may limit the growth and intelligence potential of a child by furnishing a less than desired prenatal environment. In some communities, poor nutrition has such an effect that children begin to show inadequate physical growth as early as infancy. A lack of energy and stamina prevents children from learning at their best intellectual level, which causes them to fall behind in school. In contrast, in other communities, eating too much food (or the wrong kinds of food) causes as many as 20% of children to be obese (Skinner & Skelton, 2014).

Children who become obese may develop motor skills more slowly than other children because physical movement is more tiring for them. Obese children are also likely targets of taunting by playmates and so run a risk of lacking a strong and supportive group of friends. Lack of a strong support system can lead to depression as the child reaches adolescence (Ting, Huang, Tu, et al., 2012).

Nutrition also plays a vital role in the body's susceptibility to disease because poor nutrition limits the body's ability to resist infection. Lack of calcium could leave a child prone to rickets, a disease that affects growth by causing shortening or bowing of long bones. Lack of vitamins can lead to visual impairments, poor healing, and poor bone growth. Excessive obesity is linked with the development of type 2 diabetes in children as young as 6 years of age (Sizer & Whitney, 2011) as well as being linked to hypertension and heart disease.

### *QSEN Checkpoint Question 28.2*

## EVIDENCE-BASED PRACTICE

Preventing obesity is a major healthcare goal worldwide. To determine if preschoolers are aware of what an average weight child looks like in contrast to one who is overweight, nurse researchers recruited 17 children between 4 and 5 years of age from preschool settings. Each child was weighed and measured for height so their body mass index (BMI) could be calculated and then shown images of children of various body shapes and sizes. All the children were able to correctly identify the body shape that depicted an overweight child as if they understood the concept of overweight. When asked if they liked their own body shape, however, even those who were overweight answered “yes” or apparently had difficulty applying the concept of overweight to themselves (Burgess & Broome, 2012).

John shares a similar body shape with his mother and is overweight. The nurse identifies which statement by John as typical according to the study?

- a. “No one looks fat in my family.”
- b. “I like the way I look in my uniform.”
- c. “We look like the people in these pictures.”
- d. “People shouldn’t worry about what they look like.”

Look in [Appendix A](#) for the best answer and rationale.

## Nutrition Guidelines for a Healthy Diet

Since 1980, a new edition of the *Dietary Guidelines for Americans* has been published every 5 years with the goal of promoting health and preventing disease (available at <http://health.gov/dietaryguidelines/2015/guidelines/executive-summary/>). The 2015–2020 edition of *Dietary Guidelines* focuses on healthy eating patterns. Because patterns of eating are established in early childhood and persist throughout a lifetime, it is paramount to educate parents to ensure healthy eating in children. Parents model eating patterns for their children.

Eating patterns represent the totality of all foods and beverages consumed. Nutritional needs should be met primarily from foods, especially nutrient-dense foods. Vegetables, fruits, whole grains, and dairy are associated with reduced risk of many chronic diseases and improved health in children. The new guidelines state that eating patterns can be adaptable and tailored to the individual’s social-cultural and personal preferences. It is important to explore the family’s preferences when providing nutrition education.

Physical activity is also a key recommendation. No specific recommendations are made for children under the age of 6 years, but youth ages 6 to 17 years need at least 60 minutes of physical activity per day. This can include aerobic exercise as well as muscle and bone strengthening activities 2 or more days each week.

Differences in calories for males and females start at age 9 years. They range from 1,000 calories a day for a 2-year-old to 2,400 calories a day for an 18-year-old male and

1,800 calories a day for an 18-year-old female. [Table 28.1](#) lists recommended servings for children from the five food groups. In addition, good nutrition in children should follow a number of healthy eating pattern guidelines including:

**TABLE 28.1 FOOD GROUP SERVINGS FOR CHILDREN**

Recommended Daily Amounts				
Group	Examples of Foods	Children 2–6 Years of Age	Older Children	Major Nutrients Provided By the Food Group
Grains	Cereals, rice, pasta (best if whole-grain and enriched)	6 servings	6–11 servings	Thiamine, niacin, riboflavin (if enriched), iron (if enriched), incomplete protein, carbohydrates
Vegetables	Vegetables (yellow and green)	3 servings	3–5 servings	Vitamin A, iron, calcium, carbohydrates (include vitamin A source at least every other day)
Fruit	Oranges, apples, lemons	2 servings	2–4 servings	Vitamin C (include vitamin C daily), carbohydrates
Dairy	Whole milk and other milk products such as yogurt and cheese	2 servings	2–3 servings	Calcium, phosphorus, complete protein, riboflavin, niacin, vitamin D (if vitamin D–fortified milk used), fats
Protein	Muscle meats (veal, beef, pork) dry beans, eggs, fish, poultry	2 servings	2–3 servings	Complete protein, iron, thiamine, riboflavin, niacin, vitamin B <sub>12</sub> , fats

From Office of Disease Prevention and Health Promotion. (2016). *Top 10 things you need to know about the 2015–2020 Dietary Guidelines for Americans*. Retrieved from <http://health.gov/news/dietary-guidelines-digital-press-kit/2016/01/top-10-things-you-need-to-know/>

- **Eat a variety of foods.** Choices from all food groups—dairy, protein, fruits, vegetables, and grains—should be included in meals every day. It is also

important to vary choices within each food group because not all foods within a group are nutritionally equivalent.

- **Balance the food you eat with physical activity and maintain or improve your weight.** Although the tendency for obesity may be inherited, being overweight in early life also seems to play a long-term role. Urge parents to be certain their infants receive all the nutrients they need for the substantial growth they are undergoing (including a percentage of fat because this is important for myelination of nerves); at the same time, it is important that infants not be overfed so they do not become obese (Kmietowicz, 2012). Physical activity, balanced with calcium intake, is the secret to strong bones and the reduction of osteoporosis (Jones, 2011).
- **Choose a diet with plenty of grain products, vegetables, and fruits.** Foods with starch and fiber are more beneficial for gastrointestinal function than more processed foods. Fiber, in particular, has been linked to the lowered incidence of a variety of illnesses such as constipation and perhaps colon cancer in later life (Brownawell, Caers, Gibson, et al., 2012). Fiber can be included as early as during preschool years in the form of whole-grain cereals and raw fruits such as apples.
- **Choose a diet low in saturated fat and trans fats.** According to the *2015-2020 Dietary Guidelines*, “Healthy eating patterns limit saturated and *trans* fats. Less than 10% of daily calories should come from saturated fats. Foods that are high in saturated fat include butter, whole milk, meats that are not labeled as lean, and tropical oils such as coconut and palm oil. Saturated fats should be replaced with unsaturated fats, such as canola or olive oil.” For children, fat intake does not need to be restricted for the first 2 years of life because fat is necessary for myelination of spinal nerves. Thereafter, fat intake can be tailored to meet the guidelines of 30% of total intake (saturated fat should be less than 7% of total intake) for both children and adults.
- **Choose a diet moderate in sugars.** Too much sugar in a diet can contribute to both dental caries and obesity (Danyliw, Vatanparast, Nikpartow, et al., 2012). In addition, refined sugar such as is used in soft drinks, prepared foods, candy, and chocolate represents empty calories, or is high in calories yet provides no essential nutrients. Although children need adequate carbohydrates for energy, parents can give their children a good start by preventing excessive sugar intake.
- **Choose a diet moderate in salt and sodium.** The taste for salt is acquired and plays a role in both heart disease and hypertension. If unsalted or only lightly salted solid food is offered to infants from the time they begin solid food, they do not develop a desire for heavily salted foods. It is helpful to assess the diet of school-age children and check whether they are eating a diet heavier in salt than necessary because of the availability of many salty after-school snacks.
- **If drinking alcoholic beverages, do so in moderation.** Adolescents are at increased risk for establishing unhealthy patterns of alcohol use, particularly

binge drinking, as they begin to explore adult life. Educating them about the long-term consequences, such as liver disease, from long-term alcohol use is as important as educating them on the importance of healthy nutrition to help ensure proper growth (see [Chapter 33](#) for a discussion of adolescents).

### Components of a Healthy Diet

Eating a variety of foods from all five food groups in moderation is a way of guaranteeing the intake of a balanced diet of proteins, carbohydrates, fats, vitamins, and minerals ([Fig. 28.3](#)).

**Figure 28.3** Good nutritional habits developed early in life provide a child with a health advantage.

#### *Protein*

Protein is the major component of bones, skin, hair, and muscle and is responsible for a wide variety of essential functions in the body. Because it is essential for growth, protein intake is crucial for children. Complete proteins contain all amino acids; incomplete proteins do not, but combining two types of incomplete proteins (e.g., pasta and beans) allows the body to construct complete proteins.

#### *Carbohydrate*

Carbohydrates are the main and preferred fuel of the body to supply energy, so they are essential to the functioning of body systems and the neurologic system, in particular. This makes carbohydrates vitally important to infants and toddlers because their brain cells are actively growing. As all athletes learn, sugar supplies an immediate but short-term source of energy; starches, as a rule, supply sustained energy.

## *Fat*

Dietary fat is a second source of energy for the body. It can be an immediate energy source or can be stored if not used, then released when energy is required. Some fat deposits also serve as insulating material for subcutaneous tissues; in infants, fats are necessary to ensure myelination of nerve fibers.

## *Vitamins*

Vitamins are organic compounds essential for specific metabolic actions in cells. They do not produce energy but are needed by cells to produce energy. For children, fat-soluble vitamins (A, D, K, and E) are mainly supplied by fortified dairy products, fortified cereals, and plant or fish oils. Such vitamins are not absorbed from the gastrointestinal tract by themselves but only if accompanied by fat molecules, which is why fish and plant oils are such good sources of these. Once absorbed, they are used by the cells for growth and function or are stored in the liver or fat cells for later use. Because fat-soluble vitamins can be stored by the body this way, an infant or child can ingest too many of them, although overdosing usually occurs from overuse of supplements rather than from dietary sources.

Water-soluble vitamins (B complex and C) do not need fat for absorption and are not stored well in the body, so they must be taken daily to maintain effective levels in the body. They are found most abundantly in fruits and vegetables. Sources and functions of all the essential vitamins and results of their deficiencies are summarized in [Table 28.2](#).

**TABLE 28.2 VITAMINS ESSENTIAL FOR HEALTH**

<b>Vitamin</b>	<b>Selected Dietary Sources</b>	<b>Function in Body</b>	<b>Results of Deficiency</b>
<i>Fat Soluble</i>			
A (retinol)	Liver, carrots, spinach	Important for night vision and corneal integrity and growth	Keratinization of the eye (xerophthalmia) and blindness
D	Egg yolk, margarine, salmon, fortified milk, fortified cereals	Regulates absorption of calcium and phosphorus for bone growth	Rickets (bone deformity) in growing children
E	Margarine, corn oil, peanuts	An antioxidant that protects red blood cells from destruction by oxygen	In immature infants, severe anemia from destruction

K	Cabbage, spinach, pork, best source: green leafy vegetables	Aids blood clotting (synthesis of prothrombin)	of red blood cells Bleeding from lack of sufficient clotting action
<i>Water Soluble</i>			
B complex:			
Thiamine	Wheat germ, yeast, pork	Important for use of glucose in cells	Beriberi, a disease that causes nerve paralysis
Riboflavin	Beef, chicken, liver, avocados, milk	Breaks down fatty acids and amino acids for energy	Red swollen tongue, inflamed eyes, fissures of lips
Niacin	Peanuts, rice bran, liver	Converts glucose to energy; involved in carbohydrate, protein, and fat metabolism	Pellagra (diarrhea, mental confusion, dermatitis, death)
Vitamin B <sub>6</sub> (pyridoxine)	Liver, herring, salmon, chicken, fish, pork, eggs	Metabolizes amino acids and glucose	Neuritis, depression, nausea, vomiting
Vitamin B <sub>12</sub> (cobalamin)	Lamb, beef kidney, egg yolk, animal products	Blood formation; DNA and RNA synthesis; myelin formation; carbohydrate, protein, and fat metabolism	Macrocytic, megaloblastic anemia (large, nonfunctioning red blood cells)
Folic acid (folacin)	Liver, asparagus, bran	Red and white blood cell structure	Poor red blood cell formation
C (ascorbic acid)	Broccoli, collards, citrus fruit	Collagen structure, antioxidant	Scurvy (weakness, easy bleeding, joint pain)

All fat-soluble vitamins can be absorbed only in the presence of lipids and can be transported only in the presence of protein.

### *Minerals*

Minerals are necessary for building new cells as well as for the regulation of body processes such as fluid and electrolyte balance, nerve transmission, and muscle contractions, making them vital for optimal health in a growing infant or child. Minerals

are classified according to the amounts needed daily. If more than 100 mg is needed daily, a mineral is a *macronutrient* (a major mineral). If the amount needed is less than 100 mg, it is a minor mineral or *micronutrient*. Trace minerals refer to those needed in only extremely small amounts. Sources and functions of various minerals and results of their deficiencies are shown in [Table 28.3](#).

**TABLE 28.3 MINERALS ESSENTIAL FOR HEALTH**

<b>Mineral</b>	<b>Selected Dietary Sources</b>	<b>Function in Body</b>	<b>Results of Deficiency or Excess</b>
<i>Macronutrients</i>			
Calcium	Milk, hard cheese	Formation of bone and teeth, muscle contractility	Improper bone growth and maintenance shown by diseases such as rickets in children
Phosphorus	Milk, meats	Formation of bone and teeth, used in cell structure, aids use of glucose	Deficiency unlikely as long as calcium and protein needs are met
Sodium	Table salt	Regulates fluid volume and pH	Deficiency rare but excess leads to hypertension in genetically determined individuals
Chloride	Table salt	Formation of hydrochloric acid, regulates body fluid with sodium	Deficiency rare except with vomiting, which causes loss of hydrochloric acid
Potassium	Meats, dried fruits	Major cation of cells, essential for electrical conduction in muscle and therefore in heart action	Deficiency leading to muscle weakness and heart irritability, occurs in people taking diuretics because potassium is excreted with urine
Sulfur	Milk, meat, eggs	Essential for protein formation and cell growth	Deficiency rare as long as protein intake is adequate
Magnesium	Cocoa, nuts, green leafy vegetables	Relaxation of muscles after contraction	Deficiency leads to muscle contraction
<i>Micronutrients</i>			

Iodine	Seafood, dairy, iodized salt	Formation of thyroxine and regulation of metabolic rate	Reduced basal metabolic rate, goiter (enlarged thyroid gland)
Iron	Meats, fish, dried fruits, nuts, fortified cereals	Formation of hemoglobin, transport of oxygen to body cells	Deficiency leads to microcytic (small) and hypochromic (pale) red blood cells (iron-deficiency anemia); excess leads to infiltration of tissue (hemosiderosis)
Copper	Nuts, raisins, legumes	Formation of collagen and nerve fibers	Anemia, neutropenia, and severe bone demineralization
Fluoride	Fluoridated water	Reduces dental caries and demineralization from bone	Dental caries
Zinc	Meat, eggs, seafood	Formation of eyes, male reproductive organs, insulin, and taste sensation	Diabetes-like symptoms because of decreased insulin production, poor taste sensation leading to poor food intake
Manganese	Nuts, grains, legumes	Formation of enzymes	Deficiency unlikely
Molybdenum	Organ meats, grains	Mobilizes iron in body	Deficiency apparently unknown
Cobalt	Many sources	Formation of red blood cells in bone marrow	Deficiency rare as long as animal food sources are ingested
Selenium	Seafood, kidney, liver	Immunoglobulin formation and prevention of oxidation of cells	Deficiency unknown
Chromium	Meat, cheese, grains	Glucose metabolism	Deficiency seen only in severe malnutrition
Silicon	Many sources	Aids growth of connective tissue and bone	Retarded growth and bone deformity
Nickel	Many sources	Duplication of growth of cells	Has not been determined to be essential for health in humans

Vanadium	Many sources	Lipid metabolism	Has not been determined to be essential for health in humans
Tin	Many sources	Blood formation	Has not been determined to be essential for health in humans

## Promoting Adequate Nutritional Intake in Vegetarian Diets

Increasing numbers of adults of childrearing age are vegetarians; therefore, many women during pregnancy and children during their years of most rapid growth eat such diets (Krebs & Primak, 2011). Families select vegetarian diets for many reasons, including:

- Ecologic: If everyone ate lower on the food chain, world hunger could be reduced.
- Medical or health related: Avoiding animal foods stops the ingestion of hormones and chemicals used in meat and poultry production as well as lowers serum cholesterol and saturated fat, thereby reducing the frequency of atherosclerosis and obesity.
- Philosophical: They may hold a belief that killing animals for food is unnecessary or wrong.
- Spirituality: Religions such as Hinduism and Seventh-Day Adventist promote a vegetarian lifestyle. Islam and Judaism also have some restrictions on what meat can be eaten.
- Economic: Vegetables and grains are less expensive than animal-based food.

Although a balanced vegetarian diet is sufficient during childhood, careful assessment and family education may be necessary to ensure a child's intake is adequate for growth. Urge parents to become knowledgeable about good nutrition so they are aware of ways to include essential nutrients in vegetarian diets for growing children, particularly if their children participate in active sports.

Five main types of vegetarian diets commonly seen include:

- The lacto-ovo-vegetarian diet, which includes dairy products ("lacto"), eggs ("ovo"), and plants (vegetables, fruits, and grains)
- The ovovegetarian diet, which includes eggs but excludes dairy products
- The lacto-vegetarian diet, which includes dairy products but excludes eggs
- The vegan diet, which excludes all animal products and consists of only vegetables, fruits, and grains
- The macrobiotic diet, which is a primarily vegetarian diet. Its main sources of protein are grains, seeds, and nuts, but small quantities of egg, fish, and wild game can be added.

The vegan diet is obviously the most restrictive of these diets, so it is usually recommended that parents be extremely conscientious about including a variety of foods to help ensure their children are receiving adequate nutrients. All families who eat vegetarian diets need to be conscientious that their children receive adequate amounts of

several specific nutrients.

### *Protein*

Lacto-ovo-vegetarian, ovo-vegetarian, and lacto-vegetarian diets provide all of the essential amino acids for growth (both eggs and dairy products provide complete proteins). Vegan diets can also supply essential amino acids by cereal and legume combinations such as peanut butter and wheat bread, corn and lima beans, pasta and beans, corn tortillas and beans, or chickpeas and sesame seeds. Complementary proteins do not have to be eaten at the same meal to be effective, as long as varied plant proteins are consumed over the course of a day.

### *Calcium*

Dairy products such as milk and cheese supply the usual source of calcium for children. When dairy products are not eaten, calcium must be obtained from other sources such as green leafy vegetables (broccoli, spinach, or grain products) or calcium-fortified tofu or soy flour.

### *Iron*

Because there may be an association between iron-deficiency anemia and learning deficits, children need to consume good sources of iron ([Black, Quigg, Hurley, et al., 2011](#)). Meat is the richest source of iron. With meat omitted from a diet, parents should include this from foods such as legumes, whole grains, fortified cereals, dark-green leafy vegetables, or dried fruits. Vitamin C enhances the duodenal absorption of iron found in plants, so eating fruits and vegetables rich in vitamin C such as oranges or broccoli aids iron absorption.

### *Vitamins*

Vitamin B<sub>12</sub> is unique among vitamins because it is present only in animal products ([Whitney & Rolfes, 2012](#)). This includes eggs and milk. Children who totally omit animal sources need to have this vitamin supplemented daily. Reliable supplements of vitamin B<sub>12</sub> include vitamin B<sub>12</sub> tablets or fortified foods such as commercial breakfast cereals, soy beverages, and some brands of nutritional yeast.

Riboflavin is a B vitamin normally supplied by fortified milk. When dairy products are not eaten, it can be supplied by soy milk, vegetables, or brewer's yeast, all of which contain all the B vitamins except vitamin B<sub>12</sub>. Good sources of riboflavin in vegan diets are whole and enriched grains and cereals, nuts, and dark-green leafy vegetables.

Vitamin D is necessary for calcium and phosphorus metabolism and is normally supplied in fortified milk. It is not present in plant foods and therefore must be supplemented in a vegan or ovo-vegetarian diet by vitamin D drops or tablets. Exposure to sunshine also supplies vitamin D but is generally an inadequate source ([Whitney & Rolfes, 2012](#)).

## Minerals

Zinc is present primarily in animal foods but is also present in brewer's yeast, nuts, and wheat germ; therefore, zinc deficiency is not a problem with vegetarian diets. Iodine is supplied normally by seafood. In a vegan or vegetarian diet, it can be supplied by seaweed and iodized table salt. Many families add a small amount of powdered kelp (a seaweed) to food two or three times a week to ensure an adequate iodine intake. Calcium, as mentioned previously, can be supplied by green leafy vegetables or a daily supplement.

## Total Calories

Plant foods have fewer total calories than meats. Generous servings of nuts and legumes are recommended to take the place of meat servings. All other recommended serving sizes for various caloric level patterns are the same as those presented in meat-containing food guidelines (available at <http://thePoint.lww.com/Flagg8e>).

## Theories of Child Development

A *theory* is a systematic statement of principles that provides a framework for explaining a phenomenon. Developmental theories are theories that provide road maps for explaining human development.

**Developmental tasks** are a skill or a growth responsibility arising at a particular time in an individual's life, the achievement of which will provide a foundation for the accomplishment of future tasks. It is not so much chronologic age as the completion of the task that defines whether a child has passed from one developmental stage of childhood to another. For example, children are not toddlers just because they are 1 year plus 1 day old; they become toddlers when they have passed through the developmental stage of infancy. For reference, however, childhood is generally divided into the seven age periods shown in [Table 28.4](#).

**TABLE 28.4 BASIC DIVISIONS OF CHILDHOOD**

Stage	Age Period
Neonate	First 28 days of life
Infant	1 month–1 year
Toddler	1–3 years
Preschooler	3–5 years
School-age child	6–12 years
Adolescent	13–17 years
Late adolescent	18–21 years

A number of types of developmental theories have been proposed to describe how children grow emotionally, psychologically, and intellectually as they pass through these different periods. *Sociocultural theories* are those that stress the importance of environment on growth and development. *Learning theory* suggests children are like blank pages that can be shaped by learning. Cognitive theorists such as Piaget stress learning skills are the key to achieving success in life. *Epigenetic theories* stress that genes are the true basis for growth and development. Previously discounted as too simplistic, epigenetic theories are being revised and given new credence based on new knowledge about genes now available through the Human Genome Project and the mapping of all human genes (Naidoo, Pawitan, Soong, et al., 2011).

Still, other theories deal mainly with negative aspects of childrearing that can lead to mental illness in children, either immediately, or later when a child reaches adulthood (see discussion on Freud that follows). Erikson is a psychoanalyst who discussed positive aspects necessary for normal growth and development so that a mentally healthy and productive adult will result (Erikson, 1993).

## FREUD’S PSYCHOANALYTIC THEORY

Sigmund Freud (1856–1939), an Austrian neurologist and the founder of psychoanalysis, offered the first real theory of personality development (Freud, 1962; Freud & Brill, 1995). The theory, based on Freud’s observations of mentally disturbed adults, described adult behavior as being the result of instinctual drives of a primarily sexual nature (*libido*). He described child development as being a series of psychosexual stages in which a child’s sexual gratification becomes focused on a particular body part at each stage. These stages are summarized in Table 28.5.

**TABLE 28.5 SUMMARY OF FREUD’S AND ERIKSON’S THEORIES OF PERSONALITY DEVELOPMENT**

	Freud’s Stages of Childhood		Erikson’s Stages of Childhood	
	<i>Psychosexual Stage</i>	<i>Nursing Implications</i>	<i>Developmental Task</i>	<i>Nursing Implications</i>
Infant	Oral stage: Child explores the world by using the mouth.	Provide oral stimulation by giving pacifiers; do not discourage thumb sucking.	Developmental task is to form a sense of trust versus mistrust. Child learns to love and be loved.	Provide a primary caregiver. Provide experiences that add to security.
Toddler	Anal stage: Child learns to control	Help children achieve bowel and	Developmental task is to form a sense of autonomy	Provide opportunities for independent

	urination and defecation.	bladder control without undue emphasis on its importance.	versus shame. Child learns to be independent and make decisions for self.	decision making, such as choosing own clothes.
Preschooler	Phallic stage: Child learns sexual identity through awareness of genital area.	Accept children's sexual interest, such as fondling his or her own genitals, as a normal area of exploration.	Developmental task is to form a sense of initiative versus guilt. Child learns how to do things (basic problem solving) and that doing things is desirable.	Provide opportunities for exploring new places or activities. Allow free-form play.
School-age child	Latent stage: Child's personality development appears to be nonactive or dormant.	Help children have positive experiences with learning so their self-esteem continues to grow.	Developmental task is to form a sense of industry versus inferiority. Child learns how to do things well.	Provide opportunities such as allowing child to assemble and complete a short project.
Adolescent	Genital stage: Adolescent develops sexual maturity and learns to establish satisfactory relationships with others.	Provide appropriate opportunities for the child to relate with opposite and own sex relationships.	Developmental task is to form a sense of identity versus role confusion. Adolescents learn who they are and what kind of person they will be.	Provide opportunities for an adolescent to discuss feelings about events important to him or her. Offer support and praise for decision making.

### Criticisms of Freud's Theory

To construct his theory, Freud relied on his knowledge of people seen in his practice and looked at circumstances that lead to mental illness (Freud & Brill, 1995). This “looking at illness” rather than “looking at wellness” perspective limits the applicability

of the theory as a health promotion measure. The theory is also criticized as being gender biased because females are viewed in a less favorable light than males. Gender bias has the potential to perpetuate gender inequality, which doesn't provide a level playing field for women (Brandt, 2011).

### *QSEN Checkpoint Question 28.3*

#### **TEAMWORK & COLLABORATION**

John, at 6 years old, is a school-age child. What should members of the nurse's interprofessional team recognize when caring for school-age children according to Freud?

- a. It's important for parents to teach children creativity during this time.
- b. Children develop their moral compass or spirituality during school-age years.
- c. Freud saw the school-age period as a largely latent or inactive period.
- d. Every school-age child needs responsibilities in order to learn trust and integrity.

*Look in Appendix A for the best answer and rationale.*

## **ERIKSON'S THEORY OF PSYCHOSOCIAL DEVELOPMENT**

Erik Erikson (1902–1996) was trained in psychoanalytic theory but later developed his own theory of psychosocial development, a theory that stresses the importance of culture and society in development of the personality (Erikson, 1993). One of the main tenets of his theory, that a person's social view of self is more important than instinctual drives in determining behavior, allows for a more optimistic view of the possibilities for human growth. Whereas Freud looked at ways mental illnesses develop, Erikson looked at actions that lead to mental health. He describes eight developmental stages covering the entire life span. At each stage, there is a conflict between two opposing forces. The resolution of each conflict, or accomplishment of the developmental task of that stage, allows the individual to go on to the next phase of development. Table 28.5 summarizes Erikson's developmental stages through adolescence as compared to Freud's stages.

### **The Infant**

According to Erikson (1993), the developmental task for infants is learning **trust versus mistrust** (other terms are "learning confidence" or "learning to love"). When an infant is hungry, a parent feeds and makes the infant comfortable again. When an infant is wet, a parent changes his or her diaper and the infant is dry again. When an infant is cold, a parent holds the baby closely. By these simple processes, infants learn to trust that when they have a need or are in distress, a parent will come and meet that need.

If care is inconsistent, inadequate, or rejecting, infants learn mistrust; they become fearful and suspicious of people and then of the world. Like a burned child who avoids fire, emotionally burned children shun the potential pain of further emotional

involvement. This can cause children to be “stuck” emotionally at this stage, although they continue to grow and develop in other ways.

Fortunately, because not all children achieve developmental tasks readily, each task need not be resolved once and for all the first time it arises. The problem of trust versus mistrust, for example, is not resolved forever during the first year of life but arises again at each successive stage of development. Children who enter school with a sense of mistrust may come to trust a teacher with whom they form a close relationship; given this second chance, children can overcome early mistrust. Likewise, children who come through infancy with a sense of trust intact may have a sense of mistrust activated at a later stage if their parents divorce under unpleasant circumstances or if the child is maltreated.

## The Toddler

The developmental task of the toddler is to learn **autonomy versus shame or doubt**. Autonomy (self-governance or independence) arises from a toddler’s new motor and mental abilities. Children not only take pride in the new things they can accomplish but also want to do everything independently, whether it is pulling the wrapper off a piece of candy, selecting a vitamin tablet out of a bottle, flushing the toilet, or replying, “No!”

Infants appear to have difficulty differentiating between their bodies and those of others; they think of their bodies as extensions of their parents or their primary caregivers. When infants approach toddlerhood, they begin to make the differentiation. As they recognize they are separate individuals, toddlers also realize they do not always have to do what others want them to do. From this realization comes the reputation toddlers have for being negativistic, obstinate, and difficult to manage.

This reputation probably exists because parents misinterpret children’s cues. For example, children’s refusal to accept help putting on shoes may be seen by a parent as disobedience, whereas children may view this as insisting on performing a task they can do independently—a positive expression of autonomy.

Children who are constantly told not to try things because they will hurt themselves may be left with a stronger sense of doubt than confidence at the end of the toddler period. Children who are made to feel it is wrong to be independent may leave the toddler period with a stronger sense of shame than autonomy.

If parents recognize that toddlers need to practice those things they are capable of doing, at their own pace and in their own time, their children will develop a sense of being able to control both their muscles and impulses. However, if children leave this stage with less autonomy and shame or doubt, they can be disabled in their attempts to achieve independence and can lack confidence in their abilities to achieve well into adolescence and adulthood (Fig. 28.4).

**Figure 28.4** A toddler enjoys active, independent exploration as part of building a sense of autonomy. Here, a boy plays outdoors on playground equipment, a setting that allows for independent decision making.

### *What If . . . 28.2*

**John's parents repeat that they find him cold and unloving. The nurse knows he lived in a series of foster homes before he was adopted into their family. What developmental task has John been unable to complete? Could it be related to the frequent moves? What actions could the nurse recommend his new parents take to try to strengthen his unfulfilled developmental task at this point?**

## **The Preschooler**

The developmental task of the preschool period is learning **initiative versus guilt**, or learning how to do things such as drawing, building an object from blocks, or playing dress up. Children initiate motor activities of various sorts on their own or no longer merely respond to or imitate the actions of other children or their parents. The same is true for language and fantasy activities.

Another word for initiative is creativity. Whether children leave this stage with a sense of initiative outweighing a sense of guilt depends largely on how parents respond to self-initiated activities. When children are given much freedom and opportunity to initiate motor play such as running, bike riding, sliding, and wrestling or are exposed to

such play materials as finger paints, sand, water, and modeling clay, their sense of initiative is reinforced. Initiative is also encouraged when parents answer a child's questions (intellectual initiative) and do not inhibit fantasy or play activity. In contrast, if children are made to feel their motor activity is bad (perhaps in a small apartment or in a hospital), their questions are a nuisance, or their play is silly, they can develop a sense of guilt over self-initiated activities that will persist in later life. Those who do not develop initiative have limited brainstorming and problem-solving skills later in life; instead, they wait for clues or guidance from others before acting. They may also be unable to use simulated learning effectively (Rutherford-Hemming, 2012).

### The School-Age Child

Erikson (1993) viewed the developmental task of the school-age period as developing **industry versus inferiority**, or self-confidence rather than inferiority. During the preschool period, children learned initiative (i.e., how to do things). During school age, children learn how to do things *well*. A school-age child, while doing a project, will ask, "Am I doing this right? Is it okay to use blue?" When they are encouraged in their efforts to do practical tasks or make practical things and are praised and rewarded for the finished results, their sense of industry grows (Fig. 28.5). Parents who see their children's efforts at making and doing things as merely "busy work" or who do not show appreciation for their children's efforts may cause them to develop a sense of inferiority rather than pride and accomplishment.

**Figure 28.5** School-age children develop a sense of industry by working on projects that result in a feeling of accomplishment.

During this stage of life, a child's world grows to include the school and

community; success or failure in those settings can have as lasting an impact as experiences at home. Children with an intelligence quotient of 80 or 90 (slightly below normal), for example, may have a learning style so different from the average child's that they have difficulty competing. This leads to repeated failures in their efforts to learn and reinforces a sense of inferiority even when their sense of industry has been rewarded and encouraged at home. However, children whose sense of industry has not been supported at home may have it revitalized at school through the efforts of a committed teacher. A nurse during a hospitalization could also fulfill this role.

### *What If . . . 28.3*

**John's father does not allow his 3-year-old twins to play with finger paints. If they play with crayons, he insists they color between the lines. According to Erikson, which is more important for preschoolers: allowing free-form play or teaching children that neatness and accuracy count?**

## **The Adolescent**

The new interpersonal dimension that emerges during adolescence is the development of a sense of **identity versus role confusion**. To achieve this, adolescents must bring together everything they have learned about themselves as a son or daughter, an athlete, a friend, a fast-food cook, a student, a garage band musician, and so on, and integrate these different images into a whole that makes sense. If adolescents cannot do so, they are left with role confusion or are left unsure of what kind of person they are or what kind of person they want to become. Some adolescents may seek a negative identity: being identified as a drug abuser or runaway is not a positive identification but may be preferable to seemingly having no identity at all. Body piercing and tattooing are ways adolescents can help establish their identity because they are outward expressions of who adolescents think they are (Fig. 28.6).

**Figure 28.6** Adolescents express their identity in different ways. Body piercing and tattoos makes a strong statement.

### **The Late Adolescent**

The developmental crisis of late adolescence is achieving a sense of **intimacy versus isolation**. Intimacy is the ability to relate well with other people in preparation for developing future relationships.

A sense of intimacy grows out of earlier developmental tasks because people need a strong sense of identity before they can reach out fully and offer deep friendship or love to others. Because there is always the risk of being rejected or hurt when offering love or friendship, individuals cannot offer it if they do not have confidence that they can cope with rejection or if they did not develop a sense of trust as an infant or autonomy as a toddler. This is important for maternal and child health nursing because parents without a sense of intimacy may have more difficulty than others accepting a pregnancy and beginning to love a new child.

### QSEN Checkpoint Question 28.4

#### QUALITY IMPROVEMENT

John, who is 6 years old, is a school-age child. According to Erikson, the nurse should identify which developmental task to integrate health promotion activities with during this period?

- How to be creative
- How to think abstractly
- How to trust others
- How to do things well

Look in [Appendix A](#) for the best answer and rationale.

### A Criticism of Erikson's Theory

Erikson's main contribution to human development was the creation of stages, so that development can be broken down into separate phases for study. A criticism of his theory is that life does not occur in easily divided stages, and trying to divide it that way can create superficial divisions.

### PIAGET'S THEORY OF COGNITIVE DEVELOPMENT

Jean Piaget (1896–1980), a Swiss psychologist, introduced concepts of cognitive development, or the way children learn and think. The theory has roots similar to those of both Freud and Erikson, but with differing aspects ([Inhelder & Piaget, 1958](#)). Piaget defined four stages of cognitive development, within the stages of growth, then finer units or **schemas**. To progress from one period to the next, children reorganize their thinking processes to bring them closer to adult thinking. These stages of cognitive development are summarized in [Table 28.6](#).

**TABLE 28.6 PIAGET'S STAGES OF COGNITIVE DEVELOPMENT**

Stage of Development	Age Span	Nursing Implications
<i>Sensorimotor</i>		
Neonatal reflex	1 month	Stimuli are assimilated into beginning mental images. Behavior entirely reflexive.
Primary circular reaction	1–4 months	Hand–mouth and ear–eye coordination develop. Enjoyable activity for this period: a rattle or tape of parent's voice.
Secondary circular reaction	4–8 months	Infant learns to initiate, recognize, and repeat pleasurable experiences from environment. Good toy for this period: mirror; good game: peek-a-boo.

Coordination of secondary reactions	8–12 months	Infant can plan activities to attain specific goals. Good toy for this period: nesting toys (i.e., colored boxes).
Tertiary circular reaction	12–18 months	Child is able to experiment to discover new properties of objects and events. Good game for this period: throw and retrieve.
Invention of new means through mental combinations	18–24 months	Transitional phase to the preoperational thought period. Good toys for this period: those with several uses, such as blocks or colored plastic rings.
Preoperational thought	2–7 years	Thought becomes more symbolic; can arrive at answers mentally instead of through physical attempt. Comprehends simple abstractions but thinking is basically concrete and literal. Child is egocentric (unable to see the viewpoint of another). Displays static thinking (inability to remember what they started to talk about so at the end of a sentence children are talking about another topic). Concept of time is now, and concept of distance is only as far as they can see. <b>Centering</b> or focusing on a single aspect of an object causes distorted reasoning. No awareness of reversibility (for every action there is an opposite action) is present. Unable to state cause–effect relationships, categories, or abstractions. Good toy for this period: items that require imagination, such as modeling clay.
Concrete operational thought	7–12 years	Concrete operations includes systematic reasoning. Uses memory to learn broad concepts (fruit) and subgroups of concepts (apples, oranges). Classifications involve sorting objects according to attributes such as color; seriation, in which objects are ordered according to increasing or decreasing measures such as weight; and multiplication, in which objects are simultaneously classified and seriated using weight. Child is aware of reversibility, an opposite operation or continuation of

		reasoning back to a starting point (follows a route through a maze and then reverses steps). Understands conservation, sees constancy despite transformation (mass or quantity remains the same even if it changes shape or position). Good activity for this period: collecting and classifying natural objects such as native plants or sea shells. Expose child to other viewpoints by asking questions such as, “How do you think you’d feel if you were a nurse and had to tell a boy to stay in bed?”
Formal operational thought	12 years	Can solve hypothetical problems with scientific reasoning. Good activity for this period: “talk time” to sort through attitudes and opinions.

From Piaget, J. (1961). *The growth of logical thinking from childhood to adolescence*. New York, NY: Basic Books, with permission.

## The Infant

Piaget referred to the infant stage as the first four stages of the **sensorimotor stage**. Sensorimotor intelligence is practical intelligence because an infant is not yet able to use words and symbols for thinking and problem solving at this early age. At the beginning of life, babies relate to the world through their senses, using only reflex behavior. During this stage, infants learn objects in the environment—their bottle, blocks, their bed, or even a parent—are permanent and continue to exist even though they are out of sight or changed in some way. For example:

- Infants will search for a block hidden by a blanket, knowing the block still exists.
- Infants can recognize a parent remains the same person whether dressed in a robe and slippers or pants and a T-shirt.
- Infants are only ready to play peek-a-boo when they’ve mastered permanence because only then do they realize the person playing with them exists behind his or her hands.
- Infants identify that they are a separate entity from objects. They learn where their body stops and their bed, playthings, or parent begins.

A great deal of the mouthing and handling of objects by infants and the delight of watching a caregiver appear is part of discovering permanence.

Infants can identify their parents as different from other adults as early as 4 months of age. The world begins to make sense and the developmental task of achieving trust falls into place when the concept of **permanence** has been learned (i.e., infants know their parents exist and will return to them). Gaining a concept of permanence also contributes to separation anxiety, which can begin between 8 and 12 months of age.

During this stage, infants continue to cry for their parents because they know their parents still exist even when out of sight.

## The Toddler

The toddler period is one of transition as children complete the fifth and sixth stages of the sensorimotor period and begin to develop some cognitive skills of the *preoperative* period, such as symbolic thought and egocentric thinking (see [Chapter 30](#)). Children use trial and error to discover new characteristics of objects and events. A toddler sitting in a high chair who keeps dropping objects over the edge of the tray is exploring both permanence and the different actions of toys. For example, during these periods, toddlers:

- Complete their understanding of object permanence.
- Begin to be able to use symbols to represent objects.
- Start to draw conclusions only from obvious facts that they see.

## The Preschooler

Preschool children move on to a substage of preoperational thought termed *intuitive thinking*. During this period, when young children look at an object, they are able to see only one of its characteristics. For example, they see a banana is yellow but do not notice that it is also long. Intuitive thinking is noticeable when children are learning about medicine (they observe it tastes bitter but cannot understand it is also good for them).

Intuitive thinking contributes to the preschooler's lack of **conservation** (the ability to discern truth, even though physical properties change) or **reversibility** (ability to retrace steps). For example, if preschoolers see water poured from a short, fat glass into a tall, thin one, they will notice only one changing characteristic. They might say there is now more water in the second glass (because the level has risen) or there is less water in the second glass (because the second glass is thinner). When the water is poured back into the first glass, they still will not understand the amount of water is unchanged, only its appearance. This immature perception leads children to make faulty conclusions as it did during the toddler period. It takes more years of development and practice for children to learn that when thought processes (i.e., knowing the amount of water did not change) and perceptions conflict, thought processes are more trustworthy.

Preschool thinking is also strongly influenced by **role fantasy** or how children would like something to turn out. Children use **assimilation** (taking in information and changing it to fit their existing ideas) as a part of this. For example, because a child wants to go outside and play, he says the outside is calling him to come and play. Children believe their wishes are as real as facts and dreams are as real as daytime happenings during this stage. They perceive animals and even inanimate objects as being capable of thought and feelings (e.g., a dog took their doll because the dog was feeling sad, a footstool meant to trip them). This phenomenon is often called “magical

thinking.” Magical thinking fades as, later on, children learn **accommodation** (they change their ideas to fit reality rather than the reverse).

### *QSEN Checkpoint Question 28.5*

#### **PATIENT-CENTERED CARE**

John, who is 6 years old, says his broken leg wants to get better. When choosing an accurate and empathetic response, the nurse should be aware John is using what form of cognition?

- a. Magical thinking
- b. Deductive reasoning
- c. Concrete operational thinking
- d. Sensorial thought

*Look in [Appendix A](#) for the best answer and rationale.*

### **The School-Age Child**

Piaget viewed school age as a period during which *concrete operational thought* begins because school-age children can be seen using practical solutions to everyday problems as well as begin to recognize cause-and-effect relationships. A child who understands water does not change in amount just because it is poured from one glass to another has grasped the concept of conservation. Conservation of numbers is learned as early as age 7 years, conservation of quantity at age 7 or 8 years, conservation of weight at age 9 years, and conservation of volume at age 11 years ([Wadsworth, 2003](#)). Reasoning during school age tends to be inductive or proceeds from specific to general: A school-age child holding a broken toy reasons the toy is made of plastic, and therefore, all plastic toys break easily.

### **The Adolescent**

Adolescence is the time when cognition achieves its final form or when formal operational thought begins. When this stage is reached, adolescents are capable of thinking in terms of possibility—what could be (**abstract thought**)—rather than being limited to thinking about what already is (concrete thought). This makes it possible for adolescents to use scientific reasoning. They can use deductive reasoning in addition to the induction reasoning they used during school age or can move from the general to the specific (e.g., plastic toys break easily, the toy they are holding is plastic; therefore, it will break easily).

### **A Criticism of Piaget’s Theory**

Piaget is criticized because he used only a small sample of subjects to establish his theory (his own children). Because children today begin activities to learn counting and identifying color or reading much earlier than they did at the time the theory was

devised, the age groups and norms may no longer be accurate. Playing computer games during the preschool period will probably impact the rate and type of children’s cognitive developments in the future.

**QSEN Checkpoint Question 28.6**

**SAFETY**

John is a school-age child, but he still has difficulty learning Piaget’s concept of conservation. The nurse recognizes this implies which statement about John?

- a. He doesn’t understand why his mother insists he recycle plastic or metal soda cans.
- b. He doesn’t understand that, when crossing a two-way street, he must look both right and left.
- c. He feels angry because his sister’s piece of pie is long and thin where his is short and fat.
- d. He has an imaginary friend.

*Look in Appendix A for the best answer and rationale.*

**KOHLBERG’S THEORY OF MORAL DEVELOPMENT**

One more developmental theory that has relevance to maternal and child health nursing is Kohlberg’s (1927–1987) theory of moral development. A German psychologist, Kohlberg (1984) studied the reasoning ability of boys and, based on Piaget’s development stages, developed a theory on the way children gain knowledge of right and wrong or moral reasoning. These stages, as described by Kohlberg, are summarized in Table 28.7.

**TABLE 28.7 KOHLBERG’S STAGES OF MORAL DEVELOPMENT**

Age (in Years)	Stage	Description	Nursing Implications
<i>Preconventional (Level I)</i>			
2–3	1	Punishment/obedience orientation (“heteronomous morality”). Child does right because a parent tells him or her to and to avoid punishment.	Child needs help to determine what are right actions. Give clear instructions to avoid confusion.
4–7	2	Individualism. Instrumental purpose and exchange. Carries out actions to satisfy own needs rather	Child is unable to recognize that like situations require like actions. Unable to take responsibility for self-care

		than society's. Will do something for another if that person does something for him or her.	because meeting own needs interferes with this.
<i>Conventional (Level II)</i>			
7–10	3	Orientation to interpersonal relations of mutuality. Child follows rules because of a need to be a good person in own eyes and eyes of others.	Child enjoys helping others because this is nice behavior. Allow child to help with bed making and other such activities. Praise for desired behavior such as sharing.
10–12	4	Maintenance of social order, fixed rules, and authority. Child finds following rules satisfying. Follows rules of authority figures as well as parents in an effort to keep the system working.	Child often asks what the rules are and if something is right. May have difficulty modifying a procedure because one method may not be right. Follows self-care measures only if someone is there to enforce them.
<i>Postconventional (Level III)</i>			
Older than 12	5	Social contract, utilitarian law-making perspectives. Follows standards of society for the good of all people.	Adolescents can be responsible for self-care because they view this as a standard of adult behavior.
Older than 12	6	Universal ethical principle orientation. Follows internalized standards of conduct.	Many adults do not reach this level of moral development.

From Kohlberg, L. (1984). *The psychology of moral development*. New York, NY: Harper & Row, with permission.

Recognizing where a child is developmentally according to these stages can help identify how children may feel about an illness such as whether they think it is fair that they are ill. Recognizing moral reasoning also helps determine whether children can be depended on to carry out self-care activities such as administering their own medicine or whether children have internalized standards of conduct so they do not cheat when away from external control. Moral stages closely approximate cognitive stages of development because children must be able to think abstractly (be able to conceptualize an idea without a concrete picture) before being able to understand how rules apply even when no one is there to enforce them (Juujärvi, Pesso, & Myyry, 2011).

## A Criticism of Kohlberg's Theory

Kohlberg's (1984) theory is frequently challenged as being male-oriented because his original research was conducted entirely with boys. Carol Gilligan (1993), a sociologist, argues that there are two modes of moral reasoning: the ethic of justice that focuses on individual rights and the ethic of care that focuses on responsibilities in relationships. She suggests that girls may not score well on Kohlberg's scale because, being more concerned with relationships than are boys, they make moral decisions based on individual circumstances or the effect of their actions on others at a much younger age than boys, which skews their results on a standard male-influenced scale.

## Using Growth and Development in Practice

An assessment of children's growth and development should be included in all children's nursing care plans because whether they are growing and developing within usual parameters is a significant mark of wellness. Because nurses do not work alone but as members of a healthcare team, Box 28.6 shows an interprofessional care map illustrating both nursing and team planning for supporting a child's growth and development.

### BOX 28.6

#### Nursing Care Planning

##### AN INTERPROFESSIONAL CARE MAP FOR A CHILD WITH A DEVELOPMENTAL CONCERN

John Olson is a 6-year-old, mildly overweight boy brought into an emergency department because his leg is broken from a bicycle accident. His parents tell you that although John has lived with them for 3 years, they find him cold and unloving. They ask you what they can do to change this.

**Family Assessment:** Family lives in a three-bedroom house in suburbs. Father works as a plumber; mother has a part-time job as a substitute grade-school teacher.

**Patient Assessment:** At 4 months of age, John was taken away from his mother because she was not caring for him adequately. He then moved among 12 different foster homes until he was finally adopted at age 3.5 years. His adoptive parents have 3-year-old twins of their own.

**Nursing Diagnosis:** Interrupted family processes related to inability of child to meet parents' developmental expectations

**Outcome Criteria:** Child demonstrates greater participation in family activities and improved response to parents' attempts to bond with him by 3 months' time.

Team Member	Assessment	Intervention	Rationale	Expected Outcome
-------------	------------	--------------	-----------	------------------

	<b>Assessment</b>	<b>Intervention</b>	<b>Rationale</b>	<b>Outcome</b>
<i>Activities of Daily Living, Including Safety</i>				
Nurse	Assess if family has thought through impact of bicycle accident on child's daily activities.	Suggest some obvious accommodations needed for cast care (e.g., no tub bathing, difficulty with stairs, no bike riding).	If a family is already under stress, an accident can compound family concerns.	Family members state they realize accidents are not anyone's "fault" and are prepared to make adjustments needed.
<i>Teamwork and Collaboration</i>				
Nurse/primary care provider	Assess if parents feel psychological counseling would be appropriate for child.	Assist parents with gaining a consultation if they feel they would welcome this.	Consultation with a skilled professional can offer parents information on specific actions to take.	Parents state whether they feel situation merits more skilled help at this time.
<i>Procedures/Medications</i>				
Nurse/primary care provider	Assess what emergency actions are necessary for a child with a fractured tibia.	Apply cast; give instructions for cast care. Keep pain or discomfort to a minimum.	Definite measures to prevent pain are important in promoting a sense of trust.	Patient states he understands cast care and states emergency department experience was at best an adventure, and at worst, not an ordeal.
<i>Nutrition</i>				
Nurse	Obtain a 24-hour recall dietary history to assess for usual calcium and vitamin D	Suggest additional sources of calcium or vitamin D if needed.	Calcium is important for good bone healing and is absorbed best in the presence of	Patient states he understands calcium will help healing and is willing to ingest more if

	intake.		vitamin D.	needed.
<i>Patient-Centered Care</i>				
Nurse	Assess what parents understand about the development of trust in early life.	Suggest ways to initiate a sense of trust by demonstrating dependability and a warm, loving relationship.	Even if a sense of trust is not achieved as an infant, it can be achieved at a later developmental stage.	Parents state they are willing to identify and begin more active steps toward improving relationship with son.
<i>Psychosocial/Spiritual/Emotional Needs</i>				
Nurse	Assess what type of ideal child parents thought they were adopting.	Suggest measures that could bring parents and child closer together such as a “game night,” always eating meals together, or quiet “talk times” before bed.	Identifying differences between expectations and reality can help people understand dissatisfactions.	Patient and parents state they are willing to begin an active program of shared activities.
<i>Informatics for Seamless Healthcare Planning</i>				
Nurse	Assess if patient or parents have “walked through a day” to identify their child’s needs after returning home.	Discuss with patient and parents adjustments they recognize patient will have to make to attend school with a cast in place.	Small needs not met can grow into major needs before a return appointment and can interfere further with a sense of trust.	Patient and parents state they understand adjustments that need to be made and will work them out together with child.

*What If . . . 28.4*

**The nurse is interested in exploring one of the 2020 National Health Goals**

related to growth and development (see [Box 28.1](#)). Most government-sponsored money for nursing research is allotted based on these goals. What would be a possible research topic to explore that would be applicable to the Olson family, pertinent to these goals, and advance evidence-based practice?

## KEY POINTS FOR REVIEW

- Knowledge of growth and development is important in health promotion and illness prevention because it lays the basis for assessments and anticipatory guidance.
- Including growth and development guidelines in nursing care helps to achieve care that not only meets QSEN competencies but also best meets a family's total needs.
- Genetic factors that influence growth and development are gender, ethnicity, intelligence, and health.
- Environmental influences include quality of nutrition, socioeconomic level, the parent-child relationship, ordinal position in the family, and environmental health.
- To meet growth and development milestones, children (like adults) need to follow basic guidelines for a healthy diet, such as eating a variety of foods, maintaining an ideal weight, avoiding extreme levels of saturated fat, eating foods with adequate starch and fiber, and avoiding too much sugar.
- Temperament is a child's characteristic manner of thinking, behaving, or reacting. Helping parents understand the effect of temperament is a nursing role.
- Common theories of development are Freud's psychoanalytic theory and Erikson's theory of psychosocial development. Both of these theories describe specific tasks children must complete at each stage of development to become a well-adapted adult.
- Piaget's theory of cognitive development describes ways children learn.
- Kohlberg advanced a theory of moral development or how children use moral reasoning to solve problems.
- Although growth and development occur in known patterns, the rate that a child develops and grows varies from child to child. Caution parents not to be concerned that two siblings are very different as long as they both fit within usual parameters.

## CRITICAL THINKING CARE STUDY

Andrew is a preschooler who "hates" his first days at preschool. He lives with his mother Berkley, a calculus teacher; his father Edgar, a physicist; and Molly, his 5-day-old baby sister. His mother is disappointed at his reaction to school. She tells you, "We worked so hard to prepare him for school. Taught him his whole alphabet and how to count to 100. He's so excited about learning he wanted to practice writing his name rather than go to a friend's birthday party." She asks you what could be wrong. How can she make his first school experience better?

1. What additional information would you like to know before you advise his

mother? What are some reasons you can think of as to why he might not be enjoying preschool?

2. Could temperament be playing a role in why Andrew is not fitting in well at preschool? Are there other indications he doesn't approach new situations well?
3. As a preschooler, should Andrew be interested in exploring new things and going new places? Is there a reason he doesn't want to leave his house to go to school just now?

## 29

# Nursing Care of a Family With an Infant

*You meet Ms. Simpson, 19 years old, at a pediatric clinic when she brings in her 2-month-old son, Bryan. She looks tired and tells you she is exhausted because her baby is “awake all night, crying constantly.” She stopped breastfeeding and changed to formula to see if that would help. It didn’t. She also began giving him cereal. That didn’t help either. She tells you his bowel movements are normal. When you weigh Bryan, you find he has gained weight well. When you talk to him, he demonstrates a social smile.*

*Previous chapters described the newborn and the capabilities with which children are born. This chapter adds information about the dramatic changes, both physical and psychosocial, that occur during the first year. Such information can build a base for care and health teaching for the age group.*

**What condition common to early infancy might Ms. Simpson be describing? What factors might be playing a role? What suggestions could you make to help her enjoy caring for Bryan more?**

## KEY TERMS

**baby-bottle syndrome**

**binocular vision**

**deciduous teeth**

**eighth-month anxiety**

**extrusion reflex**

**hand regard**

**natal teeth**

**neck-righting reflex**

**neonatal teeth**

**object permanence**

**pincer grasp**

**seborrhea**

**social smile**

## OBJECTIVES

After mastering the contents of this chapter, you should be able to:

1. Describe normal infant growth and development and associated parental concerns.
2. Identify 2020 National Health Goals related to infant growth and development that nurses can help the nation achieve.
3. Assess an infant for normal growth and development milestones.
4. Formulate nursing diagnoses related to infant growth and development and associated parental concerns.
5. Identify expected outcomes to promote optimal infant growth and developmental needs as well as manage seamless transitions across differing healthcare settings.
6. Using the nursing process, plan nursing care that includes the six competencies of Quality & Safety Education for Nurses (QSEN): Patient-Centered Care, Teamwork & Collaboration, Evidence-Based Practice (EBP), Quality Improvement (QI), Safety, and Informatics.
7. Implement nursing care related to normal growth and development of an infant, such as encouraging eye–hand coordination.
8. Evaluate expected outcomes for achievement and effectiveness of care.
9. Integrate knowledge of infant growth and development with the interplay of the nursing process, the six competencies of QSEN, and Family Nursing to promote quality maternal and child health nursing care.

Traditionally, infancy is designated as the period of time from 1 month to 1 year of age. In these important months, an infant undergoes such rapid development that parents sometimes believe their baby looks different and demonstrates new abilities every day. During this time, an infant typically triples birth weight and increases length by 50%. Babies' senses sharpen, and with the process of attachment to a primary caregiver, they form a first social relationship. Because of the growth and learning potential that occurs, this first year is a crucial one.

Without proper nutrition, a baby will not grow and physically thrive; without proper stimulation and nurturing care by a consistent caregiver, an infant may not develop a healthy interest in life or a feeling of security essential for future development (Olusanya & Renner, 2013). [Box 29.1](#) highlights 2020 National Health Goals addressing this important developmental stage.

### BOX 29.1

#### Nursing Care Planning Based on 2020 National Health Goals

A number of 2020 National Health Goals focus on the promotion of health during the infant year. These include:

- Increase the proportion of mothers who exclusively breastfeed until 6 months of age from a baseline of 14.1% to 25.5%.
- Reduce the rate of infant deaths from a baseline of 6.9 out of 1,000 live births to 6.7 out of 1,000 live births.
- Increase immunization levels for universally recommended vaccines among young children for such diseases as diphtheria, tetanus, poliomyelitis, pertussis, measles, mumps, rubella, and varicella (chickenpox) from varying actual levels to the target level of 90%.
- Increase age-appropriate vehicle restraint system use in children aged 0 to 12 months from 86% to 95%.
- Decrease the number of infants who die from sudden infant death syndrome (SIDS) from 0.55 out of 1,000 live births to 0.50 out of 1,000 live births ([U.S. Department of Health and Human Services, 2010](#); see [www.healthypeople.gov](http://www.healthypeople.gov)).

Nurses can help the nation achieve these goals by educating parents about the importance of using infant car seats, continuing exclusive breastfeeding for 6 months, and instigating measures to prevent SIDS such as placing infants to sleep on their backs.

## *Nursing Process Overview*

### FOR HEALTHY DEVELOPMENT OF AN INFANT

#### **ASSESSMENT**

Nursing assessment of an infant begins with an interview with the primary caregiver. Important areas to discuss include nutrition, elimination, growth patterns, and development. An infant's height, weight, and head circumference are important indicators of growth, so they should be measured and plotted on standard growth charts (see [Chapter 28](#)) ([Parsons, George, & Innis, 2011](#)).

Typical infant appearance is shown in [Box 29.2](#). The physical assessment of an infant must be done quickly yet thoroughly because a baby can tire or become hungry, making it difficult to judge overall behavior and temperament. It's best if a parent is present to make the infant feel comfortable. Using a calm, unhurried approach helps an infant feel safe enough to accept your interventions.

#### **NURSING DIAGNOSIS**

Much of your assessment of an infant and family will focus on basic needs such as sleep, nutrition, and activity and the parents' adjustment to their new role. Examples of nursing diagnoses include:

- Ineffective breastfeeding related to maternal fatigue
- Disturbed sleep pattern (maternal) related to baby's need to nurse every 2 hours

- Deficient knowledge related to normal infant growth and development
- Imbalanced nutrition, less than body requirements, related to infant's difficulty sucking
- Health-seeking behaviors related to adjusting to parenthood
- Delayed growth and development related to lack of stimulating environment
- Risk for impaired parenting related to long hospitalization of infant
- Readiness for enhanced family coping related to increased financial support
- Social isolation (maternal) related to lack of adequate social support
- Ineffective role performance related to new responsibilities within the family

### **OUTCOME IDENTIFICATION AND PLANNING**

Outcomes established for infant care need to be realistic based on the family's new circumstances. Parents of infants, especially first-time parents, must do a lot of adjusting, and this takes time. Try to suggest activities that can be easily incorporated into the family's lifestyle.

If your assessment data indicate that a child needs more exposure to language and you know both parents work during the day, for example, you might suggest the parents ask their child's caretaker to talk to their infant more. Encourage parents to spend additional time each evening reading or reciting nursery rhymes to their baby. Working together, these combined actions should increase the baby's language skills. Parents also might find it helpful to be referred to online resources for further information (see [Chapter 28](#)).

### **IMPLEMENTATION**

One of the most important interventions of the infant period is teaching new parents about normal growth and development milestones, such as the age range for rolling over or reaching for objects. Whenever possible, this information should be anticipatory so parents are not surprised by a new skill and instead are prepared for changes and developments before they occur.

### **OUTCOME EVALUATION**

Evaluate expected outcomes at each visit to detect that changes in growth and development are occurring. Helping parents understand the total developmental profile, not just a single element, provides the most important description of their child. Variation is so much the rule rather than the exception that a 2-month variation from the average during the infant year is considered normal. Many 4-month-old infants, for example, have mastered most of the 4-month skills and some of the 5-month skills, yet they may still be at a 3-month level on one or two other criteria.

Examples of expected outcomes include:

- Mother states she feels fatigued but able to cope with sleep disturbance from night waking.
- Parents state five actions they are taking daily to encourage bonding.
- Father states both he and spouse are adjusting to new role as parents.
- Parents verbalize appropriate techniques they use to stimulate infant.

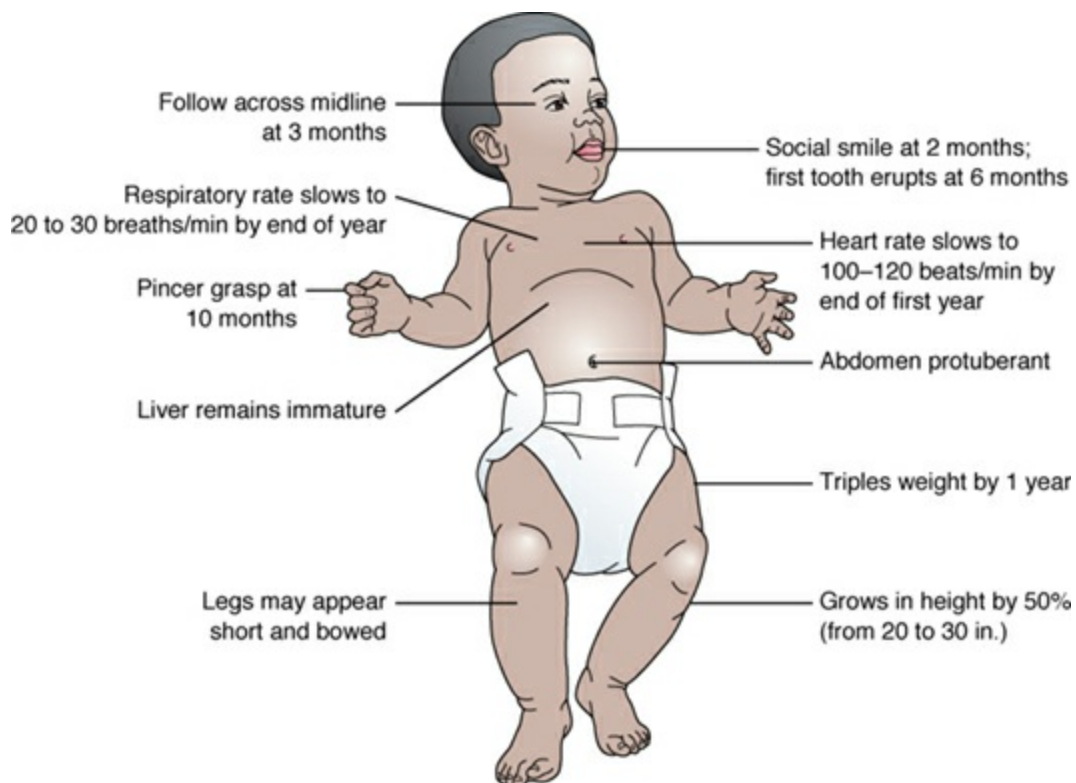

- Infant demonstrates age-appropriate growth and development.
- Infant exhibits weight, height, and head and chest circumference within usual norms.

## BOX 29.2

### Nursing Care Planning Using Assessment

#### APPEARANCE OF THE AVERAGE INFANT

## Growth and Development of an Infant

Infants grow rapidly both in size and in their ability to perform tasks during their first year. A standard schedule for healthcare visits is for 2-week, 2-month, 4-month, 6-month, 9-month, and 12-month visits ([American Academy of Pediatrics \[AAP\], 2017](#)). These visits are important for the infant because they provide time for immunizations and health assessments; they are also important for parents because they provide an opportunity for parents to ask questions about their child's growth pattern and developmental progress. They provide opportunities for healthcare providers to assess for potential problems as they first appear.

Anticipatory guidance offered at these visits can help parents prepare for the rapid changes that mark the first year of life. When appropriate, encouraging parents to join clubs or networking groups is another way to help increase their knowledge base and

confidence level to care for their rapidly growing infant. [Table 29.1](#) details the usual procedures done at infant health maintenance visits. The vaccines administered during the first year are discussed in [Chapter 34](#) (also available at <http://thePoint.lww.com/Flagg8e>).

**TABLE 29.1 HEALTH MAINTENANCE SCHEDULE, INFANT PERIOD**

<b>Physical Health</b>	<b>Physical Examination</b>	<b>Frequency</b>
Developmental milestones including psychosocial interaction	History, observation	Every visit
	Ages and Stages Questionnaire	At 9 months
Growth milestones	Height, weight, head circumference plotted on standard growth chart; physical examination	Every visit
Vision and hearing	History, observation	Every visit
Physical examination		Every visit
Nutritional adequacy	History, observation	Every visit
Parent–child relationship	History, observation	Every visit
Sleep positioning counseling	Discussion of placing infants on back to sleep; using “tummy time” for play periods during the day	Every visit up to 9 months
Unintentional injury counseling	Discussion of safety measures to take with infants	Every visit
Dental health	History, physical examination	Every visit after teeth erupt
	Fluoride varnish	Recommended every visit starting at 6 months with tooth eruption
Anemia	Hematocrit, hemoglobin	12-month visit
Lead screening	Point of Care rapid lead screening	12-month visit
Tuberculosis screening	Purified protein derivative (PPD) test (if warranted)	If indicated based on risk

Newborn screening	Heel blood sample	At 2-week visit
<i>Immunizations</i>		
Review of history and health record; teaching parent about any risks and side effects; administering immunization in accordance with healthcare agency policies		
<i>Haemophilus influenzae</i> type B	Hib	2-, 4-, 6-, and 12-month visits
Varicella	VAR	12-month visit
Inactivated poliomyelitis	IPV	2-, 4-, and 6-month visits
Pneumococcal disease	PCV	2-, 4-, 6-, and 12-month visits
Diphtheria, tetanus and pertussis (whooping cough)	DTaP	2-, 4-, 6-, and 12–15 months
Hepatitis B	HepB	Birth, 2-month, and 6- or 12-month visits
Rotavirus	RV	2-, 4-, and possibly at 6-month visit depending on manufacturer
Influenza	IIV	Yearly at 6-month or later visit
Mumps, measles, and rubella	MMR	12- or 15-month visit
Varicella	Var	12- or 15-month visit
Hepatitis A	HepA	12- or 15-month visit
<i>Anticipatory Guidance</i>		
Infant care	Active listening and health teaching	Every visit
Expected growth and developmental milestones before next visit	Health teaching	Every visit
Poison and unintentional injury prevention	Educate parents about infant safety, such as using car seats and locking up poisons; provide telephone number of national poison control center (800-122-1222)	Every visit

## Problem Solving

Any problems expressed by parent during course of the visit	Active listening and health teaching regarding nutrition, exercise, language development	Every visit
---	--	-------------

Centers for Disease Control and Prevention. (2013). *Recommended immunizations for children (birth through 6 years) United States, 2013*. Washington, DC: Author

## PHYSICAL GROWTH

The physiologic changes that occur in the infant year reflect both the increasing maturity and growth of body organs.

### Weight

As a rule, most infants double their birth weight by 4 to 6 months and triple it by 1 year. During the first 6 months, infants typically average a weight gain of 2 lb per month. During the second 6 months, weight gain is approximately 1 lb per month. The average 1-year-old boy weighs 10 kg (22 lb); the average girl weighs 9.5 kg (21 lb). An infant's weight, however, is relevant only when plotted on a standard growth chart and compared to that child's own growth curve (available at <http://thePoint.lww.com/Flagg8e>).

### Height

An infant increases in height during the first year by 50%, or grows from the average birth length of 20 in. to about 30 in. (50.8 to 76.2 cm). Height, like weight, is best assessed if it is plotted on a standard growth chart. Infant growth is most apparent in the trunk during the early months. During the second half of the first year, it becomes more apparent as lengthening of the legs occurs. At the end of the first year, the child's legs may still appear disproportionately short, however, and perhaps bowed. For accuracy, measure infants lying supine on a measuring board even if they are beginning to be able to stand (see [Chapter 34](#), [Box 34.9](#)).

### Head Circumference

By the end of the first year, the brain already reaches two thirds of its adult size. Head circumference increases rapidly during the infant period to reflect this rapid brain growth.

Some infants' heads appear asymmetric until the second half of the first year, especially if they are always placed on their back to sleep (which they should be), causing the skull bones to flatten in the back. Suggest to parents they continue to place the infant on the back to sleep but to spend "tummy time" daily with the infant placed in a prone position to prevent this flattening. This early head distortion will gradually correct itself as the child sleeps less and spends more time with the head in an erect

position. Persistence of asymmetry suggests an infant is not receiving enough stimulation or is spending the majority of time lying in bed.

## **Body Proportion**

Body proportion changes during the first year from that of a newborn to a more typical infant appearance. By the end of the infant period, the lower jaw is definitely prominent and remains that way throughout life.

The circumference of the chest is generally less than that of the head at birth by about 2 cm. It is even with the head circumference in some infants as early as 6 months and in most by 12 months. The abdomen remains protuberant until the child has been walking well for some time, generally well into the toddler period. Cervical, thoracic, and lumbar vertebral curves develop as infants hold up their head, sit, and walk. Lengthening of the lower extremities during the last 6 months of infancy readies the child for walking and often is the final growth that changes the appearance from “babylike” to “toddlerlike.”

## **Body Systems**

In the cardiovascular system, heart rate slows from 110 to 160 beats/min to 100 to 120 beats/min by the end of the first year. The heart continues to occupy a little over half the width of the chest. Pulse rate may slow with inhalation (sinus arrhythmia), but this does not become marked until preschool age. That the heart is becoming more efficient is shown by a decreasing pulse rate and a slightly elevated blood pressure (from an average of 80/40 to 100/60 mmHg).

Infants are prone to develop a physiologic anemia at 2 to 3 months of age. This occurs because the life of a typical red cell is 4 months, so the cells the child had at birth begin to disintegrate at that time, yet new cells are not yet being produced in adequate replacement numbers. Hemoglobin in an infant becomes totally converted from fetal to adult hemoglobin at 5 to 6 months of age. Infants may experience a decrease in serum iron levels at 6 to 9 months as the last of iron stores established in utero are used.

The respiratory rate of an infant slows from 30 to 60 breaths/min to 20 to 30 breaths/min by the end of the first year. Because the lumens of the respiratory tract remain small and mucus production by the tract to clear invading microorganisms is still inefficient, upper respiratory infections occur readily and tend to be more severe than in adults.

At birth, the gastrointestinal tract is immature in its ability to digest food and mechanically move it along. These functions mature gradually during the infant year. Although the ability to digest protein is present and effective at birth, the amount of amylase, which is necessary for the digestion of complex carbohydrates, is deficient until approximately the third month. Lipase, necessary for the digestion of saturated fat, is decreased in amount during the entire first year.

The liver of an infant remains immature, possibly causing an inadequate conjugation

of drugs (if a drug should be necessary for treatment of illness) and the inefficient formation of carbohydrate, protein, and vitamins for storage. Until age 3 or 4 months, an **extrusion reflex** (food placed on an infant's tongue is thrust forward and out of the mouth) prevents some infants from eating effectively if they are offered solid food this early (not recommended). Newborns can drink from a cup as long as a parent controls the fluid flow. An infant can independently drink from a cup by age 8 or 10 months.

The kidneys remain immature and not as efficient at eliminating body wastes as in an adult. The endocrine system remains particularly immature in response to pituitary stimulation, such as adrenocorticotrophic hormone, or insulin production from the pancreas. Without these hormones functioning effectively, an infant may not be able to respond to stress as effectively as an adult.

An infant's immune system becomes functional by at least 2 months of age; an infant can actively produce both immune globulin (Ig)G and IgM antibodies by 1 year. The levels of other immunoglobulins (IgA, IgE, and IgD) are not plentiful until preschool age, which is the reason why infants continue to need protection from infection ([Goldson & Reynolds, 2011](#)).

The ability to adjust to cold is mature by age 6 months. By this age, an infant can shiver in response to cold (which increases muscle activity and provides warmth) and has developed additional adipose tissue to serve as insulation. The amount of brown fat, which protected the newborn from cold, decreases during the first year as subcutaneous fat increases.

Although the fluid in body compartments shifts to some extent, extracellular fluid accounts for approximately 35% of an infant's body weight, with intracellular fluid accounting for approximately 40% by the end of the first year, in contrast to adult proportions of 20% and 40%, respectively. This proportional difference increases an infant's susceptibility to dehydration from illnesses, such as diarrhea, because loss of extracellular fluid could result in loss of over a third of an infant's body fluid.

## Teeth

The first baby tooth (typically a central incisor) usually erupts at age 6 months, followed by a new one monthly. Fluoride supplementation should be administered at 6 months of age ([AAP, 2017](#)). However, teething patterns can vary greatly among children. [Figure 29.1](#) illustrates the usual ages of deciduous (baby teeth) eruption by tooth type.

**Figure 29.1** A typical eruption pattern of deciduous teeth.

Some newborns (about 1 in 2,000) may be born with teeth (**natal teeth**) or have teeth erupt in the first 4 weeks of life (**neonatal teeth**). The lower central incisors (see Fig. 29.1) are the teeth most frequently involved in this early growth. These very early teeth may be membranous and so may be reabsorbed (supernumerary or extra teeth). If they are loosely attached, they are usually removed before they loosen spontaneously and are aspirated by the infant. In most infants, natal or neonatal teeth are deciduous or are fixed firmly. These should not be removed because no other teeth will grow to replace them until the permanent teeth erupt at age 6 or 7 years. **Deciduous teeth** are essential for allowing proper growth of the dental arch. If they are injured, children need conscientious follow-up to be certain there is space for permanent teeth to erupt effectively or that permanent teeth are not discolored (de Amorim Lde, Estrela, & da Costa, 2011).

## MOTOR DEVELOPMENT

An average infant progresses through systematic motor growth during the first year, strongly reflecting the principles of cephalocaudal (head to toe) and gross-to-fine motor development. Control proceeds from head to trunk to lower extremities in a progressive, predictable sequence. As different infants show individual variations in accomplishing different tasks, the ages given here are only averages.

To assess motor development, both *gross motor development* (ability to accomplish large body movements) and *fine motor development*, measured by observing or testing

*prehensile ability* (ability to coordinate hand movements), are evaluated.

## Gross Motor Development

Four positions—ventral suspension, prone, sitting, and standing—are used to assess gross motor development.

### Ventral Suspension Position

*Ventral suspension* refers to an infant's appearance when held in midair on a horizontal plane and supported by a hand under the abdomen (Fig. 29.2A). In this position, the newborn allows the head to hang down with little effort at control. One-month-old infants lift their head momentarily and then drop it again. Two-month-old infants hold their head in the same plane as the rest of their body, a major advance in muscle control. By 3 months, infants lift and maintain their head well above the plane of the rest of the body in ventral suspension.

**Figure 29.2** (A) The ventral suspension position. (B) The prone position.

A *Landau reflex* is a new reflex that develops at 3 months. When held in ventral suspension, the infant's head, legs, and spine extend. When the head is depressed, the hips, knees, and elbows flex. This reflex continues to be present in most infants during the second 6 months of life, but then it becomes increasingly difficult to demonstrate. It is an important reflex to assess because a child with motor weakness, cerebral palsy, or other neuromuscular defects will not be able to demonstrate the reflex.

At 6 to 9 months, an infant also demonstrates a *parachute reaction* from a ventral suspension position. This means that when infants are suddenly lowered toward an examining table, the arms extend as if to protect themselves from falling. Children with cerebral palsy do not demonstrate this response because they flex their extremities too tightly.

### Prone Position

When lying on their stomach, newborns can turn their head to move it out of a position where breathing is impaired, but they cannot hold their head raised for an extended time

(see Fig. 29.2B). By 1 month of age, they lift their head and turn it easily to the side. They still tend to keep their knees tucked under their abdomen, however, as they did as a newborn. Two-month-old infants can raise their head and maintain the position, but they cannot raise their chest high enough to look around yet. Their head is still held facing downward.

A 3-month-old child lifts the head and shoulders well off the table and looks around when prone. The pelvis is flat on the table, no longer elevated. Some children can turn from a prone to a side-lying position at this age.

Four-month-old infants lift their chests off the bed and look around actively, turning their head from side to side. They are able to turn from front to back. The first time, this tends to occur as an extension of lifting the chest combined with a **neck-righting reflex**, which begins at this age. This reflex causes babies to lose their balance and roll sideways when lifting the head up. The baby is frightened by the sudden feeling of rolling free and probably cries. After this happens a few more times, however, a baby begins to delight in this new accomplishment.

Most babies turn front to back first and then, 1 month later, back to front. When taking a health history, ask which way a child turned first. Those with spasticity may turn first back to front. This is not necessarily an indication of spasticity because some healthy babies turn back to front first also.

Five-month-old infants are able to rest weight on their forearms when prone. They can turn completely over, front to back and back to front. By 6 months, infants can raise their chests and the upper part of their abdomens off the table.

By 9 months, a child can creep from the prone position. Creeping means the child has the abdomen off the floor and moves one hand and one leg and then the other hand and leg, using the knees on the floor to locomote (Fig. 29.3).

**Figure 29.3** Creeping. When infants creep, they move forward with one arm and leg and then the other arm and leg, carrying the torso above and parallel to the floor. (leungchopan/Shutterstock.com)

### Sitting Position

When placed on his or her back and then pulled to a sitting position, a newborn has extreme head lag; this lag is present until about 1 month (Fig. 29.4). In a sitting position, the back appears rounded and an infant demonstrates only momentary head control.

**Figure 29.4** An infant is pulled to a sitting position to demonstrate head lag. Notice how evident this is in the very young infant.

By 2 months, infants can hold their head fairly steady when sitting up, although their head does tend to bob forward and will still show head lag when pulled to a sitting position. A 4-month-old child reaches an important milestone by no longer demonstrating head lag when pulled to a sitting position.

A 5-month-old infant can be seen to straighten his or her back when held or propped in a sitting position. By 6 months, infants can sit momentarily without support. They anticipate being picked up and reach up with their hands from this position. Some parents expect a child this age to be able to sit securely and may be worried because their sitting posture is still extremely shaky when it is normal (Fig. 29.5). Infants are capable of movement by hitching or sliding backward from this position. Alert parents

that an infant this young is capable of moving from one spot to another in this way so they are prepared for this and can prevent unintentional injuries.

**Figure 29.5** A 6-month-old infant not quite ready to sit on his own. Notice how he is propped with pillows to maintain the position.

A 7-month-old child can sit alone but only when the hands are held forward for balance. An 8-month-old child can sit securely without any additional support ([Fig. 29.6](#)). This is a major milestone in development that should always be considered in an assessment. Children with delayed cognitive or motor development may not accomplish this step at this time. At 9 months, infants sit so steadily that they can lean forward and regain their balance. They may still lose their balance if they lean sideways, which is a skill not achieved for another month.

**Figure 29.6** At 8 months of age, an infant sits independently.

### Standing Position

A newborn stepping reflex can still be demonstrated at 1 month of age. In a standing position, the infant's knees and hips flex rather than support more than momentary weight. At 3 months, infants try to support part of their weight on their feet.

At 4 months, infants are able to support their weight on their legs. They are successful at doing this because the stepping reflex has faded. By 5 months, the tonic neck reflex should be extinguished, and the Moro reflex should be fading.

By 6 months, infants nearly support their full weight when in a standing position. A 7-month-old child bounces with enjoyment in a standing position. Nine-month-olds can stand holding onto a coffee table if they are placed in that position. Ten-month-olds can pull themselves to a standing position by holding onto the side of a playpen or a low table, but they cannot let themselves down again as yet.

At around 11 months, an infant learns to "cruise" or move about the crib or room by holding onto objects such as the crib rails, chairs, walls, and low tables (Fig. 29.7). At 12 months, the child can stand alone at least momentarily. Some parents expect children

to walk at this time and may be disappointed to see their child is merely standing still. A child has until about 22 months of age to walk and still be within the normal limit, however (Fig. 29.8).

**Figure 29.7** An 11-month-old child cruising along the walls. Further childproofing of the house will be necessary to keep the child safe. (Photo Researchers, Inc.)

**Figure 29.8** There is a wide variation in the age at which children take a first step, typically ranging from 8 to 15 months. Here, a child has mastered walking.

***QSEN Checkpoint Question 29.1***

**TEAMWORK & COLLABORATION**

Bryan is 2 months old, and the nurse is collaborating with the occupational therapist in his care. When planning care, the nurse identifies that John should sit securely at what age?

- a. 2.5 months
- b. 6 months
- c. 8 months
- d. 12 months

*Look in [Appendix A](#) for the best answer and rationale.*

## Fine Motor Development

One-month-old infants still have a strong grasp reflex so they hold their hands in fists so tightly that it is difficult to extend their fingers. As the grasp reflex fades, a 2-month-old infant will hold an object for a few minutes before dropping it. The hands are held open, not closed in fists.

By 3 months, infants reach for attractive objects in front of them. Their grasp is unpracticed so they usually miss them. You can assure parents this is part of normal development so they do not think their child is nearsighted or farsighted or has poor coordination.

When they reach 4 months, infants bring their hands together and pull at their clothes. They will shake a rattle placed in their hand. **Thumb opposition** (ability to bring the thumb and fingers together) begins, but the motion is a scooping or raking one, not a picking-up one, and is not very accurate. This limits the infant to handling large objects (Fig. 29.9). Palmar and plantar grasp reflexes have disappeared.

**Figure 29.9** By age 4 months, an infant is able to manipulate large objects.

Five-month-old children can accept objects that are handed to them by grasping with the whole hand. They can reach and pick up objects without the object being offered and often play with their toes as objects. Fisting that persists beyond 5 months suggests a delay in motor development. Unilateral fisting suggests hemiparesis or paralysis on that side.

By 6 months, grasping has advanced to a point where a child can hold objects in both hands. Infants at this age will drop one toy when a second one is offered, however. They can hold a spoon and start to feed themselves (with much spilling). The Moro, the palmar grasp, and the tonic neck reflexes have completely faded. A Moro reflex that persists beyond this point should arouse suspicion of neurologic disease.

Seven-month-old infants can transfer toys from one hand to the other. They hold a first object when a second one is offered. By 8 months, random reaching and ineffective grasping disappear as a result of advanced eye–hand coordination.

A major milestone at 10 months is the ability to bring the thumb and first finger together in a **pincer grasp** (Fig. 29.10). This enables children to pick up small objects such as crumbs or pieces of cereal from a high chair tray. They use one finger to point to objects. They offer toys to people but then cannot release them.

**Figure 29.10** An infant almost ready to demonstrate a pincer grasp.

At 12 months, infants can hold a crayon well enough to draw a semi-straight line. They enjoy putting objects such as small blocks in containers and taking them out again. They can hold a cup and spoon to feed themselves fairly well (if they have been allowed to practice) and can take off socks and push their hands into sleeves (again, if they have been allowed to practice). They can offer toys and release them.

## DEVELOPMENTAL MILESTONES

In addition to the gross and fine motor skills developing at this time, language and play behavior also reach major milestones. For easy reference, motor and cognitive development and play throughout this year are summarized in [Table 29.2](#).

**TABLE 29.2** SUMMARY OF INFANT GROWTH AND DEVELOPMENTAL MILESTONES

Month	Motor Development	Fine Motor Development	Socialization and Language	Time Reflexes Fade	Play

0-1	Largely reflex actions	Keeps hands fistled; able to follow object to midline with eyes			Enjoys watching face of primary caregiver; needs play time in prone position
2	Holds head up when prone	Demonstrates social smile	Makes cooing sounds; differentiates cry	Grasp reflex fading	Enjoys bright-colored mobiles
3	Holds head and chest up when prone	Follows object past midline with eyes	Laughs out loud	Landau reflex is strong	Spends time looking at hands (hand regard); "tummy time" important during the day
4	Turns back to front; no longer has head lag; bears partial weight on feet			Stepping, tonic neck, extrusion reflexes are fading	Needs space to practice turning
5	Should turn readily front to back and back to front			Tonic neck reflex fading	Handles rattles well
6	Beginning to show ability to sit	Uses palmar grasp	May say vowel sounds ( <i>oh-oh</i> )	Moro and tonic neck reflex have faded	Enjoys bathtub toys, rubber ring for teething
7	Reaches out to be picked	Transfers objects hand	Shows beginning		Likes objects that are good

	up; first tooth (central incisor) erupts	to hand	fear of strangers	size for transferring	
8	Sits securely without support		Fear of strangers peaks	Enjoys manipulation, rattles, and toys of different textures	
9	Creeps or crawls (abdomen off floor)		Says first word ( <i>da-da</i> )	Needs safe space for creeping	
10	Pulls self to standing	Uses pincer grasp (thumb and finger) to pick up small objects		Plays games like patty-cake and peek-a-boo	
11	Cruises (walks with support)			Cruising can be main activity	
12	Stands alone; some infants take first step	Holds cup and spoon well; helps to dress (pushes arm into sleeve)	Says two words plus <i>ma-ma</i> and <i>da-da</i>	Landau reflex fades	Likes toys that fit inside each other (pots and pans); nursery rhymes; will like pull toys as soon as walking

## Language Development

Language develops step by step the same as motor development. Infants begin to make small, cooing (dovelike) sounds by the end of the first month. By 2 months, they can differentiate their cry. For example, parents can begin to distinguish a cry that means “hungry” from one that means “wet” or from one that means “lonely.” This is an important milestone in development for an infant; asking if a parent can tell the

difference in crying is a good way to assess how far a parent has progressed in the task of parenting (Mesman, Oster, & Camras, 2012). A first-time parent usually has more difficulty making the distinction in crying than one who has experienced this before.

In response to a nodding, smiling face, or a friendly tone of voice, a 3-month-old infant will squeal with pleasure or laugh out loud. The same as with differentiating a cry, this is an important step in development because it makes a baby even more fun to be with. Parents spend increased time with infants at this age, not just to care for them but because they enjoy watching them smile at attention.

By 4 months, infants are very talkative, cooing, babbling, and gurgling when spoken to. They definitely laugh out loud. By 5 months, an infant says some simple vowel sounds (e.g., “goo-goo,” “gah-gah”).

At 6 months, infants learn the art of imitating. They may imitate a parent’s cough, for example, or say “Oh!” as a way of attracting attention. The amount of talking infants do increases still more at 7 months. They can imitate vowel sounds well (e.g., “oh-oh,” “ah-ah,” “oo-oo”). By 9 months, an infant usually speaks a first word: “da-da” or “ba-ba.” Occasionally, a mother may need reassurance that “da-da” for daddy is an easier syllable to pronounce than “ma-ma” for mommy. German mothers report the first word their babies say is “here,” which is “da” in German. By 10 months, an infant masters another word such as “bye-bye” or “no.” By 12 months, infants can generally say two words in addition to “ma-ma” and “da-da,” and they use those two words with meaning.

### **QSEN Checkpoint Question 29.2**

#### **INFORMATICS**

Beginning verbal communication is one of the most important tasks that infants need to achieve. The nurse teaches Bryan’s mother that by 12 months of age he should display which characteristics?

- a. “Children this age can usually say around two words, plus ‘ma-ma’ and ‘da-da.’”
- b. “One-year-olds can usually say more words than they are able to understand.”
- c. “A 12-month-old child can express his or her basic needs verbally.”
- d. “An infant who is this age usually can’t understand spoken words.”

*Look in [Appendix A](#) for the best answer and rationale.*

#### **Play**

Parents often ask what toys their infant would enjoy. Because 1-month-olds can fix their eyes on an object, they are interested in watching a mobile over their crib or playpen. Mobiles are best if they are black and white or brightly colored and light enough in weight so they move when someone walks by. Be sure they face down toward the infant, not toward the adult standing beside the crib. Musical mobiles provide extra stimulation. One-month-old children also spend a great deal of time watching their

parents' faces, appearing to enjoy this activity so much a face may become their favorite toy. Help parents understand they are not spoiling infants by sitting and holding them for long periods of time, just studying each other, in these early months. Parents will enjoy recalling such calm moments later, when they are stacking blocks, winding up toys, or playing table games with their growing child.

Hearing is a second sense that is a source of pleasure for children in early infancy. Even newborns listen to the sound of a music box or a musical rattle. They stir and seem apprehensive at the sound of a raucous rattle. Two-month-old infants will hold light, small rattles for a short period of time but then drop them. They are attuned to mobiles or cradle gyms strung across their crib. They continue to spend a great deal of time just watching the people around them.

Three-month-old infants can handle small blocks or small rattles. Four-month-olds need a playpen or a sheet spread on the floor so they have an opportunity to exercise their new skill of rolling over. Rolling over may be so intriguing that it can serve as a toy for the entire month.

Five-month-old infants are ready for a variety of objects to handle, such as plastic rings, blocks, squeeze toys, clothespins, rattles, and plastic keys. Check that all of these are small enough that an infant can lift them with one hand, yet big enough that he or she cannot possibly swallow them.

A 6-month-old child can sit steadily enough to be ready for bathtub toys such as rubber ducks or plastic boats if carefully supervised. Because they are starting to teethe, most at this age enjoy a teething ring to chew on.

Because 7-month-old infants can transfer toys, they are interested in items such as blocks, rattles, or plastic keys that are small enough to be transferred easily. As their mobility increases, they begin to be more interested in brightly colored balls or toys that previously rolled out of reach.

Eight-month-old infants are sensitive to differences in texture. They enjoy having toys with different feels to them, such as velvet, fur, and fuzzy, smooth, or rough items.

The 9-month-old infant needs the experience of creeping. This means time out of a crib or playpen so there is room to maneuver. Many 9-month-olds begin to enjoy toys that go inside one another, such as a nest of blocks or rings of assorted sizes that fit on a center post. Some are more interested in pots and pans that stack rather than toys.

By 10 months, infants are ready for peek-a-boo and will spend a long time playing the game with their hands or with a cloth over their head that they can easily reach and remove. They can clap, so they are also ready to play patty-cake. These games have a positive value, just as laughing out loud did for the 3-month-old. They make the baby feel like an active part of the household. A family feeling begins to grow as the baby begins to actively participate in this type of game.

By 11 months, children have learned to cruise or walk by holding on to low tables. They often find this so absorbing that they spend little time doing anything else during the month. Twelve-month-old infants enjoy putting things in and taking things out of containers. They like little boxes that fit inside one another or dropping small blocks

into a larger box. As soon as they can walk, they will be interested in pull toys. A lot of time may be spent listening to someone saying nursery rhymes or listening to music.

Although there is an advantage to television watching for children during the preschool age because it can help them learn language, the AAP recommends infants not be exposed to television (AAP, 2012b). They don't need exposure to the amount of violence seen on TV (remember children's cartoons may be the worst offenders of this), and interaction with real people (their parents or siblings) is less confusing and a better experience for them without it.

### *What If . . . 29.1*

**Bryan's mother asks the nurse for advice on a good toy for him now that he is 2 months of age. What does the nurse recommend?**

## **DEVELOPMENT OF SENSES**

Like other facets of development, maturation of the senses proceeds progressively during the infant year.

### **Vision**

One-month-old infants are able to regard an object in the midline of their vision (something directly in front of themselves) as soon as it is brought in as close as about 18 in. (46 cm). They follow the object a short distance if it moves but not across the midline as yet. They study or regard a human face with a fixed stare. Two-month-old infants focus well (from about age 6 weeks) and so are able to follow moving objects with the eyes (although still not past the midline). The ability to follow and focus in this way is a major milestone in development, indicating that an infant has achieved **binocular vision**, or the ability to fuse two images into one (Fig. 29.11). Teach parents to make a point of initiating eye-to-eye contact with newborns right from birth as a method of stimulating vision as well as a way of promoting socialization.

**Figure 29.11** A 2-month-old infant focuses steadily and lifts her head up while prone. Note her interest in the stuffed bear.

Three-month-old infants can follow an object across their midline. They typically hold their hands in front of their face and study their fingers for long periods of time (**hand regard**). Blind children also demonstrate this phenomenon, however, so it may not be so much a test of vision as of cognitive or exploratory development. Up until 6 months of age, it is not unusual for infants to experience some difficulty with establishing eye coordination. After 3 months, however, an infant whose eyes still cross the majority of the time should be examined by a primary care provider to be certain the muscles that control side-to-side vision are not impaired.

Four-month-old infants are able to recognize familiar objects, such as a frequently seen bottle, rattle, or toy animal. They eagerly follow their parents' movements with their eyes. By 6 months, infants are capable of organized depth perception. This increases the accuracy of their reach for objects as they begin to perceive distances correctly.

Seven-month-olds pat their own image in a mirror. Their depth perception has matured to the extent that they can perform such tasks as transferring toys from hand to hand. By 10 months, an infant looks under a towel or around a corner for a concealed object (the beginning of **object permanence**, or an awareness that an object out of sight still exists).

Most parents are aware that infants enjoy mobiles and also a crib mirror. Occasionally, parents supply so many of these that they can overwhelm the infant with too many patterns and objects dangling above the crib. Ask parents to consider how all these trappings must appear from an infant's viewpoint.

In a hospital environment, because hospital walls tend to be bland, assess that

infants receive adequate visual stimulation (Fig. 29.12). If a child's movement is restricted in any way, such as by a cast, move the position of a mobile or mirror from time to time to provide a new view. Photos of family members or pictures drawn by older brothers or sisters can be posted near the crib. Ask parents if there are any items from home that the infant would normally see during the course of the day while being fed, changed, or bathed. Bringing those items into the hospital, if possible, could help visual stimulation.

**Figure 29.12** A 2-month-old infant enjoys watching a simple mobile.

## Hearing

That an infant can hear can be demonstrated at birth by the way a newborn quiets momentarily at a distinctive sound such as a bell or a squeaky rubber toy. By 1 month, this reaction is even more marked. Hearing awareness becomes so acute by 2 months of age that infants will stop an activity at the sound of spoken words. Many 3-month-old infants turn their head to attempt to locate a sound. At 4 months of age, when infants hear a distinctive sound, they turn and look in that direction.

By 5 months of age, infants demonstrate they can localize sounds downward and to the side, by turning their head and looking down. Six-month-olds have progressed to being able to locate sounds made above them. By 10 months, infants can recognize their name and listen acutely when spoken to. By 12 months, infants can easily locate sounds

in any direction and turn toward them. A vocabulary of two words plus “ma-ma” and “da-da” also demonstrates that an infant can hear.

During the first year, infants appear to enjoy soft, musical sounds or cooing voices (Box 29.3); they are startled by harsh, raucous rattles or loud bangs. Urge parents to choose for an infant’s first toys ones that make these types of welcoming sounds. Recordings of maternal heart sounds can be soothing to very young infants. For the hospitalized infant, a recording of family voices might be a soothing reminder of their presence. Encourage parents to read to their child daily from the beginning of life through the early school-age years, not only because the sound of the parent’s voice is comforting but also because this increases language development dramatically.

### BOX 29.3

#### Nursing Care Planning Tips for Effective Communication

A healthcare visit for Bryan is over, and you dress him while his mother talks to her healthcare provider.

*Tip:* Role model effective communication with infants to help parents learn to incorporate language development as they give care. Infants appreciate someone talking to them even if they don’t understand the words. Use language that involves the infant and promotes vocabulary development, such as the naming of colors.

**Nurse:** Are you ready to go home? Your mother said you’re going to pick up Daddy and then go shopping. Do you know about shopping? That’s when you ride in a buggy while your mother buys things. Look what a cute yellow sweater you have. It matches the yellow duck on your shirt. Ducks say quack, quack, quack when they talk. Okay. You look ready. Let’s find your mother.

### Touch

Infants need to be touched so they can experience skin-to-skin contact. Clothes should feel comfortable and soft rather than rough; diapers should be dry rather than wet. Teach parents to handle infants with assurance yet gentleness. Remind parents that right now their child is a baby; he or she will have time enough to become a strong man or woman later.

### Taste

Infants demonstrate they have an acute sense of taste by turning away from or spitting out a taste they do not enjoy. When infants are introduced to solid food at about 6 months, urge parents to make mealtime a time for fostering trust as well as supplying nutrition by being certain feedings are done at an infant’s pace and the amount offered fits the child’s needs and not the parent’s idea of how much should be eaten.

### Smell

Infants can smell accurately within 1 or 2 hours after birth. They respond to an irritating smell by turning their head away from it. They appear to enjoy pleasant odors and learn early in life to identify the familiar smell of breast milk. Teach parents to be alert to substances that cause sneezing when sprayed into the air, such as room deodorizers or cleaning compounds, and to keep irritating odors of this nature out of their child's environment.

## EMOTIONAL DEVELOPMENT

Socialization, or learning how to interact with others, is an extensive phenomenon. One-month-old infants show they can differentiate between faces and other objects by studying a face or the picture of a face longer than other objects. They are calm and feed well for the person who has been their primary caregiver.

When an interested person nods and smiles at a 6-week-old infant, the infant smiles in return. This is a **social smile** and is a definite response to the interaction, not the faint, quick smile that younger infants, even newborns, demonstrate. It is a major milestone because it reflects growing maturity in a number of areas, most notably vision, motor control, and intelligence. Cognitively challenged children or children with spasticity may not demonstrate a social smile until much later in the infant year.

By 3 months, infants demonstrate increased social awareness by readily smiling at the sight of a parent's face (Fig. 29.13). Three-month-old infants laugh out loud at the sight of a funny face. By 4 months, when a person who has been playing with and entertaining an infant leaves, the infant is likely to cry or show that the interaction was enjoyable. Infants at this age recognize their primary caregiver and prefer that person's presence to others. By 5 months, infants may show displeasure when an object is taken away from them. This is a step beyond showing displeasure when a person leaves.

**Figure 29.13** A 3-month-old smiles delightedly at her father's happy face. This indicates increased social awareness.

By 6 months, infants are increasingly aware of the difference between people who regularly care for them and strangers. They may begin to draw back from unfamiliar people. Seven-month-old infants begin to show obvious fear of strangers. They may cry when taken from their parent, attempt to cling to the parent, and reach out to be taken back. Parents may view this as a bad trait or a regression in socialization. Help them appreciate that it is actually a big step forward because it shows that their infant can differentiate between people and also can recognize the difference between persons to trust and others.

*Fear of strangers* reaches its height during the eighth month, so much so that this phenomenon is often termed **eighth-month anxiety**, or stranger anxiety (Levine, 2011). Remember that an infant at the height of this phase will not go willingly from a parent's arms to a nurse's arms. Taking a few minutes to talk to the child and parent first so you are perceived as a friend, not a stranger, is time well spent.

Nine-month-old infants are very aware of changes in tone of voice. They cry when scolded not because they understand what is being said but because they sense their parent's displeasure. By 12 months, most children have overcome their fear of strangers and are alert and responsive again when approached. They like to play interactive nursery rhymes and rhythm games and "dance" with others. They also like being at the table for meals and joining in family activities.

## COGNITIVE DEVELOPMENT

In the first month of life, an infant mainly uses simple reflex activity. There is little evidence infants at this early age see themselves as separate from their environment. However, this does not mean they cannot respond actively or interact with people. They demonstrate they are very people oriented moments after birth by cuddling against an adult's chest.

### Primary and Secondary Circular Reaction

By the third month of life, a child enters a cognitive stage identified by Piaget (1952) as *primary circular reaction*. During this time, the infant explores objects by grasping them with the hands or by mouthing them (Fig. 29.14). Infants appear to be unaware of what actions they can cause or what actions occur independently, however. For example, if an infant's hand should accidentally strike a mobile across the crib, the infant appears to enjoy watching the brightly colored birds move in front of him but makes no attempt to hit the mobile again because he does not realize his hand caused the movement.

**Figure 29.14** Infants explore the world by mouthing objects or fingering them. This also helps them separate self from environment.

At about 6 months of age, infants pass into a stage [Piaget \(1952\)](#) called *secondary circular reaction*. Now when infants reach for a mobile above the crib, hit it, and watch it move, they realize it was their hand that initiated the motion, and so they hit it again.

By 10 months, infants discover object permanence. Infants are ready for peek-a-boo once they have gained this concept. They know their parent still exists even when hiding behind a hand or blanket and wait excitedly for the parent to reappear.

As infants reach 1 year of age, they are capable of reproducing new events (they deliberately hit a mobile once, it moves, and they hit it again). They drop objects from a high chair or playpen and watch where they fall or roll. This is a frustrating activity for parents because it involves a great deal of reaching and picking up. It is an important activity for infants, however because it confirms their awareness of the permanence of objects and how they are able to control events in their world.

### ***QSEN Checkpoint Question 29.3***

#### **QUALITY IMPROVEMENT**

The nurse is discussing object permanence with Bryan's mother. Which action by her infant best illustrates that he understands object permanence?

- a. The child looks for the mother after she walks away.
- b. The child cries when either hungry or lonely.

- c. The child prefers a large yellow ball to a small red one.
- d. The child smiles when the mobile on the crib jingles.

*Look in [Appendix A](#) for the best answer and rationale.*

## The Nursing Role in Health Promotion of an Infant and Family

The nursing role with infants is wide ranging because infants are so dependent on their caregivers for safety, learning, and emotional development.

### PROMOTING ACHIEVEMENT OF THE DEVELOPMENTAL TASK: TRUST VERSUS MISTRUST

[Erikson \(1993\)](#) proposed that the developmental task of the infant period is to form a sense of trust (see [Chapter 28](#)). Infants who have numerous caregivers, who may be fed 1 day on a rigid schedule and the next only when they are hungry, who sometimes are treated roughly and sometimes gently, or who don't always have their needs met can have difficulty learning to trust. Cultures can vary in how they address care of an infant and promote trust. Variations in cultural influences for the same infant should be explored, so the infant is provided with consistency of care and can anticipate an expected response ([Box 29.4](#)).

#### BOX 29.4

#### Nursing Care Planning to Respect Cultural Diversity

Although development follows set patterns during the infant year, the care of them is more dependent on cultural factors. One difference is in the way mothers carry their infants. Western mothers tend to carry infants in their arms and so have to put them down to work or into a stroller to shop. South American women carry their infants in shoulder slings or on their hips, positions that allow a woman to continue to work or walk while holding an infant close. Infants who are held with their legs outspread that way tend to develop deeper hip sockets and have less hip dysplasia (see [Chapter 27](#)).

The amount of infant bathing that is done is also inconsistent across cultures. In the United States, most infants are bathed daily. In colder climates or countries where warm, clean water is not readily available, infant bathing is more limited. The use of diapers varies also. In hot climates, infants are often not diapered. Being aware of these cultural differences leads to better understanding of the reasons for an individual woman's particular method of childrearing.

It is important for infants to establish the ability to love, or trust, early in life in this way because development is sequential. If a first developmental step is inadequate, this

inadequacy can pervade all future steps. In reference to trust, the end result could be an adult unable to instill a sense of trust in his or her own child, perpetuating the inadequacy from generation to generation.

How do parents (or a nurse) encourage a sense of trust in an infant? Trust arises primarily from a sense of confidence that one can predict what is coming next. This does not mean parents should set up a rigid schedule of care for their infant. However, it does imply that parents should study their infant's reaction to activities and then establish a workable schedule based on that (e.g., breakfast, bath, playtime, nap, lunch, walk outside, quiet playtime, dinner, story, and bedtime). This gentle rhythm of care gives infants a sense of being able to predict what is going to happen and gives life consistency.

All little children thrive on routine such as the same story read over and over again, the same bedtime rituals, or the same spoon every day for lunch. Infancy is not too early for children to learn family traditions such as decorating for a holiday because this type of repetition can help them feel secure in their world. Some parents have difficulty accepting routine as important to a child. They may be so tired of their own work schedules that they want to raise their children as free spirits. Do not discourage this philosophy; however, you might suggest a few modifications to instill some order into infants' lives.

Just as it is important that there is a rhythm to the care, it is also important that the care is mainly given by one person (Fig. 29.15). This person can be the mother, father, grandparent, a conscientious babysitter, a foster parent, or anyone who can give consistent care. For infants ill at birth who are hospitalized for months, this person is often a primary nurse or case manager. You may have to encourage parents who are reluctant at first to interact with their infant not to feel self-conscious about talking to a baby who does not talk back. Pointing out the importance of such interactions and role modeling them while caring for children help parents use this type of stimulation as they care for their baby's physical needs.

**Figure 29.15** An infant’s sense of trust develops through warm interpersonal relationships. Here, a mother and infant share a bonding moment.

Women who work outside their home during the first year of a baby’s life (at least 90% of women) should try to arrange for one person to care for their child while they are away from home or choose a day care center that will provide a consistent caregiver. Urge them to discuss their methods of child care with alternative caregivers to prevent disrupting an infant’s routine. When a child is admitted to a hospital, document and list this information on an infant’s electronic record.

Urge parents to make certain that not only will the number of caretakers for their child be limited but also that caretakers will be actively interacting with their child. Passively caring for infants—not talking to them or touching or stroking them while feeding or changing them—amounts to little more than not being with them at all. An increasing number of parents are installing video cameras to make sure a caretaker is actively interacting with their baby to instill a sense of trust in their child. Nursing actions designed to help an ill infant develop a sense of trust in addition to individual caretaking are detailed in [Table 29.3](#).

**TABLE 29.3 WAYS FOR NURSES TO HELP AN ILL INFANT DEVELOP A SENSE OF TRUST**

Area of Care	Nursing Actions
Nutrition	Encourage mothers to continue to breastfeed if possible while their infant is hospitalized; provide privacy and support as necessary.

If a parent is not present to do so, hold the infant no matter what feeding method is used (e.g., gavage, total parenteral, oral, enteral). If this is not possible, hold infants for a time after or between feedings so they receive holding equal to what they would ordinarily receive with being fed.

If infant feeding is not oral, provide a pacifier (medical condition and parent preference considered) five or six times daily for sucking pleasure.

**Dressing change** Use nonallergenic tape to avoid irritation while it is applied and reduce pain when removed.  
Use stockinette, rolled gauze, or Kling gauze to hold a bandage in place rather than tape if possible.  
To prevent chilling, be certain irrigation solutions are warm; keep exposure during dressing changes to a minimum.  
Restrain only those body parts necessary for safety.  
Describe what you are doing in a nonthreatening tone of voice as you give care to give comfort.

**Medicine administration** Flavor oral medicine to disguise disagreeable taste. Never add medicine to formula to prevent changing the formula's taste.  
Comfort the infant after injections or intravenous insertion by holding and rocking or immediately give the infant to a parent.  
Check intravenous sites frequently for infiltration and pain. Role model for parents how to hold the infant despite tubing and restraints.

**Rest** Encourage parents to rock infants to sleep. Do this yourself if no parent is present.  
Always wake infants gently because it is frightening (for anyone) to be awakened by a stranger.  
If bed rest is necessary, check for irritated elbows, heels, and knees from rubbing against sheets; protect with long sleeves or pants or a Kling bandage.

**Hygiene** Check the temperature of bath water for comfort and to prevent chilling or burning.  
Change diapers frequently to reduce discomfort from irritation.  
To avoid caries, begin toothbrushing with first tooth.

**Pain** Hold and comfort an infant in pain.  
Do not ask parents to restrain a child for a painful procedure. Allow parents to comfort the child afterward because that is a better parent role.  
Reduce painful procedures to a minimum (e.g., combine blood

Stimulation	<p>drawing so only one puncture is necessary for many tests).</p> <p>Remember that infants focus longest on a human face. Face them directly to talk to them.</p> <p>Provide a crib mirror or a mobile because visual stimulation seems satisfying to an infant.</p> <p>If no mobile is available, create one from string or strips of adhesive tape, colored paper, cotton balls, or colored tongue blades. For safety, hang the mobile high enough for the infant to see but not reach.</p> <p>During the second half of the first year, infants need to try to crawl. Put a pad or sheet on the floor and encourage them to come to you while you stand by to offer reassurance. If contagion or immunosuppression is not a problem, bring the infant’s crib to the nursing desk where the infant can still interact with you while you do necessary paperwork.</p>
-------------	--

## PROMOTING INFANT SAFETY

Unintentional injuries are a leading cause of death in children from 1 month through 24 years of age. These are second only to acute infections as a cause of acute morbidity and primary care provider visits ([Centers for Disease Control and Prevention \[CDC\], 2011](#)).

Most unintentional injuries in infancy occur because parents either underestimate or overestimate a child’s ability. Nursing interventions that help parents become sensitive to their infant’s developmental progress, therefore, not only help establish sound parent–child relationships but also guard infant safety ([Box 29.5](#)).

### BOX 29.5

#### Nursing Care Planning Based on Family Teaching

#### UNINTENTIONAL INJURY PREVENTION MEASURES FOR INFANTS

**Q.** Bryan’s mother is worried about keeping him safe. She asks, “How can I prevent accidents at this age?”

**A.** Here are some tips to help prevent specific types of unintentional injuries:

#### Potential Unintended Injury

#### Prevention Measures

General	<p>Be aware that the frequency of injury is increased when parents are under stress. Take special precautions at these times.</p> <p>Choose babysitters carefully and explain and enforce all precautions when sitters are in charge.</p>
Aspiration	<p>Be certain any object an infant can grasp and bring to the</p>

	<p>mouth is either safe to eat or too big to fit in the mouth. Do not offer foods such as popcorn or peanuts because these are easily aspirated. Store baby powder out of reach; inspect toys and pacifiers for small parts that could be aspirated if broken off.</p>
Falls	<p>Never leave an infant on an unprotected surface, such as a bed or couch, even if the infant is in an infant seat. Place a gate at the top and bottom of stairways; do not allow your infant to walk with a sharp object in the hands or mouth.</p> <p>Raise crib rails and make sure they are locked before walking away from the crib.</p> <p>Do not leave a child unattended in a high chair; avoid using an infant walker near a stairway.</p>
Motor vehicle	<p>Never transport an infant in an automobile unless the infant is buckled into an age-appropriate seat in the back seat of the car. Be aware of the proper technique for tethering the car seat to the car.</p> <p>Do not be distracted by an infant while driving.</p> <p>Do not leave an infant unattended in a parked car (the infant can become dehydrated from excess heat, can move the gear shift, or be abducted).</p>
Suffocation	<p>Allow no plastic bags within infant's reach; don't use pillows in cribs.</p> <p>Store unused appliances such as refrigerators or stoves with the doors removed.</p> <p>Buy a crib that is approved for safety (spacing of rails is not over 2 3/8 in. [6 cm] apart).</p> <p>Remove constricting clothing such as a bib or pacifier string from neck at bedtime.</p>
Drowning	<p>Do not leave infants alone in a bathtub or unsupervised near water (even buckets of cleaning water).</p>
Animal bites	<p>Do not allow an infant to approach a strange dog; supervise play with family pets.</p>
Poisoning	<p>Never present medication as a candy; buy medications in containers with safety caps; put away in a high cabinet immediately after use; never leave medication in a pocket or handbag.</p> <p>Never take medication in front of infants. Place all medication and poisons in locked cabinets or overhead</p>

	shelves. Do not use lead-based paint in any area of the home. Hang plants or set on high surfaces. Post telephone number of the national poison control center by the telephone (1-222-1222).
Burns	Test warmth of formula and food before feeding (use extra precaution with microwave warming). Do not smoke or drink hot liquids while holding or caring for an infant. Buy flame-retardant clothing for infants; turn handles of pans toward back of stove. Use a sunscreen on a child over 6 months when out in direct or indirect sunlight and limit the child's sun exposure to less than 30 minutes at a time. If a vaporizer is used, use a cool-mist, not a hot-mist type; remain in room to monitor so child cannot reach vaporizer. Monitor infants carefully near candles. Do not leave infants unsupervised near hot-water faucets. Keep a screen in front of a fireplace or heater. Do not allow infants to blow out matches or candles (don't teach infants that fire is fun). Keep electric wires and cords out of reach; cover electrical outlets with safety plugs.
General	Be aware some infants are more active, curious, and impulsive and therefore more vulnerable to unintentional injury than others.

### Aspiration Prevention

Aspiration is a chief injury threat to infants throughout the first year. Round, cylindrical objects are more dangerous than square or flexible objects in this regard. A 1-in. (3.2-cm) cylinder, such as a carrot or hot dog, is particularly dangerous because it can totally obstruct an infant's airway. A deflated balloon can be sucked into the mouth, obstructing the airway in the same way. Educate parents who feed their infant formula not to prop bottles. By doing this, they are overestimating their infant's ability to push the bottle away, sit up, turn the head to the side, cough, and clear the airway if milk should flow too rapidly into the mouth, allowing an infant to aspirate.

Other instances of aspiration occur because parents underestimate their infant's ability to grasp and place objects in their mouth. Even a newborn can wiggle to a new position to reach an attractive object such as a teddy bear with small button eyes. Newborns' grasp and sucking reflexes automatically cause them to grasp and pull the

object into their mouth. Caution parents to be certain nothing comes within an infant's reach that would not be safe to put into the mouth. Using clothing without decorative buttons and checking toys and rattles to ensure they have no small parts that could snap off or fall out are good steps for parents to follow.

A test of whether a toy could be dangerous if an infant puts it inside the mouth is whether it fits inside a toilet paper roll. If it does, it is small enough to be aspirated. When solid foods are introduced, encourage parents to offer small pieces of hot dogs or grapes, not large chunks for this reason. Children under about 5 years of age should not be offered popcorn or peanuts because of the danger of aspiration.

As infants become more adept at handling toys, parents need to reassess toys for loose pieces or parts. If parents are going to offer an infant a pacifier, they should use one that has a one-piece construction with a flange large enough to keep it from completely entering the child's mouth (Fig. 29.16).

**Figure 28.16** Many infants enjoy sucking on a pacifier to help them fall asleep. This may also help prevent sudden infant death syndrome.

**QSEN Checkpoint Question 29.4**

**EVIDENCE-BASED PRACTICE**

Scalding injuries occur in infants when caretakers spill hot beverages while holding them in their lap or, toward the end of the first year, the infant is able to pull a pan of hot liquid off the stove. To confirm the incidence of this type of injury, researchers studied the admission records of an urban pediatric emergency department in Ireland. Of 280 children seen for burns, 161 (57%) were scalds. Of these, 79% occurred in children under 5 years of age, 65% were caused by hot beverages, 16% were caused

by hot water, and 16% by hot food. The areas of children most affected were upper limbs and upper trunks. The researchers concluded that more parent education as to the danger of scalding is needed to reduce the number of these very painful injuries in young children (Yates, McKay, & Nicholson, 2011).

Based on the study, the nurse is most concerned about which remark by Bryan's mother?

- a. "I never drive without a cup of coffee in my cup holder."
- b. "I'm going to switch to drinking tea to reduce my caffeine intake."
- c. "I drank coffee during Bryan's pregnancy; it's why he's so high strung."
- d. "I'm a coffee addict; I always have a fresh cup in my hand."

---

---

## Fall Prevention

Falls are a second major cause of infant injuries. As a preventive measure, no infant, beginning with a newborn, should be left unattended on a raised surface. Normal wiggling can bring even a newborn to the edge of a bed, couch, or table top, resulting in a fall.

Teach parents to be prepared for their infant to turn over by 2 months of age. From that time on, they must be especially vigilant not to leave the baby unattended on a changing table or counter. If the child sleeps in a crib, the mattress should be lowered to its bottom position so the height of the side rails increases; rails should be no more than 2<sup>3</sup>/<sub>8</sub> in. apart, narrow enough so children cannot put their head between them. Two months is about the maximum length of time infants can safely sleep in a bassinet; they need the protection of a crib and high side rails before they turn over.

All of these safety precautions apply to the hospital environment as well as to the home. Be sure crib sides are raised and secure before you walk away from a crib, even for just a moment. Also ensure the space between the mattress and headboard is small enough that an infant's head could not become trapped. Make sure cords from nursing call bells or other equipment are out of an infant's reach.

## Car Safety

Teaching car safety for infants (as well as for the whole family) is an important protective health measure. The use of car seats for newborns is discussed in Chapter 18. Infants should be placed in backward facing seats in the back seat because an inflating front seat airbag could suffocate an infant (AAP, 2012a). Backward-facing car seats should continue to be used without interruption until age 2 years or until the child reaches the highest weight or height allowed by the car safety seat's manufacturer. If parents are firm about keeping infants in car seats even when they are fussy or impatient, children will eventually become more comfortable and accepting of car seats.

**QSEN Checkpoint Question 29.5**

## SAFETY

The nurse reviews infant safety with Bryan's mother. It is most important to teach his mother about preventing which common injuries among infants?

- a. Drowning and hypersensitivities
- b. Poisoning and suffocation
- c. Auto accidents and burns
- d. Aspiration and falls

*Look in [Appendix A](#) for the best answer and rationale.*

### Safety With Siblings

As infants become more fun to play with at about 3 months of age, older brothers and sisters grow more interested in interacting with them. You may need to remind parents that children under about 5 years of age, as a group, are not responsible enough or knowledgeable enough about infants to be left unattended with them. They might introduce an unsafe toy or engage in play that is too rough for an infant. Some preschoolers may be so jealous of a new baby they will physically harm an infant if left alone.

### Bathing and Swimming Safety

As babies begin to develop good back support, many parents begin to bathe them in an adult tub. Caution parents to never leave an infant unattended in a tub, even when propped up out of the water or sitting in a bath ring or bath seat. Normal wiggling can easily cause a baby to slip down under the water. This applies to a hospital setting as well.

Many communities offer infant swim programs for babies as young as 6 months. If an infant is enrolled in one of these programs, parents may become overconfident about their infant's ability to operate safely in water. Urge them to think carefully before enrolling their infant in such a program, because, although infants can dog paddle momentarily in a swimming pool, this action does not mean they can sustain that position for any length of time in a bathtub or pool by themselves. As a second danger, being able to swim momentarily may cause children to lose their instinctive fear of water and so be in more danger when around water than children who are still naturally more cautious. Such programs can also cause hypothermia and spread microorganisms because infants this age are not yet toilet trained. Exposure to chlorinated water might damage lung epithelium, which then has the possibility to become a precursor to childhood asthma (Klootwijk & Krul, 2011).

### Childproofing

Toward the end of pregnancy, parents need to begin preparing for their infant's arrival by childproofing their home. As soon as infants begin teething at 5 to 6 months, they

chew on any object within reach to lessen gumline pain. Remind parents to thoroughly check for possible sources of lead paint, such as painted cribs, playpen rails, or windowsills before this time to avoid lead poisoning (CDC, 2014). Paints safe for baby furniture should be marked “Safe for use on surfaces that might be chewed by children.” If an infant is going to play on the floor, urge parents to move furniture in front of electrical fixtures or buy protective caps for outlets. Infants are especially fascinated by the holes in electric outlets and will probe them with (often wet) fingers. Parents may need to install safety gates at the top and bottom of stairways as additional safety measures before the infant crawls.

Urge parents to move all potentially poisonous substances from bottom cupboards and store them well out of their infant’s reach. Infants of any age should not be left unattended in carriages, high chairs, grocery shopping carts, or strollers. Baby walkers are extremely dangerous because infants can maneuver them near stairways and fall the length of the stairs.

When infants begin creeping, remind parents to recheck bottom cupboards and stairways for safety. When the child begins to walk, higher areas, such as coffee tables, need to be cleared of dangerous items. In a hospital setting, assess low counter areas for dangerous objects. Do not leave possibly dangerous supplies in an infant’s room.

By 10 months, achievement of a pincer grasp makes infants able to pick up very small objects. Remind parents to check play areas or areas such as tabletops for pins or other sharp objects that could be swallowed. At this point, some of an infant’s toys may now be 10 months old and need to be checked to be certain they are still intact and safe.

Although infants can seem very independent and able to take care of themselves toward the end of the infant year, their judgment about what situations could be dangerous is immature. As soon as they can walk, they’re able to venture into the street or a swimming pool if not carefully supervised (Fig. 29.17). In a hospital setting, a 12-month-old child can wander into an elevator, out of the hospital, into a laboratory area, or fall down a flight of stairs if not supervised (Ibrahim, Wood, Margulies, et al., 2011).

**Figure 29.17** Once walking begins, the extended range of activities brings an infant in contact with potentially dangerous places or objects unless the house is childproofed. The bathroom is an important room in which to begin childproofing.

### *What If . . . 29.2*

**Bryan’s mother is interested in “childproofing” her house. What questions would the nurse want to ask to determine whether the house is safe for a 2-month-old?**

## **PROMOTING NUTRITIONAL HEALTH OF AN INFANT**

The best food for an infant during the first 12 months of life (and the only food necessary for the first 6 months) is breast milk (see [Chapter 19](#) for tips on breastfeeding). A breastfed or partially breastfed infant should receive 400 IU of vitamin D supplement starting at 2 weeks of age ([AAP, 2017](#)). How long mothers continue to breastfeed is an individual choice, although it is recommended that infants be exclusively breastfed for 6 months. It is optimal if breastfeeding is then continued through the entire first year ([Whitney & Rolfes, 2012](#)). There is some research

indicating early weaning from breastfeeding can lead to an increased incidence of obesity (Townsend & Pitchford, 2012). For infants whose mothers choose not to or are unable to breastfeed, a commercial iron-fortified formula will supply adequate nutrition for the infant year (Krebs & Primak, 2011) (for types of commercial formulas, see <http://thePoint.lww.com/Flagg8e>). Supplementation is generally unnecessary with iron-fortified commercial formula. Although after 6 months, if the water supply does not contain fluoride, fluoride may need to be supplemented. Infants who are changed to cow's milk before 1 year of age should receive a supplementary form of vitamin C and iron and possibly fluoride to make up for the deficiency of these components in cow's milk. However, the practice of switching to cow's milk is not recommended because the protein in it is difficult for an infant to digest, possibly leading to such intestinal irritation that slight but continuous gastrointestinal bleeding occurs, which results in anemia.

### Recommended Dietary Allowances for Infants

Because children's nutritional needs vary so much from infancy through adolescence, the recommended allowances of calories, protein, vitamins, and minerals also vary with each period of development (see Chapter 28).

The entire first year of life is one of extremely rapid growth, so a high-protein, high-calorie intake is necessary. Calorie allowances can be gradually reduced during the first year from a level of 120 calories per kilogram of body weight (50 to 55 calories per pound) at birth to approximately 100 calories per kilogram (45 calories per pound) of body weight at the end of the first year to prevent babies from becoming overweight.

Although heredity plays a role, a baby who is overweight during the first year of life is more likely to become an adult who is obese than one whose weight is within normal limits. Such long-term effects occur because overfeeding in early life may produce large numbers of excess fat cells (adipocytes) used to store fat. Because these cells are permanent and remain filled with fat, once they are present, weight regulation can become difficult throughout life. Breastfed infants gain less weight than those who are formula fed and so usually tend to be somewhat lighter in weight and have less risk of becoming overweight (Thilo & Rosenberg, 2011).

### Introduction of Solid Food

From a nutritional standpoint, a normal full-term infant can thrive on breast milk or a commercial iron-fortified formula without the addition of any solid food until 6 months (Conti, Patel, & Bhat, 2011). Delaying solid food until this time also helps prevent overwhelming an infant's kidneys with a heavy solute load. Although difficult to document, it also may delay the development of food allergies in susceptible infants and be yet another way to help prevent future obesity (Gaffney, Kitsantas, & Cheema, 2012).

Most parents are eager to begin feeding their infant solid food, hoping this will help

their child sleep through the night. So eager, in fact, some parents do begin food before the recommended time without apparent ill effects, possibly because much of the food is not processed by the gastrointestinal tract, but rather passes through undigested because of the immaturity of the digestive system, and decreased amounts of amylase and lipase (digestive enzymes).

Generally speaking, parents can tell infants are physiologically ready for solid food when they are nursing vigorously every 3 to 4 hours and do not seem satisfied or when they are taking more than 32 oz (960 ml) of formula a day and do not seem satisfied.

### Introducing Solid Food

Infants are not ready to digest complex starches until amylase is present in saliva at approximately 2 to 3 months. Biting movements begin at approximately 3 months. Chewing movements do not begin until 7 to 9 months. Therefore, foods that require chewing should not be given until this age.

In addition to these cautions, the extrusion reflex needs to fade before infants accept food readily. With the extrusion reflex intact, when anything is placed on the anterior third of an infant's tongue, it is automatically extruded or thrust out of the mouth by the tongue (Fig. 29.18). This is a lifesaving reflex in early infancy because it prevents infants from swallowing or aspirating foreign objects that touch the mouth. The reflex fades at 3 to 4 months at about the same time the gastrointestinal tract has matured to be ready to digest solid food.

**Figure 29.18** A 3-month-old baby demonstrates an extrusion reflex.

Caution parents not to interpret this action as a food dislike but recognize it as the reflex action that it is.

## Techniques for Feeding Solid Food

The introduction of solid food begins a new type of interaction between parents and their infant and can require a period of adjustment (AAP, 2017). A typical pattern for the introduction of solid food beginning at 6 months includes:

- Iron-fortified infant cereal mixed with breast milk, orange juice, or formula; it aids in preventing iron-deficiency anemia, is the least allergenic type of food, and is the most easily digested so it is usually the first food offered.
- Vegetables; these are a good source of vitamin A and add new texture and flavors to the diet.
- Fruit; these are the best sources of vitamin C and a good source of vitamin A.
- Meat is a good source of protein, iron, and B vitamins.
- By 6 months of age, egg yolk, a good source of iron, can be added.

Commercial jar food is used in the hospital environment, but the appropriate consistency table food is recommended for home use. Caution parents to omit wheat, tomatoes, oranges, fish, and egg whites if there are allergies in the family because these foods are those most likely to cause allergies. Also, parents should never use honey as a sweetener because it may contain botulism spores and never use cow's milk because it can cause microscopic intestinal bleeding.

Teach parents to offer new foods one at a time and to allow their child to eat that item for about 3 to 7 days before introducing another new food. This system helps parents to detect a possible food allergy in addition to allowing the infant to get used to the new experience.

A newborn's stomach can hold approximately 2 tablespoons (30 ml). By 1 year, a stomach can hold no more than about 1 cup (240 ml). For this reason, when they begin eating solid food, infants rarely take more than 2 tablespoons (30 ml) at a time.

For the first solid food feeding, it is best if an infant is held in the parent's arms as if for breastfeeding or bottle feeding. This reduces the newness of the experience and minimizes the amount of stress associated with it. Some infants accept new experiences of this type readily, whereas other infants resist heartily. If an infant does not take readily to solid food, advise parents to wait a few days and then try again. Remind them this is not a contest to see whose child takes cereal, vegetables, or fruit first.

Babies have distinct taste preferences even at young ages and may spit out a food because they do not like the taste. Even after the extrusion reflex has faded, some infants continue to spit out food. This is because, when infants drink from a bottle or breast, they press their tongue and the nipple against their hard palate. When an infant tries to eat solid food using the same technique, it appears the child is spitting out the food. A parent who knows an infant's cues will be able to distinguish taste preferences from inadequate management of solid food. [Box 29.6](#) lists pointers to help make the introduction of solid foods a positive experience.

**TIPS TO HELP INTRODUCE SOLID FOODS TO INFANTS**

**Q.** Bryan's mother has already started feeding him solid food. She asks, "When and how should I have begun food?"

**A.** It's best if infants are exclusively breastfed for 4 months so infants typically are ready for solid food at 4 to 6 months of age. Usual guidelines to help introduce solid foods include:

- Introduce one food at a time, waiting 3 to 7 days between new items.
- Introduce the food before formula or breastfeeding when the infant is hungry.
- Introduce small amounts of a new food (1 or 2 teaspoons) at a time.
- Respect infant food preferences; a child cannot be expected to like all new tastes equally well.
- Use only minimal to no salt and sugar on solid food to minimize the number of additives.
- Remember that the extrusion reflex is present for the first 4 to 6 months of life, so any food placed on an infant's tongue will be pushed forward and extruded.
- To prevent aspiration, *do not* place food in bottles to drink with formula.
- Even though you don't like a particular food, introduce it with a positive, "You'll like this" attitude. It could be your child's favorite.

If a parent is going to prepare baby food, the parent needs to avoid preparing spinach, carrots, beets, green beans, and squash because these can contain excessive amounts of nitrates that are not processed well by infants. Commercial baby food has the nitrates removed and so does not present this problem.

### *Cereal*

Infant cereal is fortified with B vitamins and iron. It is supplied as a precooked, fine dry powder to which expressed breast milk, infant formula, or juice is added. Adding sugar to cereal is unnecessary. Extra sugar in the diet can lead to diarrhea in young infants and beginning caries in older infants.

Fortified cereal costs no more than unfortified cereal, so remind parents to buy the fortified product. The first cereal introduced is usually rice cereal because fewer children are allergic to rice products than to wheat and corn products. Usually, this is offered twice a day, in the morning and evening. Once the child has taken rice cereal for 1 week, if they wish, parents can try another kind.

Caution parents not to mix cereal into the infant's bottle because, as it is necessary to cut a larger hole in the bottle nipple for the cereal and milk mixture to flow freely, there is a danger an infant may aspirate if the hole cut is too big or if the parent then

uses that nipple for formula without cereal added. This practice also denies the child the opportunity of learning to eat from a spoon and experiencing different food tastes and textures.

Infant cereal is so rich in iron that parents should continue feeding it at least through the first year. Ideally, children should eat infant cereal until age 3 or 4 years because few popularly advertised products can match the nutrients of fortified infant cereal.

### *Vegetables and Fruit*

Because the iron content in vegetables is generally higher than that of fruits, vegetables are usually the second food added to the diet (after 6 months of age). To prepare their own, a parent simply cooks a vegetable and then blends or processes it, so it does not have to be chewed. Caution parents not to add butter, sugar, or salt to the preparation because infants have difficulty digesting fats until almost the end of the first year, and the added salt or sugar is unnecessary. By filling ice-cube trays with the blended vegetables, parents can make a 1-week supply and defrost a cube at a time. An ice cube is approximately 1 oz, or one fourth the size of a jar of baby food.

If parents use commercial baby food, they should begin with level 1 types (single ingredient and pureed) and feed from a dish rather than directly from the jar. This is because, if the spoon carries salivary enzymes from an infant's mouth back to the food jar, the enzymes will quickly liquefy what remains in the jar. Also, there is a danger of transferring bacteria (principally streptococci) from an infant's mouth to the jar. Then, if the parent keeps the jar for another feeding in the next 24 hours, bacteria will multiply rapidly because the contents serve as a culture medium. Baby food jars should be refrigerated once they are opened, and manufacturers recommend they be used no longer than 48 hours after they were first opened.

When vegetables are added to the diet, they are usually offered at lunch. Remind parents to offer both green and yellow vegetables. Help them to remember that their own dislike of a particular vegetable does not mean their child will feel the same way about it. If they do convey distaste for a food, their child will pick up on the feeling and may not like the vegetable either.

Fruit is usually offered 1 week after beginning vegetables (after 6 months of age). It can be given in addition to cereal for breakfast and dinner. Raw mashed banana is easy to prepare with just a fork; peaches are easily prepared in a blender. As with vegetables, parents should offer a selection so an infant is exposed to different tastes and textures.

### *Meat and Eggs*

Meat is usually introduced at 9 months of age because this is the time an infant's iron stores are beginning to be depleted. Parents can grind a portion of the meat they have prepared for their own meal so it is tender, or they can use commercially prepared baby food. If they use commercial baby meat, remind them to use the plain meat preparations, not vegetable and meat dinners because these contain mostly vegetables.

Chicken has the advantage of being low in cholesterol, but this is not a priority with infants. Beef and pork have more iron than chicken, so encourage parents to offer a variety. When meat is added to an infant's diet, it is usually added as part of the evening meal in place of cereal.
